that position), and BF, which is then equal to the line BI [Margin: a. 4. primi — Euclid, *Elements* I.4]; for the sides BA, AF are equal to the sides BA, AI, and they contain right angles. Since, therefore, the sides BK, KI are equal to the sides BH, GF — or HF —

Diagram, "3.^a fig." (third figure). A construction of solid and dotted lines meeting at the central point A, for the case where the plane is parallel to the axis of the world (the lines CF and AG being parallel). Labels read: G at the upper left (on a dotted line) and again G at the lower right (dotted); E at the top; F at the left (on a dashed horizontal line through A); A at the center; B at the right; D below and right of A; C at the bottom. All labels legible.

Diagram, "4.^a fig." (fourth figure). A construction with solid and dotted lines converging on A. Labels read: K at the top; I just below and left of K; F at the far left; A at the center-left; E at the center; G at the lower left with H beside it; C and D at the bottom (C left, D right). The rays extend to a vertex at the far right whose label could not be resolved [?]. Otherwise legible.

Diagram, "5.^a fig." (fifth figure). A construction (partly dotted) for the case in which the line AB is taken smaller so as to fit a narrower foundation. Labels read: I at the top; E at the upper right; K at the right; F at the far left (dashed); A at the center; B at the right; D below center; G and H at the lower left. A small mark near the foot beside G/H could not be resolved with confidence [?].

Diagram, "6. fig.^a" (sixth figure). A construction of solid and dotted lines meeting at A. Labels read: F at the left (dashed); A at the center; E at the upper right; B at the far right; G at the lower left (dotted); H below center; C beneath H; D at the center; I at the bottom; K at the bottom center. All labels legible.

are equal, and the base BI equals the base BF, the angles BKI and BHF will be equal [Margin: a. 8. primi — Euclid, *Elements* I.8].

In the third figure, moreover, the proposed plane — drawn through the line CF — will nowhere meet the side AD in the foundation (with which the line AG then coincides, as was said), since the line CF is parallel to it. And so in that case the plane is equidistant from the axis, and so on.

And so, if in the first figure the interval BH is transferred with the compass into the foundation — which we have here repeated — from A up to E, then the line AE that is drawn will be the common section of the proposed plane and of the hour-6 circle (that is, of the upper or lower plane of the parallelepiped), since it is equal to BH itself; and it will make the angle AEB equal to the angle BHA [Margin:

b. 7. sexti — Euclid, *Elements* VI.7], because the angle B in the foundation is equal to the angle A in the first figure, the sides BA, AE are proportional to the sides AB, BH, and the angles E and H are each less than a right angle. Likewise, if the angle FAD in the foundation is made equal to the angle AGF of the first figure, then AF will be the common section of the proposed plane and of the lateral plane in the parallelepiped.

So too, if in the second figure the interval BH is transferred from G up to H, and the angle IGD is made equal to the angle AGF, then GH will be the section made by the proposed plane in the upper plane of the parallelepiped, and GI the section made by the same proposed plane in the lateral plane of the parallelepiped. And if in the fourth figure the interval BH is transferred in the foundation from K up to P, and the angle QKD is made equal to the angle AGF, then KP will be the section of the proposed plane and of the upper plane of the parallelepiped, while kQ [*sic*, lowercase k as printed] will be the section of the same proposed plane and of the lateral plane in the parallelepiped.

Moreover, in the fifth figure — since here the line AB is smaller than the line AB of the foundation, so that the line BH cannot be transferred into the foundation (being smaller than the section of the proposed plane and of the foundation), and this section must instead be investigated by means of the angle ACB, or AHB — if the angle SRA is made in the foundation equal to the angle ACB, and the angle TRA is set equal to the angle AGF, then RS will be the common section of the upper plane of the parallelepiped and of the proposed plane, while RT will be the common section of the same proposed plane and of the lateral plane of the parallelepiped. Finally, if in the sixth figure the line BH is transferred in the foundation from V up to X, and the angle YVD is made equal to the angle AGF, then VX will be the common section of the proposed plane and of the upper plane of the parallelepiped, while VY will be the common section made by the proposed plane in the lateral plane of the parallelepiped.

[Margin: Compositio horologij à Verticali declinatis, simulque ad Horizontem inclinati — The construction of a dial declining from the vertical and at the same time inclined to the horizon.]

With these things thus prepared: if, the position of the style and its length being given, one describes the meridian line, the equinoctial line, and the hour-6 line, as we taught in the scholium to Proposition 37 of Book 3 of the *Gnomonics*, then from the hour-6 line, on both sides of the center of the dial, one must cut off a line equal to the line AE, or GH, or KP, or RS, or VX — according as the first, second, fourth, fifth, or sixth dial is to be described. And from the meridian line too, on

both sides of the center, one must take off a line equal to the line AF, or GI, or KQ, or RT, or VY; and finally the parallelogram must be completed in the manner of the parallelogram IEIHIEIH [?] of chapter 5. For if onto the sides of this parallelogram parallel to the hour-6 line one transfers, on both sides — beginning from the meridian line — the intervals of the line EA, or HG, or PK, or SR, or XV in the foundation, starting from the side BC; and onto the sides of the same parallelogram parallel to the meridian line one transfers, beginning from the corners, the intervals of the line AF, or GI, or KQ, or RT, or VY in the foundation, starting from the side AD; then the hour-lines will be described, each through three points, as in the preceding dials of chapters 4 and 5. Their order should be sought from Proposition 37 of Book 3 of the *Gnomonics*.

Diagram. A single large rectangular figure (the composite "foundation") into which the constructions of the several dials described above are laid together. The four corners of the rectangle are B (top left), C (top right), A (bottom left), D (bottom right). Along the top edge, from left to right, run the points B, S, E, H, P, F, I, T, Y, X, C (a small additional mark near P could not be resolved [?]). Down the left edge run B, M, L, A; down the right edge run C, O, N, D. Along the bottom edge, from left to right, stand the points A, G, K, R, V, D, each marked with the figure it belongs to: A ("1.^a", first figure), G ("2.^a", second), K ("4.^a", fourth), R ("5.^a", fifth), V ("6.^a", sixth). The third figure has no vertex here, because in that case the plane is parallel to the axis and meets the side AD nowhere. An interior point H lies near the left side below B. Numerous straight lines cross the interior, representing the common sections (AE/GH/KP/RS/VX and AF/GI/KQ/RT/VY) of the several proposed planes with the planes of the parallelepiped. All corner and edge labels legible except the mark noted at P.

HOROLOGIA MERIDIANA, POLARIA, ET AEQVINOCTIALIA.

[Meridian, Polar, and Equinoctial Dials]

CAPVT IX.

[Chapter 9]

These three dials, since they are more easily laid out by the methods we handed down in the *Gnomonics* than from the parallelepiped, are deliberately passed over here; for their construction has been explained fully enough in our *Gnomonics*, so that it would be superfluous to repeat it here — especially since they are of less frequent use than horizontal dials and those declining from the vertical. We must now treat of the arcs of the signs of the zodiac, of the arcs of the

lengths of days and nights, and of the hours reckoned from sunrise and sunset, as well as of the unequal hours. All of these — except the unequal hours (since their delineation can be drawn from the *Gnomonics*, and they rarely come into use) — we shall depict only on the horizontal dial and on the dial declining from the vertical. This is both because these two kinds of dial are the more frequently used (for dials are generally constructed either horizontal or declining from the vertical, such as those drawn on walls standing perpendicular to the horizon), and because in all cases the method of construction is the same, as will be clear from what follows.

ARCVS SIGNORVM ZODIACI IN Horologio Horizontali, ac Verticali.

[The Arcs of the Signs of the Zodiac in a Horizontal and a Vertical Dial]

CAPVT X.

[Chapter 10]

Since the tip of the style's shadow, when the Sun is at the beginning of Aries ♈ or of Libra ♎, describes on any plane dial a straight line, but when the Sun is at the beginnings of the other signs traces a conic section — a hyperbola, a parabola, an ellipse, or finally a circle, as we demonstrated in the *Gnomonics* — we shall lay out arcs of this kind on a horizontal and on a vertical dial in the following way.

Let the figure of the zodiac rays, together with the hour-lines, be prepared in this way. [Margin: Radij signorum Zodiaci quo pacto ducantur — How the rays of the zodiac signs are drawn.] Draw across, at any convenient place, a straight line BI for the axis of the world; at B erect the perpendicular BE for the radius of the equator; and from B, having described an arc of a circle FEG at any interval, count off on it, on both sides from E, the maximum declination of the Sun, 23° 30', as far as F and G. Now draw the line FG, which will be bisected at right angles at H by the radius of the equator BE (by Corollary 1 of Proposition 10 of Book 13, or by the scholium to Proposition 27 of Book 3, of Euclid); from H, at the interval HF or HG, describe a circle, and divide it into 12 equal parts. This will indeed be done easily if — with the same compass-opening by which you described the circle — from the four points

Diagram. A large bordered figure in two stacked parts, showing the rays of the zodiac signs together with the hour-lines, for a horizontal dial (upper) and a vertical dial (lower).

Upper part: a large circle with radiating solid and dotted lines converging near the top edge at points labelled (left to right) C, B, B; below them M and D toward the center-top. Within and below the circle are the points P (center), F (left, on the horizontal diameter) and H, E (center, one above the other). Two small circle-marks (o) sit at the left and right ends of a horizontal line through the circle. Along the descending rays at the lower left are hour-numbers 4, 5, 6, 7, 8 and the paired numbers "1.11", "2.10", "3.9" with "12"; matching numbers appear at the lower right (12, "1.11", "2.10", "3.9", 4-8, 5, 6, 7). At the upper right is a smaller square inset carrying the labels B, I along its top and, within it, L, C, L, B, N, A, M, D, N, M down its right side, with K, I and G lower in the inset [several of these inset labels are faint — see flags below].

Lower part: a fan of solid and dotted lines radiating from a cluster of central points labelled C (top), and below it B, H, E, A (with a small b). Along a horizontal line run the hour-numbers 4, 3, 2, 1, 12, 11, 10, 9, 8, 7. The rays terminate at zodiac glyphs down the left side and down the right side. On the left, from top down, are read: ♂ (Taurus), then a point on the "6" line marked ♈ with F beside it (Aries), ♊ (Pisces), ♒ (Aquarius), and ♑ (Capricorn) at the foot [some left-hand glyphs faint]. On the right, from top down, are read: ♋ (Cancer)/♌ (Leo), ♍ (Virgo, on the "6" line), ♎ (Libra) with G beside it, ♐ (Sagittarius, on the "7" line), and a lower glyph near the foot [the exact right-hand glyph sequence is partly abraded]. Letter-labels F, G mark the ends of the equinoctial (Aries–Libra) line; BF and BG are the Cancer and Capricorn rays as described in the text.

Because more than two labels in this figure are faint or abraded (several inset letters in the upper part and several zodiac glyphs in the lower part), this diagram is a

in which the circumference of the circle is cut by the lines FG and BE, you cut off equal parts on both sides — that is, join by straight lines the pairs of points equally distant from the point F, or G, these lines cutting the arc FEG in four points. For the lines drawn from B through these points will give the rays of the signs lying between Aries ♈ and Libra ♎, and Cancer ♋, and Capricorn ♑. Of the lines BF and BG, one will be assigned to the sign Cancer ♋ and the other to the sign Capricorn ♑; and finally the line BE will be ascribed to the signs Aries ♈ and Libra ♎. The order of the intermediate signs will be understood from the drawing of the arcs on the dial. We demonstrated this construction of the zodiac rays in the *Gnomonics*, Book 1, Proposition 1, and at the end of Book 8.

But if the parts of the circle described from H are cut into 30 equal parts, and again the pairs of points equally distant from F, or G, are joined by straight lines,

the arc FEG will be cut at points through which the lines drawn from B will give the rays of all the degrees of the signs,

and the arcs between E and the said points — arcs intercepted from the arc FEG — will measure the declinations of the signs and of the degrees of the signs from the equator.

[Margin: The hour-line: in what way it is to be fitted to the rays of the signs.]

After this, from the triangle CBD of the horizontal or vertical dial constructed in chapter 4 (we take the horizontal one as our example), let the straight line BC, which represented the axis, be transferred onto the axis BI — whether to the left of the equator's radius BE or to the right — from B as far as C; and onto the equator's radius from B let the line BD of that same triangle CBD be transferred, as far as D. For the line CD, once drawn, will give the twelve-o'clock hour, which we shall draw more exactly as follows. Describe an arc of a circle Ik from C toward B at any interval you please, and on it count off — for the horizontal dial — the altitude of the pole, but for the vertical dial the complement of the pole's altitude, as far as k. For the line CK, when drawn, will again give the twelve-o'clock hour and will pass through the point D. Then, on the meridian line of the dial, take a straight line DE equal to BD itself; and whether above the equinoctial line FG or below it, take with the compass all the intervals between E and the hour-points of the equinoctial line. (Any interval taken on one side of the meridian line is equal to another interval on the other side of the meridian line, so that the interval of hour 1 is equal to the interval of hour 11,

Diagram. A large composite ray-figure (*figura radiorum*) for the horizontal dial, filling most of the page within a ruled rectangular border. It has two parts.

Upper part: a large circle with many solid and dotted lines radiating from points near its top edge. Along the top run the labels [C?], B, B (left of center), and B, I (over a square construction-inset at the upper right). Within the circle are the points P (left of center, on the horizontal diameter), F (further left on that diameter), and H, E (near the center, one above the other). Two small open circles (o) mark the left and right ends of the horizontal line through the circle. At the upper right a square inset carries, reading down its interior, the labels L, C, L, B; N, A; M, D; N; M; K, I; G, and along its right edge the vertical sequence B, M, D, M. Along the descending rays at the lower left are the hour-numbers 12[?], "1.11", "2.10", "3.9", then 4, 5[?], and lower down 7, 8, 6, 6; the lower right mirrors these with 12, "1.11", "2.10", "3.9", 4, 8, 5, 7, 6, 6.

Lower part: a fan of solid and dotted lines radiating from a central cluster labelled C (top), and below it B, H, E, A (with a small b). Along a horizontal line run the hour-numbers 4, 3, 2, 1, 12, 11, 10, 9, 8, 7. The rays terminate at zodiac glyphs down the left and right sides. On the left, from top down: ♉ [Taurus], then ♈ [Aries] on the "6" line with F beside it, then a glyph [?], ♊ [Pisces], ♒ [Aquarius], and ♐ [Capricorn] at the foot. On the right, from top down: ♋ [Cancer], ♌ [Leo], ♍ [Virgo] on the "6" line, ♎ [Libra] with G beside it, then (on the "7" line) ♏ [Scorpio], ♐ [Sagittarius], and a lower glyph [?] near the foot. The letters F and G mark the ends of the equinoctial (Aries–Libra) line.

- More than two labels in this figure are faint or abraded (several inset letters in the upper part; several zodiac glyphs in the lower part)

and the interval of hour 2 to the interval of hour 10, and the interval of hour 3 to the interval of hour 9, and so on.) Then transfer these onto the equator's radius from B, marking points on the equator's radius itself. For straight lines drawn from C through these points will give hours 1 and 11; 2 and 10; 3 and 9; 4 and 8; 5 and 7. And the line CP, drawn parallel to the equator's radius, will belong to both instances of hour 6. Now if you carry the said hour-lines — drawn from C through the points on the equator — over to the other side of the line CP, so that each pair always makes equal angles with CP (which is easily done by means of an arc of a circle described from C at any interval; for if the hour-lines drawn on the side of the equator's radius are carried over to the other side by marking points on an arc I described from C, then straight lines drawn from C through these points will give the remaining hour-lines), you will have the remaining hours, as is clear in the figure.

[Margin: Another way of drawing the hours in the ray-figure.]

But if we transfer the hour-lines lying between C, the center of the dial, and the equinoctial line FG from C onto the equator's radius, we shall find on the equator's radius the same points through which the hour-lines are to be drawn in the ray-figure.

[Margin: A more convenient way of drawing the hours in the ray-figure.]

But we shall draw these same hour-lines most conveniently, without transferring the said intervals onto the equator's radius, in this way. On the line CDK of the twelve-o'clock hour, drawn in the ray-figure as we taught above, take any point O; through it draw OQ parallel to the axis CI, cutting the six-o'clock line CP (which is parallel to the equator's radius) at P. From P, at the interval PO, describe a circle and divide it into 24 equal parts, beginning from O, or Q, or from the line

CP. Join with straight lines each pair of points equally distant from O or Q, these lines cutting the line OQ at points which are to be carefully marked. For straight lines drawn from C through these points will give the hours, as before, and — if everything has been done accurately — will pass through the points marked on the equator's radius. And if each part of the circle described from P is bisected, and then divided into 4 equal parts, we shall in the same way draw the lines belonging to the half-hours and to the quarter-hours.

[Margin: The drawing of the arcs of the signs on a horizontal or vertical dial.]

With these things thus prepared, we shall draw the arcs of the signs in this way. From the ray-figure just constructed we take the portion of the twelve-o'clock line CDK lying between C and the radius issuing from B — the portion nearest to the point C — and we transfer it onto the dial (which for this purpose ought to be drawn with the hour-lines hidden, so that afterward only their portions between the sign ♋ [Cancer] and the sign ♑ [Capricorn] are made distinct, since the other parts are superfluous, being parts on which the shadow of the style cannot fall. So you see in the example that the hour-lines outside the arcs of the signs are marked only with dots, as being superfluous and useless) — transferring it from the center C along the meridian line toward the equinoctial line, and marking a point on the meridian line. Then in the same way we take the portion of the line of hours 1 and 11 lying between the same point C and the said radius, and carry it over onto the dial from the center C onto the lines of hours 1 and 11 toward the equinoctial line, likewise marking two points on those two hour-lines. And so we proceed with the remaining hour-lines that cut the said radius, always transferring the intervals of those lines lying between C and the said radius onto the dial from the center C onto the corresponding hour-lines, marking points on them.

[Margin: Which arcs are to be assigned to which signs, on a horizontal dial as much as on a vertical one.]

It must be observed here, however, and in what follows, that the intervals of the lines falling from C toward the equator's radius BE are to be transferred from the dial's center C onto those hour-lines which extend from the center C toward the equinoctial line FG, as we have done for the lines of hours 12, 1, and 11, and so on, up to both instances of hour 6. But the intervals of the hour-lines falling on the other side of the six-o'clock line CP — those which cannot cut the equator's radius BE — are to be transferred onto the corresponding lines of the dial from C, the dial's center; these lines, beyond the dial's center, recede ever farther and farther from the equinoctial line, as here they fall above the six-o'clock line: such

as, in our example of the horizontal dial, are the lines of hour 7 after noon and the line of hour 5 after midnight, and so on. The points of these, however, have not been marked on our dial, because of the narrowness of the space. Once the points have been marked in this way on the hour-lines, if through them we duly draw a curved line — so that nowhere does it make an angle, but always proceeds uniformly — the arc so described will be the one assigned, on a horizontal dial, to the sign ♋ [Cancer], since the tip of the gnomon's shadow runs along it when the Sun is at the beginning of Cancer. But on a vertical dial that arc must be ascribed to the sign ♑ [Capricorn]. We shall draw the arcs of the other signs in no other way, if we transfer the hourly intervals lying between C and the other rays of the signs onto the dial from the center C onto the corresponding hour-lines, and so on. Further, the arcs between the dial's center C and the equinoctial line — the line assigned to the signs ♈ [Aries] and ♎ [Libra] — belong, on a horizontal dial, to the northern signs, while the others, beyond the equinoctial line, belong to the southern signs. The contrary is to be understood on a vertical dial, and on all others that are not horizontal. And each of the intermediate arcs looks to two signs, as you see on the dial here set forth.

[Margin: Another way of drawing the arcs of the signs.]

We shall delineate these same arcs of the signs if we transfer the hourly intervals lying between the equator's radius and the rays of the signs (whenever this can conveniently be done) onto the corresponding hour-lines on the dial, beginning from the equinoctial line, and so on. That the arcs of the signs are correctly drawn in this way, we demonstrated in Book 2 of the *Gnomonics*, Proposition 2.

[Margin: The drawing of the horizontal line on a vertical dial, and its functions.]

Furthermore, on a vertical dial there must be drawn, through A, the position of the style, a line parallel to the equinoctial line — or perpendicular to the meridian line — which is usually called the horizontal line, since it is the common section of the dial's plane and the horizon, and onto which the shadow of the style is cast when the Sun is on the horizon, that is, when it rises or sets. This horizontal line beautifully shows at what hour the Sun, being on any given parallel, rises or sets, provided that the arc of that parallel cuts the horizontal line. For where the arcs of the signs intersect the horizontal line, there the Sun rises and sets, when it stands at the beginnings of those arcs of the signs. This same horizontal line divides the whole dial into a southern and a northern part, and likewise into a diurnal and a nocturnal part, as we shall explain more fully below in chapter 11, when we shall have drawn the arcs of the signs on a dial

declining from the vertical. On this matter too we have written more in Proposition 14 of Book 2 of the *Gnomonics*.

[Margin: Which arcs of the signs, on any dial, are hyperbolas, or parabolas, or ellipses.]

We shall also easily understand from the ray-figure which arcs of the signs drawn on the dial are hyperbolas, and which are parabolas or ellipses. For whenever the twelve-o'clock line CK cuts two rays of opposite signs — rays equidistant, on either side, from the equator's radius BE — the arcs of those signs will be two opposite and equal hyperbolas. But when the same line CK cuts the radius of some sign between C and the equator's radius BE, while being parallel to the radius of the opposite sign, then the arc of that sign whose radius is cut will be a parabola, and the opposite sign will have no arc. Finally, when the line CK cuts some radius between C and the equator's radius BE, but neither runs equidistant from the radius of the opposite sign nor cuts it (except beyond the point B, when produced), then the arc of that sign whose radius is cut will be an ellipse, and the opposite sign too will have no arc. All this we demonstrated geometrically in Book 1 of the *Gnomonics*. We shall recognize the same on other dials, if in place of the meridian line we take the line of the style on declining dials, and in the ray-figure take the line of the pointer or style of the zodiac in place of the twelve-o'clock line, as will be clear from what follows. In that case the line CK (which on a horizontal, a vertical, and a horizon-inclined dial is the twelve-o'clock line, but on declining dials is the line of the style) will cut the rays of any opposite signs whenever the angle BCD of the pole's altitude above the dial's plane — the angle which the line CK makes with the axis CI — is less, for example, than the opposite and external angle IBG which the radius BG of the opposite sign makes with the same axis IB, this being the angle of the complement of the opposite sign's declination. But when the two said angles are equal, the line CK will be parallel to the radius of the opposite sign. And finally, when the angle BCD of the pole's altitude above the dial's plane is greater than the angle IBG of the complement of the declin-

-ation of the opposite sign, the line CK will neither cut the radius of the opposite sign nor be parallel to it. All of which is clear from Proposition 28 of Book 1 of Euclid.

For the rest, in what way the arcs of the southern signs may be drawn from the arcs of the northern signs on a horizontal dial, or the arcs of the northern signs from the arcs of the southern signs on a vertical dial; or likewise by what method two arcs of two opposite signs (namely when in the ray-figure the line CK cuts the

rays of two opposite signs) may be drawn by one and the same operation (which is indeed very pleasant to know, and very useful) — you will find explained in Book 2, Proposition 2, of our *Gnomonics*.

[Margin: By what art a larger or smaller dial with the arcs of the signs may be drawn from the ray-figure, for a given larger or smaller style.]

Now if, from the lines drawn so far in the ray-figure, a larger or smaller dial is to be delineated for a given gnomon larger or smaller than AB, we must proceed as follows. Having drawn separately the triangle CBD together with the style AB — as in the dial of chapter 4, and as you see was done alongside the ray-figure — produce the straight lines BC, BA, BD; and from BA cut off a straight line BN equal to the smaller or larger style proposed, and through N draw LM parallel to CD. Then transfer the line BL onto the axis CI of the ray-figure — whether to the left or to the right of the equator's radius BE — from B as far as C; and onto the equator's radius from B transfer the line BD of that same triangle CBD, as far as D, so that CB is equal to BL itself, just as the line CB in the ray-figure is equal to the line CB. For if at B, the point now marked, a perpendicular BM is raised to CI, to serve as the equator's radius, and from B on either side the rays of the other signs are drawn out, as was set forth at the beginning of this chapter (which, however, we have not drawn in this figure of ours, so as to avoid confusion of the lines), then the arcs of the signs will be described in proportion to the given style BN, as before — if the intervals of the hour-lines issuing from C, lying between C and the rays of the signs now drawn afresh (which hour-lines indeed do not change at the same elevation of the pole, even if a larger or smaller dial is to be drawn, just as the hour-lines on the dial remain the same at the same altitude of the pole), are transferred onto the hour-lines of the dial, secretly produced, from the center C, and so on. But the equinoctial line must be drawn on the dial perpendicular to the meridian line, through a point that is as far distant from the dial's center C as, in the ray-figure, the line CM is — the CM intercepted between C and the equator's radius just drawn — or as far as the line LM is in the triangle constructed separately: just as also, on our dial, the line CD between the dial's center and the equinoctial line is equal to the line CD in the ray-figure between C and the equator's radius, or to the line CD in the triangle drawn separately.

THE ARCS OF THE ZODIAC SIGNS ON A DIAL DECLINING FROM THE VERTICAL. — CHAPTER XI.

[Margin: The hour-line: in what way the rays of the signs are inscribed on it.]

Once the rays of the signs have been drawn, as we set forth in the preceding chapter, take from the triangle CBD of the dial declining from the vertical — which we constructed in chapter 5 — the straight line BC, which represented the world-axis, and transfer it onto the axis BC [?] of the ray-figure, whether to the left or to the right of the equator's radius BE, from B as far as C; and onto the equator's radius from B transfer the line BD of that same triangle CBD, as far as D. For the line drawn from C through D will be the line of the pointer, or style, just as on the horizontal dial that same line CD was the meridian line D in the ray-figure. Then, on the line

Diagram. The ray-figure (*figura radiorum*) for a dial declining from the vertical, occupying the lower half of the page.

Upper-left construction: a square/triangular framework whose top edge carries the labels B, L, C, L. Down its left side, and within the crossing (X) of its diagonals, appear M, N, A, D, N, M, with G and I lower, and the labels "10" and H at the foot of the left vertical.

Main figure: a large circle (the dial), across whose upper part an arc carries the ascending rim hour-numbers 2, 3, 4, 5, 6, 7, 8, 9 (left to right). Near the left-center is the node cluster I, B with A and c beside it, from which many solid and dotted rays fan downward. Interior points read D, E, L, K, M, H, F. Dashed curved lines are labelled "hor. 10" and "hor. 8" (and a third, "hor. 6" [?]). Along the descending rays at the lower left run the hour-numbers 10, 8, 11, 7, 12, 9; the lower-right side carries 10, 11, 12, 6, 1. Around the bottom rim run the hour-numbers 1, 2, 3, 4, 5, 6 (with several repeated further along the arc).

- Many hour-number and letter labels are faint, crowded, or partly abraded (well more than two flagged/uncertain)

of the style of the dial, take a straight line DI equal to BD itself; and whether above the equinoctial line or below it, take all the hourly intervals between the point I and the equinoctial line, and by means of the compass transfer them onto the equator's radius from B, marking points on the equator's radius itself. For straight lines drawn from C through these points will give the hour-lines corresponding to those hours — lines drawn through the points transferred onto the equator's radius.

We shall obtain these same hour-lines if, on the dial, we take the hourly intervals between C, the dial's centre, and the equinoctial line, and transfer them onto the equator's radius from B, marking points on it. For it is by these points that the hour-lines are to be drawn, as before.

[Margin: Another way of describing the hours in the ray-figure.]

Now if at any time some hour-line on the dial does not cut the equinoctial line — even when produced to infinity — but runs parallel to it, then in the ray-figure it must be drawn from C as the straight line CK, parallel to the equator's radius. For this line will correspond to that hour, just as on the horizontal and vertical dials: because the line of the 6th hour is parallel to the equinoctial line, in the ray-figure the straight line CP has been drawn from C parallel to the equator's radius, corresponding to the 6th hour, as is clear from the preceding chapter.

But in this way the ray-figure yields only those hour-lines which cut the equinoctial line on the dial, since only their intervals have been transferred onto the equator's radius. In our example these are the hours 4.5.6.7.8.9.10.11.12 after midnight and 1.2.3 after noon. Therefore, to obtain the other hours — those which neither cut the equinoctial line nor are parallel to it, namely all those which, after cutting the equinoctial line, have been produced beyond the centre C (in the same example, the hours 4.5.6.7.8.9.10.11.12 after noon and 1.2.3 after midnight, whose intervals cannot be transferred onto the equator's radius) — we shall proceed as follows. Through C, the dial's centre, we shall draw the straight line CP parallel to the equinoctial line, as was done in the accompanying dial of this chapter; and through C, in the ray-figure, the straight line CK parallel to the equator's radius, which will correspond to the straight line CP on the dial, as has been said. Then we shall transfer the hour-lines drawn from C through the points of the equator's radius onto the other side of the straight line CK, so that the two lines on either side always make equal angles with CK. This is easily done by means of a circular arc described from C at any chosen radius. For if the arcs intercepted between the straight line CK and the hour-lines drawn from the side of the equator's radius are transferred to the other side — marking points on the arc described from C — then straight lines from C through these points will give the hours which do not cut the equinoctial line but have been produced beyond the centre C. Thus two lines equidistant from the straight line CK will belong to the two hours of the same number: the one which cuts the equator's radius (that is, the one drawn from C toward that radius) to the hour that cuts the equinoctial line; the other, transferred to the other side of the straight line CK, to the hour of the same number produced beyond the centre C, which does not cut the equinoctial line — exactly as was done on the horizontal and vertical dials. For there too the lines transferred beyond the straight line CP in the ray-figure denote, by number, the same hours which on the dial are denoted by the lines that cut the equator's radius, since it is the intervals of these latter that have been transferred onto the equator's radius, not those of the former. In our example the

line of hour 3 to the left of CK corresponds to hour 3 after noon, since this cuts the equinoctial line on the dial; but the line of hour 3 to the right of the same CK looks to hour 3 after midnight, because this does not cut the equinoctial line on the dial. By the same reasoning the lines of hours 4 and 5 to the left belong to the hours after midnight, because these cut the equinoctial line on the dial; while the lines of the same hours to the right of CK denote the same hours after noon, because these do not cut the equinoctial line on the dial, and so on.

Furthermore, the lines of those hours which cut the equinoctial line on the dial either barely, or very far from the point I or the centre C — such as, in our dial, hour 4 after midnight and hour 3 after noon — we shall transfer into the ray-figure in this way. We shall bisect at the point E the line of the index [linea indicis] CD, which lies between the dial's centre C and the equinoctial line; and from E we shall draw a line parallel to the line of that hour which barely cuts the equinoctial line — a parallel that makes with the line of the index an angle equal to the angle which the line of that hour makes with the same line of the index toward the same side. For if this parallel conveniently cuts the equinoctial line, we need go no further in the division of the straight line CD; but if not, we shall again bisect ED at G, and again bisect GD, and so on, until a straight line drawn from the last point of division, parallel to the line of the said hour, conveniently cuts the equinoctial line. In our example the straight lines GF, GH are parallel to the lines of hour 3 after noon and hour 4 after midnight, cutting the equinoctial line at F and H, and the straight line GD is a quarter of the straight line CD. Then let the same fraction that GD is of CD — namely DO of DI — be taken on the same line of the index, and let CQ be the same fraction of the axis CB; that is, let DI and CB be divided into as many equal parts as CD has been divided. On the axis CQ, in the ray-figure, let a length CA equal to CA be cut off from the axis CB; and through A let AL be drawn parallel to the equator's radius BD, serving as a kind of new equator's radius with respect to the lines GF, GH drawn on the dial. For if the intervals OF, OH are transferred onto this parallel AL, marking the points M and L on the said parallel AL, then the straight lines CL, CM drawn to them will correspond to the said lines of hours 3 and 4, which cut the equinoctial line on the dial too far from the point I or the centre C. We shall use this same device on horizontal and vertical dials whenever some hour-lines cut the equinoctial line either barely, or too far from the dial's centre — such as the lines of hours 5, $5\frac{1}{4}$, $5\frac{1}{2}$, $5\frac{3}{4}$ after noon, and $6\frac{1}{4}$, $6\frac{1}{2}$, $6\frac{3}{4}$, 7 after midnight.

Moreover, we shall also draw all the hour-lines in the ray-figure most accurately, without transferring them from the dial onto the equator's radius, in this way. Having drawn the straight line CD as before, to correspond to the line of the

index, we shall take on it, produced, any point H, through which we shall draw the line HI parallel to the axis BC; and through C another line CK parallel to the equator's radius BD, which cuts the former line HI at K. Then, with centre K and radius KH or KI, we shall divide the described circle into 24 equal hours, beginning not from the point H (as was done on the horizontal and vertical dials, because here the straight line CD does not represent the meridian line, or the line of hour 12, as it did there) but from some other point, which we shall find as follows. The interval IR we shall transfer from the dial onto the equator's radius from B as far as E, and through E, from C, we shall draw the straight line CE, which will represent hour 12 — provided the interval BE is equal to the interval IR between I and hour 12 on the equinoctial line. Therefore, the division must begin from the point of the circle which corresponds to the point F, where the line of hour 12, CE, cuts the straight line HI: namely from the point G, which is given by the straight line FG drawn at right angles to HI, either upward or downward. Or else, the interval between I and any hour on the equinoctial line — whichever proves more convenient for this purpose — we shall transfer onto the equator's radius from B, marking a point on the radius itself, and through this point, from C, we shall draw a straight line which will represent the assumed hour and will cut HI at a point; and from that point, if a perpendicular be raised to HI, it will reach the very same

part to which the point G belongs, if the assumed hour and hour 12 lie on the same side of the style-line; but the opposite part, if the assumed hour lies on one side of the style-line and hour 12 on the other. This perpendicular will give on the circumference another point, from which the division of the circle into 24 equal parts can begin just as well as from G. Indeed it will be very useful for this second point to be investigated: for if the division-points of this second point coincide with the division-points of the point G, the matter succeeds as intended; if not, some error committed somewhere must be corrected. It is also better to begin the division of the circle from this second point rather than from the first, G, when hour 12 is very close to the style-line. For then the perpendicular FG cuts the circumference too obliquely, so that the point G can scarcely be taken without error. I mean this to be understood also in dials declining from the horizon, and in those declining from the vertical and at the same time inclined to the horizon. After this, from the division-points we shall drop hidden perpendiculars to the straight line HI. For these will cut HI at points through which straight lines drawn from C will give the hour-lines, as before. And from the division-points we shall easily judge to which hours the lines correspond on the dial: for the points running from G toward H denote those hours which on the dial follow hour 12 toward the style-line, namely 11, 10, 9, 8, and so on, in our example, as is clear

from the figure. Those hidden perpendiculars to HI from the division-points of the circle we shall likewise draw easily. If perchance two points on either side are equidistant from the point H (which happens only when the style-line is itself an hour-line, or is equidistant from the two nearest hour-lines), then the straight lines joining to HI the two points equally distant from H will be perpendicular. But if two points on either side of H are unequally distant, take the interval of any point from H or I in the upper semicircle and transfer it into the lower semicircle from the same point H or I. For the straight line joining these two points equidistant from H or I will be perpendicular to HI. And in the same way the intervals of the points of the lower semicircle from H or I are transferred into the upper semicircle, marking points on it, and so on.

[Margin: The description of the arcs of the signs on a dial declining from the vertical.]

With all this prepared, we shall describe the arcs of the signs on the dial from the ray-figure, just as on the horizontal and vertical dials: namely, by transferring the intervals of the hours intercepted between C and the radii of the signs onto the corresponding hours of the dial, from the dial's centre C; or else by transferring the hour-intervals set between the equator's radius and the radii of the signs onto the corresponding hour-lines of the dial, from the hour-points of the equinoctial line, and so on. And if the style-line happens to be the same as some hour-line, or equidistant from the two nearest hour-lines on either side, then each of the aforesaid intervals must be transferred onto the two hour-lines equidistant on either side from the style-line, just as was done on the horizontal and vertical dials.

Diagram. The ray-figure (*figura radiorum*) for a dial declining from the vertical, occupying the lower half of the page and facing the framed plate on the opposite page. From an apex C at the top of a vertical line, a broad fan of solid and dashed straight lines (the radii of the hours and of the signs) spreads downward and outward. This figure faces the framed plate

- C (apex, top): dial centre / vertex of the ray-fan
- K (upper left, beside C): endpoint of the line CK parallel to the equator's radius
- Q (just below C): node point
- A, E, L (row left of centre): construction points on the axis / parallel
- B (below the A–E–L row): base point
- D (lower left): construction point

- R (below B): construction point
- N (right of centre): construction point
- P (far right, with dashed line running off toward the gutter): endpoint of line CP
- M, H (left side, H above M): construction points
- F (lower right): construction point
- Hour-numbers read along the rays: I, II, 12 (lower left); 2, 3 (lower right); and 4, 5, 6, 8 among the descending rays
- Zodiac glyphs decorate the ray-ends: Capricorn (♑) at the top; Pisces (♓) and Aquarius (♒) upper left; and, among the lower rays, Virgo (♍), Aquarius (♒), Taurus (♉) and further worn glyphs [?]

Many hour-number and letter labels are faint, crowded, or partly abraded (well more than two uncertain)

[Margin: Which arcs are to be assigned to which signs on a dial declining from the vertical.]

We have written more, bearing on the more accurate description of the arcs of the signs, in Proposition 2 and its scholium in Book 3 of our *Gnomonics*.

The arcs above the equinoctial line — the line which is assigned to the signs Aries (♈) and Libra (♎) — belong to the southern signs; those below the equinoctial line belong to the northern signs, just as on the vertical dial. Whether the arcs of these signs are hyperbolas, or parabolas, or ellipses, we shall easily understand from what we wrote in the preceding chapter, by carefully examining whether the style-line CD cuts the radii of the opposite signs or not, and so on.

The horizontal line [*linea Horizontalis*] — the line onto which the shadow falls at sunrise or sunset — is drawn through A, the place of the style, perpendicular to the meridian line; such is the straight line AL. This line shows at what hour the Sun rises or sets when it stands in any given parallel whose arc cuts the horizontal line. For where the arc of some sign intersects the said line among the hours after midnight, there the Sun rises; and where the arc of some sign cuts the same line among the hours after noon, there the Sun sets. Thus you see that the Sun, when it is at the beginning of Capricorn (♑), rises about hour 7½; in Sagittarius (♐) and Aquarius (♒), before hour 7½; in Scorpio (♏) [?] and Pisces (♓) (♓), about hour 6¾; in Aries (♈) and Libra (♎), at hour 6.

This same horizontal line divides the whole dial into two parts, of which the lower, being the larger, faces south when the dial is in its proper position, while

the upper, being the smaller, faces north — so that the former may be called the southern dial, the latter the northern. Each is to be so placed that the horizontal line is parallel to the horizon and occupies the upper position. On the northern dial, however — which faces us when we turn to the dial — the things that are on the right (when the horizontal line is set above) become the left, and vice versa, and the arcs of the southern signs are changed into the arcs of the opposite northern signs, and conversely. But once both dials are set in their proper position, all the lineaments above the horizontal line must be cut away as superfluous. Again, this same horizontal line divides the whole constructed dial into two: that part which is below the horizontal line (the horizontal line being set parallel to the horizon) may be called the Diurnal, because it shows the hours by day; the other, above the horizontal line, may be called the Nocturnal, because it would show the night hours if the Sun's rays could penetrate the earth and illuminate the dial itself. Hence the portions of the arcs of the signs may not inappropriately be named the diurnal arcs on the diurnal dial, and on the nocturnal dial the nocturnal arcs of the same signs.

[Margin: The description of the horizontal line on a dial declining from the vertical, and its various functions.]

Diagram. The constructed declining dial (*horologium*), drawn as a large circle whose upper part touches the top edge of a tall rectangular frame. From the top of the circle a fan of hour-lines (solid and dashed) descends through the disc. Along the top edge of the frame appear the labels B ... B (with a small c beside the first). In the upper-right corner of the frame is a separate right-angled sub-construction (the scaled triangle with its parallel LM): its labels, read top to bottom along the right margin, are B, L, C, L, B, then N, A, then M, D, then K, I, then M, B.

- Along the left inner edge, hour-numbers run down the descending rays: 1½[?], 1·11, 2·10, 9, 8, 4, 5, 6, 7 [reading uncertain — worn]
- Interior labels within the disc: M, D, P, F, H, E
- Zodiac glyphs mark several ray-ends around the lower circle (worn) [?]

Many labels are crowded and partly abraded (well more than two uncertain)

Diagram. A second ray-figure (the separately-drawn, scaled construction), beneath the dial and within the same frame. From an apex C at the top of a vertical line, solid and dashed rays fan symmetrically downward. Near the centre is a small triangle with H and E over A, and B to its left.

- C (apex, top): vertex of the ray-fan

- B, E, A, H (central triangle cluster): base and style points; a small b lies just below
- F (left, on a horizontal line): construction point
- G (left, on a lower horizontal line): construction point
- Hour-numbers along the middle horizontal band, left to right: 4, 3, 2, 1, 12, 11, 10, 9, 8
- Lower hour-numbers along the descending rays: 5, 6, 7, 8
- Zodiac glyphs at the ray-ends: Capricorn (♑) and Leo (♌) upper right; Virgo (♍) and Libra (♎) at right; Pisces (♓), Aquarius (♒) and further worn glyphs at lower left; Capricorn (♑) at the bottom

Many labels are crowded and partly abraded (well more than two uncertain)

But if, from the lineaments so far drawn, a larger or smaller dial is to be constructed for a given size of style, we shall do it in this way. Let the triangle of the dial CBD be drawn separately, together with the style BA taken from the dial (as you see has been done beside the ray-figure), and let BA be produced as far as you please. Then, on BA, having taken the straight line BN equal to the given style, let LM be drawn through N parallel to CD. For if on the axis BC of the ray-figure a length CA equal to CA be cut off by the straight line BL, and from A the radii of the signs be drawn, and all the rest be done as before, the arcs of the signs will be described for the size of the given style BN, just as before.

[Margin: How, from the ray-figure, a dial with the arcs of the signs may be constructed for a larger or smaller style.]

were drawn earlier for the given style BA. For the hour-lines, both in the ray-figure and on the dial, remain exactly the same at the same elevation of the pole and the same declination of the plane. The equinoctial line, however, is to be drawn perpendicular to the style-line, at a distance from the centre C of the dial equal to the straight line LM. All of this is to be done in the same way on other dials as well — even on ones that decline and are at the same time inclined — as is plain from our *Gnomonics*.

[Margin: How the arcs of the signs are described on any dial whatever, with no regard to the hour-lines.]

We shall likewise describe the arcs of the signs on any dial, taking no account of the hours, in the following way. In the ray-figure, having drawn the straight line CD — which on a horizontal, vertical, or horizon-inclined dial represents the meridian line, but on the others the style-line — let there be marked, on the

radius issuing from B that lies farthest from the point C (such as, in the ray-figure of this chapter, is the radius $\mathfrak{S}$ [Cancer], which lies nearest to point H), below the line CD, as many points at small distances from one another as you please. (For the more crowded these points are, the more accurately the arcs of the signs will be described.) Through these points let straight lines be emitted from C, after the manner of the hour-lines. Then, below the point where the radius of the equator was marked off from the last of those lines — namely the line drawn through the lowest point marked on that radius — let there be marked in the same way, on the radius of the equator, as many points at small distances apart as can conveniently be marked, and through them let straight lines likewise be emitted from C. Taking also another point B very close to the point C, and drawing BM parallel to the radius of the equator, let points again be marked on this line BM, below the last line so far drawn from C, at small distances from one another, and through them let straight lines be emitted from C. Finally, having drawn the straight line CP parallel to the radius of the equator — the line which, on the dial, represents the line drawn through the centre equidistant from the equinoctial, such as is the line of the 6th hour on a horizontal, vertical, or horizon-inclined dial — let the lines drawn so far be transferred, by means of an arc of a circle described from C, to the other side of the straight line CP.

After all this, let the intervals on the radius of the equator between B and the lines so far drawn from C be transferred, with the help of compasses, from the point E of the dial of chapter 10, or from the point I of the dial of this chapter 11 (which is as far from the equinoctial line, along the style-line, as the straight line DB in the triangle CBD), to either side onto the equinoctial line, by impressing points on the equinoctial line itself. Through these points let hidden straight lines be emitted from the centre of the dial, after the manner of the hour-lines; and these correspond to the straight lines emitted from C in the ray-figure,

just as, above, the hour-lines of the dial corresponded to the lines drawn from C in the ray-figure. Hence, so that it may be easily recognized which hidden lines of the dial correspond to which lines of the ray-figure, numbers must be attached to the lines of the ray-figure: thus 1 to the style-line CD, 2 to the next line, 3 to the third, 4 to the fourth, and so on. And the same numbers must be assigned to the hidden lines of the dial: 1 to the style-line; but to the lines next to it on either side, 1; to the third lines on both sides, 3; and so on. For the lines issuing from C that do not cut the radius of the equator, we shall draw the corresponding lines on the dial in this way. We shall transfer the portion of the straight line CD intercepted between C and the line BM from the centre of the dial onto the style-line, impressing a point on it. Through this point we shall draw a line parallel to the

equinoctial line, and below it we shall cut off from the same style-line a straight line equal to the portion of the line BM lying between B and the line CD, impressing a point on it. For if from this point we transfer, onto the line drawn parallel and next to the equinoctial line, straight lines equal to the portions of BM lying between B and the lines not yet transferred to the equinoctial line, impressing points on the said parallel line, then the straight lines emitted from the centre of the dial through these points will correspond to those lines which could not be transferred to the equinoctial line.

When all this has been properly done, the arcs of the signs will be described, as we taught before — namely, if we transfer the intervals of the straight lines issuing from C in the ray-figure, measured between C and the radii of the signs, from the centre of the dial onto the corresponding hidden lines, transferring each single interval onto the two straight lines on either side of the style-line that correspond to it (on declining dials as well), and so on. In this way the arcs of the signs will be delineated more accurately than by the hour-lines alone, because the hour-lines are sometimes farther apart than is fitting for this task, whereas our hidden lines keep a smaller distance from one another; and from this it comes about that more numerous points are available for the arcs of the signs.

You may also, if you prefer, first draw from the centre of the dial straight lines a little apart on either side of the style, in such a way that the pairs on either side cut off equal parts from the equinoctial line; and then transfer the intervals on the equinoctial line between E and these lines onto the radius of the equator from B, as was said above concerning the hour-lines, and so on. But I prefer the former method, because by it the points obtained on the radius, at the point farthest from C, are less far apart than by this latter one. We have explained this matter using the letters of the horizontal dial of the previous chapter, even though no lines other than the hour-lines were drawn on it.

THE ARCS OF THE LENGTHS OF THE DAYS on any dial.

CHAPTER XII.

Just as we have so far described the arcs of the signs, which the tip of the shadow traverses when the Sun is at the beginnings of the signs, so too the arcs of the lengths of the days are usually described — the arcs which the same shadow traverses when the artificial day contains a given number of hours, such as 10 hours, or 8, or 11, or 13, and so on. For this to be done, one must first construct a figure containing the radii of the parallels of the Sun that mark off a determined

number of hours above the horizon, after the manner of the figure containing the radii of the signs, which we described in chapter 10.

[Margin: How the radii of the diurnal arcs are drawn.]

So, having described from A an arc of a circle CD at any interval, and having drawn the straight line AB as the radius of the equator — that is, as the diurnal radius of the 12th hour — let the complement of the elevation of the pole above the horizon be laid off from B on either side, as far as C and D. Then let the straight line CD be drawn, cutting AB at E; and from E, at the interval EC or ED, let a circle be described and divided into 48 equal parts, beginning from C or D. For if two division-points equally distant from C or from D are joined by hidden straight lines, CD will be cut at points through which the diurnal radii are to be emitted from A: so that AD is the radius of hour 0, the one next to it the radius of hour 1, the next the radius of hour 2, and so on up to AC, which is the radius of hour 24, as appears in the figure. And the arc of the circle CBD, comprised between AB — the diurnal radius of the 12th hour, or radius of the equator — and the said diurnal radii, measures the declinations of the parallels of the Sun which those radii represent; that is, the parallels whose diurnal arcs above the horizon comprise as many hours as are assigned to the individual radii. All of this we have demonstrated geometrically at the end of the *Gnomonics*.

Diagram. The ray-figure for the arcs of the lengths of the days. A protractor-like construction: from an apex **A** at the top (with a short vertical style-stub above it) a dense fan of straight and dashed radii descends. A large arc **CD** sweeps over the fan, with **C** at the upper left and **D** at the upper right. Down the central vertical axis lie **A** (apex), **E** (on the horizontal diameter through the fan), and **B** (lower down). Along the left margin, hour-numbers label the descending rays, read top to bottom: 24, [23 and 22 not visible], 21, 20, 19, 18, 17. Along the lower arc, hour-numbers run left to right: [worn glyph ~"15"/"16" — reads uncertain], 14, 13, 12 (split by the axis), 11, 10, 9, [8]. On the right margin (about D) the sequence continues up toward 0, with a legible "0" near the top-right and worn "4", "5", "6" below it.

- A (top, on axis): apex from which the diurnal radii issue; AD = radius of hour 0, AC = radius of hour 24
- C (upper left): left end of arc CD
- D (upper right): right end of arc CD
- E (centre, on horizontal diameter): intersection of CD with the axis AB
- B (lower, on axis): point below E

- Left-margin ray-labels (top→bottom): 24, 21, 20, 19, 18, 17
- Lower-arc ray-labels (left→right): [~15?], 14, 13, 12, 11, 10, 9, [8]
- Right-margin ray-labels: 0, [4?], [5?], [6?]

Several peripheral hour-labels are abraded (more than two uncertain)

[Margin: How the diurnal arcs are described on the dial.]

Now if we transfer any diurnal radius into the ray-figure of the signs from the point B, after the manner of some radius of a parallel, we shall describe its arc in exactly the same way as we described the arcs of the signs in the two preceding chapters. Into the ray-figure of chapter 10 were transferred the radii of hours 10 and 14; but into the ray-figure of the preceding chapter, the radii of hours 8, 10, 14, and hour 0 — such being the radii issuing from B, which are distinguished by dots or little lines.

This page is dominated by a large framed engraved plate carrying two labelled constructions for Chapter XI (the declining dial and its ray-figure). Both are crowded and heavily abraded; more than two labels in each are uncertain.

Diagram. The constructed declining dial : a large disc whose top touches the upper edge of the frame, with a fan of solid and dashed hour-lines descending from a point near the top. Along the top edge of the frame run the labels **B ... B ... B ... I** (a small **c** beside the first B). In the upper-right corner of the frame is a separate right-angled sub-construction, its labels read roughly top-to-bottom / left-to-right: **L, C** (top), **N, K I, M, D**, with **B** at the outer right. Interior points of the disc, read down the middle and to the sides: **P, M, H, E, F, G**.

- Top frame-edge: B, B, B, I (small c beside first B)
- Corner sub-construction (upper right): L, C, N, K, I, M, D, B
- Disc interior: P (upper middle), M (right of centre), H and E (mid, on a horizontal), F (left, lower), G (right, lower)
- Left-margin hour-line labels (top→bottom): [1?], "1·11", "2·10", 9, 8; then along rays 8, 7 (left) and 6, 6 (right)

Many labels crowded and partly abraded (well more than two uncertain)

Diagram. The ray-figure (scaled construction) beneath the dial and within the same frame. From an apex **C** at the top, solid and dashed rays fan symmetrically downward across a central cluster with **B**, and near it **E, A, H**; **F** lies on a horizontal line to the left, **G** on a lower horizontal line to the right. Hour-numbers run along the middle band and the descending rays (left to right along the lower

band: 4, 3, 2, 1 near the axis; 5, 6, 7, 8 continuing). Zodiac glyphs mark the ray-ends around the margins.

- C (apex, top): vertex of the ray-fan
- B, E, A, H (central cluster): base/style points
- F (left, on a horizontal line): construction point, near Aries ♈
- G (right, on a lower horizontal line): construction point, near Libra ♎
- Zodiac glyphs at ray-ends, left margin (top→bottom): [worn], ♊ [Gemini, uncertain], ♉ (Taurus), ♈ (Aries, at F), ♐ (Pisces), ♑ (Aquarius), ♐ (Capricorn, bottom)
- Zodiac glyphs at ray-ends, right margin (top→bottom): ♐ [Capricorn, uncertain], ♌ (Leo), ♍ (Virgo), ♎ (Libra, at G), ♏ (Scorpio), ♐ (Sagittarius), ♐ (Capricorn)
- Hour-numbers, lower band (left→right): 4, 3, 2, 1, 12, 11, 10, 9, 8; lower rays: 5, 6, 7, 8

Many labels crowded and partly abraded (well more than two uncertain)

HOURS FROM SUNRISE AND SUNSET on a horizontal dial, and on one declining from the vertical.

CHAPTER XIII.

The description of the hours from sunrise and sunset by means of the diurnal and nocturnal arcs is very easy. For this purpose we have excerpted the following little tables from the scholium of Proposition 33, Book 1, of our *Gnomonics*, in which it appears at once which hours from sunrise and sunset correspond to which hours from noon and midnight in any diurnal or nocturnal arc. To these we have added a table of the EQUINOCTIAL LINE, from the scholium of Proposition 19, Book 1, of the same *Gnomonics*, by which it is immediately known which hours from noon or midnight, and from sunrise or sunset, meet one another [se mutuo succe(n)t — abbreviated form, "succeed / coincide with"] at one and the same point of the equinoctial line.

*In the tables below, the Latin row-labels are: **Horæ ab occasu** = hours from sunset; **Horæ à med. noct.** (also written **med.nocte**) = hours from midnight; **Horæ à meridie** (also **à merid.**) = hours from noon; **Horæ ab ortu** = hours from sunrise. The centre column carries the noon/midnight label at which the reckoning switches. Row-labels and cell values are transcribed verbatim.*

Arcus diurnus horarum 8. in quo Sol oritur hora 8. à med. noc. & hora 16. ab occ. & hora 24. ab ortu. (Diurnal arc of 8 hours, in which the Sun rises at hour 8 from midnight, hour 16 from sunset, and hour 24 from sunrise.)

These pages continue Chapter XIII, presenting the hour-correspondence tables for the several diurnal and nocturnal arcs (the "arcs" whose catchword closed the previous page), followed by the table for the equinoctial line and the worked explanation of how to lay out the hours from sunrise and sunset on any sundial.

The recurring Latin row-labels mean: *Horæ ab occasu / ab oc. / ab or.* = hours from sunset / hours from sunrise; *Horæ à meridie* = hours from noon; *Horæ à med. noct. / à med. noc. / à media nocte* = hours from midnight; *Horæ ab ortu* = hours from sunrise. In each three-row table a column represents one instant expressed in two or three reckonings; the centre label-cell marks where the noon↔midnight (or sunrise↔sunset) reckoning switches, and is blank in the outer rows.

Diurnal arc of 10 hours, in which the Sun rises at hour 7 from midnight, hour 14 from sunset, and hour 24 from sunrise. [*Arcus diurnus horarum 10. in quo Sol oritur hora 7. à med. noc. & hora 14. ab occasu & hora 24. ab ortu.*]

	3	4	5	6	7	8	9	0	1	2	3	4	

Although in the preceding tables only whole hours have been laid out, they are to be understood as applying to half-hours and quarter-hours as well, and so on. Thus, for example, just as on the equinoctial line the 8th hour from noon or midnight, the 2nd hour from sunrise or sunset, and the 14th hour from sunrise or sunset all pass through one and the same point, so too through one and the same point on that same equinoctial line will pass the 8½ hour from noon or midnight, the 2½ hour from sunrise or sunset, and the 14½ hour from sunrise or sunset. In the same way, not only are the 12th hour from noon or midnight, the 6th hour from sunrise or sunset, and the 18th hour from sunrise or sunset drawn through a single point of the equinoctial line; but the 12¼ hour from noon or midnight, the 6¼ hour from sunrise or sunset, and the 18¼ hour from sunrise or sunset will also intersect one another at one and the same point of that same equinoctial line, and so on.

[Margin: Descriptio horarum ab or. vel occ. in quovis horologio. — The drawing of the hours from sunrise or sunset on any sundial.]

Therefore, if the hours from sunrise and sunset are to be drawn on any sundial whatever, we must first find, among the hours from noon or midnight, the points of the diurnal arcs of 10 and 14 hours — that is, we must first lay out the arcs of 10 and 14 hours by the foregoing precepts, imprinting only their points on the lines of the hours from noon or midnight, as we have done here in the horizontal sundial and in the one declining from the vertical. Next we must turn back to the

tables of those same diurnal arcs. For in them we shall find very quickly through which hours from noon or midnight — that is, through which points of the said diurnal arcs (marked in the hours from noon or midnight) — each hour from sunrise or sunset is to be drawn. By the same method the table of the equinoctial line is to be used.

Diagram. A sundial hour-line construction figure enclosed in a rectangular frame. From an apex cluster at the top-centre, a fan of straight hour-lines spreads downward and outward to the left and right, crossed by dotted lines representing the equinoctial line and the diurnal/nocturnal arcs. The left-hand hour-lines are labelled with Roman numerals, the right-hand ones with Arabic numerals; the dotted arc/equinoctial lines carry their own hour-numbers where they cross.

- Apex cluster (top-centre, the style/gnomon points): C, B, F, D set in a row, with E just below, and A at the vertex of a small inverted triangle where the lines converge.
- Left side, hour-lines from top downward (Roman numerals): XIII, XII, XI, X, IX.
- Right side, hour-lines from top downward (Arabic numerals): 11, 12, 13, 14, 15, 16 (a further topmost right-hand label is worn — [?]).
- Dotted-line (equinoctial / arc) hour-labels visible along the descending dotted curves: 6, 7, 8 [these three legible; other dotted-line numbers present but not resolvable].
- A dense central fan of small labels close to the vertex A — Roman I, II, III, IIII and numerous small Arabic numerals (including 12 below the vertex, and values in the teens and low twenties) — marking the hour-points where the lines cross. These small central labels are too closely set and worn to resolve individually [?].

The figure is a labelled informational diagram; several central and dotted-line labels are illegible and should be re-examined.

For in it we shall see at once through which hour from noon or midnight the same hour from sunrise or sunset must pass on the equinoctial line. Thus you see that in both sundials the 1st hour from sunrise is drawn through the 8th hour from midnight of the diurnal arc of 10 hours, through the 7th hour from midnight of the equinoctial line, and through the 9th hour from midnight of the diurnal arc of 14 hours. The 2nd hour from sunrise, in turn, [is drawn] through the 9th hour from midnight of the diurnal arc of 10 hours, through the 8th hour from midnight of the equinoctial line, and through the 7th hour from midnight of the diurnal arc

of 14 hours; and so on in succession you discern the other hours from sunrise drawn through the three points that follow in that order. Likewise you see, in both sundials, that the 15th hour from sunset passes through the 8th hour from midnight of the diurnal arc of 10 hours, through the 9th hour from midnight of the equinoctial line, and through the 10th hour from midnight of the diurnal arc of 14 hours. Likewise the 16th hour from sunset [passes] through the 9th hour from midnight of the diurnal arc of 10 hours, through the 10th hour from midnight of the equinoctial line, and through the 11th hour from midnight of the diurnal arc of 14 hours; and so on in succession, through the three points that follow in that order, you will find the other hours from sunset drawn.

And if it happens that only two points are found for some hour, that hour must be drawn through those two, or else a third point corresponding to that hour must be sought — in the nocturnal arc, or to be investigated in some other diurnal arc. Thus you will find that the 13th hour from sunset in both sundials is drawn through two points, namely through the 8th hour from midnight [of] the equinoctial line; yet in the sundial declining from the vertical the same 13th hour from sunset is also drawn through the 6th hour from midnight of the nocturnal arc of 14 hours. For the portion of the diurnal arc of 10 hours that lies above the horizon is the nocturnal arc of 14 hours. But whenever only a single point is found for some hour from sunset, another point must be taken in the nocturnal arc for the same hour reckoned from sunrise. Thus you see that the 22nd hour from sunset is drawn, in the declining sundial, through the 3rd hour from noon of the diurnal arc of 10 hours, and through the 5th hour from midnight of the nocturnal arc of 14 hours — which 22nd hour, in the nocturnal sundial, signifies the 22nd hour from sunrise, as will be explained a little below. Or indeed the same 22nd hour from sunset must be drawn through the 2nd hour from noon of the diurnal arc of 8 hours, namely through point E. By the same reasoning the 23rd hour from sunset is drawn through the 5th hour from midnight of the equinoctial line (and, in so far as it is reckoned from sunrise) through the 6th hour from midnight of the diurnal arc of 8 hours, and through the 3rd hour from noon of the diurnal arc of 8 hours, and so on; and also through point F, that is, through the [?] hour of the diurnal arc of 8 hours.

[Margin: Quæ horæ in horologio boreali pertineant ad horas ab or. & quæ ab horas ab occ. — Which hours on the northern sundial pertain to the hours from sunrise, and which to the hours from sunset. (Printed "ab horas"; read as *ad horas*, "to the hours.")]

Finally, if the foregoing tables are carefully weighed, all the hours from sunrise and sunset will easily be described, provided you remember to take, for the hours from sunset, the same hours from sunrise in the nocturnal arcs. And if this is not yet sufficient for describing some hour from sunrise or sunset, another point must be sought in the diurnal arc of 8 hours or the nocturnal arc of 16 hours.

Moreover, since the portion of the sundial lying above the horizontal line — which we have called the nocturnal sundial — presents a sundial to be placed on the face of a north-facing wall, if its parts are inverted (as was said above at the end of Chapter 4): in order that we may know which lines produced beyond the horizontal line pertain to the hours from sunrise and which to the hours from sunset, let this method be followed. Let there be carefully considered, in that portion, in so far as the sundial [...]

it is a nocturnal sundial — which hours are to be reckoned from sunrise and which from sunset. For the hours from sunset, in that portion in so far as it is a nocturnal sundial, are to be counted from sunrise; and the hours from sunrise are to be reckoned from sunset in the same portion, in so far as it presents the northern sundial [*horologium boreale*]. And thus we shall distinguish the hours from sunrise from the hours from sunset in that portion, according as it is a nocturnal sundial.

All the hours that are counted from sunrise in the portion of either sundial lying below the horizontal line — that is, in the diurnal sundial — are likewise to be counted from sunrise in the nocturnal sundial, if they cross the horizontal line before they cross the meridian line; and the same must be said of the hours from sunset. But the hours from sunrise in the diurnal sundial, if they cross the meridian line before the horizontal, are to be reckoned in the nocturnal sundial from sunset; and the hours from sunset [are to be counted] from sunrise. Thus the hours 23, 22, 21, 20 in the nocturnal sundial are to be counted from sunrise, because in the diurnal sundial they are reckoned from sunset and cross the meridian line before they reach the horizontal. These same hours, therefore, will have to be counted from sunset in the northern sundial. But the hours 11, 12, 13, 14, 15 in the same nocturnal sundial will belong to the hours from sunset, because in the diurnal sundial they answer to those same hours and cross the horizontal line before they intersect the meridian; and so these same hours will have to be counted from sunrise in the northern sundial.

In both of our examples, so that the sunrise-hour lines might be distinguished from the sunset-hour lines, we have attached to the hours from sunrise the ancient number-signs, thus: I, II, III, IIII, V, VI, VII, VIII, etc.; while to the hours

from sunset we have assigned the common number-signs, as 11, 12, 13, 14, 15, 16, 17, etc. Finally, the lines of the hours reckoned from noon and from midnight are distinguished only by points [dots].

Diagram. The large upper figure on printed p. 34 — the hour-line web of the declining (nocturnal/northern) sundial discussed in this chapter, continuing the construction begun on the preceding pages. A long vertical line (the meridian / stylus line) rises at the center; from a cluster of points near the center a dense fan of solid and dotted hour-lines radiates outward to the right and downward. The confidently legible labels are:

- Central and adjacent point letters: **C** (top of the vertical line), **K** (left of C), **A** (the principal point of convergence, center-left), **L** (right of A), **B** (below A), **E** (right of B), **N** (right of E), **F** (right of N) — B, E, N, F stand in a row along the horizontal line.
- Left-side point letters: **D, H, I, S**.
- Hour-numerals from sunrise (Roman, "ancient" signs): **I, II, III, IIII, V, VI, VII, VIII** along the lower left, and **IX** (upper left); further Roman signs (X–XVI) run up the left margin but are small and rotated.
- Hour-numerals from sunset (Arabic, "common" signs), running clockwise down the right and lower edge: **24, 23, 22, 21, 20, 19, 18, 17, 16, 15, 14, 13, 12, 11, 10, 9, 8** and, near the center, **1, 2, 3**.

Many of the smaller rotated hour-numerals along the rays cannot be resolved individually and the exact ray-to-label assignments are not all legible. [Several labels [?]]

Diagram. The smaller framed (ruled square) figure at the foot of printed p. 34 — the nocturnal / northern (boreal) sundial, its hour-lines radiating symmetrically to left and right from a small central gnomon-triangle. A vertical meridian line runs through the frame from top to bottom. At the center the little triangle carries the letters **c, B, F, D** (across the top), **E** (just below), and **A** (at the apex). The legible hour-labels are:

- Roman hour-signs down the left side: **XIIII, XIII, XII, XI, X, IX, VIII**.
- Arabic hour-signs interspersed and on the right: **6, 23, 22** (left/lower) and **7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 18** (center and right), with **12** on the meridian at bottom.

The two wings of numerals mirror one another about the meridian; several of the small numerals are faint. [Several labels [?]]

Now, since in all the aforesaid sundials the gnomon or stylus must be fixed in its proper place at right angles to the plane of the sundial, it will not be out of place to repeat briefly here, from our *Gnomonics*, what we wrote in Book 4, Proposition 12 about setting the stylus at right angles and about restoring it to its proper position should it happen to have been deflected from it.

The stylus, then, will be set at right angles and restored to its proper position as follows. From A — the place of the stylus on the meridian line of the horizontal sundial of this chapter — let a straight line AB be taken equal to the length of the stylus; and, drawing through B the straight line CD perpendicular to AB, so that the parts BC and BD are also each equal to the stylus, let the straight lines AC and AD be joined. Then, taking on AD a straight line AE that is likewise equal to the stylus, let a straight line CF be cut off equal to the interval CE. For if the stylus AB makes right angles with the plane of the sundial at A, the interval CF must be equal both to the interval between C and the tip of the stylus and to the interval between D and the tip of the stylus, as we demonstrated in the passage cited. But if the said intervals are not equal, the gnomon must be shifted back and forth, before it is fixed, until those intervals become equal; for then it will make right angles and will have its proper position.

The same must be done in other sundials, provided that the straight line AB, equal to the stylus, is taken on the line of the stylus, or on any other straight line drawn through the place of the stylus, in case the meridian line does not pass through the place of the stylus. We have set an example of this in the horizontal sundial of the hours from sunrise and sunset of this chapter, as appears in the triangle ACD. Whoever wishes for more about the place of the stylus, its setting, its size, and the elevation of the pole above the plane of the sundial, let him read Propositions 12 and 13 of Book 4 of our *Gnomonics*.

[Margin: Qua ratione stylus ad rectos angulos statuatur in horologio, & in proprium situm restituatur, si ab eo dimotus sit. — By what method the stylus is set at right angles in the sundial, and restored to its proper position if it has been displaced from it.]

THE DESCRIPTION OF SUNDIALS ON ANY SURFACE WHATEVER, BY MEANS OF THE SHADOW OF THE STYLUS OF SOME HORIZONTAL SUNDIAL OR OF ANY OTHER

CAPVT XIII.

Giovanni Battista Vimercati [Ioannes Baptista Vimercatus], in his booklet on the description of sundials, hands down a certain very easy and very simple method of describing sundials from the shadow of the stylus of a horizontal sundial, while the sun is shining, roughly as follows.

Once a horizontal sundial has been fixed — accurately drawn on some flat board, on which a straight line has been drawn corresponding to the meridian line of that horizontal sundial — let another plane be fixed on the same board. This second plane may either adhere to the board or lie parallel to it (if another horizontal sundial is to be described); or it may stand perpendicular to it, or inclined, and cut the meridian line of the board at right angles (if a vertical, equinoctial, or polar sundial, or one inclined to the horizon, is to be described); or it may cut the meridian line at unequal angles (if a sundial declining from the vertical is proposed for drawing, whether it is also inclined to the horizon or not); or, finally, it may not cut the meridian line at all, but make on the board a line parallel to it, or coincide with the meridian line itself (if a meridian sundial, or one declining from the horizon, is to be constructed) — always, however, keeping account of the declination and inclination of the sundial to be described.

Next, having taken the place of the stylus on the plane of the sundial to be constructed, let a gnomon of any size be fixed there, perpendicular to the plane of the sundial. Then, moving the board — together with the horizontal sundial fixed on it — back and forth, in some spot exposed to the sun so that it can indeed be lit by it, until the tip of the stylus's shadow on the horizontal sundial falls successively on the several hours of the tropic of Cancer [♋ — the summer solstice arc], let the several tips of the shadow of the [future sundial's] stylus be marked successively for the several hours on the future sundial; and in this way the points of all the hours of the tropic of Cancer will be found on the future sundial. And if the same is done on the tropic of Capricorn [♏ — the winter solstice arc], and on the equinoctial line, or on the arc of any other sign, or finally on any other line of the sundial (even one that is not an hour-line), and if the corresponding points on the future sundial are joined either by straight lines or by curves, as the case requires, the sundial will have been described on the proposed plane.

By this device any point whatever of the horizontal sundial can be transferred to the future sundial, if the board — together with the sundial fixed on it — is turned about until the tip of the shadow falls on a given point on the horizontal sundial, and, at the same moment of time, the tip of the shadow of the future sundial's own stylus is likewise marked on the future sundial. A sundial thus described, however, if it is to be transferred onto some wall, will have to be enlarged in proportion to the given length of the stylus, as we shall teach in Chapter 17; for a plane as large as is required for drawing a sundial on a wall cannot conveniently be turned about on the board.

By this art, from a horizontal sundial drawn by the foregoing precepts, another horizontal one can easily be laid out to any given size of stylus, even the smallest — something that can scarcely be accomplished by other precepts. Indeed, by the same device a sundial may be described on any non-flat surface, such as a concave one, if several points are marked on it for each hour and then suitably connected by lines that nowhere form angles. Add, too, that the hours can be laid out in this way even on a cylinder standing perpendicular to the horizon, as we set forth in Book 8 of the *Gnomonics*. In place of the horizontal sundial we shall be able to use, if one is available, a concave spherical sundial, which we taught how to construct in the same Book 8 of the *Gnomonics*; for on it the tips of the shadows can be marked much more accurately than on the former.

[Margin: Qua ratione in quavis superficie per umbram styli horologii alicuius Horizontalis horologia describantur. — By what method sundials are described on any surface whatever by means of the shadow of the stylus of some horizontal sundial.]

THE CONSTRUCTION OF SUNDIALS STANDING AT RIGHT ANGLES TO THE HORIZON, FROM A HORIZONTAL SUNDIAL

CAPVT XV.

Once some horizontal sundial has been accurately constructed, from it one can describe any other sundial that stands at right angles to the horizon — such as either kind of vertical dial, either kind of meridian dial, and any dial declining from the vertical — by an easy and agreeable operation, which here it is convenient to repeat from the scholium of Chapter 10 of Book 6 of our *Gnomonics*, omitting the demonstrations of the individual operations, since they can be sought from that scholium. And since in this matter there is very frequent use of perpendicular lines, the work will be made easier if, in drawing them, we

use some set-square — that is, an instrument consisting of two rulers joined together at a right angle with the greatest care.

Let there be, then, an Italian horizontal sundial, containing (of course) the hours from sunset of the Sun, on which...

Diagram. The large figure filling the center of printed p. 36 — an Italian horizontal sundial used to lay out a dial declining from the meridian toward the east by 30 degrees (the construction of this chapter). The four cardinal points are lettered around the edge: **ORTVS** (East, at top), **OCCASVS** (West, at bottom, printed inverted), **SEPTEN[TRIO]** (North, at the left, set sideways), and **MERID[IES]** (South, at the right, set sideways). Two long parallel rules cross the field from upper right to lower left; a small circle (the "great circle" to which the declining dial is parallel) sits near the center, from which a dense radiating web of solid and dotted hour-lines spreads out.

Confidently legible labels:

- Point letters (capitals): **H, G, D, L, F, E, N, C, K, A, B, P, M, Q, O, X, S.**
- Lowercase / Greek construction letters near the center: **ε, π, τ, α** (and other small letters that do not resolve).
- Hour-numerals around the rim: **23, 22, 21, 17, 16, 15, 14, 13, 12, 11, 10, 9, 8, 7, 6, 5, 4.**

The construction points named in the text below (A, B, C, E, F, I) are among the central cluster. The figure is extremely crowded; many of the small central letters and numerals cannot be resolved individually, and their exact placement is uncertain. [Several labels [?]]

the stylus is AB, and its place is at A, and so on; and let it be proposed to describe from it a sundial declining from south toward east by 30 degrees. At A let there be constructed the angle BAC equal to the complement of the declination (all the construction lines ought to be made hidden except the hour-lines, the horizontal line, the meridian, the equinoctial, and the line of the stylus; indeed it would be better if the lines of the horizontal sundial too were hidden, so that the confusion of the multitude of lines might be avoided) — namely, such an angle as the great circle, to which the declining sundial is parallel, makes with the meridian. Now this angle BAC must incline toward south and west (the horizontal sundial being placed in its proper position) if the sundial to be described declines from south toward east, or from north toward west; but the same angle BAC must incline toward south and east, if the sundial to be described declines from south toward west, or from north toward east.

Then, on the straight line CA, at A, let a perpendicular AE be raised, making with the meridian AI the angle of declination EAI; and from it, toward the north, let a straight line AE be cut off equal to the stylus of the future sundial. Let EF also be cut off, which should be equal to the stylus AB of the horizontal sundial...

let there be drawn through E and F, parallel to CA, the lines EG and FH — that is, perpendicular to AE. Then FH will be the horizontal line in the declining dial, and F the place of the stylus, whose length is AE.

[Margin: The horizontal line, and the place of the stylus.]

We shall draw the meridian line as follows. From the point I, where the meridian line of the horizontal dial cuts the line EG, draw a perpendicular IK to EG; extended as far as you like in both directions, it will be the meridian.

[Margin: The meridian line.]

We shall find the centre of the dial on the meridian line IK in this way. From I, raise a perpendicular IL to the meridian line AI of the horizontal dial. Then, from A, the place of the stylus of the horizontal dial, describe a circle BMRQ with radius equal to the length of the stylus AB — used only for this purpose, that all lines drawn from A to the circumference of this circle (which, as will become clear, must often be drawn) may be equal to the stylus AB. From A, perpendicular to AI, draw the line AM as far as the circumference of the said circle, and toward the same side to which IL was drawn. Then, from N, the centre of the horizontal dial, draw the straight line NM through M; let it be produced so as to cut IL at L, and along the meridian, toward the horizontal line FH, mark off IK equal to the line IL. For K will be the centre of the declining dial, in such a way that the upper parts of the dial extend from the horizontal line FH toward K, and the lower parts toward I.

[Margin: The centre of the dial.]

The straight line KF, drawn from the centre K of the dial through F, the place of the stylus, will be the line of the stylus. Although in the present example it is nearly parallel to the meridian line AI of the horizontal dial, and therefore cuts the equinoctial line at almost right angles, you must not suppose on that account that this necessarily happens in every declining dial; it happened by chance in our example. In other declining dials you will find the contrary.

[Margin: The line of the stylus.]

Next, the straight line OP, drawn through the point O — where the equinoctial line of the horizontal dial cuts the line EG — perpendicular to the line of the stylus KF, will be the equinoctial line. In our example it does not, to the senses, differ from the equinoctial line of the horizontal dial, because, as we said, the line of the stylus cuts the equinoctial line of the horizontal dial at nearly right angles — which will not happen in other declining dials.

[Margin: The equinoctial line.]

To make the description of this equinoctial line more accurate, we shall find on the meridian line KI — produced toward I — the point P through which it must pass, as follows. From A and I, toward opposite sides, raise two perpendiculars AQ and IL to the meridian line AI of the horizontal dial. From Q, where AQ cuts the circle BMRQ, draw through R — where the meridian line of the horizontal dial cuts its own equinoctial — the straight line QR, cutting IL at S. Then, if on the meridian line KI produced a segment IP is cut off equal to IS, the equinoctial line must be drawn through O and P, and it will make right angles with the line of the stylus KF, provided no error has been made.

Indeed, if you wish, we shall also find yet another point H, on the horizontal line FH, through which it must likewise pass, in this way. From A, raise a perpendicular AV to the meridian line AI of the horizontal dial — that is, a line parallel to the equinoctial of that same dial (which will easily be drawn if OV is taken equal to TA, for then the line AV will be parallel to TO) — cutting EG at V. For the perpendicular VH to EV will give on the horizontal line the sought point H. We shall, however, detect it more easily thus: draw from N, the centre of the horizontal dial, the perpendicular to the meridian AI — that is, the line of the 6th hour from noon or from midnight — and let it cut the line GE at X. Then the straight line KX will be the line of the 6th hour in the declining dial, and it will cut the horizontal line FH at H. Through this point H the equinoctial line must be drawn, since the 6th-hour line and the equinoctial line always intersect the horizontal line at the same point.

By the same device with which we described the equinoctial line in the declining dial, we shall lay out all the hour-lines.

[Margin: The hour-line.]

To make this clearer, suppose, for example, that the 23rd hour from sunset is to be drawn in the declining dial. Since in the horizontal dial this hour-line does not cut the line GEV — for one must always consider at what point the horizontal dial's line (the one to be drawn in the declining dial) meets GEV, since it is

through that point that the line must be drawn in the declining dial — we shall produce it until it cuts GEV at the point G, through which the 23rd hour must be drawn. To have another point of the same hour on the horizontal line FH, we shall draw through A, the place of the stylus, a line Aa parallel to the 23rd-hour line DG of the horizontal dial, and let it cut GEV at a. (This parallel will easily be drawn if Ga is taken equal to DA, and so on.) For a perpendicular aY drawn to GEV — that is, parallel to EF or IZ — will give on the horizontal line the point Y, through which the same 23rd hour must be drawn.

In the same way, the 22nd hour, produced until it cuts GEV at b, must be drawn through b. Then, taking bf equal to the line eA, so that the drawn line Af is parallel to the 22nd-hour line, and drawing fd perpendicular to GEV — or parallel to EF or IZ — the same 22nd hour must also be drawn through the point d. Again, the 15th hour must be drawn through the point i — where the 15th hour of the horizontal dial cuts GEV — and also through the point g on the horizontal line, onto which falls the line hg, drawn perpendicular to GEV from the point h, onto which in turn falls Ah, drawn parallel to the 15th-hour line of the horizontal dial.

In just this way we shall lay out, in the declining dial, any line whatever of the horizontal dial — even one that is not an hour-line — provided that, when produced, it cuts the line GEV.

[Margin: A general rule for describing any line whatever in the declining dial from the horizontal dial.]

For every such line must be drawn through the point where it cuts the line GEV, and through the point on the horizontal line onto which falls the perpendicular to GEV — the perpendicular raised from that point of GEV onto which falls the line drawn from A, the place of the stylus, parallel to the line that is to be described. Moreover, all the lines of the hours from noon and from midnight will pass through K, the centre of the declining dial. Hence it is enough if they are drawn through the centre K and through those points at which they meet the line GEV in the horizontal dial. They will, however, be drawn more precisely if for each one a third point is also found on the horizontal line.

Lastly, on the lines described in the declining dial from the horizontal dial, we shall find the points through which the arcs of the [zodiacal] signs are to be drawn, as follows.

[Margin: The points of the arcs of the signs.]

Suppose, for example, that on the 22nd-hour line db the point of the arc of Capricorn [♑] is to be found. From A, the place of the stylus of the horizontal dial, through the Capricorn point at hour 22, draw the hidden line A22, cutting the line GEV at the point m; from m raise a perpendicular ml to GEV, cutting the 22nd-hour line db at l. For through the point l the arc of Capricorn must be drawn, so that, when the Sun is at the beginning of Capricorn, the tip of the stylus's shadow falls at the point l.

We shall find this point likewise, even if the 22nd-hour line has not yet been drawn, in this way. From m, where the hidden line A22 cuts the line GEV, raise a perpendicular mn to A22m, on whichever side you please; and from A, the place of the stylus, raise to the same A22m another perpendicular Ap, extending as far as the circumference of the circle, but toward the side opposite to that on which mn was drawn. For from p, through the Capricorn point at hour 22, the line p22 is drawn, cutting the perpendicular mn

at n; and if from the line mn we cut off a segment equal to the earlier perpendicular ml, the point l will be the Capricorn point at hour 22 that is sought. And so, once the two points d and b — through which the 22nd hour must be drawn — have been found, as was explained above, if this third point l, belonging to Capricorn, is also found, the 22nd hour will be drawn most precisely through the three points d, b, l, provided those three points lie on a straight line, as the case requires. Otherwise, do not doubt that an error has been made. But if a point of Cancer [♋], or of some other sign, is also found for the same hour, we shall have four points through which the 22nd hour must be drawn. This fourth point, belonging to Cancer, cannot be found for the 22nd hour in our example, because the hidden line drawn from A through the Cancer point at hour 22 of the horizontal dial cannot cut the line GEV, as is evident. This is proof that the plane of the declining dial is not illuminated at the 22nd hour when the Sun is at the beginning of Cancer.

By this same procedure we shall project any point whatever of the horizontal dial onto the declining dial, in such a way that, at the very moment when the shadow of the horizontal dial's stylus falls on that point, the shadow of the declining dial's stylus falls on the projected point.

[Margin: A general rule for projecting any point whatever of the horizontal dial onto the declining dial.]

For if through the given point in the horizontal dial a hidden line is drawn from A, the place of the stylus, cutting the line GEV — for if it does not cut it, the

proposed point cannot be transferred onto the declining dial — such as was the line A22m for transferring the Capricorn point of the 22nd hour; and if from the point where GEV is cut a perpendicular is raised to GEV, on the side of A, that is, below the line GEV in the declining dial (for the horizontal line FH occupies the highest place in it)

Diagram. The large construction figure filling the centre of printed p. 38 — the declining-dial layout of this chapter (the same crowded construction shown on printed p. 36 in the preceding pages, reprinted here so it stays before the reader). The four cardinal points are lettered around the field: **ORTVS** (East, at the top), **OCCASVS** (West, at the bottom, printed inverted), **SEPTEN[trio]** (North, at the left, set sideways), and **MERID.** (South/Meridies, at the right, set sideways). Two long parallel rules cross the field from upper right toward lower left; a small circle (the "great circle" to which the declining dial is parallel) sits near the centre, from which a dense radiating web of solid and dotted hour-lines spreads out.

Confidently legible labels:

- Capital point-letters: **G, D, L, E, F, N, C, K, A, B, P, M, Q, R, O, X, S, H, T, V, Y.**
- Small Greek construction-letters near the centre: **ε, π, τ, α** (other small letters do not resolve).
- Hour-numerals around and within the figure: **23, 22, 21** (upper region, near G/D/L) and **16, 15, 14, 13** along the lower edge (13 beside H); **19** and a further numeral near the centre are only partly legible.

The figure is extremely crowded; many small central letters and interior numerals cannot be resolved individually, and their exact placement is uncertain. [Several central labels [?]]

if the given point lies between A and the line GEV — as, for the Capricorn point at hour 22, the perpendicular ml did — [then the perpendicular is dropped toward A]; but toward the side of the horizontal line FH, that is, above the line GEV in the declining dial, [the perpendicular is raised] if the line GEV lies between A and the proposed point, as do the Capricorn points of hours 16, 17, and 18 in our example. Then, to this hidden line, from that same point of the line GEV and from A, let two other perpendiculars be raised toward opposite sides — such as were mn and Ap. And from the point where the circumference of the circle is cut by the perpendicular drawn from A, let a hidden line be drawn through the proposed point; it will cut the other perpendicular — the one raised from the point of the

line GEV — at a point. The distance of this point, taken with the compass from that same point of GEV and transferred onto the perpendicular raised from the same point to the line GEV, will give the sought point in the declining dial — such as was the point l for the Capricorn point at hour 22. By this technique, in order to find the point s, belonging to Cancer, on the line gi of the 15th hour, we drew, in our example, from A, through the Cancer point at hour 15,

the line Aq of the horizontal dial's 15th hour. At q, where it meets the line GEV, we raised the perpendicular qr; and to the same Aq, at A, on the opposite side, we raised another perpendicular At. From t, through the Cancer point at hour 15, we drew the line tr, which cuts qr at r; and finally, from the line qr we cut off a segment qs equal to qf, the perpendicular drawn from q to GEV. For the tropic of Capricorn, however, no point can be found at the 15th hour, because at that hour the tropic of Capricorn has no point in the horizontal dial. Therefore the 15th hour must be terminated on the horizontal line at the point g. But if some given point lies on the line GEV, it will be common to both dials — namely, the horizontal and the declining — so that no further transfer is needed.

Now, this transfer of the horizontal dial's points onto the declining dial can also be carried out even without raising two perpendiculars to the line drawn from A through the given point — one at A, equal to the stylus, such as Ap was for the Capricorn point of hour 22, and the other from the intersection [of that line with GEV], toward the opposite side, such as mn was. For if on the line CD, toward either side, Aε is taken equal to the stylus, and from ε, through the given point of hour 22 in Capricorn (for example), a line is drawn cutting GV, then mε will be equal to mn; and this, transferred onto ml, will give the sought point l. For since A22 is to Ap as m22 is to mn, then, by alternation, A22 will be to m22 as Ap is to mn.

[Margin: (a) Euclid VI.4]

By the same reasoning, A22 will be to m22 as Aε is to mε. Therefore the stylus Ap (or Aε) has the same ratio to mn as to mε; and consequently mn and mε are equal.

[Margin: (b) Euclid V.9]

And so, by this method, we are freed from the two perpendiculars Ap and mn — which is no small saving.

If a dial declining from the north toward the west is to be described, one must take on the line AE a segment AE equal to the stylus of the future declining dial, toward the south, and beyond it another segment EF equal to the stylus of the

horizontal dial. Then through E and F draw EG and FH parallel to AD; of these FH will be the horizontal line, and the lower parts of the dial will slope from it toward A. The rest is to be completed just as in the dial declining from the south toward the east.

[Margin: A dial declining from the north.]

Furthermore, if a vertical dial is to be described that does not decline but is parallel to the prime vertical, one must take on the meridian line of the horizontal dial — beginning at the place of the stylus A — a segment equal to the stylus of the future vertical dial, toward the north if the dial is a southern one, but toward the south if a northern one is to be constructed. Beyond this, take another segment equal to the stylus of the horizontal dial, marking two points on the meridian line; drawing two perpendiculars to the meridian through these points, the more distant one will give the horizontal line, and so on.

[Margin: A vertical dial.]

Finally, if a meridian [due-east or due-west] dial is to be composed, one must take, on the line drawn from A (the place of the stylus) perpendicular to the meridian line AI, the length of the stylus for the future dial — toward the west if an eastern dial is to be described, but toward the east if a western one; and beyond this another segment equal to the stylus of the horizontal dial, marking two points on that perpendicular. If through these two lines parallel to the meridian are drawn, the more distant will be the horizontal line, and so on.

HORARVM A MERIDIE ET MEDIA NOCTE IN QVOLIBET PLANO — A far easier description of the hours from noon and from midnight, on any plane whatever, whether equidistant from the horizon or perpendicular to it, by means of a plane rule divided into certain parts and used as an instrument.

CAPVT XVI.

When, in recent days, the most illustrious Lord Jacobus Curtius [Jacob Kurz von Senftenau] — privy councillor of his Imperial Majesty Rudolph II, and now the same emperor's legate to the Supreme Pontiff Sixtus V, a man most distinguished both in every branch of learning and especially in mathematics — was conversing familiarly with me, in his customary kindness and affability, about

various matters pertaining to the mathematical disciplines, to my great delight, he shared with me many excellent things of this kind. Among them was this: that any plane rule whatever can be divided into parts in such a way that, by means of it, as by a very simple instrument, the hours from noon and from midnight can be described most easily — both on a plane parallel to the horizon and on any other perpendicular to the horizon. Since this greatly pleased me, I resolved to explain briefly, in this place, the division of that rule and its use, so that from these records of mine, such as they are, some grafted fruits of that outstanding genius might also be plucked.

Let there be, then, a plane rule ABCD of any length (a length seems to me sufficient for this purpose if it equals half a foot, roughly as in the example proposed here). Near its outermost edges AB and DC let two parallels, not far from them, be drawn: EF and GH. Of these, the first, EF, is to be divided into hours; the second, GH, into degrees of the pole's altitude, in the following way.

[Margin: The division of the plane rule into parts, most suited to the description of the hours from noon and from midnight.]

With centre I, describe an arc of a circle KL. From it cut off — with the same compass-opening with which the circle was described — the sixth part KM; bisect it at N, and take the arc ML equal to the arc MN, so that the quadrant KL, containing 90 degrees, results, since the arc KM contains 60 degrees and ML contains 30. Then, dividing the arcs KN, NM, and ML each in two, and each of those parts into five equal parts, and finally each of these into three equal particles, the whole quadrant KL will be cut into 90 degrees. Here the last division has not been carried out, on account of the narrowness of the space; instead, each part comprises three degrees.

Next, describe another quadrant of the circle, OP; and by drawing straight lines through every fifteen degrees of the arc KL, the quadrant OP will be cut into six equal parts, which represent the six hours of the equator. These being subdivided into half- and quarter-hours, draw the straight line QR perpendicular to the radius IK, at such a distance from the centre I that its portion QR — intercepted between Q and the line drawn from I through the 75th degree of the arc KL (that is, through the 5th and 7th hour of the arc OP) — is a little smaller than each of the two parallels EF and GH, or at any rate equal to them. This line QR will be cut, at points, by the hidden hour-lines sent out from I. All these points, transferred with the compass — beginning from Q, onto the parallel EF, starting from the point E — will give on the rule the hours, and the half- and quarter-hours, from 12 up to 5 after noon and 7 after midnight.

But so that $5\frac{1}{4}$, $5\frac{1}{2}$, $5\frac{3}{4}$, 6, and $6\frac{1}{4}$, $6\frac{1}{2}$, $6\frac{3}{4}$ — which are not comprised on the line EF — may be described on the proposed plane, we shall take IS, a quarter of the line IQ, and through S draw ST perpendicular to IQ (that is, parallel to QR). We shall divide it by the straight lines sent out from I through the hours and parts of hours of the arc OP, just as the line QR was divided; and we shall transfer the parts of the line ST, starting from the point V, onto a line drawn on the other face of the rule ABCD, parallel to the edges of the rule.

[Margin: In what way the more distant points may be marked on the rule more accurately.]

But if the interval ST — up to the $5\frac{3}{4}$ hour from noon, or the $6\frac{1}{4}$ hour from midnight — were longer than the rule, one would have to draw YZ parallel to QR through Y, the point that bisects IS, so that IY is an eighth part of the line

(continuing Cap. XVI, on the plane dividing-rule for laying out the hours from noon and from midnight)

an eighth part of the line IQ. And if the interval YZ, up to the $5\frac{3}{4}$ hour from noon, were still longer than the rule, IY would again have to be bisected, and a parallel to QR drawn through its midpoint, and so on. In our example it would be enough to take IS, a quarter of the line IQ; but since the line drawn from I through the $5\frac{3}{4}$ hour from noon cuts the line ST very obliquely and runs out too far — so that the point T can scarcely be distinguished without error — we shall subdivide IS continually in half. Then, through the point Y (which here cuts off, and this is sufficient, IY, half of IS), we shall draw YZ parallel to ST, and it will be conveniently cut at Z by the line drawn from I through the $5\frac{3}{4}$ hour from noon.

For if we repeat the line YZ on ST as many times as IY is contained in IS — that is, in the given example, twice — we shall arrive at the point T, onto which the said line drawn from I through the $5\frac{3}{4}$ hour from noon necessarily falls; and thus the interval ST will be found more precisely. This interval, however, we have not here transferred onto the line VX, on account of its shortness. From this line VX, then, we shall describe on the proposed plane the hours that are missing on the line EF, as we shall teach below in the use of this rule.

We shall use the same device in precisely determining the point R on the line QR, if it happens to be cut too obliquely by the line IR — the point onto which the line IR, drawn from I through the 5th hour from noon, falls. That is: we shall repeat four times on QR the portion of the line ST between S and the said 5th hour from noon, since IS is a quarter of the line IQ; or we shall repeat eight times on QR the portion of the line YZ between Y and the said 5th hour from noon, since IY is an

eighth part of IQ. And by the same reasoning the longer intervals of the line ST quadrupled, or of the line YT octupled, transferred onto the line QR, will exhibit more accurately the points $4\frac{1}{4}$, $4\frac{1}{2}$, and $4\frac{3}{4}$ from noon.

Diagram. The plane dividing-rule instrument for laying out hour-lines. On the left is a quadrant with its centre at the upper-left, from which a dense fan of hour-lines radiates down to a graduated arc; the arc carries hour-numbers 1 through 6 and its degree-subdivisions. On the right is the rectangular rule ABCD, along whose length run several parallel graduated scales (numeric divisions rotated 90°), each headed by a rubric. The scales are printed at very small size and the individual numeric divisions do not all resolve even under magnification.

Readable labels (left construction / quadrant):

- Upper-left corner: I (centre of the radiating hour-lines)
- Along the top edge: O, P, K [?]
- On or near the arc: L, M, N
- Hour-numbers along the arc: 1, 2, 3, 4, 5, 6 (with intervening degree ticks)
- Lower termini of the radiating lines: Q, R
- Lower-left: T

Readable labels (right-hand rule ABCD and its scales):

- Corner/edge letters: K, G, F [?], C, D, B, X
- Scale-column rubrics (rotated), reading across:
 - H. à. mer. [Horæ à meridie — hours from noon]
 - H. à. med. noc. [Horæ à media nocte — hours from midnight]
- Horizont[ales] [for horizontal dials]
- Vertic[ales] [for vertical dials]
- Horizontales
- Verticales
- Hor. à. mer.
- H. à. med. noc.
- Scale-point letters: V, N, Q, H
- Legibly-read scale numbers (not exhaustive; the fine interior divisions do not all resolve): 90, 84, 81, 78, 72, 63, 60, 42, 36, 30, 27, 24, 21, 19, 18, 12, 9, 6, 3, with hour-fractions such as $6\frac{1}{2}$, $5\frac{3}{4}$, $5\frac{1}{2}$, $5\frac{1}{4}$ printed among them. The complete cell-by-cell scale values are not individually legible even under magnification.

[The figure is dense and several small labels are uncertain]

Having in this way divided the line EF into hours and parts of hours, we shall distribute the line GH into pole-altitudes in the following way. Drawing lines from I through each single degree of the quadrant KL, let their intervals — those comprised between I and the line QR — be transferred with the compass onto the line HG from the point H. Toward the inner part, toward EF, let the complements of the degrees (through which the lines transferred from I are drawn) be marked; and toward the outer part, toward the side CD, let the numbers of the degrees themselves — those whose lines have been transferred — be inscribed. The inner numbers will serve for horizontal dials, the outer for vertical dials and for those declining from the vertical, as we shall say below. But since in this way the line GH contains only the pole-altitudes from 90 degrees down to 15 for horizontal dials, and from 0 up to 75 for vertical and declining dials, then, so that we may designate the remaining degrees on the proposed plane, we shall also draw on the other face of the rule ABCD a line a b, parallel to the edges of the rule, and...

and onto it, from the point b, we shall transfer the portions of the lines drawn from I through each single degree, laid off between I and the line ST, as you see done in the example, up to the 6th degree for horizontal dials, and up to the 84th degree for vertical and declining dials. But if some of the lines drawn from I cut the lines QR, ST very obliquely, their points on the said lines will have to be found by the device prescribed a little earlier — namely by doubling on the line ST the intervals of the line YZ (between Y and the lines coming from I), and octupling those same intervals on the line QR; and by quadrupling the intervals of the line ST on the same line QR, and so on. By means of this line a b, then, we shall mark on the given plane the degrees of pole-altitude that are missing on the line GH, as will be clear in use.

If one wishes, two other smaller parallels c d, e f may be drawn in the middle of the rule; and onto c d the points of the hours of the line YZ may be transferred, beginning from the point c, while onto the line e f, from the point f, the intervals of pole-altitude between I and the line YZ. For by means of these lines c d, e f we shall lay out even the smallest dials.

But since the lines between I and the line QR, near Q, exceed one another only by a small excess — being nearly equal to one another — it comes about that they can scarcely be transferred onto the line HG without confusion. We shall therefore have done rightly if we describe those nearly-equal intervals separately in some place. Thus you see that from the point H four lines have been drawn separately, onto which are transferred the segments of the lines from I through

degrees 5, 6, 9, 12, intercepted between I and the line QR; and to these lines coming out from H are attached the complements of the said degrees, namely degrees 87, 84, 81, 78, for horizontal dials. For vertical dials the degrees themselves are to be set opposite — as 3 next to 87, and 6 next to 84, and 9 next to 81, and 12 next to 78, and so on. And the same device can be applied to other lines as well, as in a b and e f.

Diagram. The construction of a horizontal dial for latitude 60°. From a radiant apex at the top a broad fan of straight hour-lines spreads out to left and right, its outer rays numbered. A long roughly-horizontal line (the equinoctial line CD) crosses the figure through the centre E, carrying hour-numbers. Below and around the centre A a further set of solid and dotted lines gives the hour-lines of the dial-plane and the transferred construction points. (This same woodcut is reprinted on the following page — see fig-p618-1.)

Readable labels:

- Apex cluster (top centre): a small triangular gnomon-mark with G beneath it, and nearby small letters C [?], F [?], b [?]
- Outer rays (left, descending): 6, 5, 4
- Outer rays (right, descending): 5, 6, 7, 8
- The crossing line (equinoctial CD), left to right: C, 3, 2, 1, E (centre), then above it 12 and the point O, the point H (dotted), then 11, 10, 9, and D at the right end
- Centre and interior points: A (the dial-centre, below the equinoctial line), I (below A), M (below I), X, E (lower centre)
- Left-hand descending labels: K, 10, T, Q [?] (small "o"), N, II, B, G, I, "1 2" (= 12)
- Right-hand descending labels: X, 8, L, 7, 6, V, S, s, e, D, 4, 3
- Lower interior points: R, P, I, 2, and Y at the foot

[Several small apex and side labels are uncertain]

[Margin: The use of the preceding plane rule in describing dials.]

[Margin: The horizontal dial.]

equal to the line IQ, as we shall demonstrate a little below in the horizontal dial. In the same way we shall cut the lines VX, a b, and likewise c d, e f, into more parts, if we take IS equal to the line between V and the 3rd hour, and also the line IY equal to the line between c and the 3rd hour, and draw through S and Y lines parallel to QR, and so on.

The use of the aforesaid rule is as follows. Let it be required, in the first place, to describe a horizontal dial for latitude 60 degrees. Draw two lines AE and CD cutting each other at right angles at E — of which let AE represent the meridian line, and CD the equinoctial line. Transfer onto CD, on both sides from E, all the hour-points of the line EF, beginning each time from the point E. This may be done either with the compass, or by the service of the rule itself, the point A being set so that it answers at right angles to the point E — that is, with the point E and the rule's edge AB coinciding with the line ED. For if the hour-points of the side AB — all of which answer at right angles to the hour-points of the line EF — are then marked on the line ED, the said hour-points of the rule ABCD will have been transferred onto the line ED. These points will be marked more precisely if, with the rule's plane set transverse (at right angles) to the plane of the dial in that position, perpendiculars to the side AB are drawn from the hour-points of the side AB: for these will fall onto the points that are to be marked on the line ED. Let the same hour-points of the line EF then be transferred in the same way onto the line EC, beginning in both cases from E. This will be done with the help of the rule, if the rule is turned over so that the side AB becomes the lower one, and the point A coincides with the point E, and the side AB with the line EC, and so on. After this, let the portion of the line GH, comprised between H and the inner degree of the latitude of the place for which the dial is being constructed, be transferred onto the meridian line from E up to A. This will be done without the compass, by means of the rule, if its point C coincides with the point E, and the side CD with the line EA, and so on — provided, however, that the same degrees have been marked on the side CD, and also on the transverse plane, as has been said concerning the hour-points...

Diagram. The same construction of the horizontal dial for latitude 60°, reprinted from the facing page. This is the identical woodcut as fig-p617-1: the radiant fan of hour-lines from the top apex, the equinoctial line CD through the centre E, the dial-centre A, and the surrounding solid and dotted construction lines and transferred points. The readable labels match fig-p617-1 (apex with G and small letters C/F/b [?]; outer rays 4–6 left and 5–8 right; the crossing line C, 3, 2, 1, E, 12/O, H, 11, 10, 9, D; interior points A, I, M, X, E, R, P; left-hand K, 10, T, Q [?], N, II, B, G, "1 2"; right-hand X, 8, L, 7, 6, V, S, s, e, D, 4, 3; foot Y).

[Reprinted woodcut; several small labels uncertain]

as has been said concerning the points to be marked on the plane AB and on the transverse plane. For the point A will be the centre of the dial, and the lines drawn from A through the points of the equinoctial line CD will give the hours

from noon and from midnight. In our example, which is constructed for latitude 60 degrees, the line AE has been taken equal to the portion of the line GH between H and the inner 60th degree. The hours to the left of the meridian line are to be counted from noon, and those to the right of it from midnight.

But if from AE one cuts off AF equal to the portion of the line a b on the rule between b and the 60th degree, and through F draws a line parallel to CD, and transfers onto it the hour-points of the line VX, then from A, through the points of this parallel, the same hour-lines will be drawn — indeed more of them than through the points of the line CD. And if there is still cut off from the me-[ridian...]

—drawn from the meridian line AG, equal to the portion of the line ef lying between f and the same 60th degree on the rule; and if through G a line is drawn parallel to CD, and onto it are transferred the hour-points of the line cd, then still further hour-lines will be drawn from A through the points of this parallel — indeed more of them than through the points of the parallel drawn through F. And so, if these two parallels through F and through G are drawn, all the hours and their subdivisions can be conveniently laid out on the dial.

But if the plane of the dial is very large, so that the line CD is extremely long, then the points of all the hours — even of those not drawn on the line EF — can be marked on it, without our drawing the parallels through F and through G, in the following way. Take, with the compass, the intervals of those hours that are not contained on the line EF, measuring them off on the line VX starting from the point V, and lay them off four times over on the line CD, beginning on both sides from the point E. Or else take the same intervals on the line cd and lay them off eight times over on the same line EF, and so on. For the intervals of the line EF are quadruple the intervals of the line VX, and octuple the intervals of the line cd, as is clear from the construction.

That in this way a horizontal dial is correctly described, we shall now easily demonstrate as follows. [Margin: A demonstration of the use of the aforesaid rule.] Since the line QI in the earlier figure is equal to the portion Ql of the line QR intercepted between Q and the line drawn from I through 45 degrees — that is, through the 3 o'clock or 9 o'clock hour — (because, the angle QIl being a half-right angle, the angle QIl is also a half-right angle [a], and therefore the lines QI and QI[?] are equal [b]); it follows that if, from the point E of the later figure, an arc is described at the interval QI, or QL — that is, at the portion of the line EF on the rule lying between E and the 3 o'clock or 9 o'clock hour — and this arc is cut at H by another arc described from A at the interval of the portion Qh of the line QR, lying between Q and the complement of the pole's altitude at the horizon in

question; and if the lines EH and AH are then drawn: then the triangle AEH of the later figure will be entirely equilateral and equiangular with the triangle hIQ of the earlier figure. [Margin: a: Euclid, *Elements* I.32. b: Euclid, *Elements* I.5.] That is, the side AE will equal the side hI, the side EH the side IQ, and the side AH the side Qh; the angle E will equal the angle I, the angle A the angle h, and the right angle H the right angle Q.

Now since I is the angle of the complement of the pole's altitude — for onto the intervals carried over onto the line GH from the point I we inscribed the complements of those degrees through which the lines drawn from I pass, for horizontal dials — the angle E will likewise be the angle of the complement of the pole's altitude. Therefore, if the triangle AEH is revolved about the meridian AE until it stands at right angles to the horizon, and the dial is set in its proper position, with A pointing south and E pointing north, then AH will be the axis of the world and HE the common section of the equator and the meridian. For since the axis of the world makes with the meridian line of the horizontal dial the angle of the pole's altitude, while the equator makes the angle of its complement, let the line EB be taken equal to the line EH, and from B let a circle be described and divided into 24 [hours], through the divisions of which the hidden lines are drawn out; these cut the equinoctial line CD in the points through which the hour-lines are to be drawn from A. And it is evident that CD is cut by the lines drawn from B in just this way, on account of the equality of the lines EB and IQ, and so on — as QR is cut by the lines drawn out from I in the earlier figure, on account of the equality of the same lines, which we demonstrated in *Gnomonics* Book II, Proposition 1.

A different general explanation of the rule set out above. [Margin: A different general explanation of the rule set out above.] From this it follows that the hour-points of the line EF on the rule are nothing other than the sections of the hour-circles and of the equinoctial line in a horizontal dial, taken with the semidiameter of the equator set at IQ; whereas the portions of the line GH, between H and the inner degrees, are the semidiameters of the horizon for the various pole-altitudes, always with respect to the same semidiameter of the equator QI — which is indeed equal to the segment of the line EF lying between E and the 3 o'clock or 9 o'clock hour.

The style (gnomon). [Margin: The style.] If from H a perpendicular HI is dropped to AE, then HI will be the length of the style, and its place will be at I.

But since the rule does not contain the intervals of the line QR between Q and the lines drawn from I through the individual degrees, we shall construct the triangle

AEH on the dial itself, in order to find the place of the style and its length, in this way. Bisect AE at b, and describe a semicircle EHA; from b, at the interval bA or bE, if the line EH — equal to the segment of the line EF on the rule between H and the 3 o'clock or 9 o'clock hour — is fitted within it, then AH will be the axis of the world. For the angle AHE, being in a semicircle, is a right angle [c] — which the axis necessarily makes with the equator. [Margin: c: Euclid, *Elements* III.31.] Or else let two lines be drawn out from A and from E, the lines AH and EH, meeting each other at H, of which the one with AE forms the angle of the pole's altitude and the other the angle of its complement.

The vertical dial. [Margin: The vertical dial.] In just the same way we shall describe a vertical dial for a proposed pole-altitude, if in place of the segment of GH between H and the inner degree of the pole's altitude we take the segment of that same GH between H and the outer degree of the pole's altitude for the place where the dial is being constructed; or (what comes to the same thing) the segment of that same line GH between H and the degree of the complement of the pole's altitude interior to it, and cut off from the meridian a line EA equal to it, so as to have A, the centre of the dial. For since, in the earlier figure, the line Ih, through 30 degrees, was made the semidiameter of the horizon for 60 degrees with respect to the semidiameter of the equator IQ, as we showed, — because the angle h, which subtends 60 degrees, gives the line Ip through 60 degrees, that is, through the complement of the 30 degrees — Ip will be the semidiameter of the vertical dial with respect to the same semidiameter of the equator IQ. (For with IQ set as the semidiameter of the equator, QR will be at right angles to it, and Ip, forming right angles with QR — the axis of the world — establishes the angle p, of the complement of the pole's altitude, namely the very angle that the vertical makes with the axis, because Ip is the angle of the pole's altitude, taken as 60 degrees, and so on.) The same reasoning holds for the other pole-altitudes. For the intervals of the line GH on the rule, between H and the outer degrees, are always the semidiameters of vertical dials, just as the intervals between H and the inner degrees are the semidiameters of horizontal dials — which is demonstrated in the same way, as was said of the lines Ih and Ip in the earlier figure. The hours from noon, however, are contained in a vertical dial to the right of the meridian line, and those from midnight to its left.

Now the dial just laid out, if this alteration of the hours is made, will become a vertical dial for latitude 30 degrees — since the line EA is equal to the segment of the line GH on the rule between H and the outer 30th degree, namely the same segment that was taken in the inner degrees for a horizontal dial at 60 degrees. From this it follows that a horizontal dial is a vertical one for the complement of

the same latitude, and conversely: because any inner degree that serves for horizontal dials is the complement of the outer degree that serves for vertical dials, and conversely; so that the very same line EA is to be taken for the horizontal dial of one place, and for the vertical dial of another place whose pole-altitude is the complement of the pole-elevation at the former place.

The declining dial. [Margin: The declining dial.] Let it be required, next, to lay out a dial declining from south toward the west by 60 degrees, for latitude 30 degrees. Having drawn two lines AE and CD cutting each other at right angles at E — of which let AE, perpendicular to the horizon, represent the meridian line, and CD, parallel to the horizon, the common section of the plane of the declining dial with the plane of the horizontal dial — let there be formed below CD the angle of declination BEF, on the right of the meridian line if the dial declines from south toward the west, but on the left if toward the east. Let the line GH cut EF at E at right angles, and onto GH transfer from the point E, on both sides, the hour-points of the line EF by means of the rule described above, as was said in the construction of the horizontal dial. Then on EF take EF equal to the segment of the line GH lying between H and the inner degree of the proposed latitude, just as in the description of the horizontal dial — here, between H and the inner 30th degree; and from F, drawing out hidden lines through the points of the line GH, mark their intersections with the line CD. Finally, on EA take EA equal to the segment of the same line GH lying between H and the outer 30th degree, or between H and the complement of the proposed latitude in the inner degrees — here, between H and the inner 60th degree — as was said in the construction of the vertical dial.

For the point A will be the centre of the dial, from which the lines drawn out through the points marked on CD will indicate the hours from noon and from midnight. For, as is clear from what was demonstrated a little earlier, those hidden lines drawn out from F make a horizontal dial, in which the equinoctial line is GH. If, then, the plane drawn through the lines EF and GH is conceived to be moved until it is parallel to the horizon, the hour-circles will cut the line CD — lying in the plane of the declining dial — in the points at which the hour-lines drawn out from F meet it. Since, therefore, A is the centre of the declining dial, just as it is of the vertical dial — (for at the same point the axis of the world meets the common section of the meridian and of the vertical circles, as is evident) — it is clear that the lines drawn from A through the points marked on the line CD are the hour-lines; and their order here is the same as in the vertical dial.

But so that all the hours may be conveniently drawn, one must cut off from AE the line AI, equal to the segment of the line ab on the rule described above, between b and the outer 30th degree of the proposed latitude, or the inner 60th degree of its complement. For if through I one draws the line KL parallel to CD, and forms the angle of declination EIM as before, and the line NO cuts IM at right angles at I, onto which the hour-points of the line VX are transferred on both sides from I; and if, finally, the line IM is taken equal to the segment of the line ab, between b and the inner 30th degree of the given latitude, as in the horizontal dial: then the lines drawn out from M through the points of the line NO, cutting across the line KL, will meet it in points through which the lines drawn out from A will give the hours, as before. And if this is not enough, one must in the same way employ the lines cd and ef, divided on the same rule described above, and so on.

The 6 o'clock hour. [Margin: The 6 o'clock hour.] The 6 o'clock hour is drawn thus. From F raise a perpendicular to EF, or from M a perpendicular to IM. For where the former cuts the line CD, and the latter the line KL, through that point the line of the 6 o'clock hour is to be drawn.

The style-line. The equinoctial line. The axis of the world. The altitude of the pole above the declining dial. The style and its place. The meridian dial. [Margin: The style-line. The equinoctial line. The axis of the world. The altitude of the pole above the declining dial. The style and its place. The meridian dial.] Now if from F a perpendicular is dropped to CD, cutting CD at D, the line AD thus drawn will be the style-line; and if through D a perpendicular PQ is raised to it, this line will be the equinoctial line in the declining dial. And if on the equinoctial line a line DP is taken equal to DF, whether above D or below, then AP thus drawn will be the axis of the world, and DAP the angle of the pole's altitude above the plane of the dial. Moreover, if DR is drawn from D perpendicular to the axis AP, it will be the semidiameter of the equator; and RS, drawn from R perpendicular to the style-line AD, will give the length of the style, whose place will be at S. Finally, the line drawn through S parallel to CD will be the horizontal line — all of which we demonstrated in the *Gnomonics*, Book III, Proposition 1.

Let it be required, last of all, to lay out a meridian dial. Draw the line CD (in the figure of the immediately preceding example), which, being parallel to the horizon of the equator, forms at E the angle of the complement of the pole's altitude, or the angle of the equator's altitude, DEH — (with the dial set in its proper position, and the point D pointing south) let it be the common section of the equator and of the plane of the dial. Then onto the line GH transfer from E, on

both sides, the hour-points of the line EF by means of the rule described above. For the lines drawn through these points to GH, as perpendiculars, will give the hours from noon and from midnight, in this order. The perpendicular to GH through E, when drawn, will give the 6 o'clock hour; below it, going downward, follow the hours 7, 8, 9, 10, and 11 from midnight in an eastern dial, while the same 6 o'clock hour is preceded, above E, by the hours 5, 4, 3, 2, and 1 from midnight. But in a western dial the 6 o'clock hour, below E, is preceded by the hours 5, 4, 3, 2, and 1 from noon, and the same 6 o'clock hour, above E, is followed by the hours 7, 8, 9, 10, and 11 from noon. [Margin: The place of the style and its magnitude.] The place of the style is at E, and its length is comprised as equal to the segment of the line GH between E and the 3 o'clock or 9 o'clock hour. All of which is manifest from what we demonstrated in the scholium to Proposition 25 of *Gnomonices* Book II.

Horologii cuiusvis ad maiorem, minoremve formam reductio.

The reduction of any dial to a larger or smaller form.

CAPVT XVII.

By what method any dial whatever may be reduced to a larger or smaller form. [Margin: By what method any dial whatever may be reduced to a larger or smaller form.] Since it often happens that dials described according to the foregoing precepts must be enlarged onto walls or planes, or else restricted to a smaller form, we shall briefly teach in this chapter by what method this ought to be done. On some straight line AF take as many equal parts AB, BC, CD, DE, EF as the style of the dial already described, so that the whole line AF, thus composed, is not less than the longest shadow cast by the style. And on another line GM take just as many parts GH, HI, IK, KL, LM, equal to the style of the future dial, whether the style GH here is larger or smaller than the style AB. Then, dividing each of these parts of both lines into any number of equal particles — (the easiest division of all will be to bisect each part first; then to bisect each particle again; and so on, as far as can conveniently be done; for the more particles there are, the more accurately the future dial will be described) — inscribe upon them the corresponding numbers, as appears in the figure. By means of these two lines we shall describe, from any dial, another larger or smaller one, according as the style GH of the future dial is larger or smaller than the style AB of the given dial, in this way. Through the place of the style of the given dial draw a line

Diagram. Two parallel horizontal scales (measuring rules), one above the other, each divided into forty small equal divisions and lettered at every eighth division. These are the two lines AF and GM used in this chapter to enlarge or reduce a dial.

- Upper rule (left to right): **A** (start, at 0), **B** (at division 8), **C** (at 16), **D** (at 24), **E** (at 32), **F** (at 40); the division-numbers **8, 16, 24, 32, 40** are printed beneath B, C, D, E, F respectively. To the right of F the rule continues as a plain (undivided) line.
- Lower rule (left to right): **G** (start, at 0), **H** (at division 8), **I** (at 16), **K** (at 24), **L** (at 32), **M** (at 40); the division-numbers **8, 16, 24, 32, 40** are printed beneath H, I, K, L, M respectively. To the right of M the rule continues as a plain line.

—parallel to the meridian line, if the place of the style does not lie on the meridian itself; and through the place of the style in the future dial draw a similar line, which in a dial at right angles to the horizon will be perpendicular to the horizon. Then, having drawn a hidden line from the place of the style in the given dial through any hour on the tropic of Cancer [☿], or of Capricorn [♊], or on the equinoctial line, draw from the place of the style in the future dial another, similar hidden line, making of course with that first line an angle equal to that which

[The two divided rules of the preceding page recur here as the head-band of the folio; see fig-p621-1.]

the hidden line of the given dial makes with the first line that is parallel to the meridian line. This will easily be done if, from each place of the style of both dials, a circle is described at any one and the same interval, and, on the arc between that first hidden line drawn in the given dial and this hidden line drawn through the given hour, an equal arc is taken in the future dial, beginning from that first hidden line and proceeding toward the same side to which the given hour inclines from the hidden line. For the hidden line drawn out from the place of the style of the future dial through the end of this arc will form, with that first hidden line, an angle equal to that which the two said hidden lines contain in the dial proposed. Finally, transfer the interval between the style of the given dial and the point of the proposed hour onto the line AE, and carefully note the parts of the line AF comprised within that interval. For if just as many parts are taken with the compass on the line GM and transferred from the place of the style of the future dial onto the hidden line last drawn, the point of that same hour on the tropic of Cancer [☿], or of Capricorn [♊], or on the equinoctial line, will be

obtained. In no other way shall we carry over all the other points of the proposed dial into the future dial.

To do this more expeditiously, it will not be out of place first to draw out hidden lines from the place of the style of the given dial through all the hour-points of the tropic of Cancer, and to make just as many issue from the place of the style of the future dial, comprehending in a circle described from the place of the style arcs equal to the arcs that those hidden lines in the given dial cut off from a circle equal to it, likewise described from the place of the style. For thus we shall expeditiously, by means of the lines AF and GM, cut off on the hidden lines of the future dial intervals like the intervals of those hidden lines of the given dial, so that the points of all the hours on the tropic of Cancer are found. The same is afterwards to be done for the hour-points of the equinoctial line, of the tropic of Capricorn [♊], and of any other sign, if need be. For if the corresponding hour-points are at last joined by straight lines, and the points of the sign-arcs by curved lines, a larger or smaller dial will have been described, according to the given length of the style.

But if the style GH of the future dial has to the style AB of the proposed dial a multiple or submultiple proportion — as not rarely happens in practice, when a dial made for some wall is to be transferred onto that wall in a larger form (for, the dial once described, we may choose another style, double, triple, tenfold, or twentyfold the first, and so on, according as the magnitude of the dial to be described requires) — we shall most expeditiously construct the larger or smaller dial in this way. Draw on the wall a horizontal line, one, that is, parallel to the horizon; choose on it a place for the style; and through this, by means of a circle described from the place of each style, draw the style-line, forming with the horizontal line an angle equal to the angle that the style-line makes with the horizontal line in the proposed dial. Then transfer the interval on the style-line of the given dial, between the horizontal line and the equinoctial line, onto the style-line of the future dial, downward from the horizontal line, as many times as this style contains that one, marking a point on the style-line itself. Likewise transfer the interval on the horizontal line of the proposed dial, between the place of the style and the equinoctial line, onto the horizontal line of the future dial (toward the same side to which the equinoctial line inclines in the given dial), from the place of the style, as many times too as this style comprehends that one, marking a point also on the horizontal line. For the line drawn across through this point and through that other one marked on the style-line will give the equinoctial line of the future dial.

Now if all the intervals on the horizontal, equinoctial, and style-lines of the given dial — both between the place of the style and the hour-lines, and between the common section of the horizontal line and the equinoctial, and the hour-lines — are multiplied, on the corresponding lines of the future dial, as many times as the one style embraces the other; and if the same is done for the intervals of the hour-lines between the equinoctial line, or the horizontal line, and the arcs of Cancer [♋] and Capricorn [♐], as well as of the other signs: then all the points will be found in the future dial through which the hour-lines and the sign-arcs must run. And if at any time some lines do not cut the horizontal line in the given dial, they must be produced, hidden, until they cut it, so that their points can be transferred onto the horizontal line of the future dial. But perhaps we shall dispatch the matter more conveniently if in the given dial we draw one parallel to the horizontal line, or two in any way, which will conveniently cut the hour-lines (some of them being produced, if need be). For if in the future dial other parallels to the horizontal line are drawn, so that their distances from the horizontal line comprehend the distances of those in the given dial from the horizontal line as many times as the one style is contained in the other, the intervals of these onto those must be transferred, just as we said concerning the intervals of the horizontal line, the equinoctial, and the style-line, and so on.

More on this subject, written at length, you will find in the last proposition of Book IV of our *Gnomonics*.

THE FINDING OF THE MERIDIAN LINE.

(*MERIDIANAE LINEAE INVENTIO.*)

CAPVT XVIII.

[Margin: The finding of the meridian line.]

[Margin: An instrument most convenient for observing shadows, in place of a gnomon.]

Although in my commentary on the *Sphere*, where I dealt with the offices of the meridian circle, and in the scholium to Proposition 23 of Book 1 of the *Gnomonics*, I have written much about the finding of the meridian line [linea meridiana], nevertheless, because the matter is of such outstanding usefulness in the treatment of sundials [horologia], I shall here repeat — without demonstration, since the demonstration may be sought from the *Gnomonics* — that method of finding the meridian line which is taken from the Analemma. To find the meridian line on any given day, then, first learn the place of the Sun from an

ephemeris or from some other source. Then, on a plane parallel to the horizon, observe the shadow of a fine thread hanging freely. For this purpose I usually employ the instrument you see depicted here. In it a square [norma] CDE is fixed at right angles to the flat ruler AB, along the line DI, parallel to the two edges of the ruler — so that the side DH of the square stands like a kind of gnomon set upright to the horizon, or like a freely hanging thread, once the ruler AB has been laid upon a plane parallel to the horizon. By this means we shall, with little trouble, mark without any perceptible error two points along the length of the shadow's tip, cast from the edge HD.

But if on the square's arm CD, which is raised above the horizon, a line FG is drawn parallel to the side DH, and a hole is made near the point G, so that a plumb-line — a fine thread hung from the hole F with a weight attached — can move freely within it, then this same instrument will also serve very conveniently for examining any proposed plane, to determine whether or not it is parallel to the horizon. For when the thread FG grazes the arm CD and coincides with the line FG, the plane on which the ruler AB is set will be parallel to the horizon. Now, along the length of the shadow's tip cast from the side DH — or along the middle of the width of the shadow which the freely hanging thread casts — let two points A and B be marked, a little apart from each other, as in the following figure, and through them let the straight line AB be extended. This line will be the common section of the underlying plane and of that vertical circle [verticalis] which at the moment of observation passes through the center of the Sun.

Once the shadow has been observed, let the Sun's altitude be taken at once, by means of a quadrant or some other instrument. I say *at once*, because it is best that the Sun's altitude be observed immediately after the two points in the shadow have been marked, before the straight line is drawn through them — lest there be danger in delay, since, on account of the Sun's daily motion, the shadow shifts continuously and the Sun at once comes to lie in a different vertical circle.

After this, let an Analemma be described, in which the meridian is FGHI; the common section of the horizon and the meridian is GI; the common section of the prime vertical and the same meridian is FH; the common section of the same meridian and the equator [aequator] is LM; and finally the common section of the meridian and the parallel of the Sun [parallelus Solis], on which the Sun stands at the time of observation, is the straight line NO. This last is easily drawn by means of the Sun's known declination [declinatio], if the arc of declination LN or MO is found, as I taught in Chapter 10. Then, having computed the Sun's altitude, found from I as far as P, and from G as far as Q, we shall draw the straight line PQ. By

the scholium to Proposition 27 of Book 3 of Euclid, this line will be parallel to GI itself, and hence it is the common section of the meridian and of the parallel to the horizon passing through the center of the Sun at that time. It will cut the vertical diameter FH at R, and the diameter of the Sun's parallel NO at S. Then, having described from R about PQ, at the interval RP or RQ, the semicircle PTQ, let the perpendicular ST be drawn from S to PQ, cutting the circumference PTQ at T; and let the straight line RT be joined.

If, then, the point S falls between Q and R, and the observation is made before noon, we shall construct at the center C — from which, taken anywhere on the shadow-line AB, a circle of any size has been described — an angle ACD equal to the acute angle TRQ, running from east toward south; that is, from A, the eastern point, toward D, as is seen in circle A. But if the observation is made after noon, we shall make the angle ACD equal to the same angle TRQ, running from west toward south; that is, from A, the western point, toward D, as appears in circle B.

But if the point S falls exactly on the point R, then — whether the observation is made before or after noon — we shall draw through C the perpendicular DE to AB, as is clear in circle C.

If, finally, the point S lies between R and P, and the observation is made before noon, we shall make an angle ACE equal to the acute angle TRP, running from east toward north; that is, from A, the eastern point, toward E, as is manifest in circle D. But if the observation is made after noon, we shall construct an angle ACE equal to the same angle TRP, running from west toward north; that is, from A, the western point, toward E, as may be seen in circle E. For the straight line DE, always making the said angle with AB, will be the meridian line.

But if at any time the line PQ falls upon the point N — that is, if the Sun's altitude, computed from Q, terminates at N — then at the time of observation the Sun will lie on the meridian circle and will have its greatest altitude for that day; and therefore the shadow-line AB itself will be the meridian. All of this is clear from what I have demonstrated in the *Gnomonics*.

[Margin: How the diurnal and nocturnal arc, and the hour, are known from the Analemma.]

But that you may see here what an excellent use the Analemma has in matters of astronomy — I have set out its many other applications in various places of the *Gnomonics* — it will not be amiss to explain briefly in what way, from the Analemma, both the diurnal and the nocturnal arc, and the hour of the day, may be known from the Sun's known declination and its altitude above the horizon.

For once the straight line PQ has been drawn through the terminal points of the Sun's altitude, PQ, and a circle has been described about NO, the diameter of the Sun's parallel — whose center is at d, where the axis of the world ab cuts the diameter

NO — and this circle has been divided into 24 equal hours, beginning from the diameter NO (if the reckoning is of the hours counted from noon and from midnight); then, if through Z, where the diameter NO cuts the diameter of the horizon GI, a perpendicular XY is raised to NO, this XY will be the common section of the Sun's parallel and the horizon, as I have shown in the *Gnomonics*. Therefore the diurnal arc will be XNY, and the nocturnal arc YOX; and consequently the number of hours contained in these arcs will indicate the length of the day and of the night. And now, if from the point S the perpendicular SV is drawn to NO, cutting the circumference of the Sun's parallel at V, the hours contained in the arc NV will indicate how many hours the Sun is distant, whether before noon, or

Diagram. The principal figure of this chapter: a large analemma. A great circle (representing the Sun's parallel-and-hour circle) is divided around its rim into 24 hour-marks, of which the readable numerals are, running across the top and down the right, 1 2 3 4 5, then 6 7 8 9 10 11 12, and down the left 11 10 9 8 7 6. Within it are inscribed the meridian and its cross-lines, the horizon diameter, the Sun's-parallel diameter, and a family of oblique construction lines and hour-lines converging near a central point. Below and to the left stand five small orientation circles labelled A, B, C, D, E, each a circle with center marked and cross-diameters (top D, bottom E, sides A/B), illustrating the five cases of the meridian-line angle treated on the preceding page (circles A–E).

Readable labels in the large analemma: on the rim and upper area — I, F, P, L, N, G, D; along the central vertical and to its right — R (appearing at several points along one line), S, K, Z, d, M; and around the lower and right portion — V, X, Y, O, T, and the small letters f, b, e. The center of the parallel is marked d.

- N, O: endpoints of the Sun's-parallel diameter
- G, I: endpoints of the horizon diameter
- Z: intersection of NO with GI
- X, Y: endpoints of the perpendicular XY (common section of Sun's parallel and horizon)
- S, V: point S and its perpendicular foot V on the parallel's circumference
- A, B, C, D, E: the five small orientation circles below

- Several further small peripheral letters and the interior hour-line labels could not be resolved with confidence [?].

after — according as the observation is made before or after noon. And if the hour reckoned from sunset is desired, in the Italian manner: if indeed the observation is made before noon, the division of the circle NXOY into 24 equal hours must be begun from the point Y and carried on through the point O; for then the arc YOY will indicate at once how many hours have elapsed since sunset. But if the observation is made after noon, the same division must be begun from the point X and carried on through the point O; for the arc XONV will show the hours passed since sunset. In the same way, if the hour reckoned from sunrise is sought, in the manner of the Babylonians and of the Balearic Islands, the division of the circle must be begun from the point X and carried on through N, if the observation is made before noon, but from the point Y if after noon. Not otherwise shall we find the unequal (seasonal) hour, if the semidiurnal arc NX is distributed into six equal parts, and so on.

[Margin: How the Sun's altitude is investigated by the Analemma, from the known hour and the Sun's declination.]

Conversely, from the known hour we can arrive at a knowledge of the Sun's altitude by means of the Analemma, provided the Sun's declination is not unknown. For if, according to the amount of the declination, the diameter NO of the Sun's parallel is described, and about it the circle NXOY is described and divided into hours, and from V, the known hour, the perpendicular VS is drawn to NO, and finally through S the straight line PQ is drawn parallel to the diameter of the horizon GI, then both GQ and IP will be the arc of the Sun's altitude above the horizon.

[Margin: How the Sun's altitude is elicited in the Analemma from the length of the shadow of any style.]

Nor should this be passed over: that we can determine the Sun's altitude from the gnomon's shadow alone, in case we happen not to have at hand some other instrument for observing it, in the following way. On the plane parallel to the horizon, on which we took up the shadow AB above, let the tip of that same shadow be marked as accurately as possible at the time of observation. Then, having taken on the Analemma a straight line Ke equal to the side of the square DH, or to any style whatever (as has been done in the figure), let there be raised at e, perpendicular to FH, the line ef equal to the length of the shadow. For the straight line drawn from f through the center of the Analemma K, when

produced, will cut off from the meridian the arc IP of the Sun's altitude, as I demonstrated in the *Gnomonics*.

ANOTHER FINDING OF THE MERIDIAN LINE, BY THREE OBSERVATIONS OF THE SUN, without knowledge of the altitude of the pole, or of the declination, or of the Sun's place in the zodiac: together with the finding of the altitude of the pole, the declination, and the Sun's place in the ecliptic, and the rising and setting amplitude.

(ALIA INVENTIO LINEAE MERIDIANAE PER TRES SOLIS OBSERVATIONES sine cognitione altitudinis poli, & declinationis, locique Solis in Zodiaco: vna cum inuentione altitudinis poli, declinationis, locique Solis in Ecliptica, & amplitudine ortiua, occiduaque.)

CAPVT XIX.

Although that method of finding the meridian line from the Analemma, given in the preceding chapter, is most excellent, nevertheless — because it requires both the known altitude of the pole and the place of the Sun, so that the Analemma may be constructed for the given pole-altitude and the parallel drawn in it according to the declination of the Sun's place — it is worthwhile to subjoin here another procedure, taken from Pedro Nunes [Pedro Nunes] the Portuguese, in Book 2 of *On Navigation*, Chapter 16,

[Margin: The finding of the meridian line, the altitude of the pole, the Sun's declination, and the rising and setting amplitude, from three observations, on the common astrolabe.]

by which, from only three observations of the Sun, we may — by the description of certain circles on the common astrolabe — draw out both the meridian line on a plane parallel to the horizon, and the altitude of the pole of that place where the observation is made, together with the declination and the Sun's place in the zodiac, and the rising and setting amplitude. From this it will readily be understood how splendid is that invention of Ptolemy [Ptolemy], whereby all the celestial circles are described on a plane in that form and proportion in which they are seen from the antarctic pole upon the plane of the equator: since not only the things we here propose, but very many other astronomical problems as well, can be dispatched by it — which is not the place to explain. But in what way we can project any circle whatever, whether a great circle or not a great circle,

onto a plane, will be made clear from our *Astrolabe*, constructed with geometrical demonstrations, which we shall shortly, God willing, bring to light. Now let us come to the matter proposed.

Let there be, then, on a plane parallel to the horizon, a circle ABCD, whose center E represents the horizon, and in which two hidden diameters AC, BD cut each other at right angles at the center E. Now, having set a style at E — or, what I prefer, having set the side DH of the instrument described above at E — let the shadow EF be observed in the morning, and at the same instant of time the Sun's altitude, measured by the arc AG. Then, after one hour or another, let the shadow EH be observed again, and at the same time the Sun's altitude AI. And thirdly, after some interval of time, the shadow EK and the Sun's altitude AL. Then, drawing from B through the points of altitude G, I, L three hidden straight lines cutting the semidiameter AE at M, N, O: from the first shadow EF let the straight line EP be cut off, equal to EM; from the second shadow EH the straight line EQ, equal to EN; and finally from the third shadow EK the straight line ER, equal to EO. And through the three points P, Q, R, by the scholium to Proposition 5 of Book 4 of Euclid, let a circle PQR be described, cutting ABCD at f, whose center is S. For the straight line ES, drawn through the points E and S, will be the meridian line; and the angle IEF will be that which the vertical circle drawn through the center of the Sun at the first observation makes with the meridian. And when the perpendicular TV has been drawn through E to ES, it will be the common section of the proposed plane and of the prime vertical; and VF, VH, VK will be the latitudes of the shadows at the times of the observations — that is, the distances of the verticals drawn through the center of the Sun from the vertical properly so called.

Diagram. A compound geometric construction in two parts. **Upper left:** a quadrant-like figure — an arc from A (top) through E, D to B (bottom), with a network of chords among the interior points; readable labels I (left), H, E, G, D (upper), M, N, L, F (interior), K (lower left), C, B. This is the small inset showing the shadow-altitude triangles. **Lower/main:** a large circle (the horizon circle ABCD, center E) crossed by the meridian and by the circle PQR and its oblique secants, with a long slanting line rising to the point δ (delta / "d") at the top. Readable labels: at top, two marks near δ ; along the central vertical Y, A/I/G, M, S, d, N, O, E, X, q; on the right descending, b, L, f, F, P, D, V, H, Z, K, P; the great secant lines run from T (=B, the lower center from which the secants radiate) outward. The lower center point is marked B (with T alongside).

- ABCD: horizon circle, center E

- AC, BD: the two hidden diameters (right angles at E)
- EF, EH, EK: the three observed shadows
- G, I, L: the three points of the Sun's altitude
- M, N, O: intersections on the semidiameter AE
- P, Q, R: the three constructed points; circle PQR cuts ABCD at f, center S
- ES: the meridian line
- TV: perpendicular to ES through E (common section with the prime vertical)
- V, F, H, K: feet of the shadow-verticals
- X, Y: where circle PQR cuts the meridian; Z, a, b, d and δ : points of the auxiliary construction below
- Several small interior and peripheral labels (including the delta-marks at top and the crowded lower-right cluster) could not be resolved with confidence [?].

[Margin: Demonstration of the above operations.]

After this, from the point T, through the points X and Y — where the circle PQR cuts the meridian line — let two straight lines TX, TY be drawn, cutting the circle ABCD at Z and a. Let the arc Za be bisected at b, and let the straight line Tb be drawn, cutting the meridian at d. For the arc Vb will be the complement of the altitude of the pole, and the arc bZ the complement of the Sun's declination, and its meridian altitude the arc eZ; and finally the arc Vf will be the rising or setting amplitude. And if the two quadrants bh, bp are taken, pZ will be the Sun's declination; and hence, this declination being known, its place in the zodiac will not be unknown. The latitude of the place — that is, its distance from the equator — will be the arc pV; and the altitude of the pole above the horizon will be the arc Ib, equal to pV itself.

The demonstration of this operation depends entirely on the description of the astrolabe. To make it plainer, we shall conceive the astrolabe to be described with the eye placed at the nadir — that is, at the other pole of the oblique horizon, the one opposite the zenith. In this way it will come about that the horizon with its parallels is described on the plane of the horizon in just the same way as the equator with its parallels is described, by Ptolemy, on the plane of the equator when the eye is placed at the antarctic pole; while the equator

and its parallels, take on in our construction the very situation and shape that the horizon and its parallels have in Ptolemy's construction. For since the poles of the horizon are as far distant from the poles of the equator as the poles of the

equator are from the poles of the horizon, it follows that the horizon with its parallels is seen in the plane of the horizon — from the one pole of the horizon — in the very shape in which the equator itself with its parallels appears, from the antarctic pole, in the plane of the equator; and, conversely, that from the same pole of the horizon the equator with its parallels appears in that same plane of the horizon in the shape in which the horizon with its parallels is seen, from the same antarctic pole, in the plane of the equator.

This being so, if the circle ABCD is taken in the astrolabe as the horizon, then E will be its pole — that is, the zenith [vertex capitis] — just as, when ABCD is taken as the equator, E is the pole of the world. The straight lines EF, EH, EK will be the vertical circles drawn through the Sun at the times of observation, just as, according to Ptolemy, all the straight lines drawn through the center E represent the meridians passing through the poles of the world. Through the points M, N, O will be described the parallels of the horizon, whose declinations from the horizon are AG, AI, AL — that is, the circles of altitude passing through the Sun — drawn from the center E, just as by Ptolemy the parallels of the equator having those same declinations are described from E through those same points M, N, O. These parallels will cut the straight lines EF, EH, EK at P, Q, R, because of the equality of the straight lines EM and EP, EN and EQ, EO and ER; so that at the times of observation the Sun stands at the points P, Q, R — that is, at the common intersections of the vertical circles and of the parallels of the horizon drawn through the Sun. And since the Sun on one and the same day is taken to occupy one and the same parallel of the equator, the circle PQR, described from S, will be the parallel of the equator on which the Sun then lies — after the fashion of a parallel of the horizon in Ptolemy's construction, as it would be if the equator were the horizon and the horizon the equator.

Therefore, since the centers of the parallels of the horizon in the astrolabe lie on the meridian line of the astrolabe, the straight line drawn through E and S will be the meridian line, and the angle IEF will be the one that, at the first observation, the meridian makes with the vertical circle EF. The straight line TV will be the prime vertical [Verticalis primarius], cutting the meridian at right angles; VF, VH, VK will be the latitudes of the shadows [latitudines umbrarum] at the times of observation; and the point V corresponds to the zenith of the place.

Now, just as in Ptolemy's astrolabe the point b, which bisects the arc Za, falls at the pole of the horizon and of its parallels — so that d is the zenith in the astrolabe (for the pole of the horizon, b, on the equator ABCD, is always equally distant from the points Z and a, upon which fall the straight lines TX, TY drawn

through the extreme points of the diameter of the parallel of the horizon PQR, as is clear from the construction of the parallels of the horizon) — so likewise, when ABCD is taken as the horizon with E as its pole, that same point b will fall at the pole of the equator and of its parallels, so that d in our astrolabe is the visible pole of the world. And if the quadrants bh, bp are taken, the straight lines Th, Tp will cut the meridian line EY at the extreme points of the diameter of the equator, g and q, so that the straight line gq, bisected at a, [yields] a circle described from a with radius aq, which, passing through TV, represents the equator, just as in Ptolemy's astrolabe it expresses the horizon — as is established from the construction of the horizon in the common astrolabe. In our figure, however, since the point g is too far distant from E to be marked, the straight line gq has not been bisected; instead a has been taken on the meridian line as the center of the three points T, q, V, and from it the equator TqV has been described.

Therefore Vb will be the complement of the pole's altitude — namely the distance of the zenith V from the visible pole b; the latitude of the place will be Vp — that is, the distance of the zenith V from the equator p; the altitude of the pole [will be] Ib; the complement of the declination [will be] bZ, and the declination itself pZ; the Sun's meridian altitude [will be] eZ; and finally the rising or setting amplitude [will be] Vf. All of which are evident from the manner of describing the circles in the common astrolabe.

Easy as this method is, and very well suited for use when the Sun is in the northern signs (provided everything is laid out accurately as we have prescribed), it becomes difficult and inconvenient when the Sun lingers in the southern signs, because then the parallel of the Sun falls below the point q and requires a diameter of unmanageable size.

[Margin: Finding the Sun's declination, the altitude of the pole, the meridian line, and the rising or setting amplitude, from three observations, by means of spherical triangles.]

But let us now teach how to investigate, by means of spherical triangles, the same things we found with the astrolabe, from the same three observations. Let ADB be the horizon, AIB the meridian, K the visible pole of the world, and I the zenith of the place. Let the two latitudes of the shadow observed on the horizon be those from which similar arcs CD, DE are taken on the western semicircle of the horizon, if the observations are made in the afternoon; but if before noon, let the same arcs be taken on the eastern semicircle of the horizon. Through the points C, D, E let three vertical circles IC, ID, IE descend from the zenith I, on which the known altitudes of the Sun are CF, DG, EH — of which the one nearest the pole K,

namely CF, is the smallest of all — so that in those three observations the Sun stood at the points F, G, H, through which the parallel of the Sun in which it then lingers will pass throughout. Through each pair of points F,G; G,H; H,F let arcs of great circles FG, GH, HF be described; and, FG and FH being bisected at L and M, let four arcs of great circles KF, KL, KM, KH descend from the pole K, of which KL cuts the arc FH at N. Now the arcs KF, KH [Margin: (a) — prop. 28 of the third [book]] will be equal, because the straight lines subtending them, KF and KH, are equal by the definition of a pole, since they are drawn from the pole K all the way to the parallel of the Sun. The angles at M too will be right angles. For since the two arcs MF, MK are equal to the two arcs MH, MK, and the base KF to the base KH, as we have shown, the angles at M will be equal by proposition 18 of our [treatise on] spherical triangles, and therefore right angles. By the same reasoning the angles at E [?] will be right angles.

Therefore, since in the triangle FGI the arcs IF, IG are known — being the complements of the known altitudes of the Sun, CF and DG — and since they contain the known angle FIG (because its arc CD is known; for we assume the latitudes of the shadows CD, DE, and hence CE as well, to be known by observation; and, to make the calculation more reliable, the said arcs may be taken on the horizon in any whole number of degrees, and the altitudes of the Sun observed when the shadow of the stylus extends precisely through the points C, D, E) — the arc FG too will be made known, by Practice 19 of our spherical triangles, especially if we use the second method of that practice, which is the easier. For it is convenient to cite here those practices which we have collected separately, excerpted from the propositions, at the close of the [treatise on] spherical triangles. In the same way the arcs GH and FH will also become known — since the arcs IG, IH are known, being complements of the known altitudes of the Sun DG and EH, and contain the known angle GIH because the arc DE is known; and since the arcs IF, IH contain the known angle FIH because the arc CE is known.

Next, from the three known arcs FG, FH, GH we shall likewise come to know the angle GFH, by Practice 18 of the same spherical triangles, especially if we employ the second way of that practice, as the easier.

Now, since in the right triangle FLN the arc FL is known — being half of the known arc FG — and moreover the adjacent angle LFN has been made known, the other non-right angle LNF will also be made known, by Practice 5 of our spherical triangles. And hence, in the same triangle, from the known arc FL and the known opposite angle LNF, the arc FN opposite the right angle will also be

made known, by Practice 3 of our spherical triangles; and when this is subtracted from the known arc FM — namely from the half of the known arc FH — the arc MN will be left known.

Therefore, since in the right triangle KMN the arc MN has been made known, together with the adjacent angle MNK (which is equal, by proposition 6 of our spherical triangles, to the already-known angle FNL at the vertex), the other non-right angle MKN will be produced known, by Practice 5 of our spherical triangles. And hence, in the same triangle, from the two non-right angles MNK, MKN being known, the arc KM opposite the angle MNK will also be known, by Practice 4 of our spherical triangles.

Diagram. A compound geometric construction in two parts — the same demonstration figure that appears on the preceding page, here reprinted so the reader can follow the spherical-triangle argument.

- **Upper-left inset** — a quadrant-like arc from A (top) descending through E, D to B (bottom), with a dense network of chords among the interior points. Readable labels: A (top), E (upper right), H (upper-left interior), I (far left), G (interior, near D), D (right of arc), M, N, L (interior triangle cluster), F (lower center), C (near F), K (lower left), B (bottom).
- **Main figure (lower/right)** — a large circle crossed by the meridian and by an oblique construction, with two slanting lines rising to two δ [delta] marks at the top. Readable labels along and within it: at top, two δ marks; on the central vertical, Y, then A/I/G, M, S, d, N, O, E, and below it X, R, q, with q q at the foot; on the right flank, b, L, f, F, P (twice), D, V, H, Z, K, and P; the secant lines radiate from the point T (with B alongside) at the lower left.

Several of the small, overlapping interior and rim labels — including the two δ marks at the top and the crowded lower-right cluster — could not be resolved with confidence [?].**

Again, since in the right triangle FKM the two arcs FM, KM about the right angle are known, the arc FK opposite the right angle will also be made known, by Practice 7 of our spherical triangles — which arc is indeed equal to the complement of the Sun's declination, as we said above; and consequently the declination itself will not be hidden.

After this, since in the right triangle FKM the arc FK opposite the right angle is known, as well as the arc KM about the right angle, the angle KFM opposite the arc KM will also be found, by Practice 1 of our spherical triangles.

In the triangle FHI too, since all three arcs are known, the angle HFI will also be known, by Practice 18 of our spherical triangles, especially by the second, easier way; and when this is subtracted from the angle KFM, just found, the angle KFI will also be left known.

Wherefore, since in the triangle KFI the two arcs FK, FI are known and contain the known angle KFI, the arc IK too will be produced known, by Practice 19 of our spherical triangles, especially by the second, easier way — namely the complement of the pole's altitude; and thus the altitude of the pole itself, BK, will not be unknown.

Likewise, since in the same triangle FIK the three arcs are known, we shall also come to know, by Practice 18 of our spherical triangles — chiefly by the second, easier way — the angle FIK, which the vertical circle IC, drawn through the Sun at the time of the observation in which the Sun's altitude was found to be CF, makes with the meridian toward the visible pole. Therefore, if on a plane parallel to the horizon a rectilinear angle is made with the shadow-line of that observation, of as many degrees as are contained in the arc BC of the angle FIK just found, then the line forming that angle will be the meridian.

Finally, the Sun's declination and the pole's altitude now being known: if it be arranged that as the sine of the complement of the pole's altitude is to the sine of the declination found, so the whole sine [radius] is to another, there will be produced the sine of the rising or setting amplitude, as we demonstrated in the Gnomonics, Book I, proposition 34.

THE FINDING OF THE DECLINATION OF ANY WALL FROM THE PRIME VERTICAL CIRCLE.

CHAPTER XX.

Before a sundial [horologium] can be laid out on a proposed wall, it is first necessary to find its declination from the vertical [circle] properly so called; which can be done by means of the Analemma, in the manner we set forth in the scholium to proposition 23 of Book I of the Gnomonics. Let AB be a wall perpendicular to the horizon, on which the straight line CD is drawn parallel to the horizon; and let there be fixed in it a stylus CE of any length, perpendicular to the wall. (Here too I would rather choose the instrument of chapter 18: for if its point D is placed at the point C, the side DH will serve as the gnomon perpendicular to the wall.) And let there be observed, at whatever time the Sun lights up the wall — whether before or after noon — the tip of the shadow EF

which the stylus casts, namely the point F. (The declination will be found more exactly if on some flat board the straight line CD is drawn and the board itself is applied to the wall so that the straight line CD is parallel to the horizon and the stylus is placed at C.) Through this point [F] let the perpendicular FD be drawn to the straight line CD; which is easily drawn on the wall in this way. Apply to the wall a fine thread with a plumb-bob, so placed that it passes through the point F, and mark on the wall any point D through which the thread passes. For a straight line drawn through F and D will be perpendicular to CD, since the thread is perpendicular to the horizon. Then, the perpendicular CG being drawn from C to CD, equal to the stylus assumed, let the straight line GD be joined. CDG will then be the angle of declination of the proposed wall from the vertical [circle] drawn through the Sun at the time of observation; and from this, once found, we shall investigate the declination of the same wall from the prime vertical in the following way.

[Margin: The angle which the vertical [circle] drawn through the Sun makes with the proposed wall.]

Diagram. The wall construction for this chapter: a rectangle (the wall AB) divided by a horizontal line CD and a vertical line. Readable labels:

- A: upper-left corner of the wall
- B: lower-right corner of the wall
- C: center point, foot of the stylus, on the horizontal line CD
- D: on line CD to the right (the marked point through which the plumb-thread passes)
- E: upper point, tip of the stylus (shadow-casting tip)
- G: point at the top, adjacent to E (the perpendicular CG equal to the stylus)
- F: the tip of the shadow, on the vertical below D
- A dotted line runs from E down to F (the shadow ray); a short shaded triangle sits at E–C–G.

Having marked the tip of the shadow F, let there at once be sought — before the straight line FD is drawn (for if any delay intervenes, the shadow will change and the Sun will occupy another vertical circle, on account of its diurnal motion) — the altitude of the Sun. Let this, [computed] in the Analemma, chapter 18 (which we have here repeated), be reckoned from the points G, I up to the points Q, P; and let the straight line PQ be joined, which will be the diameter of the parallel of the horizon drawn through the center of the Sun at the time of observation, cutting the diameter NO of the Sun's parallel at S, and the diameter FH of the

prime vertical at R. Then, a semicircle PTQ being described about PQ, from the center R with radius RP or RQ, let the perpendicular ST be drawn from S to PQ, cutting the circumference of the semicircle PTQ at T; and let the straight line TR be joined, which with the diameter FH of the vertical properly so called will form the angle TRH — the angle of declination which the vertical [circle] drawn through the Sun at the time of observation has from the vertical properly so called.

[Margin: The angle which the vertical [circle] drawn through the Sun makes with the prime vertical.]

Diagram. The analemma construction repeated from chapter 18, for finding the wall's declination. It consists of one large circle plus five small auxiliary circles beneath it.

- **Main circle** — a large graduated circle (the analemma) crossed by the horizon, the prime vertical, the parallels, and a dense web of hour-lines and projection chords. The rim is graduated with the hour-numerals 3, 4, 5, 6, 7, 8, 9, 10, 11, 12 [?], 1, 2. Readable letter-labels around and within it include: N, F, Y, P, Q, L, G at the upper rim and left flank; a column of R's and S's with d, K, Z, X, M, T on the right and lower-right; and I on the right rim. The many small, tightly-packed interior and rim labels are largely unresolved [?].
- **Five small circles** (a row beneath the main figure), each a circle divided into quadrants by two diameters, lettered in the center A, B, C, D, and E respectively; each shows D at the top, E at the bottom, C at the center, and A and B on the horizontal diameter.

Because of the extreme label density in the main circle, more than two labels there are unresolved [?].**

[Margin: How the declination of a wall — when the wall faces south and the observation is made before noon — is to be ascertained.]

And so, suppose the observation is made before noon, with the wall facing south (a case we shall learn to recognize from what we shall write at the end of this chapter). If the point S falls between Q and R — which happens only when the Sun is found beyond the prime vertical [Verticalis primarius] — the Sun will light both the wall and the prime vertical on their southern side. We therefore compare the angle TRH with the angle CDG, which we found on the wall. If TRH turns out equal to CDG, the wall has no declination and faces due south; for the

declination that the vertical [circle] drawn through the Sun then has from the wall, and its declination from the prime vertical, are one and the same —

Diagram. This is the analemma construction repeated (as before) from chapter 18, for finding the wall's declination, accompanied beneath and beside it by five small auxiliary circles. It is the same figure that was engraved on the preceding page (cf. fig-p627-2); it is re-printed here.

- **Main circle** — a large graduated circle (the analemma) crossed by the horizon, the prime vertical, the parallels, and a dense web of hour-lines and projection chords. The outer rim is graduated with hour-numerals: reading down the left flank I can make out 10, 9, 8 ... 6, 5, and reading across the top and down the right flank 3, 4, 5 ... 8, 9, 10, 11 [several rim numerals abraded/overlapped — ?]. Readable letter-labels around and within it include N, I, F, L, Q, G on the upper rim and left flank; a column of R's and S's with d, K, Z, T, M along the center and lower-right; P repeated on the right flank; Y and I on the right rim. The very numerous small interior and rim labels are largely unresolved [?].
- **Five small circles** — each a circle divided into four quadrants by a vertical and a horizontal diameter, with a large central letter identifying it (A, B, C, D, E). In each, D is set at the top of the vertical diameter and E at the bottom, a small c marks a point near the center, and the letters A and B stand at the two ends of the horizontal diameter (their left/right placement differing from circle to circle, representing the several orientation cases of the wall relative to the cardinal points). Several of the small rim-letters on these circles are ambiguous [?].

Because of the extreme label density in the main circle (a re-engraving of an already-flagged figure), more than two labels there remain unresolved [?].**

— and so the wall does not differ from the prime vertical at all.

But if the angle TRH is found to be greater than CDG, then the wall lies on the eastern side, between the prime vertical and the vertical that is at that moment drawn through the Sun; this is because, on the southern side, the vertical drawn through the Sun then stands farther from the prime vertical than from the wall. Hence, if we subtract the angle CDG — that is, the declination which the vertical drawn through the Sun has from the wall — from the angle TRH — that is, from the declination which that same vertical has from the prime vertical — the remainder will be the angle of the wall's declination from the prime vertical, running from south toward the west.

Finally, if the angle TRH is less than CDG, then the prime vertical lies on the eastern side, between the wall and the vertical that passes through the Sun; for on the southern side the vertical drawn through the Sun then stands farther from the wall than from the prime vertical. So if we take the angle TRH away from the angle CDG, the remainder will be the angle of the wall's declination from the prime vertical, running from south toward the east.

But if the point S is the very same as R — which happens when the Sun stands in the vertical properly so called [Verticalis proprie dictus] — the Sun lights the wall on its southern side, but the prime vertical not at all. The angle CDG found on the wall will then be the angle of the wall's declination from the prime vertical, and the wall will decline from south toward the east; for on the eastern side the vertical properly so called, in which the Sun then stands, is more southerly than the wall.

Finally, if the point S falls between P and R — which happens when the Sun is found on the near side of the prime vertical — the Sun lights the wall on its southern side but the prime vertical on its northern side, and so the vertical drawn through the Sun lies, on the eastern side, between the wall and the prime vertical; for the Sun's vertical is then more southerly than the wall and more northerly than the prime vertical. For this reason, if the angle TRH is added to the angle CDG, the sum will make up the angle of the wall's declination from the prime vertical, and the wall will decline from south toward the east.

[Margin: How the declination of a wall facing south is to be discovered when the observation is made after noon.]

Now suppose the observation is made after noon, with the wall still facing south. If the point S falls between Q and R — which happens when the Sun is more southerly than the vertical properly so called — the Sun will light both the wall and the prime vertical on their southern side. Accordingly, if the angle TRH is found equal to CDG, the wall again has no declination. But if TRH turns out greater than CDG, the wall lies on the western side, between the prime vertical and the vertical drawn through the Sun. Therefore, subtracting the angle CDG from the angle TRH, the remainder will be the angle of the wall's declination from the prime vertical, and the wall will decline from south toward the east. Finally, if the angle TRH is less than CDG, the prime vertical lies on the western side, between the wall and the Sun's vertical. Taking the former from the latter, then, the remainder will be the angle of the wall's declination from the vertical properly so called, and the wall will decline from south toward the west.

And when the point S falls on R — which occurs if the Sun stands in the prime vertical — the Sun will indeed light

the wall on its southern side, but the prime vertical not at all, and the angle CDG found on the wall will indicate the wall's declination from the vertical properly so called, running from south toward the west; this is because the Sun then stands in the prime vertical — that is, in the vertical properly so called — which on the western side is more southerly than the wall.

Finally, when the point S falls between P and R — which happens when the Sun is set on the near side of the prime vertical — the Sun will still light the wall on its southern side, but the vertical properly so called on its northern side. Hence the vertical in which the Sun then stands will lie, on the western side, between the wall and the prime vertical. So if the angle TRH is added to CDG, the sum will make up the angle by which the wall declines from the prime vertical, from south toward the west.

But suppose the wall inclines toward the north and the observation is made before noon. If the point S falls between Q and R — which happens when the Sun stands beyond the prime vertical — the Sun will light the wall on its northern side but the prime vertical on its southern side. The vertical drawn through the Sun will then lie, on the eastern side, between the wall and the prime vertical. Therefore, if the angle TRH is added to CDG, the angle of the wall's declination from the vertical properly so called will be produced, and the wall will decline from north toward the east.

[Margin: How the declination of a wall inclining toward the north is to be gathered when the observation is made before noon.]

But if the point S is the same as R — which happens when the Sun stands in the prime vertical — the Sun will still light the wall on its northern side, but the prime vertical not at all. The angle CDG found on the wall will give the wall's declination from the vertical properly so called, and the wall will decline from north toward the east; for the Sun then stands in the prime vertical, which on the western side is more southerly than the wall itself.

Finally, when the point S falls between P and R — that is, when the Sun is found on the near side of the prime vertical — the Sun will light both the wall and the vertical properly so called on their northern side. So if the angle TRH is found equal to CDG, the wall will have no declination, for the reason stated earlier. But if the angle TRH exceeds CDG, the wall will be set on the eastern side, between the prime vertical and the Sun's vertical. Therefore, if CDG is taken from TRH, the

remainder will be the angle of the wall's declination, from north toward the west. Finally, if the angle TRH is less than CDG, the prime vertical will lie between the wall and the Sun's vertical on the eastern side. So if we take TRH away from CDG, there will be left the angle of the wall's declination from north toward the east.

[Margin: How the declination of a wall facing north is to be extracted when the observation is made in the afternoon, and by what route.]

Now suppose the wall faces north and the observation is made in the afternoon. If the point S falls between Q and R — the Sun, of course, being set beyond the prime vertical — the Sun will light the wall on its northern side and the prime vertical on its southern side. The vertical then drawn through the Sun will be set, on the western side, between the prime vertical and the wall. Consequently, if the angle TRH is added to CDG, the angle of the wall's declination from north toward the west will be forged.

But when the point S falls on the point R — as when the Sun has occupied the prime vertical — the Sun will still light the wall on its northern side, but the prime vertical in no way. Hence the angle CDG found on the wall will indicate the wall's declination from north toward the west; for the Sun then stands in the prime vertical, which on the eastern side is more southerly than the wall itself.

Finally, when the point S falls between P and R — that is, when the Sun is found on the near side of the vertical properly so called — the Sun will light both the wall and the prime vertical on their northern side. So if the angle TRH is then found equal to CDG, the wall will have no declination at all, as was said above. But if the angle TRH is greater than CDG, the wall will be set on the western side, between the prime vertical and the Sun's vertical. If, then, CDG is taken from TRH, the remainder will be the angle of the wall's declination from north toward the east. Finally, if the angle TRH is less than CDG, the prime vertical will lie on the western side, between the wall and the Sun's vertical. So, taking the angle TRH from CDG, the angle of the wall's declination from north toward the west will remain.

All of this we also set out in the scholium on proposition 23, book 1 of the *Gnomonics* (*Gnomonices* I, prop. 23, scholium). It is to be understood, however, only when the angle CDG — which the vertical drawn through the Sun makes with the wall — and the angle TRH — which that same vertical makes with the prime vertical — incline toward the same side. That is: when, with the wall facing south, the angle CDG lies to our left as we face the wall in the forenoon, and to our right in the afternoon. (For the vertical passing through the Sun before noon

forms with the prime vertical an angle on the western side, which lies to our left as we face the wall; whereas after noon that same angle is set on the eastern side, which then lies to our right, as is clear.) Likewise when, with the wall inclining toward the north, that angle CDG lies to our right before noon as we face the wall, but to our left after noon.

But if the angle CDG does not incline toward the same side as the angle TRH — that is, if, with the wall facing south, the angle CDG is placed to our right before noon (which can happen when both the wall, declining from south toward the east, and the Sun, are only a little short of the meridian), or is placed to our left after noon (which can happen when both the wall, declining from south toward the west, and the Sun are not far from the meridian); and likewise, with the wall facing north, if the angle CDG is formed to our left before noon (as can happen when the wall, declining from north toward the east, stands but little from the meridian, and the Sun in the forenoon is not far from its rising), or to our right after noon (as when the wall, declining from north toward the west, does not recede far from the meridian, and the Sun in the afternoon stands near its setting) — if, I say, the angle CDG does not incline toward the same side as the angle TRH, then the angle CDG must always be added to the angle TRH, and the compound angle (which will then always be greater than a right angle) must be subtracted from a semicircle. For the remaining angle will indicate the wall's declination: from south toward the east, if the observation is made before noon and the wall faces south; from south toward the west, if the observation is made after noon and the wall belongs to the south; but from north toward the east, if the wall inclines toward the north and the observation is made before noon; and from north toward the west, if, the wall facing north, the observation is made in the afternoon.

[Margin: A supplement to the teaching of the scholium on proposition 23, book 1 of the Gnomonics, concerning the declination of walls.]

None of this will be difficult for anyone who attentively and carefully weighs the position of the vertical circles and of the wall.

These matters, then, which we have just explained here, are to be added to the scholium on proposition 23, book 1 of the Gnomonics, so that the doctrine for investigating the declination of walls may be rendered complete in every respect.

[Margin: The declination of a wall, when the Sun's altitude is equal to the meridian altitude.]

But suppose that on some occasion the straight line PQ, in the analemma, falls on the point N — that is, the Sun's altitude is found equal to the meridian altitude of the Sun for the day on which the observation is made. Then the Sun will stand, at the time of observation, in the meridian circle; and therefore the straight line FD will be, on the wall, the common section of the meridian and the wall, since the meridian is then drawn through E, the center of the world, and through the Sun's ray EF; and the wall itself will face south. The angle CDG, then, found on the wall, will give the wall's declination from the meridian, and consequently its complement will show the wall's declination from the vertical properly so called, which is what is sought: from south toward the east, if the shadow F falls to our right as we face the wall; but from south toward the west, if the shadow falls to our left. This, of course, is to be understood when at noon the Sun is more southerly than the zenith point.

[Margin: The easiest method of finding the declination of a wall inclining toward the south, at the time of noon.]

And so, if the observation is made at noon — namely, when in a plane parallel to the horizon the shadow of the style falls exactly on the meridian line (a time which, if it could conveniently be managed, I should always choose) — the wall's declination will be found quicker than words can tell. For the complement of the angle CDG found on the wall will give, at that time, the wall's declination from the vertical properly so called: from south toward the east, if the shadow falls on the wall to our right as we face it; but from south toward the west, if that same shadow is then made to our left. This is to be understood of a wall inclining toward the south. For a wall facing north is not lit by the Sun at noon, unless the Sun is more northerly than the zenith point, which can happen only in the torrid zone. And when this occurs, if the shadow falls to our left as we face the wall, the wall will decline from north toward the east; but if to our right, from north toward the west.

[Margin: How the declination of a plane inclined to the horizon is to be investigated.]

All of this can also be adapted to planes inclined to the horizon, provided that above the line which is drawn parallel to the horizon on such planes there is set some flat tablet upright to the horizon, and the observation is made on the face of this tablet — which forms an obtuse angle with the inclined plane.

[Margin: By what means it may be known whether the presented wall faces south or north.]

Let us now explain how we may recognize whether a given wall faces south or north. This will not be difficult, provided that we have first, in some fashion — even if not exactly and perfectly — surveyed the layout of the heavens; that is, provided we have ascertained on which side the Sun usually rises and on which it sets, and finally where it stands at noon. This can easily be learned from a magnetized needle [*acus Magnete illita*]. For since such a needle always lies, more or less, straight from north to south, once we know the north by its means, the east comes to lie on our right and the west on our left, as we face north, while we have the south at our back. We shall understand the same thing, should a magnetized needle happen not to be at hand, either from a single nighttime sighting of the pole star (if it is known to us), or from a single observation of the Sun as it rises or sets. For as we face the pole star, our front will show us the north and our back the south, our right the east and our left the west. Likewise, if we place ourselves so as to have the rising Sun on our right and the setting Sun on our left, the four quarters of the world will again correspond to the parts of our body, as just said. Once this is known, we shall test in this way whether the wall declines from the south or from the north. Facing the wall, if we have the rising Sun on our right and the setting Sun on our left, the wall faces south; but if, on the contrary, we see the Sun rise on our left and set on our right, the wall inclines toward the north. But if the wall has only so slight a declination from the prime vertical that it seems to lie but little off the meridian circle, so that it is quite hard to tell whether it faces south or north, we shall use the following device.

Along the wall — or at least along a straight line drawn on it parallel to the horizon — we shall draw, in a plane parallel to the horizon, a perpendicular line, and we shall investigate its position with respect to south and north, as just described. For if the wall deviates only a little from the meridian, the said perpendicular will likewise deviate only a little from the prime vertical, and so we shall easily understand, by the prescribed rule, whether it faces south or north. Thus, if this perpendicular has declined from south toward the east — or (what is the same) from north toward the west — the given wall will incline toward the north if it faces east, but will belong to the south if it looks toward the setting Sun. But if the said perpendicular has swung from south toward the west — or (what is the same) from north toward the east — the wall will face south if it is set against the rising Sun, but will incline toward the north if it looks upon the setting Sun. All of which we have set out more fully in proposition 23, book 1 of the *Gnomonics*.

We shall obtain the same result, for the said walls that decline only a little from the meridian, by means of the meridian line, in this way. Having found, on some plane near the wall that is level with the horizon, a meridian line, then: if this line meets the wall — or at least a straight line parallel to the wall — toward the north, the wall will face south; but if the same meridian line meets the wall (or a straight line parallel to the wall) toward the south, the wall will face north. Indeed, by means of a meridian line drawn on a plane level with the horizon and having one side laid against the wall, we can explore both the amount of the declination and its kind, as we wrote in proposition 23, book 1 of the *Gnomonics*.

At the time of noon we shall reach the same result more easily, for any wall, in this way. Wait, on some day, for the moment of noon — which must be carefully learned either by the style's shadow falling on a meridian line already found, or by the Sun's meridian altitude. For if the presented wall is then lit by the Sun, there can be no doubt that it inclines toward the south; but toward the north, if it is not lit by the Sun. But if the wall stands only a little off the meridian circle, and the roof of the building juts out so as to block the Sun's rays, then a line parallel to the wall must be drawn on the ground at some distance from the wall, so that at noon it can be lit by the Sun along its whole length. For if a style — or the side DH of an upper set-square [norma] — is set upon that line, or at least a fine thread with a plumb-bob is hung free, and the shadow of the style or thread cuts that line at noon: then, if the shadow lies on the northern side, between the said line and the wall, the wall faces south; but if, on the contrary, that line lies on the northern side, between the wall and the shadow, the wall faces north. And if the shadow does not cut the said line but falls exactly upon it at noon, the wall is parallel to the meridian circle.

This, however, must be understood of a place in the northern hemisphere having a latitude greater than $23^{\circ} 30'$ — that being the greatest declination of the Sun. For in a smaller latitude it can happen that a wall facing north is lit by the Sun at midday, while the Sun stands at the beginning of Cancer ☊ [Cancer], or nearly so, because the Sun is then more northerly than the wall itself, as is clear from a material sphere [sphaera materialis]. Yet when the Sun is more southerly than the wall itself, so that the midday shadow is cast toward the north, then those things also hold which we stated concerning the oblique sphere of a latitude greater than $23^{\circ} 30'$.

[Margin: How one may tell whether an inclined plane faces south or north.]

All these things may likewise be tested on planes inclined to the horizon, if on them we draw a line equidistant from the horizon and set upon it a flat tablet

perpendicular to the horizon. For the wall will incline toward that quarter toward which the surface of the tablet, forming an obtuse angle with the proposed plane, is found to look, according to the foregoing instructions — as is plain.

That in every place on Earth situated between the Equator and either tropic — that of Cancer ☿ or of Capricorn ♄ — the shadows of gnomons, towers, and trees on planes equidistant from the horizon retrocede naturally twice a day, when the Sun is more northerly than the place's zenith.

CAPVT XXI.

[Margin: In what places the shadows of gnomons retrocede naturally on planes parallel to the horizon.]

It seems not foreign to our purpose — since we are treating of the description of sundials, in which the shadows of gnomons take on various positions at various hours — to demonstrate, together with Pedro Nunes [Petrus Nonius] (*De Navigatione*, book 2, chapter 11), that it belongs properly to every place of the torrid zone whose zenith is less distant from the Equator than the parallel in which the Sun stands — that is, whose latitude, or pole-altitude, is less than the declination of the Sun when it is set on any given parallel — that the shadows of buildings, trees, and gnomons on planes parallel to the horizon retrocede twice a day without any miracle, once before noon and again after noon. This might seem utterly incredible to some who are little practised in astronomical matters, since in the sundial of Ahaz [Achaz], king of Judah, the sacred scriptures testify that in the time of King Hezekiah [Ezechias] the shadow went back not naturally but by divine power. But that this is not only credible but altogether necessary — and in no way opposed to, or in conflict with, that miracle which God displayed on Ahaz's sundial to King Hezekiah as a sign of his recovered health — will be clearly established from what follows.

Diagram. A large circle representing the celestial sphere in orthographic projection on the plane of the horizon, crossed by the meridian, the equator, a solar parallel, and several vertical (azimuth) circles. Labels read:

- A (top of circle): south point of the meridian / horizon
- C (bottom of circle): north point (pole-side)
- B (left of circle): one solstitial/equator terminus of the horizon
- D (right of circle): opposite terminus of the horizon (equator BED runs B–E–D)

- E (on the meridian, upper-center): intersection of equator and meridian
- F (lower left on circle): point of the Sun's rising on parallel FGH
- G (lower center on circle): intersection of the parallel with the meridian
- H (lower right on circle): point of setting on parallel FGH
- I (center): the zenith of the place
- K (left on circle, below B): terminus of vertical KLIM
- L (center, near I): point where vertical KLIM touches parallel FGH
- M (right on circle): terminus of vertical KLIM / shadow-point
- N (left on circle, below K): terminus of vertical NOPIQ
- O (center-left): point where vertical NOPIQ cuts the parallel (rising side)
- P (center, small): point where the same vertical cuts the parallel (meridian side) [?]
- Q (right on circle, upper): shadow-point on the horizon for vertical NOPIQ
- R (center, small): point where vertical FRIS cuts the parallel [?]
- S (right on circle, above Q): shadow-point at the Sun's rising
- T (upper left on circle): terminus of parallel ST opposite the Sun's parallel
- V (center, small): point on vertical XVIY [?]
- X (bottom-left on circle): terminus of vertical XVIY
- Y (below A, upper region): shadow-point on the horizon for vertical XVIY
- Z (lower center, near C): the pole
- a (lowercase, center-left near O): auxiliary construction point [?]

Let the horizon be ABCD; the meridian, AEC; the eastern semicircle of the horizon, ABC, and the western, ADC; the equator BED, cutting the meridian at E; the northern parallel of the Sun FGH, cutting the meridian (wherever) at G; the zenith of some place between the equator and the said parallel, the point I, through which let there be described — by proposition 15, book 2, of Theodosius [Sphaerics II.15] — the vertical circle KLIM, touching the parallel FGH at L; likewise another vertical, NOPIQ, cutting the same parallel FGH at the point O, between the point of contact L and the point F (at which the Sun, occupying the parallel FGH, rises), and accordingly also at another point P, between the same point of contact L and the point G (placed at noon); and lastly yet another, FRIS, passing through the point of rising F, and therefore cutting the parallel FGH at R, between the points P and G.

Now since, when the Sun is on any great circle of the sphere, the shadow of a style set at right angles to any plane does not depart from the plane of that circle, but is cast into the common section of that circle and of the said plane in which

the style is fixed (as we showed in proposition 11, book 1, of the *Gnomonics*), it follows that, when the Sun is on the vertical FRIS and at the point of rising F, the shadow of a style fixed at right angles to the horizon — or of any tower or tree in the horizon of that place whose zenith we set at I — does not depart from the said vertical FRIS, but cuts the horizon on the western side at S, where the parallel ST, opposite to the Sun's parallel, cuts the horizon; so that in the horizon the shadow is then distant from the meridian, on the southern side, by the arc AS. Then, the Sun being raised above the horizon and set at O, the Sun will be on the vertical NOPIQ, and so the shadow of the same style will cut the horizon at Q, and the distance of the shadow in the horizon from the meridian will be the arc AQ, greater than AS. But when the Sun, by its daily motion, has reached the point of contact L, so that it stands on the vertical KLIM, the gnomon's shadow will cut the horizon at M, and the distance of that shadow in the horizon will be the arc AM, greater still than AQ; and this distance of the shadow, AM, is of all those which on that day (with the Sun on the parallel FGH)

it can have from the meridian, the greatest — because the vertical KLIM, touching the parallel FGH, is of all the verticals on which the Sun can be that day the farthest from the meridian, as is manifest. And so, from the rising of the Sun at F until it has reached the point of contact L, the gnomon's shadow has advanced continuously in the horizon from S, through Q, to M, always receding more and more from the meridian.

Then, when the Sun has moved on from L to P, the Sun will again be on the vertical NOPIQ, and the shadow of the style will cut the horizon once more at Q, and the distance of the shadow from the meridian will again be the arc AQ, just as before, when it was at O — so that the shadow, once it has checked its outward course from the meridian at the point M, has retroceded in the horizon from that same point M, approaching the meridian again as far as Q. Then, the Sun being advanced from P to R, the Sun will again be on the vertical FRIS, and the gnomon's shadow will cut the horizon at S, and the distance of the shadow from the meridian will be the arc AS, just as before, when the Sun was rising at the point F — so that the shadow, still approaching the meridian, has retroceded farther back from the point M, namely as far as S, where the shadow cut the horizon at the Sun's rising, and from where it had advanced to the points Q and M. But from the point S onward the shadow will approach the meridian continuously, without any regress. For when the Sun has reached V from R, so that it stands on the vertical XVIY, the shadow will cut the horizon at Y, and its distance from the meridian will be the arc AY, less than AS; and so on, until it reaches the meridian, namely the point G.

[Margin: Same figure repeated — see fig-p632-1 below.]

The shadow will keep this same proportion of advancing and regressing after noon, as can be gathered from the same figure, if the semicircle of the horizon ADC be taken as the eastern, and ABC as the western. For as the Sun moves from G, the point of noon, through V, R, P, up to the point of contact L, so that it successively stands on the verticals XVIY, FRIS, NOPIQ, KLIM, the shadow too will successively cut the horizon at Y, S, Q, M; so that during that time it always recedes more and more from the meridian, having advanced always from A, through Y, S, Q, up to M. When the Sun has reached O and F, it will again be on the verticals NOPIQ, FRIS, and the gnomon's shadow will cut the horizon at Q, M — so that again it has checked its course, as regards its recession from the meridian at the point M, and has returned through Q toward the meridian, always approaching the meridian more and more again, until it reaches S, where the Sun will be on the vertical FRIS, and will set at the point F.

Diagram. The same figure repeated, to accompany the after-noon case. The circle and its labels correspond to fig-p631-1: horizon ABCD (A top, C bottom, B left, D right), meridian AEC, equator BED through E, solar parallel FGH through G, zenith I, pole Z; verticals KLIM (touching the parallel at L), NOPIQ (cutting it at O and P), FRIS (through F, cutting at R), and XVIY (through X, V, Y); the shadow-points S, Q, M, Y lie on the horizon, with T the terminus of the opposite parallel. As on the preceding page, the small central letters (P, R, V, a) are crowded and hard to resolve

It is clearly established from all this that which we set out to demonstrate: namely, that in every place on Earth set between the equator and any given parallel — whose zenith, that is, is less distant from the equator than the parallel; that is, whose pole-latitude is less than the declination of the assumed parallel (such as the place beneath I, if it be compared with the parallel FGH; for the latitude EI of that whole place is less than the declination EG of the said parallel — to which latitude the pole-altitude CZ is equal, as is demonstrated in [the treatise on] the sphere) — the shadow of a style forming right angles with the horizon, once set beneath I, retrocedes twice a day naturally and without any miracle, once before noon and after noon again.

The cause of this, as is clear from what has been demonstrated, is that the Sun, traversing the said parallel and advancing from its rising, stands continuously on one vertical circle after another, of which each successive one is always farther from the meridian than the preceding, until it reaches the vertical that touches that parallel — such is the vertical KLIM, which of all the verticals is the farthest

from the meridian. Thereafter the Sun, although it still advances toward the meridian circle, nonetheless returns to the same verticals on which it had stood before, until it reaches the one on which it stood when it rose; and from this it will occupy one after another, until it is found on the meridian — which verticals grow ever nearer the meridian. After noon, advancing in the same parallel, the Sun will likewise occupy various verticals receding ever more and more from the meridian, until it reaches the one that again touches the parallel and is farthest from the meridian. From this, still advancing in the parallel, it will repeat the same verticals up to the one that cuts the horizon at the point of setting. The Sun is set twice before noon and twice after noon on the same verticals — namely on all those that lie between the point of rising and of setting of the said parallel and that farthest vertical. All these things are gathered from the proposed figure.

[Margin: How, outside the torrid zone, a plane must be set up so that the shadow retrocedes on it.]

Although this is true only in the horizon of any place set between the equator and one of the two tropics — as, for example, in the horizon of Goa, Calicut [Calecut], Cannanore [Cananor], the Golden Chersonese [Aurea Chersonesus], and Mexico in New Spain [Hispania nova], from the equator toward the north; and of the Cape of Good Hope, Brazil, Peru, and Greater Java [Java maior], from the equator toward the south — nevertheless the same may be tested in the temperate zone, if on the side of the visible pole some plane, perpendicular to the meridian, is raised together with a fixed style, above which the pole has an altitude less than $23^{\circ} 30'$. For since that plane then has the same situation with respect to the Sun that the horizon of some place in the torrid zone has, the gnomon's shadow will retrocede on it just as in that horizon of the torrid zone. And if a sundial is constructed for a latitude less than $23^{\circ} 30'$, with the hyperbolas — that is, the arcs of Cancer ☿ and Capricorn ♑ — that is, on a plane inclined to the horizon of Rome by more than $18^{\circ} 30'$, but by fewer than 42°

on the northern side (for so the vertex, or pole, of this plane will fall between the equator and the tropic of Cancer ☿); or by more than 42° , but fewer than $65\frac{1}{3}^{\circ}$ (in which way the pole, or vertex, of the plane will lie between the equator and the tropic of Capricorn ♑) — then this advance and retrocession of the shadow will be most plainly observed, the sundial being set in its proper position according to its inclination to the horizon. For if from the place of the gnomon, which is between the equator and one of the two tropics, two straight lines be drawn tangent to that tropic to which the style is the nearer, the shadow of the style will, in the morning, advance from the rising of the Sun toward the equinoctial line of

the sundial, up to that tangent line, always receding from the meridian line. From this tangent line it will then regress, receding from the equinoctial line and approaching the meridian line, until the Sun reaches noon; and from noon it will again approach the equinoctial line, receding from the meridian, until it reaches the other tangent line, from which it will again retrocede toward the meridian line, receding from the equinoctial, up to the setting of the Sun.

[Margin: Our retrocession of the shadow, which we have set out, is not opposed to the retrocession of the shadow in Ahaz's sundial, [which was] wrought by divine power[?].]

This being so, what then shall we say of that so illustrious miracle in the sundial of Ahaz, shown to King Hezekiah as a sign of his health, in which the sacred scriptures relate that the shadow went back ten lines, or degrees, not naturally but by divine power? Pedro Nunes, at the passage cited, answers that the regress of the shadow, of which we have spoken, can occur only in the torrid zone — that is, between the equator and one of the two tropics — as is clear from what has been demonstrated. Since, then, the city of Jerusalem, where Hezekiah lay sick, is situated in the temperate zone, on this side of the tropic of Cancer ☊, the shadow could not have gone back without a miracle. Therefore, since the sacred scriptures testify that it did go back, it was without doubt done by a miracle. And that this is what Nunes meant, and that the answer must be so given, is manifest from the cited chapter 11, where he thus writes: *[It is not, then, absurd if in those places (namely, between the equator and the tropic of Cancer ☊, or of Capricorn ☋) the shadows advance and retrocede. Yet in this our northern region, which lies on this side of the tropic of Cancer ☊, this could not happen without a miracle, as we read it befell, by God's command, as a sign of the health of King Hezekiah.]* By these words he seems to signify that this our regress does not differ from that wrought in Ahaz's sundial, except that ours is natural, while that was effected by God's command, on account of the differing situations of places.

But this answer does not satisfy. For although that regress of the shadow cannot occur in the horizon outside the torrid zone, it nonetheless comes about — if some plane be raised, with a style, above which the pole has an altitude less than $23\frac{1}{2}^{\circ}$ [fraction uncertain; expected $23^{\circ} 30'$ — ?] — that the shadow will retrocede upon it exactly as in some horizon of the torrid zone, as we said above. If, then, anyone were to say that the plane of Ahaz's sundial had such a situation, who does not see that that regress of the shadow could have come about upon it by the powers of nature, and thus that so signal and celebrated a miracle would be emptied out? — which is by no means to be admitted. For which reason we say

that the miracle in that regress of the shadow in Ahaz's sundial was truly great: because the Sun then went back in the heaven, and the shadow truly regressed, so that after noon, when it ought to have grown, it was diminished, or before noon it was increased, when it ought to have been diminished — which cannot come about by the powers of nature. And that the Sun then indeed went back, the prophet Isaiah seems openly to affirm, writing thus in chapter 38: [*And the Sun returned ten lines by the degrees which it had gone down.*] But in our regress the shadow before noon is always diminished, and after noon perpetually increased, and the Sun advances continuously from rising to setting without any regress — although the shadow itself does regress somewhat, from north to south or the contrary, and is not carried continuously in a circle around the gnomon, as happens in every horizon outside the torrid zone, but moves in a certain manner along a straight line from east to west while the Sun is near the point of contact L, that is, while it traverses the arc OLP — especially if the regress QM, by which the Sun goes back from M to Q, be very small and almost imperceptible; which indeed can come about without a miracle, as we have demonstrated. And certainly it is an argument that the regress made in the time of King Hezekiah was very different from ours, that that event was new and unwonted in Ahaz's sundial, whereas our regress appears in the same plane every year over several days — so that the prophet Isaiah would have promised nothing new as done at God's command[?], but only what he continually observed in that sundial on certain days of the year; which would have been quite ridiculous.

[Margin: The finding, by spherical trigonometry, of the amplitudes of rising and setting, the semidiurnal arc, the Sun's altitude at the points of retrocession, its distance in the parallel from the meridian, likewise the amount of the shadow's regress, and finally the time during which the shadow advances.]

Now, the altitude of the pole CZ and the declination of the parallel FGH being known, we shall learn, in the horizon ABCD, from the doctrine of spherical triangles: the amplitude of rising BF and of setting DH; the semidiurnal arc FG; the altitude of the Sun KL at the point of contact L, and FR at the point R; the distance of the same in the parallel from the meridian at those same points L, R, namely both the arc GL and the arc GR; the arc MS of the whole regress; and finally the time in which the Sun traverses the arcs FL, LR, FR — or (what is the same) in which the shadow moves from the point S, when the Sun rises, to the point of regress M, and moves back again from M to S; and accordingly the whole time in which the shadow advances and regresses.

For, three arcs of great circles ZF, ZL, ZR being drawn from Z, the pole, to the points F, L, R: since in the right triangle CFZ (for the angle C, which the meridian makes with the horizon, is right) two arcs CZ, ZF are known — CZ being the altitude of the pole, which we now put at 20° , and ZF the complement of the declination, which we here put at $23^\circ 30'$, so that the Sun stands at the beginning of Cancer $\mathfrak{S}$ — of which ZF is opposite the right angle: let it be, as 93969 (the sine of the complement of the arc CZ, the altitude of the pole) is to 39875 (the sine of the complement of the arc ZF, opposite the right angle, which comprises $66^\circ 30'$ — that is, to the sine of the declination), so 100000, the whole sine, to another; and there will be produced the sine 42434 of the complement of the arc CF, by practical rule 8 of our Spherical Triangles; to which sine corresponds an arc of $25^\circ 7'$. And just so great is both the arc BF of the amplitude of rising (namely the complement of the arc CF) and the arc DH of the amplitude of setting; and accordingly the arc CF is $64^\circ 53'$. And so the shadow of the same style will cut the horizon at the point of setting; CF also comprises $64^\circ 53'$.

[Margin: In the same right triangle CFZ.]

In the same right triangle CFZ: if it be made, as 91706 (the sine of the arc ZF[?], the complement of the declination, opposite the right angle) is to 100000, the whole sine, so 90545 (the sine of the arc CF just found) to another, there will be found the sine 98734 of the angle CZF, opposite the arc CF, by practical rule 1 of our Spherical Triangles. The angle CZF, therefore, contains $80^\circ 52'$, and just so great is the seminocturnal arc [arcus seminocturnus]. And that angle being taken from 180° — that is, from a semicircle — the remaining angle FZG, of the semidiurnal arc FG, will be $99^\circ 8'$.

[Margin: The Sun's altitude and its distance from the meridian at the point of regress, by the same triangles.]

Next, since the two circles FGH, KLIM touch one another at L, and the arc LZ is drawn through Z, the pole of the circle FGH, it will be drawn also through the pole of the circle KLIM, by proposition 5, book 2, of Theodosius [Sphaerics II.5]; and accordingly, in the triangle ZIL, the angle ZLI, by proposition 15, book 1, of Theodosius [Sphaerics I.15], will be right. Therefore, if it be made, as 39875 (the sine of the complement of the arc ZL, about the right angle — namely, as the sine of the Sun's declination, since ZL is the complement of the Sun's declination) to 34202

(Continuation of Cap. XXI — the worked example of the twice-daily shadow-regress in the torrid zone, carried over from the previous folio, which broke off at the catchword "...to 34202.")

to 34202 (the sine of the complement of the arc IZ, opposite the right angle — that is, to the sine of the arc CZ, the altitude of the pole, since IZ is the complement of CZ), so 100000, the whole sine, to another; there will be found, by practical rule 8 of our spherical triangles, the sine 85773 of the complement of the arc IL. To this sine, in the table of sines, corresponds an arc of $59^{\circ} 4'$. Such, then, is the arc KL — namely, the complement of the arc IL — of the altitude of the Sun established at L. And the complement of the altitude of the Sun, IL, will contain $30^{\circ} 56'$.

Likewise, in the right triangle CFZ, if it be made — as 91706 (the sine of the arc ZF, the complement of the declination, opposite the right angle) is to 100000, the whole sine, so 34202 (the sine of the arc CZ, the altitude of the pole) to another — there will result, by practical rule 1 of our spherical triangles, the sine 37295 of the angle CFZ, opposite the arc CZ. The angle CFZ, therefore, contains $21^{\circ} 54'$. And when this is taken from the right angle CFI, which the vertical FRIS makes with the horizon, the angle ZFR will comprise $68^{\circ} 6'$. Just as great, too, will be the angle ZRF, since it is equal to the angle ZFR — by proposition 8 of our spherical triangles — on account of the equal arcs ZF, ZR, each of which is drawn from the pole Z to the parallel FGH and is the complement of the declination. Now, if a perpendicular arc Za be drawn from Z to FR, it will bisect both the arc FR and the angle FZR, as is established from the second case of proposition 62 of our spherical triangles, where we demonstrated that in every isosceles spherical triangle the perpendicular arc bisects both the base and the angle opposite the base.

And so, in the right triangle FZa, if it be made — as 100000, the whole sine, is to 91706 (the sine of the arc ZF), so 92784 (the sine of the angle ZFa) to another — there will arise the sine 85088, which belongs to the perpendicular arc Za, as is established from practical rule 2 of our spherical triangles; and accordingly that perpendicular arc Za will comprise $58^{\circ} 18'$. And if, in the same right triangle FZa, it be made again — as 52547 (the sine of the complement of the said perpendicular arc Za) is to 39875 (the sine of the complement of the arc ZF, opposite the right angle), so 100000, the whole sine, to another — there will be generated, by practical rule 8 of our spherical triangles, the sine 75816 of the complement of the arc Fa; and consequently that complement will be $49^{\circ} 18'$, while the arc Fa itself, which is half of the arc FR (as has been said), is $40^{\circ} 42'$. And therefore the whole arc FR — of the altitude of the Sun at R — is $81^{\circ} 24'$.

Moreover, in the triangle ZIL — whose angle L is right, as we showed above — if it be made, as 93969 (the sine of the arc ZI, the complement of the altitude of the pole, and opposite the right angle) is to the whole sine 100000, so 51404 (the sine of the arc IL, the complement of the altitude of the Sun KL, which we found above to be $59^{\circ} 4'$) to another, there will be produced, by practical rule 1 of our spherical triangles, the sine 64703 of the angle IZL, opposite the arc IL. The arc of the equator due to it, therefore, will comprise $33^{\circ} 10'$; and to this, by proposition 10 of book 2 of Theodosius [*Sphaerics* II.10], the arc GL of the parallel — by which the Sun is distant from the meridian — is similar.

Further, in the right triangle ZRa, if it be made, as 91706 (the sine of the arc ZR, the complement of the declination, and opposite the right angle) is to 100000, the whole sine, so 65210 (the sine of the arc Ra, which is half of the arc FR and which we found above to be $40^{\circ} 42'$) to another, there will result, by practical rule 1 of our spherical triangles, the sine 71108 of the angle RZa, which is half of the angle FZR itself. The said angle RZa, therefore, will embrace $45^{\circ} 19'$, and consequently the whole angle FZR $90^{\circ} 30'$. When this is taken from the angle FZI of the semidiurnal arc — found above to be $99^{\circ} 8'$ — there will remain the angle IZR, by which the Sun at R is distant from the meridian, [namely] $8^{\circ} 30'$; and just so great is the arc GR of the parallel.

Again, in the right triangle IZL, if it be made, as 93969 (the sine of the arc ZI, the complement of the altitude of the pole, and opposite the right angle) is to 100000, the whole sine, so 91706 (the sine of the arc ZL, the complement of the declination) to another, there will be produced, by practical rule 1 of our spherical triangles, the sine 97592 of the angle LIZ, that is, of the arc CK. The arc CK, then, is $77^{\circ} 24'$. If from it the arc CF — found to be $64^{\circ} 53'$ — be subtracted, the arc FK will remain, to which the arc SM, the regress of the shadow, is equal, by proposition 7 of our spherical triangles. (For the two arcs IF, IK are equal to the two arcs IM, IS, since all are quadrants and contain equal angles at the vertex I, by proposition 5 of our spherical triangles.) [And so the arc SM is] $12^{\circ} 31'$.

Finally, since the semidiurnal arc FG has been found to be $99^{\circ} 8'$ — that is, 6h 36m 32s; and the arc GL $33^{\circ} 10'$, that is, 2h 12m 40s; and therefore the arc FL $65^{\circ} 58'$, or 4h 23m 52s; and the arc GR, lastly, $8^{\circ} 30'$, or 0h 34m; and accordingly the arc FR $90^{\circ} 38'$, namely 6h 2m 32s; and consequently the arc LR $24^{\circ} 40'$, that is, 1h 38m 40s — it is plainly established that the shadow advances from S as far as M — that is, that the Sun moves from the rising-point F as far as L, the point of regress — in a span of 4h 23m 52s; that the same shadow regresses from M as far as S — that is, that the Sun passes from L to R — in a span of 1h 38m 40s; and, finally, that the

shadow advances and regresses to the same point — that is, that the Sun traverses the whole arc FR — in a span of 6h 2m 32s.

FINIS.

Horologiorum Nova Descriptio — A New Description of Sundials

[Title]

CHRISTOPHORI CLAVII BAMBER- GENSIS EX SOCIE- TATE IESV, HOROLOGIORVM NOVA DESCRIPTIO.

AB IPSO AVCTORE TVM ALIARVM rerum, tum maxime plurimarum vtillum tabularum accessione vehementer aucta.

[Translation] Christoph Clavius [Christophorus Clavius] of Bamberg, of the Society of Jesus: A New Description of Sundials. Greatly enlarged by the author himself, both with other matters and, above all, with the addition of very many useful tables.

" / "...BILE" (lower left and left). The motto is the standard *Sit nomen Domini benedictum ... laudabile* ("Blessed be the name of the Lord ... praiseworthy").]

[Two manuscript ownership inscriptions in ink flank the device: left margin, a cursive signature reading approximately "Res[?] Mon[?]" [?]; right margin, a

cursive signature reading approximately "Schÿsenhis[?]" [?]. Both are early-modern provenance marks, not printed text.]

MOGVNTIÆ, Sumptibus ANTONII HIERAT, excudebat IOANNES VOLMARI.

Cum Gratia & Priuilegio Sacræ Cæsar. Maiest.

ANNO M. DC. XII.

[Translation of imprint] At Mainz [Moguntiae], at the expense of Antonius Hierat [Anton Hierat]; printed by Ioannes Volmari [Johann Volmar]. With the grace and privilege of His Sacred Imperial Majesty. In the year 1612.

Blank page. Only the mirror-image show-through (offset) of the title-page type and device is visible; no text is printed on this side.

CHRISTOPHORI CLAVII BAMBERGENSIS, EX SOCIETATE IESV, HOROLOGIORVM NOVA DESCRIPTIO.

[Christoph Clavius of Bamberg, of the Society of Jesus: A New Description of Sundials.]

PROLEGOMENA

In this little book we shall treat only of those sundials that are in more frequent use — namely, those that lie parallel to the horizon, called horizontal dials, and those that stand perpendicular to the horizon and parallel to some vertical circle, which are called vertical dials and are commonly drawn on the walls of buildings. [Margin: *De quibus horologiis in hoc libello agendum* — Which sundials are to be dealt with in this book.] But should anyone wish to lay out other kinds of sundial — namely, dials declining from the horizon, or inclined to the horizon (among which the equinoctial and polar dials are also to be reckoned), or finally dials that both decline and incline at once — we hold that he should be referred to our *Gnomonics* [Gnomonica], where we have written of them at the fullest length. For since these have less frequent use, we deliberately pass over them in this place, so that this little book may not swell to a greater bulk than is fitting, but instead may prove more serviceable for practical use, and thus more readily obtainable.

Now since in this treatise we shall for the most part describe the hours on a given plane by a new method and procedure, without any circle divided into 24 hours and their parts, or into degrees — that is, solely by means of the lines called Tangents [lineae Tangentes], with the aid of certain other tables which you will find after the description of the sundials, together with their construction from problems of astronomy — it is necessary to have a table of the lines of Tangents ready at hand, so that from it the Tangents that are needed may be extracted. [Margin: *Nova ratio describendorum horologiorum* — The new method of describing sundials.] You will find this table too at the end of the whole little book, in the form in which the whole sine [sinus totus] comprises 1000 parts, which is enough for the present business.

For the rest, since on a given plane the Tangents cannot be marked off in as many parts as the table contains with respect to the whole sine of 1000, we shall reduce them to tenths by dropping the two figures on the right — that is, we shall take them with respect to a whole sine of 10 — yet not neglecting the fraction which the last figure on the left (which of course signifies tens), once dropped, forms together with the whole sine 10 as denominator; or rather the fraction which the two dropped figures form, in the manner of a numerator, with 100 as denominator. [Margin: *Quomodo Tangentes reducuntur ad decimas* — How the Tangents are reduced to tenths.] For example, the Tangent of 15 degrees is 268 with respect to the whole sine of 1000. If the two figures 68 are dropped, there will remain, with respect to the whole sine of 10, the Tangent $2\frac{6}{10}$. But more accurately it would be $2\frac{68}{100}$; for if the proportion is made, as 1000 is to 268, so is 10 to another number, the quotient found is $2\frac{680}{1000}$, that is, $2\frac{68}{100}$. Yet the last figure 8 on the right may be dropped without loss, keeping only the figure 6, so that the Tangent becomes $2\frac{6}{10}$ — although it could be taken as $2\frac{7}{10}$ nearly, on account of the following figure 8, which is greater than 5.

Again, the Tangent of 48 degrees 45 minutes is 1140. When the two last figures 40 are dropped, it will be, with respect to the whole sine of 10, the Tangent $11\frac{40}{100}$, or $11\frac{4}{10}$. Likewise the Tangent of 78 degrees 45 minutes is 5027. But when the last two figures 27 are dropped, there will be left the tangent $50\frac{2}{10}$ — indeed nearly $50\frac{3}{10}$, on account of the following figure 7, which is greater than five; that is, it exceeds half of one tenth, namely $\frac{5}{10}$ [of one tenth].

But if, after the two last figures are dropped, nothing remains, we shall take away only one; for the remaining figure will give the tenth-parts of one tenth of the whole sine 10. [Margin: *Quales Tangentes sumendae sint, quando duae figurae abici nequeunt* — What Tangents are to be taken when two figures cannot be

dropped.] Thus, since the Tangent of 3 degrees 45 minutes is 66, if the latter figure 6 is removed, there will remain the Tangent 6/10 of one tenth of the whole sine 10 — and a little more, on account of the dropped figure 6. But if there is only a single figure in the tangent, so that nothing can be taken away, that single figure will indicate the hundredth-parts of one tenth of the whole sine 10. So, since in the table of Tangents the Tangent of 0 degrees 11 minutes is 3, we shall have 3/100 of one tenth for the Tangent with respect to the whole sine 10. Finally, since 0 degrees 1 minute, and 0 degrees 2 minutes, and 0 degrees 3 minutes have nothing in the Tangents (seeing that the Tangents of these arcs, with respect to the whole sine of 100000, are 29, 58, 87), for the Tangent of 0 degrees 1 minute we shall take about 3/1000 of one tenth, with respect to the whole sine 10. And for the Tan-

gent of 0 degrees 2 minutes we shall take about 6/1000 of one tenth; and finally, for the Tangent of 0 degrees 3 minutes, we shall take nearly 9/1000 of one tenth. But parts as tiny as these can scarcely be marked off or noted on a plane. They may therefore reasonably be neglected — unless the gnomon [stylus] happens to be so large that it can conveniently be divided into 1000 parts or more. Alternatively, tangents this small will have to be added to the Tangent of some point already found, so that the whole Tangent, once assembled, can be carried over from the point so found — as we shall explain in Chapter 2, Number 3.

[Margin: *Quid agendum cum Tangentibus perexiguis* — What is to be done with very small Tangents.]

Furthermore, in the table of Tangents that presents the whole sine as 10000000, six figures must be dropped from each Tangent, so that they are reduced to Tangents with respect to the whole sine of 10. But in the table of Tangents in which the whole sine is set at 100000, four figures must be removed, and so on.

To draw certain particular lines in sundials more expeditiously (though this will seldom be needed), it will be worthwhile to procure a small brass plate [tabella ænea] on which several unequal quadrants — at least two, or three, or four — are drawn, each carefully divided into 90 degrees; or at any rate (which is enough) divided into 9 equal parts, so that each part takes in ten degrees, with only the first part cut accurately into 10 degrees, just as we taught in Lemma 3 of the first book of our *Astrolabe* [Astrolabio]. For in this way, on the circumference of any circle whatever, we shall be able to take an arc of any number of degrees and minutes, even though that circle is not itself divided into degrees — provided only that it has been drawn to the radius of one of those quadrants set out on the brass plate.

[Margin: *Quales quadrantes necessarij sint ad accuratam horologiorum descriptionem* — What kind of quadrants are needed for the accurate laying-out of sundials.]

One may also, if preferred, use in place of those three or four quadrants drawn on a single plate a single hollowed-out quadrant, such as the learned Theodosius Rubeus [Teodosio Rossi] of Priverno recently devised with much ingenuity — a Doctor in Sacred Theology and in both Laws, a Noble of the Sacred Imperial Court, likewise most skilled in Mathematics, and once my pupil — whose construction is as follows. On a brass lamina ABC, from point D, let a quadrant EF be drawn, divided into 90 degrees. About the same point D let a small circle be drawn, and to it let a ring [annulus] be fastened, of such thickness that a movable ruler [regula] DF can be turned about it, its fiducial line [linea fiduciæ] always pointing toward the center. Next let the parts that appear white in the figure be cut away as superfluous, so that the ruler DI can bring its fiducial line DF onto the beginning of the first degree at point G. Let the ruler also be hollowed out alongside the quadrant, so that when it is turned it can graze the plane on which the quadrant is to be used — which is done thus. With the center D placed at that point where an angle of any number of degrees is to be constructed, and the fiducial line holding the beginning of the quadrant, let the quadrant be applied to the line with which the angle is to be formed. After this, with the quadrant held fast so that it does not shift its position, let the ruler be moved until the fiducial line DF reaches the proposed degree. For the straight line drawn in that position by aid of the fiducial line will form, with the given line at D, the required angle of whatever number of degrees; or from the circumference of any circle whose center coincides with the center D, it will cut off any proposed number of degrees. But so that the course of laying out the sundials is not interrupted, we have used a different type [character] in the demonstrations, so that they may be passed over untouched by the student who wants only the practical procedures.

Diagram. The hollowed brass quadrant-instrument of Theodosius Rubeus, drawn within a square border. The solid body of the lamina is shown by close hatching along the top and the left side; the white (cut-away) region is the quadrant sector. Labels read from the scan:

- A (top-left corner of the square lamina)
- B (top-right corner)
- C (bottom-left corner)
- D (center of the small ring/pivot circle, upper-left of the field, with cross-hairs)

- E (right edge, below B — one end of the graduated arc EF)
- H (left edge, below A)
- G and F (mid-right, near together — the movable ruler DF and the degree-mark region)
- G, I, F (along the bottom edge, left of center — the ruler's lower position and the initial graduation)
- The quarter-circle arc is divided into degrees; graduation numerals (10, 20, 30 ... up to 90) run along it, but the individual small numerals do not all resolve on the scan [numeral:?].

CAPVT PRIMVM.

PROBLEMA HOROLOGIOGRAPHICVM.

Given a straight line on the plane of any sundial, to cut off from it a segment corresponding to any number of degrees you please of that great circle which the given line represents — beginning from any given point, and proceeding in either direction. And conversely, given any segment on the given straight line, to find out to how many degrees of that great circle which the given line represents on the sundial the segment corresponds.

[Margin: *Problema nouum, & ad horol. describ. vtilissimum. Problema hoc non esse ita necessarium, ut sine eo horologia construi nequeant* — A new problem, and most useful for the laying-out of sundials. That this problem is not so necessary that without it sundials cannot be constructed.]

1. Before we lay out sundials, we must demonstrate the proposed problem — a new one indeed, but one that holds well-nigh countless uses in the laying-out of sundials. Do not, however, take it as though without it sundials could not be built by the teaching of this little book. For you will feel no loss or inconvenience in laying out sundials even if you entirely neglect or pass it over. We demonstrate it here both for its remarkable subtlety and excellence and for the very great pleasure of mind you will derive from it, whenever you apply it to tracking down certain points on the hour-lines, even though those same points may already have been found by another method. Let there be, then, on the plane of any sundial — on which the gnomon is AB and its foot is at A — a given straight line CD, whether or not it passes through E, the center of the sundial; and let there be given on it a point C, from which

a corresponding segment is to be cut off — say, of 30 degrees on that celestial great circle which the line CD represents. For every straight line on a sundial is the common section of the plane of the sundial and of some great circle, as is clear from what was demonstrated in Book I of the *Gnomonics*, Proposition 11 and its scholium. From A, the foot of the gnomon, let a perpendicular AF be drawn to the given line CD; and taking on the given line a portion FG equal to the gnomon AB, let there be taken, on the perpendicular AF — whether beyond point F or on the near side — a line FH equal to the interval AG. Then with H as center let a circle IK of any size be drawn (it will be convenient if its radius is equal to the radius of one of the quadrants divided into degrees); and from the center H, through the given point C on the proposed straight line, let a line HC be drawn, cutting the circle at I. Finally, from point I let an arc IK of the proposed 30 degrees be taken — upward or downward, according as the segment of 30 degrees is to be cut off below the given point C or above it. For the line HK, once drawn, will cut off from the given line the portion CD of 30 degrees. In the figure the segment CD is cut off on both sides. This I demonstrate as follows.

[Margin: *Quo pacto ex recta abscindatur portio quotcunq; graduum* — In what way a portion of any number of degrees is cut off from a straight line.]

2. On the perpendicular AF, at A, let a perpendicular AL be erected, equal to the gnomon AB, and let the lines AG and FL be joined. Now since in triangle AFG the two sides AF, FG are equal to the two sides FA, AL of triangle FAL, and they contain equal angles — namely right angles — the base AG, that is, the line FH, will be equal to the base FL. [Margin: a — Euclid I.4.] Now imagine the triangle AFL turned about AF until it stands upright to the plane of the sundial, so that point L is set at the center of the world — that is, coincides with B, the tip of the gnomon erected at A — since AL was put equal to AB. This being so, if the plane of the circle IK is turned about the given line CD, its center H will coincide with L, the center of the world, because the lines FH and FL are equal. Therefore the segment CD on the given straight line corresponds to the arc IK, since the radii IH, KH, produced beyond the center H, cut off in the heavens as many degrees as are contained in the arc IK — an arc, namely, equal or similar to the arc IK, on account of the vertical angles at the center H being equal.

Diagram. A large, dense sundial-construction figure enclosed in a square border, with a graduated double-rule scale (the tangent line) running down its right side. It combines the stylus and its rabatment (the triangle AFL swung up to the pole), the given line CD through the sundial center E, the circle IK about the found

center H, and the intersecting hour-arcs. The labels are heavily crowded and several letters recur at more than one point of the construction. Legibly read from the scan:

- E — apex, at the top of the field
- G, Y, L — clustered just below E (G left, Y center, L right)
- H — upper left
- M, F — below H toward center (M above F)
- A — the central node, with dotted lines radiating from it
- P, T, N — to the left of A (P leftmost, then T, then N)
- B — right of A
- K, O — just below and right of A (K, then O)
- D, F — right of center, descending (D above F)
- C — appears at three places: below A left-of-center, again lower, and again to the right
- L, I — below center (L above I)
- G — again at mid-right, and again lower-center
- K — at left, and again at right
- Q, R — low center (Q left, R right)
- I — lower right
- D — bottom-left and bottom-center-right (two marks)
- H — a further mark at the right where the shadow-lines converge, beside the scale

Right-hand graduated scale (the tangent line ST / VX): two parallel vertical rules with tick-clusters near the top, lettered **V** and **S** at the head and **X** and **T** at the foot; the divisions are numbered (printed with a raised dot) **10, 10, 20, 20, 30, 30** descending the two rules.

The figure is exceptionally crowded and carries many repeated letters that cannot all be individually verified on the scan.

3. When the arc to which a segment cut from the line CD is to be made similar — beginning from point C, below C — forms, together with the arc between the lines HI and HA, a quadrant or an arc greater than a quadrant, the segment similar to that arc cannot be cut off below the given point. For a line drawn from the center H through the extremity of the arc cannot cut the line CD below C, since at H it makes a right angle with the line HA, [Margin: b — Euclid I.28.] and hence is parallel to the given line CD; or it

makes an obtuse angle, and so cuts the line CD above the line HA. Thus, if one were ordered to cut off below C, from the line CD passing through the center E, a segment of 55 or 60 degrees, the arc between the lines HI and HFA containing (say) 35 degrees, this could not be done: for the arc below I of 55 or 60 degrees, together with the arc between the lines HI and HA, would make up 90 or 95 degrees. Therefore in that case such a segment can only be cut off above the point C.

[Margin: *Quando problema est impossibile* — When the problem is impossible.]

4. But if the given line, from which the proposed degrees are to be cut off, passes through A, the foot of the gnomon — such as the line EA — then only a perpendicular AB, equal to the gnomon, need be erected upon it. For the extremity B will be the center of the circle by which the degrees are to be cut off, because when the plane of the circle drawn from B is turned about the line EA until AB is upright to the plane of the sundial, point B stands at the center of the world, namely at the tip of the gnomon. So if from the line EA, below point A, a segment of 60 degrees is to be cut off, then with the perpendicular AB (equal to the gnomon) erected and a circle drawn from B, an arc of 60 degrees is to be taken below the line BA produced, as far as Q. For the line BQ will cut off the segment AR of 60 degrees, as has been demonstrated.

[Margin: *Quando data recta transit per centrũ horologij, quid agendum* — When the given line passes through the center of the sundial, what is to be done.]

[Margin: *Qua ratione ducatur perpendicularis ad datam rectã per centrũ horol. trãseuntẽ, centrumq; circuli describendi inueniatur* — In what manner a perpendicular is drawn to a given line passing through the center of the sundial, and the center of the circle to be described is found.]

5. For the rest, to lines passing through E, the center of the sundial — such as ECD — and to all the hour-lines from midday and midnight, in sundials whose great circles (to which those lines are parallel) are not drawn through the poles of the world, we shall draw perpendiculars from A, the foot of the gnomon, with little trouble, and at the same time, by the same operation, we shall find the center H, in this way. With the gnomon AB erected at right angles to the line EA of the stylus, let two circles AM, BH be drawn from E, the center of the sundial, through A and B; and let the given line EC, passing through the center E, cut the former of them at N. For if an arc NM equal to the arc AN is taken, and the line AM is drawn, cutting the

line EC at F and the latter circle at H, then AF will be perpendicular to EC, and H will be the center of the circle to be described — that is, the line FH will be equal to the line AG; so that there is no need to take FG equal to the gnomon and to cut off FH equal to the interval AG, but it is enough to produce the line AM up to the circumference of the latter circle. Both of these will be demonstrated as follows.

Diagram. The same sundial-construction woodcut described under fig-p641-1, reprinted here on the verso so that the reader has the figure at hand while reading Chapter 1 on either side of the leaf. The lettering (E; G, Y, L; H; M, F; A; P, T, N; B; K, O; C, D, F, I, L, G, K, Q, R, D) and the right-hand tangent scale (rules V–X and S–T, numbered 10, 10, 20, 20, 30, 30) are as on p. 641. Marked a for the same reason (crowded, repeated letters).

6. Since the line EC bisects the arc ANM, by the scholium to Proposition 27 of Book 3 of Euclid it will also bisect the line AM, [Margin: a — Euclid III.3.] and therefore at right angles. Which was the first point. Next, with the gnomon BA produced until it cuts the latter circle at T, AB will be equal to AT: because EA, from the center E, cuts BT by construction at right angles, [Margin: b — Euclid III.3.] and therefore bisects it. Likewise, with the line HA produced until it cuts the same latter circle at O, the lines MH and AO will be equal, by the scholium to Proposition 3 of Book 3 of Euclid. Now since the rectangle under HA, AO — that is, under HA, MH — [Margin: c — Euclid III.35.] is equal to the rectangle under AB, AT — that is, to the square on AB, or on FG — if the common square on AF is added, the rectangle under HA, MH together with the square on AF, that is, the square on FH ([Margin: d — Euclid II.6.] for the rectangle under HA, MH together with the square on MF, or AF, is equal to the square on FH), will be equal to the squares on FG, AF, that is, to the square on AG, [Margin: e — 74. primi (Euclid I.74).] to which it is equal. Therefore the lines FH and AG are equal. Which was the second point.

This we shall demonstrate more easily as follows. Let the lines EB, EH be joined. If the triangle ABE is imagined turned about AE until the gnomon AB is upright to the plane of the sundial, and the triangle FEH turned about EF until the perpendicular HF reaches the gnomon AB — and it must necessarily reach the gnomon, since it does not depart from the plane drawn through the gnomon and the perpendicular AH, as is plain — then point H will fall on point B, on account of the equality of the lines EB, EH drawn from the center E. For if point H fell

below B, or above it, then EH would be less or greater than EB, which is absurd. Therefore FH is equal to AG, or to FL.

[Margin: *Quot gradib. segmētum data recta æquiualeat* — To how many degrees a given segment of the line is equivalent.]

7. Conversely, we must find out to how many degrees the given segment CD on the line CD is equivalent. From A, the foot of the gnomon, let a perpendicular AF be drawn to CD; and with a circle drawn from H, the center found as before, let lines HC, HD be drawn through C and D, cutting the circle at I, K. For the given segment CD will contain as many degrees as are included in the arc IK, as is clear from what has been demonstrated. So too, on the line EF drawn through the center of the sundial: if the line HE is extended until it cuts the circle IK, the arc contained between the lines HE and HA will indicate to how many degrees the segment EF is equivalent — the segment between the center of the sundial and the perpendicular AF drawn from the foot of the gnomon to the given line EF passing through the center of the sundial. To know this is at times worth the effort. Likewise, if the line BE is prolonged until it cuts the circle drawn from B, the arc between the lines BE and BP will show the degrees contained in the segment EA; and so with the rest.

[Margin: *Quo pacto per Tāgentes auferatur ex recta segmentum quocunq; graduum* — In what way, by means of the Tangents, a segment of any number of degrees is cut off from a straight line.]

8. Now if, on the line ED, the beginning of the segment to be cut off is given at the very point F of the perpendicular AF, the required portion will be cut off most conveniently by means of the Tangent lines, taking the whole sine as 10 — the values obtained if two figures are dropped from those computed with the whole sine as 1000, as we said above. We shall proceed thus. On any line ST whatever, let any number of parts be taken equal to FH, the interval between the center and the given line, of which the first is [divided] into 10

so that it is divided into equal parts. For if with a compass you take on this line as many parts as are contained in the Tangent of the proposed arc, and transfer them from point F onto the line EF — either below F or above it, as the case requires — the prescribed segment will have been cut off. For example, suppose we must cut off below F a segment of 35° . Since the Tangent of 35° is 700 (with the whole sine set at 1000), if we drop the two figures 00 there remains, relative to a

whole sine of 10, the Tangent 7. So if on the line ST, whose first division has been split into 10 small parts, you take 7 of those parts and carry them from F onto the line FC, you will locate point C, and the portion FC will contain 35° . Likewise, if the desired segment were 64° , the Tangent to be used is that of 64° , namely 2050 — that is, dropping the two figures 50, 20 $\frac{5}{10}$. For if that many parts of the line ST (taking its two undivided parts, which comprise 20 small parts, and in addition the $\frac{1}{2}$ part from the divided portion) are carried from point F below F, a more distant point D will be found, and the portion FD will comprise 64° .

9. *The demonstration is very easy. For plainly, with the whole sine set as FH, the lines FG and FD are Tangents relative to that whole sine — which is evident if, from H through F, a circle is drawn tangent to the line EF at F. And it is clear that the arcs of this circle are similar to the arcs of circle IK, described from the same center H, that are enclosed between the same lines issuing from center H.*

10. If on the line EA a segment of any number of degrees is to be cut off, starting from point A, then on any line VX one must take as many parts equal to the gnomon [stylus] as are wanted — since EA runs through the place of the gnomon — and the first of these must be divided into 10 small parts, and so on. For instance, if a portion of 60° is wanted, whose Tangent is 1732 — that is, 17 $\frac{3}{10}$, a little more — one must take on the line VX 17 $\frac{3}{10}$ parts and a little more, and carry them from A as far as R. The portion AR will then contain 60° . Exactly the same procedure holds in the other cases. For on any straight line whatever, one must always take as many equal parts of that line — the line drawn as a perpendicular from the place of the gnomon to the given line, and set between that line and the center from which we directed the circle to be described — as are required; such were the lines HF and BA in the examples just given. [Margin: *A general rule for the Tangents.*]

11. But if the beginning of the portion to be cut off is not at F or A — where the perpendicular dropped from the place of the gnomon to the given line meets it — but at some other point, say E, then it is necessary first to have determined the arc that corresponds to the segment EF (or EA) intercepted between the given point and the perpendicular. For if this arc is subtracted from the proposed degrees, or (when the proposed degrees are fewer) is itself subtracted from that arc, the Tangent of the remaining arc must be taken, and so on. For example, if from the line EA a portion of 113° is to be cut off starting from point E, one must determine the arc of the circle

described from B, lying between the lines BE and BA — if it is not otherwise known — which here comprises 53° . Subtracting these from 113° leaves 60° . The Tangent of these, then, namely $17 \frac{3}{10}$, carried from A, will give point R, and the whole segment ER will correspond to 113° . Again, if from the same line EA, starting from E, a segment of 8° is to be removed, we subtract 8° from 53° , and of the remaining 45° we carry the Tangent 10 from A toward E as far as Y. The portion EY will then contain 8° , because AY comprises 45° . How the arc between the lines BE and BA is to be found we taught a little earlier, in Number 7; and we shall teach, after the treatment of sundials, in Problem 10, how to investigate the same arc by numbers in any hour-line reckoned from noon or midnight. [Margin: *When the beginning of the portion to be cut off by the Tangents is not at the point of the perpendicular line — what to do.*]

Moreover, even without knowing the segment between the perpendicular and the point from which the degrees begin to be cut off, we shall be able to use the Tangents in this way. Let a portion of 30° be cut off from point C, both downward and upward. Through C draw the perpendicular Cb to HC, so that it is tangent to the circle described from H through C; and the arc of that circle between the lines HI and HK will be similar to arc IK. If, then, from C the Tangent of 30° (relative to the whole sine HC) is carried both ways onto the line Cb, the points a and b will be found, through which the lines drawn from H will cut off from ED the segments Cd and cd of 30° , since Ca and Cb are the Tangents of 30° of the circle described from H through C. And it is established from what has been demonstrated that the lines Ha and Hb, drawn through 30° of that circle, cut off segments of 30° .

SCHOLIVM.

1. *Now since, in order to cut off a segment of any number of degrees by means of the Tangents, one needs to divide various straight lines into ten equal parts, this division will be accomplished most easily if an equilateral triangle ABC of any size is separately constructed, whose base BC is divided most accurately into 10 equal parts, to which straight lines are drawn down from the vertex A, as appears in the triangle set before us. This will be done more easily if with a compass one takes in order 10 equal parts of any size whatever, equal*

Diagram. An equilateral triangle for dividing a line into ten equal parts, set within a rectangular frame. The apex A is at the top; the base runs from B (lower left) to C (lower right). The base BC is divided into ten equal segments, marked

from B toward C with the numerals 9, 8, 7, 6, 5, 4, 3, 2, 1 (the point 5 falling at the mid-base). From the apex A, straight lines are drawn down to each of these division points, fanning out across the triangle. Three horizontal lines cross the triangle parallel to the base, meeting its left side at E, L, H (top to bottom) and its right side at F, M, I. To the right of the triangle a second, slanting construction rises: the top edge runs from A to the upper-right corner D, and a diagonal descends from D through the points G, N, K down to C. Along the line through E–F this scale is marked with the numerals 10, 20, 30, 40 (G standing at the 40 mark).

- A (apex, top): vertex from which the dividing lines are drawn
- B (lower left): left end of the base
- C (lower right): right end of the base, and foot of the diagonal DC
- D (upper right): far corner of the added equilateral triangle ACD
- E, L, H (left side, top to bottom): intersections of the parallels with side AB
- F, M, I (right side, top to bottom): intersections of the parallels with the added construction
- G (on the E–F line, at "40"): point where the diagonal DC crosses
- N, K (on the diagonal DC, descending): further intersection points
- Base division numerals (B → C): 9, 8, 7, 6, 5, 4, 3, 2, 1
- Scale numerals along the E–F line: 10, 20, 30, 40

[Margin: *The construction of an equilateral triangle best suited for dividing lines into 10 equal parts.*]

equal parts from point C as far as B, and on the line BG let an equilateral triangle be set up. For in this way there will be no need to cut the base into 10 parts — since it is already cut — but only to draw lines from A to the parts taken. Then, so that what we intend may be carried out more precisely, upon AC let another equilateral triangle ACD be built, in such a way that DC is [Margin: *Euclid, I.27*] parallel and equal to AB itself, on account of the equal alternate angles BAC and ACD.

Therefore, if on any given line that is to be divided into 10 equal parts — provided it is not longer than the side of the triangle — one takes off the equal lengths AE, AF, DG, the portion EF of the line EFG will be equal to that given line, because the triangle AEF is likewise equilateral (by the corollary of Proposition 4 of Euclid, Book 6). And this same EF will also be divided into 10 equal parts, as is plainly established from the demonstration of the second method of dividing a given line into any number of equal parts, which we set out in the scholium on Proposition 10 of the same Book 6. The line CD, moreover, is drawn so that the line EF may be

extended more accurately and without error, and so that on it, once extended, one may take as many parts equal to EF as one wishes, as the numbers 10, 20, 30, and so on indicate.

By the same reasoning, if a larger line is to be divided into 10 parts, one takes the equal lengths AH, AI, DK (or AL, AM, DN) and draws the line HIK (or LMN); then either the portion HI or the portion LM will be equal to that larger given line, and divided into 10 equal parts.

2. *We shall also often need, in what follows, the distances of the hours (reckoned from noon and midnight, converted into degrees) from the meridian circle or from some other point, together with the Tangents of those distances — which indeed are comprised in this table, with the whole sine set at 1000.*

The distances of the hours (reckoned from noon and midnight) from the meridian, and the Tangents of those distances, with the whole sine set at 1000.

Block 1

Hours (from noon / from midnight)	$\frac{1}{4}$ / 11 $\frac{3}{4}$	$\frac{1}{2}$ / 11 $\frac{1}{2}$	$\frac{3}{4}$ / 11 $\frac{1}{4}$	1 / 11	1 $\frac{1}{4}$ / 10 $\frac{3}{4}$	1 $\frac{1}{2}$ / 10 $\frac{1}{2}$
Distance from meridian (G. = deg., M. = min.)	3° 45'	7° 30'	11° 15'	15° 0'	18° 45'	22° 30'
Tangent	66	132	198	268	339	414

Block 2

Hours (from noon / from midnight)	1 $\frac{3}{4}$ / 10 $\frac{1}{4}$	2 / 10	2 $\frac{1}{4}$ / 9 $\frac{3}{4}$	2 $\frac{1}{2}$ / 9 $\frac{1}{2}$	2 $\frac{3}{4}$ / 9 $\frac{1}{4}$	3 / 9
Distance from meridian	26° 15'	30° 0'	33° 45'	37° 30'	41° 15'	45° 0'

Hours (from noon / from midnight)	$3\frac{1}{4} / 8\frac{3}{4}$	$3\frac{1}{2} / 8\frac{1}{2}$	$3\frac{3}{4} / 8\frac{1}{4}$	4 / 8	$4\frac{1}{4} / 7\frac{3}{4}$	$4\frac{1}{2} / 7\frac{1}{2}$
meridian						
Tangent	1140	1303	1497	1732	2028	2414

Block 4

Hours (from noon / from midnight)	$4\frac{3}{4} /$ $7\frac{1}{4}$	5 / 7	$5\frac{1}{4} /$ $6\frac{3}{4}$	$5\frac{1}{2} /$ $6\frac{1}{2}$	$5\frac{3}{4} /$ $6\frac{1}{4}$	6 / 6
Distance from meridian	71° 15'	75° 0'	78° 45'	82° 30'	86° 15'	90° 0'
Tangent	2946	3732	5027	7596	15257	Infinita (infinite)

The use of this figure is also perfectly clear. For any two hours reckoned from sunrise or sunset intersect one another at that hour, reckoned from noon or midnight, which lies midway between them — that is, from which they are equally distant, as we demonstrated in the Gnomonics, Book 1, Propositions 17 and 20 and their scholia. [Margin: The use of the preceding figure.] For example, at the hour 4 from noon or midnight the following hours from sunrise or sunset intersect one another: 15 and 17; 14 and 18; 13 and 19; 12 and 20; 11 and 21; 10 and 22; 9 and 23; 8 and 24; 7 and 1; 6 and 2; 5 and 3 — because each pair of these is equally distant from that hour. By the same reasoning, at the same hour 4 from noon or midnight these fractional hours from sunrise or sunset cut one another: $15\frac{1}{2}$ and $16\frac{1}{2}$; $15\frac{1}{4}$ and $16\frac{3}{4}$; $15\frac{1}{8}$ and $16\frac{7}{8}$; $15\frac{3}{8}$ [?] and $16\frac{5}{8}$ [?]; [further fractional pairs follow, but the small stacked fractions are not legible with certainty — [?]]. Likewise, at the hour $4\frac{1}{2}$ from noon or midnight these hours cut one another: 16 and 17; $16\frac{1}{8}$ [?] and $16\frac{7}{8}$ [?]; $16\frac{1}{4}$ and $16\frac{3}{4}$; $16\frac{3}{8}$ [?] and $16\frac{5}{8}$ [?]; [remaining fractional pairs [?]]. So too, at the hour $9\frac{1}{4}$ from noon or midnight, these hours from sunrise or sunset will intersect: 9 [?] and $9\frac{1}{2}$ [?]; 8 [?] and $10\frac{1}{2}$ [?]; [?] and $18\frac{1}{2}$ [?]. And so with the rest.

And so, if on any sundial whatever you observe some hour reckoned from sunrise or sunset passing through some point of any hour reckoned from noon or midnight, you will at once know what other hour from sunrise or sunset ought to pass through the same point of the same hour from noon or midnight. For that hour will be carried through the same point which, in the figure above, is as far distant from the said hour reckoned from noon or midnight as the earlier hour from sunrise or sunset is removed from that same hour. For instance, since in the horizontal sundial of Chapter 2 you see that the hour 21 from sunrise or sunset, if it were

extended, cuts the hour 5 from noon or midnight at a certain point above the tropic of Cancer [☿], you will say that through that same point the hour 13 from sunrise or sunset must be drawn — since 21 and 13 are distant from the hour 5 reckoned from midnight by eight hours, and from the hour 5 reckoned from noon by four hours, as is seen in the figure.

Again, if for any two given hours from sunrise or sunset you wish to know at what hour from noon or midnight they cut one another, take the hour from noon or midnight midway between them, equally distant from each. Thus, if the hours 12 and 16½ from sunrise or sunset are given, you will find that they cut the hour 2¼ from noon or midnight at one point, since this hour is equally distant from those two in the aforesaid figure. In the same way you will conclude that the hours 11 and 19 from sunrise or sunset must be described through one and the same point of the hour 3 from noon or midnight, and so on.

By the same reasoning, given any hour from sunrise or sunset, if you wish to know at what hour — of which one is reckoned from noon or midnight and the other from sunrise or sunset — they cut one another, take any hour from noon or midnight that is conveniently cut by the given hour from sunrise or sunset, and another hour from sunrise or sunset as far distant from it in the same figure as the earlier
[continues below]

Diagram. A large circular hour-intersection figure set within a square frame. At the center is the point **A**, marked with two perpendicular diameters (a vertical and a horizontal line) crossing at **A**. Around this center run several concentric rings. The figure carries two curved legend bands and two rings of hour-numbers:

- The inner legend band reads **HORÆ · A · MERIDIE · VEL · MEDIA · NOCTE** ("hours from noon or midnight"), with a small cross **✚** marking the top (noon) position.
- The outer legend band reads **HORÆ · AB · ORTV · VEL · OCCASVS** ("hours from sunrise or sunset").
- An inner ring bears the Roman numerals for the hours from noon/midnight — I, II, III, IIII, V, VI, VII, VIII, IX, X, XI, XII — running twice around the circle.
- An outer ring bears the Arabic numerals for the hours from sunrise/sunset, 1 through 24.

- Between the number rings run graduated scales of tick-marks: long ticks for whole hours, shorter ticks for the half-hours, shorter still for the quarters, and points alone for the eighth-hours (as described in §3 above).

Individual peripheral numerals and the exact angular placement of the tick-divisions cannot all be resolved with certainty at this resolution; several rim labels are uncertain [?]. Marked as a

is distant from that same given hour — as, for instance, if the hour 13 from sunrise or sunset is given and you take the hour 10 from noon or midnight, the hour 7 from sunrise or sunset must be taken, and so on. On this basis was constructed, in this little book, the first table of Chapter 14 for the whole hours, because each of its hours from sunrise or sunset is as far distant, in the said figure, from the hour reckoned from noon or midnight written beneath it, as the hour 24 from sunrise or sunset is removed from that same hour.

Likewise, when any hour from noon or midnight has been taken away, any two hours from sunrise or sunset equally distant on either side of it will cut it at one and the same point. Thus the hour 10 from noon or midnight is cut, at the same point, by the hours 12 and 8 from sunrise or sunset; likewise by the hours 23 and 21, and so on.

Finally, any two hours from sunrise or sunset that are distant from each other by twelve hours — that is, by a semicircle — in the figure above, pass on the equinoctial line of any sundial through the hour reckoned from noon or midnight which holds the place midway between them, that is, which is distant from each by a quadrant, as we demonstrated in Book 1 of the Gnomonics, Proposition 19. Thus the hours 23 and 11 from sunrise or sunset, together with the hour 5 from noon or midnight, intersect the equinoctial line at one point on any sundial. You will say the same of the hours 15½ and 3½ from sunrise or sunset, and of the hour 9½ from noon or midnight. By this device we constructed the second table, set out at the beginning of Chapter 14 for the whole hours: because in that table any two hours from sunrise or sunset are distant by a semicircle, and the hour reckoned from noon or midnight placed midway between them is a quadrant distant from each.

CAPVT II.

Hours from noon and from midnight, on a plane that is parallel to the horizon.

[Margin: *Centrum horologij horizontalis.* — The center of the horizontal sundial.]

[Margin: *Linea horae 6.* — The line of hour 6.] [Margin: *Aequinoctialis linea.* — The

equinoctial line.] [Margin: *Regula generalis pro lineis per locum styli ductis.* — General rule for lines drawn through the position of the gnomon.]

1. Draw a line AB to serve as the meridian; choose on it a point C for the position of the gnomon [stylus], and erect there a perpendicular CD equal to the gnomon. On any straight line mark off any number of equal parts, of which let the first, EF, be divided into 10 equal parts by means of the equilateral triangle described above. Next take the Tangent of 48° — 1111 [numeral:?] — that is, of the complement of the pole's altitude. (In the examples we shall assume the Roman latitude of 42° , with the Tangents reckoned to a whole sine [sinus totus] of 1000.) Reduced to tenths, as I taught in the prolegomena, this comes to $11 \frac{1}{10}$. Take this with the compasses on the line whose part EF has been divided into 10 equal parts, and carry it from C, the gnomon's position, along the meridian line as far as the point G. This G will be the center of the sundial [horologium], where all the hour-lines intersect one another; and the line KL, drawn through G perpendicular to the meridian, will be the line of hour 6 from noon and from midnight.

Again, take the Tangent of 42° — 900, the altitude of the pole — which reduced to tenths is 9, and carry it from C in the same way but toward the opposite side, as far as the point B; and the line HI, drawn through B perpendicular to the meridian, will be the equinoctial line [linea aequinoctialis].

Demonstration. The proof is easy. For if at D an angle equal to the complement of the pole's altitude is set off toward G, the line making that angle will be the axis of the world [axis mundi], and will fall on the center of the sundial. But if the angle of the pole's altitude is set off toward the opposite side, the line making that angle will be the common section of the Equator and the Meridian, and will fall on the point through which the equinoctial line must be drawn, as we demonstrated in Book 2 of our *Gnomonics*, Proposition 1. Therefore, if the lines DG and DB are imagined drawn, then — the whole sine being set as DC — the line CG is the Tangent of angle CDG, the complement of the pole's altitude; and CB is the Tangent of angle CDB, the pole's altitude. It is thus clear that the points G and B are found correctly by means of the Tangents, and that KL is the line of hour 6 and HI the equinoctial line, as we demonstrated in the *Gnomonics*.

Diagram. A tall, narrow rectangular figure in the left margin: a tangent-transfer instrument (a set of parallel graduated vertical scales, to be cut out as straightedges / *normae*). Across the top run column-head letters, and each column bears a vertical italic legend and a scale of divisions. The scales are the practical realization of the "reduce-to-tenths" tangent method of §1. Many of the small

heads, zodiac glyphs, and interior graduation marks do not resolve with certainty at this resolution

- Column heads (left to right): E, M, ♄ [Saturn-like glyph or "b"] [?], X, [?], N
- Column legends (vertical italic, left to right): *Pro meridiana sinu* (for the meridian) · *Pro aequinoctiali sinu* (for the equinoctial) · *Pro linea horae 6* (for the line of hour 6) · *Pro linea horarum* (for the [other] hour-lines) · [?] · [?]
- Left scale-columns, graduated: one runs 1, 2, 3, 4, 5, 6 (each division marked "-0"); a second runs 1, 2, 3, 4; a third runs 1, 2, 3
- Central/right scale, graduated: 10, 20, 30, 40, 50, 60, 70, 80, 90, 100, then a second short run 10, 20; with letter markers Y and C beside the upper divisions and a few small zodiac glyphs [?] beside the 60–90 marks

2. By the same reasoning, whenever any straight line passes through the position of the gnomon — such as the meridian, and all the Vertical lines on a horizontal sundial — one must mark off on that line any number of parts equal to the gnomon, and divide the first of them into 10 equal parts, so that Tangents can be taken on the line, and so forth; as is clear from Chapter 1, nn. 4, 8, and 10.

Moreover, this transfer of the Tangents can also be carried out most conveniently without compasses. For if on some thicker paper — royal or imperial [*regia aut imperiali*] — the divisions of the line EF are made as described, and the paper is then cut so that the edge containing the divisions lies at the very margin and serves as a kind of straightedge [*norma*], we shall apply that straightedge to the meridian line, setting its point F at C whenever the Tangent is not greater than 10, and mark on the meridian the end of the proposed Tangent — namely, toward B, we shall mark the end of the Tangent of 9 parts in order to find the point B. But if the Tangent is greater than 10 — say $34 \frac{5}{10}$ — we shall set the point of the number 30 at C, and mark the point ending the part $4 \frac{5}{10}$ of the little line EF; and so with the rest. The same is to be understood of the other lines from which Tangents must be taken, for out of them too straightedges must be made, with their own divisions, as has been said.

[Margin: *Linea horae à mer. & med.noc.* — The line of the hour from noon and from midnight.]

3. After this, on any other straight line mark off any number of equal parts, of which let the first, MN, again be divided into 10 equal parts by means of the equilateral triangle above. If on this line one takes the Tangents of the arcs by which the hours are distant from the Meridian — from the table of the scholium

of Chapter 1, the Tangents, I say, reduced to tenths, that is, to a whole sine of 10, yet in such a way that the fractions which the following figures show are not entirely neglected, as we taught in the prolegomena — and transfers them from the point B onto the equinoctial line in both directions, the hour-points will be found. If then straight lines are sent out from these through the center of the sundial G, the hour-lines will be drawn, in this order: to us facing the sundial, the lines on the left belong to the hours from noon, and those on the right to the hours from midnight, as the numbers I, II, III, IIII, V, etc., written beside the hour-lines indicate. For example: in the table of the scholium of Chapter 1, the Tangent of the distance of hours 5 and 7 is 3732 — that is, $37 \frac{3}{10}$ and a little more, to a whole sine of 10. If, then, on the line whose part MN has been divided into 10 equal parts, one takes $37 \frac{3}{10}$ and a little more, and transfers this from B onto the equinoctial line in both directions, the points H and I will be found — hour 5 from noon and hour 7 from midnight. And so with the rest.

[Margin: *Quando tangens aliqua est nimis parua quid agendum.* — What to do when some tangent is too small.]

When, however, some Tangent is so small that it can scarcely be taken with the compasses, let it be added to the Tangent of some other point already found. For if you carry the Tangent so combined, and reduced to tenths, from that other found point onto the equinoctial line, the point sought will be found. For example: the Tangent of hour $\frac{1}{2}$ — that is, of $7^\circ 30'$ — is 132; if you add it to 268, the Tangent of hour 1 (or of 15°), you will make the Tangent 400, that is (dropping the two last figures 00) 4. This, transferred from hour 1, will give the point of hour $11 \frac{1}{2}$; and from hour 11 it will give the point of hour $\frac{1}{2}$. Likewise, since the Tangent of hour $\frac{1}{4}$ — that is, of $3^\circ 45'$ — is 66, if you add it to the Tangent 268 owed to hour 1 (or 15°), you will make the Tangent 334, that is, $3 \frac{3}{10}$ and a little more; which,

[Running head: p. 11 — *NOVAE DESCRIPT.*]

transferred from hour 1 onto the equinoctial line, will present the point of hour $11 \frac{3}{4}$, while transferred from hour 11 it will give the point of hour $\frac{1}{4}$. And so with the rest.

But in order to have three points for drawing each hour more accurately, one must take a line GA on the meridian equal to GB, and through A draw OP parallel to the equinoctial line (or to the line of hour 6) — that is, perpendicular to the meridian — and the said Tangents of the hours must, by one and the same

operation, be transferred from both B and A, on either side, onto the equinoctial line and onto the line OP.

[Margin: *Linea horaria vt accuratius ducatur, quid agendum.* — What to do so that the hour-line may be drawn more accurately.]

For example, the Tangent $37 \frac{3}{10}$ and a little more, of hours 5 and 7, which gave the hour-points H and I, is likewise to be transferred, by the same operation, from A as far as O and P. For the line drawn through H, G, P will give hour 5, and the line passing through I, G, O will give hour 7 most exactly, and so on. In the example we have drawn only the lines of the whole hours, to avoid confusion, though the points of the half-hours have nonetheless been marked on the equinoctial line.

Diagram. A large rectangular horizontal-sundial layout occupying most of the page. From a central point G, near the middle, a dense fan of straight hour-lines radiates outward; a semicircle is described about G, and the whole is crossed by many further straight and dotted lines, with hour-numerals, zodiac glyphs, and lettered intersection-points scattered throughout. This same construction is repeated on the following page (see fig-p648-1). The figure is extremely crowded; the numerous small zodiac sorts, dotted-line labels, and doubled-letter intersection points cannot all be resolved at this resolution

- P (top-left corner of the frame)
- O (bottom-left corner of the frame)
- A (on the left vertical edge, where the horizontal center-line meets it)
- G (center; the point from which all hour-lines radiate, marked with a cross **+**)
- Hour-numerals (Roman) read around the fan: I, II (upper right), VI, VII, VIII (upper left / left), V (lower left), XII, XI, X (right side)
- N, R, Q, Z, Y (right side, along the horizontal line near XII–X)
- B, D, S, T (in the central region, near G)
- K, H (along the bottom edge)
- Arabic hour-numbers (hours from sunrise/sunset) read around the border: 3, 5, 6, 10, 12, 14, 17, 18, 19, 21, 22, 23, 24 [several intervening numbers not resolved]
- Doubled-letter intersection labels: aa, bb, cc, dd, pp [and single p, d, e, m along various lines]
- Numerous zodiac glyphs mark individual lines (Aries ♈ and others) — [?], not reliably resolved

Demonstration. If the line DB (drawn only in thought) is taken equal to BQ, and at Q the angles of the hours are set off — namely 15°, 30°, 45°, 60°, 75°, etc. — the lines making those angles will fall on the hour-points of the equinoctial line, as is clear from what we demonstrated in Book 2 of our *Gnomonics*, Proposition 1. Wherefore, since — the whole sine being set as DB or BQ — those same lines cut off the Tangents of the same angles, it is plainly established that the same hour-points are found by means of the Tangents taken from the line whose portion MN is divided into 10 equal parts.

[Margin: *Regula generalis pro rectis non per locum styli ductis.* — General rule for straight lines not drawn through the position of the gnomon.]

4. By this same reasoning, whenever a straight line is perpendicular to the meridian line, or to the line of the gnomon — such as the equinoctial line, the line of hour 6, and the common sections of all the great circles drawn through the intersections of the Equator and the Horizon and of the plane of the horizontal sundial — one must take on any such line any number of portions equal to that line which is drawn, from the intersection of the given straight line with the line of the gnomon, to the tip of the gnomon, making right angles with the line of the gnomon; and the first of these portions must be divided into 10 equal parts, so that Tangents can be taken on the line, and so on — which is clearly gathered from Chapter 1.

[Margin: *Quo pacto examinari possit* — By what means it can be tested...]

Now indeed, if no error has been made in transferring the Tangents, it must be that, for any two hours — one set to the right of the meridian line and the other to the left — the Tangents taken from the table above, in the scholium of Chapter

[Running head: p. 12 — *CAPVT SECVNDVM.*]

[Margin: *...num puncta horaria absque errore inuenta in linea aequinoctiali.* — ... whether the hour-points have been found on the equinoctial line without error.]

1, and gathered into one sum, produce a line which, taken with the compasses from the line MN (divided as the equinoctial line) and transferred onto the equinoctial line, equals the line lying between the two points of those same hours. For example: if $5 \frac{7}{10}$, the Tangent of hour 2 or 10, is added to $17 \frac{3}{10}$ [?], the Tangent of hour 4 or 8, there will result the line 23; and this, taken from the line MN, will equal the interval between hours 2 and 8, or 10 and 4. Likewise, if two hour-points are taken on the same side, and the Tangent of one is subtracted from the Tangent of the other, there will remain a line which, taken with the

compasses from that same MN, will give the interval between those two hour-points of the equinoctial line. Thus, if from $37 \frac{3}{10}$, the Tangent of hour 5 or 7, you take away $17 \frac{3}{10}$, the Tangent of hour 4 or 8, there will remain the line 20; therefore 20 parts of the line MN will equal the space between hours 4 and 5, or between hours 8 and 7, and so on. And in this way you can examine, by various methods, whether the hour-points have been found on the equinoctial line without error, or not.

[Margin: *Descriptio horarum vix lineam aequinoctialem secantium*. — The drawing of the hours that scarcely cut the equinoctial line.]

5. But since some hours scarcely cut the equinoctial line — such as 5 and 7; $5 \frac{1}{4}$ and $6 \frac{3}{4}$; $5 \frac{1}{2}$ and $6 \frac{1}{2}$; $5 \frac{3}{4}$ and $6 \frac{1}{4}$ — we shall draw them if the hour-points are sought on a certain new equinoctial line, from the table of the scholium of Chapter 1, just as they were found on the equinoctial line HI — namely, in this way. Having drawn the axis GD, erect a perpendicular ST to it from any point toward the center G, say from S; and through S draw VSV perpendicular to the meridian line, which will serve as another sort of equinoctial line with respect to the gnomon that would be dropped perpendicularly from T to the meridian line. Then on any straight line take any number of portions equal to ST, and let the first of them, XY, be divided into 10 equal parts. Finally, onto the line VS transfer the Tangents of the hours reduced to tenths — with respect to the whole sine XY or ST, as was done on the equinoctial line — using the table of the scholium of Chapter 1. For by this method the hour-points will be found on the line VS. Thus you see that by the Tangent $75 \frac{2}{10}$ [?] with half of one tenth — that is, by the Tangent 76 nearly — the points V, V are found: hour $5 \frac{1}{4}$ from noon and hour $6 \frac{3}{4}$ [?] from midnight, and so on.

Diagram. The same large horizontal-sundial construction as on the preceding page (fig-p647-1), printed again here: the central radiating point G with its fan of hour-lines, the semicircle about G, and the surrounding frame with Roman hour-numerals (I, II, V, VI, VII, VIII, X, XI, XII), Arabic hour-numbers of the border, zodiac glyphs, and lettered intersection-points (P and O at the upper- and lower-left corners; A on the left edge; K, H along the bottom; N, R, Q, Z, Y at the right). As on p. 647, the small zodiac sorts, dotted-line labels, and doubled-letter points are too dense to resolve fully

But so that we need not divide the line ST into 10 parts, you will do rightly if you bisect the line BG, or from G toward B take a quarter part, and through the point of division draw a perpendicular to the Meridian. For if onto this perpendicular

you transfer the half, or the quarter part, of that tangent which is owed on the equinoctial line...

is owed to some hour, you will have on that perpendicular the point of that same hour. For example: if you want the point for hour $6\frac{3}{4}$ from midnight — which is scarcely to be had on the equinoctial line — draw a perpendicular to the meridian through the midpoint of the line BG, and on it transfer half of the Tangent 76 (nearly), the tangent owed to hour $6\frac{3}{4}$ from midnight, or hour $5\frac{1}{4}$ from noon. For in this way you will have on that perpendicular the point for hour $6\frac{3}{4}$, and so on.

The demonstration of this is that then the line ST likewise, [together with] the line BD, divides GD in half, or cuts off a quarter part of GT, etc.

But we shall set out, in Chapter 4, Numbers 1 and 10, a most thorough method by which all the hour-lines — even those that cut the equinoctial at the most remote points — are described in the most exact way, both geometrically and by Tangents, namely by investigating their points on a certain line equidistant from the meridian.

[Margin: The most thorough method of drawing all the hours is delivered here. — *Absolutissima ratio describendi omnes horas ubi traditur.*]

6. If you want several points through which the hour-lines are to be drawn, you may — if you please — draw a straight line perpendicular to the meridian line, one that represents the great circle [circulus maximus] passing through the intersections of the Equator [Æquator] with the Horizon and drawn through any point of the Meridian standing above the Horizon. This great circle will be the Horizon of some region, above which the pole is elevated by as many degrees as the point taken on the Meridian is distant from either pole of the world. But this point of the Meridian must not have, from the Equator toward the South, a distance greater than the complement of the pole-altitude [altitudo poli] of your region; nor, from the arctic pole toward the Horizon of your region, a distance greater than the pole-altitude of that same region. For [otherwise] that point could not be taken on the meridian line, as was demonstrated in Chapter 1, Number 3 — seeing that its distance from the pole of your Horizon (that is, from the place of the stylus) would be greater than 90 degrees.

[Margin: How more points for the hour-lines are to be found. — *Plura puncta pro horarijs lineis, quo pacto reperiantur.*]

For example: if a point of the Meridian is chosen 30 degrees receding from the Equator toward the South, we shall add to that distance the altitude of the pole — namely the distance of the place of the stylus from the Equator toward the northern parts — so that 72 degrees result. The Tangent of this is 3078; that is, with respect to a total sine of 10, it is $30 \frac{7}{10}$ [?] particles and a little more. If this is taken on the straight line whose portion EF was divided into 10 particles, and is transferred onto the meridian line from C, the place of the stylus, the point R will be found. Through R a straight line drawn perpendicular to the meridian line will represent the great circle, or the Horizon, which by the intersections of the Equator with our [Horizon] cuts it at the point 30 degrees distant from the Equator toward the South — above which, accordingly, the pole-altitude amounts to 60 degrees, the complement, that is, of 30 degrees.

THEREFORE, if on some straight line any number of portions equal to the interval RD are taken, and the first of them is cut into 10 equal particles, and from Table 6 the complements of the degrees of the hours at pole-altitude 60 are excerpted, we shall find — by the Tangents of these complements — the hour-points on the line drawn through R perpendicular to the Meridian line, just as on the Equinoctial line. For example, for hours 3 and 9 you will find, at pole-altitude 60 degrees, in Table 6, 49 degrees 6 minutes; the complement of this is 40 degrees 54 minutes, whose Tangent is 866, that is, $8 \frac{6}{10}$ [?] and a little more. Taken on that straight line — the one on which, we said, portions equal to the interval RD are to be taken — if you were to transfer it from R to either side of that line drawn through R, you would find the points of hours 3 and 9, etc. In the example no line has been drawn through R, so that confusion of lines might be avoided. Yet we did draw a perpendicular through C, the place of the stylus, which represents the prime Vertical [Verticalis primarius], or the Horizon, above which the pole-altitude is 48 degrees (the complement, that is, of the 42 degrees by which the same [point] is away from the Equator toward the north), and which cuts the Meridian between the Equator and the arctic pole at 42 degrees from the Equator. If onto this line there are transferred the Tangents corresponding to the complements of the arcs of Table 6, at a pole-elevation of 48 degrees (which Tangents are to be taken on the line whose portion EF was cut, as we said in Number 2 of this chapter), there will be had on it the hour-points, just as on the equinoctial line. And in this way you can describe the various Horizons of Table 6, on which the hour-points may be found, provided you observe the degrees of pole-altitude of each Horizon and count its complement from the Equator toward whichever side you prefer — so long as you remember that the complements of the arcs of Table 6 are to be taken, and not the arcs themselves.

AND indeed the Horizons described between the Equator and the center of the sundial are useful for the hours whose points can scarcely be had on the equinoctial line because they are too far [from the meridian line]. Thus you see that the points of hour $5\frac{1}{4}$ [?] from noon and $6\frac{1}{4}$ [?] from midnight are conveniently found on the Horizon CD, whereas on the equinoctial line — unless it is extended very far — they cannot be marked.

[Margin: The hours that scarcely cut the equinoctial, how they are to be drawn by Table 6. — *Horae, quae vix aequinoctialem secant, quo pacto describendae per tabulam 6.*]

BUT the far easiest way — through the Tangents of the complements of the arcs of Table 6 — you will find in the scholium of Chapter 25, Number 5; and this not only for the hours that scarcely cut the equinoctial, but for all the other hours as well.

CAPVT III. — The Hours from Noon and from Midnight, on a plane parallel to the Horizon, by another method.

[*HORAE A MERIDIE, ET MEDIA NOCTE in plano, quod Horizonti æquidistat, alio modo.*]

1. We shall describe the hour-lines exactly, and even without Tangents, by this other way. Draw any line AB for the meridian, and, taking a place for the stylus C, draw through C a perpendicular to the meridian, on which CD is made equal to the stylus. Then, having described from D an arc of a circle of any size, count off on it — downward from the line DC — the altitude of the pole (namely, in our example, 42 degrees), and upward its complement, namely 48 degrees. Through the ends of these countings let straight lines go out from D, cutting the meridian line at B and A. A will be the center of the sundial, and through B [runs] the line to be called the equinoctial, perpendicular to the meridian. But if either of the lines DA, DB cuts the meridian too obliquely, the points A, B will have to be found by tangents with respect to the total sine CD, as was delivered in the preceding chapter, Number 1.

[Margin: Meridian line. — *Meridiana linea.*] [Margin: Center of the sundial. — *Centrum horologij.*] [Margin: Equinoctial line. — *Æquinoctialis linea.*] [Margin: Hour-points 4 & 8. — *Puncta hor. 4 & 8.*]

On the line BD let equal segments BE, BF be taken; and from E and F, at the interval EF, let two arcs be described on either side, cutting each other at 4 and 8; and let the line be extended through 4, B, 8, which will be the equinoctial. The

points 4 and 8 themselves will belong to hour 4 from noon and hour 8 from midnight.

For since, by construction, the triangle E4F is equilateral, the angle BE4 will contain — by Corollary 3 of Proposition 32, Book 1, of Euclid — two-thirds of one right angle, that is 60 degrees, and will accordingly comprehend 4 hours. The point 4, therefore, belongs to hour 4 from noon, and 8 to hour 8 from midnight.

Let B2 likewise be a third part of the line B4, and B10 [a third part] of the line B8, and the point 2 will be hour 2 from noon, and the point 10 hour 10 from midnight.

[Margin: Hour-points 2 & 10. — *Puncta hor. 2. & 10.*]

For since EF is double EB by construction, E4 will also be double the same EB; and 42 is likewise double 2B (since B2 is set as a third part of B4). [a] Therefore the line 2E divides the angle 4EB in half. Since, then, the angle 4EB contains 60 degrees, the angle 2EB will comprehend 30 degrees, and so the point 2 will belong to hour 2; and for the same reason the point 10 will refer to hour 10.

[Margin: [a] 3 of the sixth [book] (Euclid VI.3). — 3. *sexti.*]

Again, on the lines BD, or BE, let equal segments B3, B9 be cut off on either side, and the point 3 will be hour 3 from noon, and the point 9 hour 9 from midnight.

[Margin: Hour-points 3 & 9. — *Puncta hor. 3[?]. & 9.*]

For since the lines BE, B9 are equal, [b] the angles BE9, B9E will be equal; but they are [together] equal to one right angle. Therefore each of them will be a half-right angle, that is, will comprehend 45 degrees, and accordingly [each] will take in three hours, etc.

[Margin: [b] 6[?] of the first [book] (Euclid — the argument, equal sides yielding equal base angles, is Euclid I.5). — 6. *primi.*]

Diagram. A large horizontal-sundial construction filling most of the page, enclosed in a rectangular frame. At its center is the dial-center **A**, lying on a horizontal line that runs left–right across the middle of the figure; from **A** a fan of straight hour-lines radiates outward, and a family of dotted construction-arcs and cross-lines fills the frame. The principal readable capital-letter points are: **A** (dial center, on the middle horizontal line); **B** (just below **A**, with **N** marked immediately above it); **C**, **D**, **F** clustered near **A** (**F** above **C**, **D** to the right of **C**); **E** (lower center, apex of the lower fan of dotted hour-lines); **G** (to the lower right of **E**); **H** (lower left, beside the numeral 3); **K** (upper edge, above the numeral 12); **L**

(upper left, above the numeral 9); **M** (upper right, above the numeral 3); **P** (bottom center); **R** (upper right, near the top edge, apex of the large quarter-arc); **S** (left, at the start of an arc); **T** (left, beside the numeral 6); **V** (center, beside the numeral 3); **X** (upper center, a crossing point); **Y** (left-center). Smaller lowercase and repeated labels are also present — **c** (upper center, with a 3), **q, f, m, n, e, r** (in two places), **h, o, a, i, d, z** — most beside dotted construction-lines.

The top horizontal line carries the hour-numerals **9, 10, 11, 12, 1, 2, 3** (running left→right, below L, K ... M). The middle horizontal line (through T, A, a, i) is marked at intervals with **6** (a "six-o'clock" line). Interior numerals mark whole hours (1–12) and half-hours, including the readable **4½, 2½, 8½, 7½**; the bottom horizontal line carries **3, 2, 1, 12, 12** at left and **9, 10, 11** at right. Many of the small interior numerals, the lowercase point-letters, and the dotted-line labels are too dense and faint to resolve individually under magnification. **More than two labels are unresolved.**

IAM — if the interval E4 is transferred from the point 4 as far as 5 and 11, hour 5 from noon and 11 from midnight will be had. In the same way, if the interval E8 is transferred from the point 8 as far as 1 and 7, hour 1 from noon and 7 from midnight will be found. And so now all the whole hours except 6 and 12 have been found; but the line of hour 6 is drawn through the center A, perpendicular to the meridian line, and the meridian itself gives hour 12.

[Margin: Hour-points 5, 11, 1 & 7. — *Puncta hor. 5. 11. 1. & 7.*] [Margin: Hour 12. — *Hora 12.*]

QVOD — if you transfer the intervals between E and the points of the odd hours, from those very points of the odd hours to either side, you will have the points of the half-hours. And you will easily understand from which number each half-hour point is to be named, from the two whole-hour numbers standing on either side of it. For the point between hour 3 and 4 will belong to hour 3½, and the point between hour 11 and 12 to hour 11½, etc. By this method, from the interval of hour 11 you will find hours 8½ and 2½; from the interval of hour 9, hours 7½ and 1½; from the interval of hour 7, hours 6½ and ½; from the interval of hour 1, hours 3½ and 9½; from the interval of hour 3, hours 4½ and 10½; and finally, from the interval of hour 5, hours 5½ and 11½.

[Margin: Half-hours. — *Semisses horarum.*]

THE quarters of the hours you will detect in the same way from the intervals of the half-hour points. For the interval between the point of any half-hour and the point E will give two points of the quarter-hours: so that the point falling between

hour 4 and $3\frac{1}{2}$ marks hour $3\frac{3}{4}$, while the point between 7 and $7\frac{1}{2}$ [marks] hour $7\frac{1}{4}$, etc. And by the same method the eighth-parts of the hours will be drawn from the points of the quarters; and from these, the sixteenth-parts, and so on.

[Margin: Quarters of the hours. — *Quadrantes horarum.*]

MODVM — This method, which Christoph Grienberger [Christophorus Gruenbergerus] recently first observed, we have undertaken to explain and demonstrate somewhat more carefully and more fully in this place, because it is most elegant. It seems to have only this one drawback: that by it not just any proposed degree of the Equator can be found on the equinoctial line, since it proceeds by a continual subdivision of the hours, and of their fragments, into two equal parts. Yet we shall need that [finer] finding of any degree whatever when describing the hours from sunrise and sunset [ab ortu & occasu], as will be said in its place in Chapter 15, Number 4. By Tangents, however, any point on the equinoctial can be found, provided its distance from the Meridian is known. Indeed, the finding of the hour-points on the equinoctial by Tangents seems preferable to the finding set out in this chapter, on this ground: that in the former [method] the finding of no point depends on the finding of another, but each is found by itself; whereas in the latter, the finding of one requires the finding of the others, as is plain. Hence, if the first point has not been exactly found, the others depending on it cannot be found accurately.

[Margin: A comparison between the method set out here and the one delivered through Tangents in the preceding chapter. — *Comparatio inter modum hic expositum, & illum, qui per Tangentes cap. praecedenti traditus est.*]

2. THEREFORE, from the interval between E and any hour-point whatever, two hour-points 6 hours apart are found on the equinoctial line, one of which is always on one side of the meridian line and the other on the other side. Thus you see that from the interval between E and hour 10, for example, hour 8 from midnight and hour 2 from noon are found, which are 6 hours apart — the one being established on one side of the meridian line, the other on the other.

[Margin: From any hour-point on the equinoctial, two hour-points are found, one to the right and the other to the left of the meridian. — *Ex quolibet puncto horario in aequinoctiali duo puncta horaria reperiri, unum ad dexteram, & alterum ad sinistram meridianae.*]

WHEN, moreover, any hour-point of the equinoctial line is proposed, we shall know which two hour-points, 6 hours apart, are to be drawn from it, by this rule. We take the complement — up to 6 hours — of the distance by which the given

hour-point is away from the meridian line. Half of this, added to that distance, will indicate by how many hours one of the points to be found is away from the meridian line, on the side on which the given point lies; while the other point, on the other side of the meridian line, will be away from the meridian line by half of that aforesaid complement, or by 6 hours from the point first found. So if the point first found is, for example, hour $7\frac{1}{2}$, the later one will be hour $1\frac{1}{2}$; and if the first point is hour $1\frac{1}{2}$, the later one will be $7\frac{1}{2}$.

[Margin: Which two hour-points are drawn from any given hour-point. — *Qua duo puncta horaria ex quolibet puncto horario dato eruantur.*]

For example, if we wish to know which hours are found from the point of hour 8 — which on the equinoctial line is 4 hours distant from the meridian line, or from hour 12 — the complement of its distance up to 6 hours will be 2, and the half of that same complement 1. One, therefore, of the points found from hour 8 will be 5 hours distant from the meridian line, toward the given point of hour 8 (because the aforesaid half, namely 1, [together with] the given distance of four hours makes 5); such is the point of hour 7. The other will be away from this by 6 hours, toward the other side of the meridian; or, on the other side of the meridian, it will be [1 hour] distant from the meridian line, such as is the point of hour 1. So too, from the point of hour 4, you will find the points of hours 11 and 5, because the complement of the given hour 4 (which is 4 hours away from the meridian line) up to 6 is 2, and half of this complement is 1. Now it is established that hour 11 is 1 hour away from the meridian line, and that hour 5 is made up of hour 1 and the given distance of 4 hours. Finally, from the point of hour $3\frac{1}{2}$ the points of hours $4\frac{3}{4}$ and $10\frac{3}{4}$ will be found. For the complement of the given hour $3\frac{1}{2}$ (which is $3\frac{1}{2}$ hours away from the meridian line) up to 6 is $2\frac{1}{2}$, and half of this is $1\frac{1}{4}$; which, added to the given distance of the hours, $3\frac{1}{2}$, makes hour $4\frac{3}{4}$ for one sought point. The other will be hour $10\frac{3}{4}$, since it is 6 hours distant from the former, or $1\frac{1}{4}$ hours from the meridian line — namely by the half of the aforesaid complement. And so on for the rest.

3. VICISSIM (conversely) — given any two hours whatever, 6 hours apart, we shall investigate the hour-point from which their points are drawn, by this other rule. The two given hours, of which one is 6 hours away from the other, we shall gather into one sum, and from the sum we shall cast away 12 whenever it can be cast away. For the sum thus made, or the remaining number, will give the hour from whose point the points of the given hours are to be drawn.

[Margin: Given any two hour-points 6 hours apart, from which hour-point they are to be drawn. — *Data quaevis duo puncta horaria 6. horis inter se distantia, ex quo puncto horario eruantur.*]

For example: the points of hours 7 and 1 are 6 hours apart, and are found from hour 8. Likewise the points of hours $7\frac{1}{2}$ and $1\frac{1}{2}$ from hour 9; and the points of hours 10 and 4 from hour 2, because their sum is 14, and, 12 being cast away, the remainder becomes 2. Finally, the points of hours 3 and 9 from hour 12, etc.

BUT you will learn, with no trouble, which hour-points on the equinoctial line are found from any hour-point, from this table.

Table of hour-points on the equinoctial line. Each "column" (block) contains three orders of numbers; the middle order is the given (assumed) hour-point, and the two outer orders — which "stand around" the middle — are the two hour-points, 6 hours apart, generated from it.

Column 1

Point A	Given hour	Point B
1	8	7
2	10	8
3	12	9
4	2	10
5	4	11
6	6	12

Column 2

Point A	Given hour	Point B
$\frac{1}{2}$	7	$6\frac{1}{2}$
$1\frac{1}{2}$	9	$7\frac{1}{2}$
$2\frac{1}{2}$	11	$8\frac{1}{2}$
$3\frac{1}{2}$	1	$9\frac{1}{2}$
$4\frac{1}{2}$	3	$10\frac{1}{2}$
$5\frac{1}{2}$	5	$11\frac{1}{2}$

Column 3

Point A	Given hour	Point B
$\frac{1}{4}$	$6\frac{1}{2}$	$6\frac{1}{4}$
$\frac{3}{4}$	$7\frac{1}{2}$	$6\frac{3}{4}$
$1\frac{1}{4}$	$8\frac{1}{2}$	$7\frac{1}{4}$
$1\frac{3}{4}$	$9\frac{1}{2}$	$7\frac{3}{4}$
$2\frac{1}{4}$	$10\frac{1}{2}$	$8\frac{1}{4}$
$2\frac{3}{4}$	$11\frac{1}{2}$	$8\frac{3}{4}$

Column 4

Point A	Given hour	Point B
$3\frac{1}{4}$	$\frac{1}{2}$	$9\frac{1}{4}$
$3\frac{3}{4}$	$1\frac{1}{2}$	$9\frac{3}{4}$
$4\frac{1}{4}$	$2\frac{1}{2}$	$10\frac{1}{4}$
$4\frac{3}{4}$	$3\frac{1}{2}$	$10\frac{3}{4}$
$5\frac{1}{4}$	$4\frac{1}{2}$	$11\frac{1}{4}$
$5\frac{3}{4}$	$5\frac{1}{2}$	$11\frac{3}{4}$

NAM — if the interval between E and any hour-point of the equinoctial line is transferred to either side, the points of the hours found will be those that stand around, in this table, the point assumed. Thus the interval between E and hour $3\frac{1}{2}$, carried on the equinoctial line from that same hour to either side, will yield the points of hours $4\frac{3}{4}$ and $10\frac{3}{4}$, because among these hours the middle one is hour $3\frac{1}{2}$, in column 4 of the aforesaid table. For every column contains three orders of numbers, of which the two extremes stand around the middle.

CONDITA — this table, moreover, was constructed according to the precept of Number 3, since any two hours standing around [a middle] differ from each other by 6 hours and make up the sum of the intermediate hour, 12 being first cast away when that sum is greater [than 12].

CONVENIVNT — all these things hold good not only for the equinoctial line, but also for any line equidistant from it, and for other straight lines equidistant from any hour-line, as we shall show in the following chapter, Number 9, where we shall accommodate all this to lines of that kind and construct for that use their own tables, like the table just given.

4. DEMONSTRATIO — furthermore, the demonstration of the finding of the hour-points from the table above is not difficult. For let there be taken...

[Continuation of Chapter III, Number 4 — the DEMONSTRATIO begun at the end of the previous folio.]

let there be taken from that table the intermediate hour 2 in the 1st column. I say that through the interval E 2 the points of hours 4 and 10 are found. For since hours 4 and 10 stand 6 hours apart from each other, the angle 4 E 10 will be a right angle. Since, therefore, a perpendicular EB has been dropped from it to the base 4 10, the angle B 4 E will be equal to the angle B E 10 [*Elements* VI.8]; but this is equal to the angle 2 E 4 [*Elements* III.27], since each comprehends two hours (for from hour 2 up to 4, and from 10 up to 12, two hours are counted). Therefore the angles 2 4 E and 2 E 4 will also be equal, and consequently the lines 2 E and 2 4 will be equal [*Elements* I.6]. So the interval E 2, from point 2, will give the point of hour 4.

Again, since in the same right triangle 4 E 10 the angle 4 10 E is equal to the angle B E 4 [*Elements* VI.8]; and this in turn is equal to the angle 2 E 10 [*Elements* III.27], because each comprehends four hours (for from hour 12 to 4, and from 10 to 2, four hours are counted): the angles 2 10 E and 2 E 10 will also be equal; and therefore the lines 2 E and 2 10 will also be equal [*Elements* I.6]. And so, through the interval E 2, from point 2, hour 10 will likewise be found. Which was to be demonstrated.

In just the same way, through the interval E 11 you will demonstrate that the points of hours $2\frac{1}{2}$ and $8\frac{1}{2}$ are found, as the table above shows. For again the angle $2\frac{1}{2}$ E $8\frac{1}{2}$ will be a right angle, since hour $2\frac{1}{2}$ is distant 6 hours from hour $8\frac{1}{2}$; and therefore the angle $2\frac{1}{2}$ $8\frac{1}{2}$ E is equal to the angle B E $2\frac{1}{2}$ [*Elements* VI.8]. But to the angle B E $2\frac{1}{2}$ the angle 11 E $8\frac{1}{2}$ is equal [*Elements* III.27], because each comprehends two hours and a half. Therefore the angles 11 E $8\frac{1}{2}$ and 11 $8\frac{1}{2}$ E will also be equal, and consequently the lines 11 E and 11 $8\frac{1}{2}$ are equal [*Elements* I.6]. Likewise, since the angle $8\frac{1}{2}$ $2\frac{1}{2}$ E is equal to the angle B E $8\frac{1}{2}$ [*Elements* VI.8], and this to the angle 11 E $2\frac{1}{2}$ [*Elements* III.27], because each comprehends hours $3\frac{1}{2}$: the angles 11 $2\frac{1}{2}$ E and 11 E $2\frac{1}{2}$ will also be equal, and consequently the lines 11 E and 11 $2\frac{1}{2}$ are equal [*Elements* I.6], and so on. And the same reasoning holds for the rest.

[Margin, keyed to the lettered citations of this demonstration: a, d, g, k — *Elements* VI.8 ("8. sexti"); b, e, h, l — *Elements* III.27 ("27. tertij"); c, f, i, m — *Elements* I.6 ("6. primi").]

CAPVT IIII.

Hours from noon and from midnight, on a plane equidistant from the horizon, by yet another method besides.

[Margin: An accurate laying-out of hours 9 and 3.]

1. Let the figure of the preceding chapter be repeated, in which the gnomon [stylus], the center of the dial [centrum horologii], the equinoctial line, and the lines of hours 6, 3, and 9 stand as they were found in Number 1 of that same chapter. But so that hours 3 and 9 may be drawn more exactly — since we need these especially in this third method, and it is therefore of great importance that they be accurately laid out — let there be erected, from any point *r* on the meridian line (one sufficiently distant from the equinoctial line), a perpendicular *rG* to the axis *AD* extended. Then, taking on *Ar* a line *AK* equal to it, and drawing through *r* and *K* the lines *HI*, *LM* parallel to the equinoctial line (that is, to the line of hour 6), let the interval *rG* be transferred from both *r* and *K*, on either side, as far as *H*, *I* and *L*, *M*. For through *L*, *A*, *I* the line of hour 9 is to be drawn, and through *M*, *A*, *H* the line of hour 3; and if there has been no error, these will pass through the points 9 and 3 on the equinoctial line.

Diagram. A large sundial-construction figure filling the lower two-thirds of the page, within a rectangular border, showing the layout of the hour-lines of a horizontal dial by the "third method." A quarter-circle arc sweeps from the upper-right corner *R* down to point *P* at the bottom. The dial center *A* lies at the right-center; the vertical (meridian/axis) line *AD* runs down through it, and horizontal lines (the equinoctial line and the line of hour 6, with the parallels *HI* and *LM*) cross the field. Numerous hour-lines radiate from *A*, and the auxiliary points *r*, *G*, *H*, *I*, *K*, *L*, *M* of the construction are marked. Readable labels (position; sense):

- *R* (top-right corner): endpoint of the large arc.
- *L* (upper horizontal line, left) with "9" beneath: hour-9 endpoint.
- *K* (upper horizontal line, center) with "12": hour-12 point.
- *M* (upper horizontal line, right) with "3": hour-3 endpoint.
- Upper-line hour marks between the endpoints: 10, 11 (between *L* and *K*); 1, 2 (between *K* and *M*).
- *X* (upper-middle): intersection of the arc with a radiating line.
- *S* (on the arc, upper-left); *f* (right, on a horizontal); *q*, *c* with "3" (right, on the arc): construction points.

- T (mid-left, on the line through A) with "6": hour-6 point to the left of center.
- A (right-center): the dial center.
- i (right, on the arc) with "6": construction point.
- Y (mid-left); r, m, F, C, D (along the horizontal below A): auxiliary points of the transfer construction (r and G the erected perpendicular).
- N, B (center-lower, near D): construction points.
- E (lower-center): equinoctial/center point of the lower construction.
- V with "3"; H with "3" (lower-left); s, o, P (bottom): further construction points.
- G, g, n (lower-right); numerous small hour numerals (1, 2, 3, ... 12, with the halves $2\frac{1}{2}$, $4\frac{1}{2}$, $7\frac{1}{2}$, $8\frac{1}{2}$) annotate the radiating hour-lines around the field.

Let there be erected from any point r on the meridian line — one far enough removed from the equinoctial line — a perpendicular rG to the axis AD extended. Taking Ar, with a line AK equal to it, and drawing through r and K the lines HI, LM parallel to the equinoctial line or to the line of hour 6, let the interval rG be transferred from r and K on both sides as far as H, I and L, M. For through L, A, I the line of hour 9 is to be drawn, and through M, A, H the line of hour 3, which — if there is no error — will pass through the points 9 and 3 on the equinoctial line.

Also, taking a line rN equal to rG, let an arc PQ be described from N, and, an occult line NH being drawn, let the arc between P and the line NH be cut into three equal parts. For the occult lines drawn out from N through the points of division will give the points of hours 1 and 2. And most easily will the arc between P and the line NH be cut into three equal parts if, with the same interval by which the arc PQ was described, one cuts off an arc PQ of 60 degrees (comprehending four hours), and takes, in the arc contained between P and the line NH, three arcs equal to the arc between Q and the line NH — the arc that contains one hour. And if the intervals found between r and the points of hours 1 and 2 are transferred from r toward I, and from K toward L and M, one will have three points apiece for drawing hours 1, 2, 3, 9, 10, 11. The hour-points on the line LM, however, can be found just as on the line HI, if a line KO equal to rG or KL is taken, and from O the arc RS is described, and so on.

[Margin: The laying-out of hours 1, 2 and 11, 10.]

Now, in order to lay out the other hours after 3 from noon and before 9 from midnight, one must take on the meridian line the lines AE, Af equal to rG or rH, and through E, f draw the lines Vb, Xc parallel to the line of hour 6; and the lines

VX, bc joined will be equal to HI and equidistant from the meridian line, as will be demonstrated in Number 6. For if the intervals of the line rH between r and hours 1 and 2 — which have been carried over into rI, KL, and KM — are transferred from T and a into the lines VX, bc, one will have the hour-points sought. So too, if on hour 3 one takes Ap, Aq equal to that same rG or rH, and draws ph, qi parallel to the line AI of hour 9, the joined line hi will likewise be equal to HI and parallel to the line AH of hour 3, and will be bisected at g, as we shall show in Number 6. Hence, if the same intervals of the line rH between r and hours 1 and 2 are transferred onto the line hi from the point g, the points of hours 7, 8, 10, and 11 will again be found.

[Margin: The laying-out of the other hours.]

Indeed, if through the points T, a, g — taken arbitrarily on the lines Ta, AI — parallels VX, bc, hi are drawn, set with respect to the meridian line and to the line of hour 3 (placed at 6 and 12, as we shall demonstrate), and cut equally at T, a, [and g], these parallels will lie between hours 3, 9 and 6, 12. If, then, Tk is taken equal to TV, and al equal to ab, and gm — the line gm being erected perpendicular to hi — equal to gh; and from k, l, m the arcs YZ, de, no are described, and the occult lines kX, lc, mh joined; and finally the arcs between Y and the line kX, likewise between d and the line lc, and also between n and the line mh, are distributed into three equal parts (which will be easy to do if, cutting off from the intervals of the semidiameters their sixth parts YZ, de, no, one takes in the arcs between the line kX and the point Y, between the line lc and the point d, and between the line mh and the point n, three equal arcs to those between Z and the line KX, between c and the line lc, and between o and the line mh): then the occult lines drawn out from the centers k, l, m through the points of division will give, on the lines TX, ac, gh, the hour-points, which — transferred from T, a, g onto the lines TV, ab, gi — will yield the hour-points sought.

[Margin: A more general laying-out of the hours.]

And in a similar way, through a point given on any hour-line, one can draw a line parallel to that hour-line which stands six hours before it, extending as far as the two hour-lines that stand three hours before it. For this parallel will be bisected at the given point. Accordingly, if from the given point a perpendicular equal to the half of that parallel is erected to it, and from its far end an arc is described, and so on, the hour-points will be found on that parallel, just as on the aforesaid lines HI, LM, VX, bc, ih. For, for example, from g — the midpoint of the line hi (which is drawn parallel to the line of hour 3, that stands six hours from the line of hour 9 on which the given point g lies, extending as far as the two lines of

hours 6 and 12, which are three hours distant from the line of hour 9 or 3) — a perpendicular gm has been erected to hi itself, equal to the half gh or gi, and from m the arc no described, and so on. And if the parallel drawn is equal to the line HI, it is enough to transfer onto it, from its midpoint, the intervals between r and the hour-points. You see that the same thing has been done on the other lines HI, LM, VX, and bc. Nor will it be difficult to judge to which hours the hour-points found belong, from the intermediate hour on which the given point lies. Thus you see that on the half gi lie the points of hours 8 and 7, which precede hour 9 from midnight; while on the half gh lie the points of hours 10 and 11, which follow that same hour 9.

It will further be not difficult to draw, through A, a straight line passing through any degree whatever of the equator. For if that degree is distant from the meridian toward the west by fewer than 45 degrees, we shall count it in the arc PQ, from P toward Q, and through the end of the counting draw from N a straight line, which will cut the line HI in a point through which the line drawn out from A will be the one sought. But if the given degree is distant from the meridian toward the west by more than 45 degrees, yet by fewer than 90, we shall count its complement in the arc YZ, from Y toward Z, and through the end of the counting draw from k a line cutting TX in a point which, carried over from T toward V, will give a point on TV through which the line drawn out from A will be the one sought. But if the given degree is distant from the meridian toward the west by more than 90 degrees, yet by fewer than 135, we shall subtract 90 and count the remainder in the arc YZ, from Y toward Z, and through the end of the counting draw a line from k. For this will cut TX in a point through which the line drawn out from A will be the one sought. Finally, if the given degree is distant from the meridian toward the west by more than 135 degrees, yet by fewer than 180, we shall subtract that distance from 180 and count the remaining degrees in the arc RS, from R toward S, and through the end of the counting draw a line from O. For this will cut KL in a point through which the line drawn out from A will be the one sought.

[Margin: By what method a line is to be drawn, by this way, through any degree whatever of the equator.]

But if any degree whatever is proposed as distant from the meridian toward the east, its point is to be found on the line rH, or VX, or KL, exactly as if the given distance were toward the west. For the point found, transferred onto the line rI, or bc, or KM, will be the one through which the line drawn out from A will be the one we seek.

For example: let there be given the 30th degree of the equator from the meridian. Having counted 30 degrees in the arc PQ, from point P toward Q, and drawn from N a line through the end of the counting, rH will be cut at point 2, through which the line drawn out from A will pass through the 30th degree of the equator from the meridian toward the west. And if r 10 is taken equal to r 2, the line drawn A 10 will be distant 30 degrees from the meridian toward the east. Again, let the degree given be 75. Its complement, 15 degrees, if counted in the arc YZ from Y toward Z, and a line drawn from k through the end of the counting, will cut TX at point 7; through which the line from A — carried over from T as far as 5 — that is, the line drawn out from A through 5, will pass through the 75th degree of the equator toward the west. And if a 7 is taken equal to T 5, the line drawn out from A through 7 will pass through the 75th degree of the equator toward the east. Likewise, let 105 degrees be given. Subtracting 90, we shall count the remaining 15 degrees in the arc YZ, from Y toward Z. For a line drawn from k through the end of the counting will cut TX at point 7, through which the line thrown across from A will pass through the point of the equator distant 105 degrees from the meridian toward the west. And if a 5 is taken equal to T 7, the line drawn out from A through 5 will proceed through the 105th degree of the equator on the eastern side. Lastly, let the given degree of the equator be 150; subtracting 150 from 180, there remain 30. Having counted 30 degrees in the arc RS, from R toward S, and drawn from O a line through the end of the counting, KL will be cut at point 10, through which the line drawn out from A will pass through the 150th degree of the equator, on the western side. And if Ka is taken equal to K 10, the line cast out from A through 2 will proceed through the 150th degree of the equator on the eastern side. And so for the rest.

2. This way here set forth — which is most beautiful and most accurate — does not differ from the method that we demonstrated in the *Construction and Use of the Instrument for Dials* by means of a certain parallelepiped, and which, following Andreas Schoner [Andreas Schöner], we employed in various places in our *Gnomonics*, except that here we have rendered the whole matter more universal; and this indeed we shall demonstrate by the following reasoning.

First we shall show: that when, in different circles, perpendicular lines are erected upon the diameters, and straight lines go out from the centers cutting off similar arcs from the circles, those perpendiculars are cut similarly — that is, into proportional parts. For let two circles CD, EF be described, arbitrarily, from the centers A, B; and upon their diameters let perpendiculars GH, IK be erected, as one pleases, which the straight lines going out from the centers — AL, AM, AD, BN, BO, BF — cut at P, Q, H and R, S, K; and let the pairs of arcs cut off, CL, EN; LM,

NO; MD, OF, be similar. *I say that the perpendiculars GH, IK are cut similarly — that is, that as GP is to PQ, so IR is to RS; and as PQ is to QH, so RS is to SK.* For since the angles GAP, IBR are equal, by the scholium on proposition 22 of book 3 of Euclid, because the arcs CL, EN are similar, and the angles G, I are right, the remaining angles APG, BRI will also be equal [*Elements* I.32]; and consequently the remaining angles APQ, BRS (from two right angles) will be equal. Since, therefore, the angles PAQ, RBS are also equal, because of the similar arcs LM, NO, the remaining angles PQA, RSB will also be equal. And in the same way, both AQH, BSK and QHA, SKB will be equal to one another. So the triangles AGP, BIR, and APQ, BRS, and AQH, BSK, are equiangular with one another. Therefore, as GP is to PA, so IR is to RB, and as PA is to PQ, so RB is to RS [*Elements* VI.4]; and hence, from equality of ratio, as GP is to PQ, so IR is to RS. And by the same reasoning, as PQ is to QH, so RS is to SK. Which was to be demonstrated.

[Margin: a — *Elements* I.32 ("32. primi"); b — *Elements* VI.4 ("4. sexti").]

Diagram. A two-part geometric figure at the upper left, illustrating the proportional-section proposition. It shows two circular arcs, each with a center, a diameter, a raised perpendicular, and radial lines cutting off similar arcs.

Readable labels:

- Upper arc (center at right, toward A): points L, M, H along the arc, with the raised perpendicular GH and the cutting points P, Q on it; D marked near the diameter foot; a lower-case construction point near the arc. A is the large capital at the right (center of this circle; diameter CD).
- Lower arc: points K, S, R along the arc, with the perpendicular IK and cutting points on it; N, O, E, F marked; B the large capital at the bottom (center of this circle; diameter EF). An "I"/"1" mark stands near the perpendicular's top.

3. *In the second place it is to be demonstrated: that when some plane is equidistant from the circle of any hour from noon or from midnight, the remaining hour-circles make, in that plane, common sections parallel to that parallel which the hour-circle six hours distant from the one to which the plane is equidistant makes; and that they stand distant on either side in that proportion in which the hour-points on the equinoctial line stand distant from the meridian line in a horizontal dial.* For let there be any plane AB, equidistant, say, from the circle of hour 3 from noon or from midnight, and let its common section with the equator be the straight line CD, which the straight line EF cuts at right angles, and on which let FE be equal to the distance of the plane AB from the center of the world, or from the circle of hour 3 to which it is equidistant. Let there then be described a circle GHIK from E,

of whatever size, and let it be cut into 24 equal parts. Now if this circle is conceived to be carried around CD until it is at right angles to the plane AB, and E is imagined to be placed at the center of the world (that is, of the equator), and the plane AB parallel to the circle of hour 3 — so that the line CD does not depart from the plane of the equator, and the circle GHIK itself is concentric with the equator — then the hour-circles from noon and from midnight will pass through the points of division of the circle GHIK, and will meet the plane AB at the points on the line CD onto which fall the straight lines drawn out from the center E through those same points of division. And since the hour-circles from noon and from midnight are perpendicular to the equator, by proposition 15 of book 1 of Theodosius, being drawn through its poles; while the plane AB, by the scholium on proposition 18 of book 11 of Euclid, is perpendicular to that same equator, being placed parallel to the circle of hour 3 (which is perpendicular to the equator, as are the other hour-circles, as was just said): the common sections of the hour-circles with the plane AB will also be perpendicular to the equator [*Elements* XI.19], and therefore, by definition 3 of book 11 of Euclid, perpendicular to CD, the common section of the equator and the plane AB. So the straight lines drawn out through the points of the line CD, perpendicular to CD itself, will be the common sections of the hour-circles and the plane AB, and parallel to one another [*Elements* I.28]; and the line LM, drawn through the point F, will be the common section of the plane AB and the circle...

[Margin: c — *Elements* XI.19 ("19. vndec."); d — *Elements* I.28 ("28. primi").]

Diagram. A large figure filling the lower half of the page: a circle GHIK inscribed within a rectangular frame ruled by many parallel vertical lines (the common sections of the hour-circles with the plane AB), crossed by horizontal lines (CD, EF, LM, AB). At the upper right a small right triangle (A–D–3) sits against the frame. Readable labels:

- A (upper, at the triangle's apex), with D below it and "3" to its right: the raised distance-construction.
- L (top-left, on the circle top) and G with "9" (top of the circle): division points.
- H with "3" (left of the circle) and K with "3" (right of center): the horizontal diameter GHIK ends / division marks.
- C (left frame edge) and D (right frame edge): the line CD across the field.
- E (center of the circle): the center from which the divisions are struck.
- F (below the circle center): point on EF where LM is drawn.

- N, N (lower-left, two adjacent points) and M, M (lower-center, two adjacent points) and B, B (right, two adjacent points): the ends of the parallel common-section lines meeting the frame.
- Small numerals 9, 3, 1 annotate the circle's divisions; dotted radial lines mark several of the 24 divisions.

the circle of hour 9, since the points G and I are six hours distant from the points H and K, through which the circle of hour 3 is drawn. Therefore, since — as we demonstrated at Num. 2 — the diameters of the circle GHIK cut the straight line CD just as the equinoctial line in a horizontal dial (or any other straight line perpendicular to the meridian line AB) cuts the diameters of the circle described from E in the figure of Cap. 3: it is plainly established, which was proposed in the second place.

4. And the segments of the straight line FC are always equal to the segments of the straight line FD — the first to the first, the second to the second, and so on — when the division is begun from the point F. (This we shall easily demonstrate as follows. In the triangles EFC and EFD, for instance, the two angles CEF and DEF are equal [*Elements* III.27], and the two angles at F, being right, are equal as well, while the side EF adjacent to them is common; therefore [*Elements* I.26] the sides FC and FD are equal; and so for the rest.) It follows that, if the straight line NMB is drawn cutting all the parallel hour-lines in the plane AB in any way whatever, its segments intercepted between the middle parallel LM and any two parallels equally distant from LM will be equal. For example, the segment MN will be equal to the segment MB. For since the straight lines CD and NB are cut proportionally by the parallel planes drawn through the parallels of the plane AB (for through these parallels planes parallel to one another — namely to the plane AB — can be drawn) [*Elements* XI.17], and since CD is bisected at F, as we showed, NB too will be bisected at M. And so for the rest.

[Margin: a — *Elements* III.27 ("27. tertij"); b — *Elements* I.26 ("26. prim."); c — *Elements* XI.17 ("17. vndec.").]

5. Once these things are established, we shall easily demonstrate the method of finding the hour-points taught in this chapter. For conceive, in the figure of Cap. 3, that through g — the point on the line of hour 9 from midnight — a plane is drawn parallel to the circle of hour 3 from noon. And since the plane of the dial, cutting the circle of hour 3, and the plane drawn through g parallel to it produce parallel common sections [*Elements* XI.16], the plane drawn through g will pass through the straight line hi, which we drew parallel to the line of hour 3, and it will be inclined to the plane of the dial in the same way as the circle of hour 3 is

inclined to it. Now since — through the things which we demonstrated at Num. 3 — the hour-circles (excepting the circle of hour 3, from which the plane drawn through g is equidistant) make, in that plane, common sections parallel to the parallel which the circle of hour 9, six hours distant from the circle of hour 3, produces, and these stand distant on both sides in that proportion in which the hour-points on the equinoctial line, or on the straight line HI, are distant from the point of hour 12: those parallels will cut the straight line hi as well — the common section of that plane with the plane of the dial — in the same proportions. Since, therefore, the circle of hour 6 is drawn through i and the circle of hour 12 through h, the parallels produced by the circles of hours 6 and 12 will meet the plane of the dial at i and h, and consequently hi will be bisected at g, inasmuch as the parallels passing through i and h are equally distant from the middle parallel drawn through g. Therefore, since the straight lines going out from the center m cut the straight line hi in the same proportions in which the equinoctial line is cut by the straight lines from the center E, or the straight line HI by the straight lines emitted from the center N — as was demonstrated at Num. 2 — other parallels will pass between i and h through the points of the straight line hi which are marked out by the straight lines emitted from the center m: namely, if the circle described from m be divided into hours, the beginning made from the line mg, just as the equator described from N was divided; exactly as was done in the arc no, by which the hour-points were found on the straight line gh.

[Margin: d — *Elements* XI.16 ("16. vnde.").]

Now the straight line qm must be taken equal to half of gh, or of gi, so that the arc between n and the straight line mh — an arc of three hours, that is, of 45 degrees — may present to us the point h, of hour 12, receding by three hours from the point g. For the segment of the straight line hi that comprises three hours is always equal to the straight line between g and the center m; just as, at Cap. 3, Num. 1, we showed that the segment of the equinoctial line B3, or B9, comprising three hours, is equal to the straight line BE between B and the center E of the equinoctial circle. By the same reasoning, the other parallels between g and i will pass through the points found on the straight line gi, since these correspond to the points on the straight line gh.

By like reasoning, the common sections VX, bc, and LM will be equal to HI itself at the hour-points, if the points of the straight line HI be transferred onto them. For first, if through the straight lines VX and bc — parallel to the line of hour 12 — planes parallel to the circle of hour 12 be drawn (in such a way that they stand at right angles to the plane of the dial, just as the circle of hour 12 stands at right

angles to that same plane of the dial), the same demonstration will apply which we applied just now, when through *hi*, parallel to the line of hour 3, a plane was drawn parallel to the circle of hour 3 and inclined to the plane of the dial in the same way as the circle of hour 3 is inclined to it. But if the parallels *VX* and *bc* are not equal to the straight line *HI*, then on the line of hour 6, *Ta*, which is perpendicular to them, the straight lines *Tk* and *al* must be taken equal to their halves *TV* and *ab*, and circles are to be described from *k* and *l*, just as the circle *PQ* was described from *N*, and so on. Then if through *LM*, parallel to the line of hour 6, a plane be drawn parallel to the circle of hour 6, inclined to the plane of the dial in the same way as the circle of hour 6 — drawn in its proper position through the straight line *Ta* and the axis *AD* — is inclined to that same plane of the dial: the same demonstration will fit in every respect, as is evident.

In no other way shall we show the same thing to happen in any straight line whatever that is drawn equidistant from some hour-line.

6. Moreover, that the straight lines *VX* and *bc* — parallel to the meridian line — are equal to the straight line *HI* and are bisected at *T* and *a* (if halves equal to *rH* be taken, *AE* and *Af*, and parallels to *Ta* be drawn through *E* and *f*, as we said at Number 1), I demonstrate thus. In the triangles *AEV* and *AfX* the angles at *E* and *f* are right [*Elements* I.29] (because the straight lines *EV* and *fX* are parallel to *Ta*), and the angles at *A* are equal [*Elements* I.4] (for since the angles *HAr* and *IAr* are equal — on account of the two sides *rA*, together with the two sides *rH* equal to the sides *rA* and *rI*, and the right angles at *r* [*Elements* I.15] — while *IAr* is equal to *XAf*, *VAE* too will be equal to that same *XAf*); and moreover the adjacent sides *AE* and *Af* are equal. Therefore the straight lines *EV* and *fX* will also be equal [*Elements* I.26]. Since, then, they are parallel — each being parallel to *Ta* — and equal, *VX* and *Ef* too will be parallel and equal [*Elements* I.33]. But *Ef* is equal to *HI*. Therefore *VX* too is equal to that same *HI*, and *Ef* is bisected at *A*. And the same must be said of the straight line *bc*.

[Margin: *e* — *Elements* I.29 ("29. primi"); *f* — *Elements* I.4 ("4. prim."); *g* — *Elements* I.15 ("15. primi"); *h* — *Elements* I.26 ("26. primi"); *i* — *Elements* I.33 ("33. prim.").]

Finally, that the straight line *hi* (if halves equal to *rH* be taken, *Ap* and *Aq*, and parallels *ph* and *qi* be dropped to *Ag*, as far as the lines of hours 12 and 6) is parallel to the line of hour 3, *AH*, and equal to *HI* itself, and bisected at *g*, as we supposed at Num. 1 — this will become manifest thus. If through *h* a parallel to *pq* be drawn, cutting the line of hour 9 at any point *g*, then *hg* will be equal to *pA*, in the parallelogram *gp* [*Elements* I.34]. Since, therefore, as was shown at Num. 3,

4, and 5, this parallel drawn through h as far as hour 6 is cut at g, bisected from the mid-hour Ag, it must fall on the point i, so that the portion gi becomes equal to the portion Aq, to which Ap and hg are equal. For only the parallel to Aq that lies between g and the straight line qi is equal to Aq, on account of the parallelogram gq. For the parallel hg, cutting the straight line qi elsewhere than at i, would make its portion between g and the line of hour 6, Ai, either less or greater than the straight line Aq, according as it fell to the right of that point i, or to the left, as is evident.

[Margin: k — *Elements* I.34 ("34. primi").]

7. But in order that the position of the parallels which the hour-circles produce — in the planes drawn through the straight lines HI, LM; VX, bc; and hi, and through the circles of hours 12, 6, and 3 — may be perceived more clearly, I say that they make, with the said straight lines at the hour-points, angles equal to the angles which the axis of the world AD, established in its proper position in the dial, makes with the hour-lines to which they are equidistant. So that the parallels in the planes drawn through the straight lines VX and bc make angles equal to the angle DAB, which the axis DA — holding its proper position (that is, when the triangle ADB is at right angles to the plane of the dial, and therefore lies in the plane of the meridian) — makes with the meridian line, to which VX and bc are equidistant. But the parallels in the planes drawn through the straight lines HI and LM make angles equal to the right angle which the same axis AD, in its proper position, makes with the line of hour 6, to which HI and LM are equidistant. Finally, the parallels in the plane drawn through the straight line hi make, with hi at the hour-points, angles equal to the angle DAp, which the same axis AD, in its proper position, makes with the line AH of hour 3, to which hi is equidistant.

The magnitude of this angle will be known thus. From the three straight lines AD, A3, and E3 of the dial of Cap. 3, let a triangle AD3 be formed — in the figure next to Num. 3 — so that D3 is equal to E3 itself. I say that the angle DA3 is equal to the angle which the axis AD, holding its proper position, makes with the line A3 of hour 3. For, the axis AD being placed in its proper position, the straight line dropped from the point D to the point 3 will be equal to the straight line E3 [*Elements* I.8], because, when the center E is placed at D — at the center of the world — the straight line E3 coincides with the straight line D3. Since, therefore, the two sides AD and A3 of the triangle AD3 in the dial of Cap. 3 are equal to the two sides DA and A3 of this triangle, and the base D3 is equal to the base D3, the

angle DA3 in that triangle will be equal to the angle A in this constructed triangle [*Elements* I.8].

[Margin: a — *Elements* I.8 ("8. primi").]

Diagram. A large master construction filling the greater part of the page: a rectangular frame enclosing a large circle (drawn partly in solid, partly in dotted arcs) with two orthogonal principal diameters (a horizontal line across the top-center and a vertical axis) and a dense web of straight and dotted radial lines representing the hour-circles and their common sections, together with several smaller subsidiary circles/arcs and shadow-triangles. Numerous hour-numerals (1–12, some repeated on opposite sides) annotate the rim and the radial lines. Because the small numerals and the many dotted radials are only partly resolvable at this resolution, the confidently read labels are listed; several small labels remain uncertain.

- Top horizontal line, left to right: L (at "9"), "10", "11" (with a cross-mark Z beside it), K (at "12"), "1", "2", M (at "3").
- R: apex of the outer arc, at top center-left.
- S: left, on the arc, marked with a small cross.
- X: principal crossing point below the top line, left of center.
- f: on a horizontal dotted section-line, mid-left.
- c (with "3"): crossing point to the right of center, where a rising oblique line meets an arc.
- q: just below c.
- o: interior point, center-left; near it descending numerals "8", "7".
- T (with "6" and "1"): on the mid horizontal line, center.
- a, i (with "6", and "d"): right side of the mid line; "7", "7½" below to the right.
- Y: left edge, mid-height; r/script mark and m nearby (mid-left).
- "4½", "2½": numerals on the central horizontal band; small "3", "1" marks between.
- N, B (with "2", "1"): left-center; F, C, D: the central shadow/section triangle (F upper, C and D below).
- A: the central origin/center of the construction, on the vertical axis; a script mark (k?) and "a", "i" to its right.
- G: right-center; "9", "6", n (right); numerals "8", "8½" near center-right.
- E: interior point, center-lower; "10", "11" beside it.

- V (with "3"): center-lower; H (with "3"): lower-left; "S", "2", small "o" (cross-marked) below.
- P: bottom center, on the lower arc.
- Bottom line hour-numerals (left to right): "1", "2", "11", "10", "9", with "12", a script "k", and "12" clustered at lower-left.

Moreover, that those parallels make angles of this kind, I demonstrate most briefly thus. For example, the parallel in the plane drawn through ih — which is equidistant from the circle of hour 3 — is equidistant [*Elements* XI.16] from the axis of the world set in its proper position (because the axis of the world and any of the parallels are sections made by parallel planes, namely by the circle of hour 3 and the plane drawn through ih); and ih itself is parallel [*Elements* XI.10] to the line A3 of hour 3. Therefore the angles constituted in that plane by the aforesaid parallels with the straight line ih will be equal to the angle which the axis, in its proper position, makes with the line of hour 3. And so for the rest.

[Margin: b — *Elements* XI.16 ("16. vnde."); c — *Elements* XI.10 ("10. vnde.").]

8. And so, if at the hour-points of the straight line ih there were constituted, with ih, angles equal to the angle A of the upper triangle — toward that side to which the axis inclines in its proper position — and if the plane in which they are constituted were carried around ih until it were equidistant from the plane of the circle of hour 3 (drawn through the axis DA in its proper position and the line A3 of hour 3), then the lines making those angles would reproduce, most exactly, the parallels of the plane drawn through ih. Now in the upper triangle the angle D, which the axis in its proper position makes with the straight line D3 on high, is right. For since AD is at right angles to the plane of the equator, it will make — by definition 3 of book 11 of Euclid — a right angle with the straight line D3 lying in the equator.

By like reasoning, if at the hour-points of the straight lines HI and LM right angles were constituted with those same straight lines, and the planes in which they lie were carried around HI and LM until they were equidistant from the circle of hour 6 (drawn through the axis DA in its proper position and the line Ta of hour 6), those perpendiculars would express to a nicety the parallels of the planes drawn through HI and LM, since they would not differ from them.

Finally, if at the hour-points of the straight lines VX and bc there were constituted with them angles equal to the angle of the pole's elevation — which the axis makes with the meridian line — and the planes in which they lie were turned about those same straight lines until they stood at right angles to the plane of the

dial, that is, equidistant from the meridian, then the lines making those angles would not differ from the parallels of the planes drawn through VX and bc.

9. Now, that the finding of the hour-points explained in the preceding chapter fits the lines HI, LM; VX, bc; and hi as well — as we advised at Num. 3 of the preceding chapter — can easily be understood, provided that on the straight lines VX and bc the line Ta of hour 6 be taken for the meridian line, and on the straight line hi the line Ag of hour 9; and then, in place of the hours surrounding hour 12, the hours surrounding hour 6 and hour 9 be taken. Only on the straight lines HI and LM is nothing to be changed; rather, everything is to be understood as on the equinoctial line, so that the table of the preceding chapter serves these two lines no otherwise than it serves the equinoctial line. But for the other lines the intermediate hours must be changed, as we shall presently say.

And so if, for example, from k, the center of the straight line VX, at the interval of the straight line VX (which is double Tk), the straight line VX be cut at f, then f will be the hour-point 4 hours distant from the line of hour 6, Tk — namely the point of hour 2 — just as in the preceding chapter the interval EF — or 39 [?], double of EB — gave the point of hour 8, or 4, likewise 4 hours distant from the meridian line. But if the third part of Tf, namely Tt, be taken, t will be the hour-point 2 hours removed from that same line of hour 6 — namely the point of hour 4. From these two points all the rest will be found, as was said at Num. 1 of the preceding chapter. And the same reasoning holds for the other lines.

But what hour-points are to be found, from any given hour-point, on the lines VX and bc (equidistant from the meridian line), and on hi (parallel to the line of hour 3), and also on a line drawn equidistant from the line of hour 9 (for lines of this kind are sometimes most convenient on certain declining planes), the following three tables teach.

Tabella pro rectis meridianæ lineæ æquidistantibus.

(Table for straight lines equidistant from the meridian line.)

The table is printed in four blocks of three columns; in each block the first column is the argument (the distance, in whole units and quarter-fractions) and the two following columns are the two corresponding hour-values.

arg	h	h	arg	h	h	arg	h	h	arg	h	h
1	2	7	$\frac{1}{2}$	1	$6\frac{1}{2}$	$\frac{1}{4}$	$\frac{1}{2}$	$6\frac{1}{4}$	$3\frac{1}{4}$	$6\frac{1}{2}$	$9\frac{1}{4}$
2	4	8	$1\frac{1}{2}$	3	$7\frac{1}{2}$	$\frac{3}{4}$	$1\frac{1}{2}$	$6\frac{3}{4}$	$3\frac{3}{4}$	$7\frac{1}{2}$	$9\frac{3}{4}$

arg	h	h	arg	h	h	arg	h	h	arg	h	h

The use of these tables is the same as that of the one placed in the preceding chapter for the equinoctial line and the straight lines equidistant from it. For if, for example (to explain the use of the first table, which serves the lines parallel to that of hour 12), the interval between k and any hour-point on the straight line VX — corresponding to some intermediate hour of the first table — be transferred to either side, the hour-points surrounding the assumed point will be found in this table. Thus the interval between k and hour 5 will give the points of hours 2½ and 8½. And so for the rest.

10. Indeed, if from the points r, K, T, a onto the straight lines HI, LM, VX, bc there be transferred the tangents of 15, 30, 45 degrees, and so on — with respect to the whole sine Nr, or Ok, or kT, or la, divided into 10 parts — then the hour-points on those straight lines, distant from those same points r, K, T, a by 15, 30, 45 degrees, and so on, will be found, just as was done on the equinoctial. This is also to be understood of the parts of hours, if the tangents of half-hours and quarter-hours be taken. Moreover, by the same reasoning you will find the point of any degree whatever, provided you have noted its distance from the point r, and from this have learned its distance from the point T, for example. Thus if a point be proposed distant 63 degrees from the meridian: since from r up to H there are 45 degrees — namely three hours — the proposed point is not to be sought on rH, but on TV, since from the point r up to T there are 90 degrees, that is, six hours. Therefore the complement of the proposed 63 degrees must be taken, that is, 27 degrees, and the tangent of this transferred from T toward V; and so for the rest. And this reasoning...

[Margin: By what method the hour-points are found by means of tangents on the meridian line, and on the lines equidistant from those of hours 6 and 3 or 9. ("Qua ratione per Tangentes reperiantur puncta horaria in lineis meridiana, & lineis hor. 6. ac 3. vel 9. æquidistantibus.")]

(continuation of Chapter IV)

[Margin: The most convenient method for hours that scarcely cut the equinoctial. ("Commodissima ratio pro horis æquinoctialē vix secantibus.")]

this is the most convenient method for hours that scarcely cut the equinoctial, especially if the straight lines VX and bc are drawn parallel to the meridian line in whatever way you please, and their halves TV and ab are each divided into 10 equal parts, treated as whole sines, with respect to which the Tangents are to be taken, so that they may be transferred onto the straight lines VX and bc...

Indeed, these same hour-lines can also be described—by means of the Tangents of the complements of the arcs of table 6—upon any perpendicular to the meridian onto which they have been carried, without the circle described from G, as was explained in the scholium of chapter 25, No. 5. Moreover, if in the plane of the sundial there be drawn, perpendicular to the line of hour 6, straight lines that recede from the meridian at equal distances—such as are, in the sundial of the preceding chapter 4, the straight lines VX and bc—and if onto them there be transferred the Tangents of the arcs of table 6 (not of their complements), reckoned with respect to the whole sine AT or Aa, then there will likewise be hour-points on these lines, so that three points are obtained for each hour, as will be clear from what we shall demonstrate at No. 5 of the scholium to chapter 25. And this method is the most beautiful of all for the hours that lie near hour 6.

CHAPTER V. [CAPVT QVINTVM.]

THE HOURS FROM NOON AND FROM MIDNIGHT, on a plane parallel to the horizon, by yet another method besides.
[HORAE A MERIDIE, ET MEDIA NOCTE in plano, quod Horizonti æquidistat, alio præterea modo.]

[Margin: The description of the hours by means of the arcs of the horizon, table 6. ("Descriptio horarū per arcus Horizontis 6. tabula.")]

1. Finally, we shall draw all the lines of the hours from noon and from midnight without difficulty, by means of the arcs of the horizon that are intercepted between the circle of hour 6 (that is, the common section of the circle of hour 6, or of the Equator, with the horizon) and the points where the horizon is cut by the hour-circles—such being the arcs that the numbers of table 6, set out beside the pole's altitude on the left-hand side, present. We shall proceed thus. In the sundial of chapter 2, from the centre G of the sundial let there be described a circle equal to some circle whose quadrant is divided into degrees; for here the centre of the sundial, the equinoctial line, and the line of hour 6 have to be found from the given style, as we taught in the earlier descriptions. Into this circle, if

from the line of hour 6, on either side, there be transferred on both sides the arcs of the horizon set out beside the pole's altitude of 42 degrees (or of whatever other altitude belongs to the region in which the sundial is described), or if from the meridian line, both below the centre G and above it, the complements of those same arcs be transferred on either side, then there will be obtained in the said circle, for each single hour, two points; and if straight lines be drawn through these from the centre G, the hours from noon and from midnight will be described, as appears in the sundial of chapter 2.

What we have said about the arcs of whole hours is to be understood also of the arcs of the halves and of the quarters of those same hours.

2. The demonstration of this description is as follows. Let the triangle GDC of the sundial in chapter 2 be swung around the meridian line GC until it stands perpendicular to the plane of the sundial—that is, until it lies in the plane of the meridian. If through D, the tip of the style, some circle be conceived parallel to the plane of the sundial—that is, lying in the plane of the horizon and concentric with it—then the hour-circles from noon and midnight, passing through the axis DG, will cut off from that circle concentric with the horizon arcs of just as many degrees as answer, in table 6, to the several hours and their fractions; and they will produce in that same circle straight lines, which are their common sections with that circle. Since, then, each of the hour-circles [Margin: Elements XI.16. ("16. undec.")] of the sundial makes lines parallel to those which the meridian, or the circle of hour 6, makes in the aforesaid circle, [Margin: Elements XI.10. ("10. undec.")] *these lines will make, in the plane of the sundial with the meridian line—or with the line of hour 6—an angle at the centre G equal to the angle which that other line makes at the centre of the [horizontal] circle. For this reason the arc of the circle described from G, the centre of the sundial, subtending that angle at the centre G, will be similar to the arc of the circle described from D, the centre of the world, subtending an equal angle at the centre D ... [and the lines drawn] through the points impressed on the circumference of the circle described from G ... are the common sections of the plane of the sundial with the hour-circles, that is, are the hour-lines.*

CHAPTER VI. [CAPVT SEXTVM.]

THE HOURS FROM NOON AND FROM MIDNIGHT, on a plane parallel to the horizon, above which the pole's altitude is so small that the centre of the sundial can scarcely be obtained. [HORAE A MERIDIE ET MEDIA NOCTE in plano, quod Horizonti æquidistat, supra quem poli altitudo tam exigua est, ut centrum horologij vix haberi possit.]

[Margin: The description of a sundial for a small elevation of the pole. ("Horologij descriptio ad exiguā poli elevationem.")]

1. Sometimes a sundial has to be described in a region where the pole's altitude above the horizon is so small that the centre of the sundial can scarcely be obtained, because it falls too far from the place of the style. For example, if the pole's altitude were 0 degrees 30 minutes, its complement being 89 degrees 30 minutes, the Tangent of this complement will contain about 1146 of those parts of which the whole sine comprises 10—parts which have to be counted off from the place of the style along the meridian line (the style, of course, being divided into 10 equal parts) in order that the centre may be obtained. This can scarcely be done unless the plane of the sundial is of almost boundless size. So too, if the pole's altitude were 2 degrees, its complement being 88 degrees, the parts to be counted off would be $286 \frac{3}{10}$ [numeral:?] and a little more—which likewise can scarcely be done. Therefore, so that a sundial may in that case be described even though the centre, through which the hour-lines are to be drawn, is not present, we shall proceed as follows. Let us suppose, in some sundial, that the centre can scarcely be obtained, or rather that it cannot be contained on the plane of the sundial at all. Since, then, the parts of the Tangent of the complement of the pole's altitude cannot be counted upward from the place of the style, we shall carry the Tangent of the pole's altitude downward from the place of the style, so that a point may be found through which the equinoctial line, making right angles with the meridian line, is to be drawn. On this line let the hour-points be found, as we taught in chapter 2 or 3, omitting No. 5 of chapter 2, where table 6—which is not universal—is used.

And next, if with the style there be set up, at the meridian line, a right angle equal to the complement of the pole's altitude—yet not toward the equinoctial

line—the line making that angle will be the axis of the world, to which, if from any point...

whatever point of the meridian line, remote from the equinoctial line, a perpendicular be raised; and if through that point a perpendicular be drawn to the meridian to serve as a new equinoctial, then upon this equinoctial there will be found, by means of the Tangents (reckoned with respect to the whole sine, which equals the perpendicular raised from the assumed point to the axis), the hour-points, just as on the former equinoctial line, as we taught in chapter 2, No. 6. Let these points, then, be joined by straight lines to the points found on the former equinoctial, and the hour-lines will be described, even though the centre of the sundial appears nowhere. By this art several equinoctial lines can be described, and hour-points sought upon them, so that the hours may be drawn through several points.

2. Moreover, if you please, let there be chosen from table 6 the altitude of the pole, on the left-hand side, whose horizon—represented by a straight line perpendicular to the meridian—can conveniently be described in the sundial, whether below the equinoctial line or above it.

[Margin: In what way a point distant any number of degrees from the Equator, whether toward the south or toward the north, is found on the meridian line. ("Quo pacto punctum quotlibet gradibus distans ab Æquatore sive versus austrū, sive versus boream, reperiat in meridiana linea.")]

The point on the meridian line through which that altitude's horizon must be drawn will be found below the equinoctial line thus. To the complement of that altitude let the altitude of the pole, for which the sundial is being constructed, be added; for the Tangent of this combined number, transferred from the place of the style, will indicate the sought point. For example: if the pole's altitude were 10 degrees, and the horizon to be described has a pole-altitude of 60 degrees, we shall add to its complement of 30 degrees the pole's altitude of 10 degrees, [and from the combined number of 40 degrees] we shall transfer the Tangent $8 \frac{4}{10}$ [numeral:?], approximately, from the place of the style, below the equinoctial line. Above the equinoctial line, on the meridian, we shall find the point of the same horizon thus: we shall compare the complement of that pole's altitude with the pole's altitude for which the sundial is being described, and subtract the smaller number from the larger. Then we shall transfer the Tangent of the remaining number from the place of the style—downward, indeed, if that complement was less than the pole's altitude for which the sundial is being made; but upward, if greater. For example: if the pole's altitude were again 10 degrees,

and the horizon to be described has a pole-altitude of 60 degrees, we shall subtract from its complement—that is, from 30 degrees—the pole's altitude of 10 degrees, and [with] the remaining number of 20 degrees we shall transfer the Tangent $3 \frac{6}{10}$ upward from the place of the style. But if the altitude for the sundial to be constructed were 40 degrees, we shall subtract from it the aforesaid complement of 30 degrees, and with the remaining number of 10 degrees we shall transfer the Tangent $1 \frac{7}{10}$, and a little more, downward from the place of the style.

3. This horizon having therefore been described, the hour-points will be investigated upon it by means of the Tangents of the complements of the arcs of table 6, as was set forth in chapter 2, No. 6. These points, joined by straight lines to the points of the equinoctial line, will give the hour-lines, even though there be no centre. And these can be described more accurately if several horizons are drawn and hour-points investigated upon them.

CHAPTER VII. [CAPVT SEPTIMVM.]

THE HOURS FROM NOON AND FROM MIDNIGHT, on a plane parallel to the horizon, above which the pole's altitude is so great that upon it the equinoctial line can scarcely be described. [HORAE A MERIDIE ET MEDIA NOCTE in plano, quod Horizonti æquidistat, supra quem poli altitudo tanta est, ut in eo linea æquinoctialis vix describi possit.]

1. A sundial has also sometimes to be described in a region where the pole's altitude above the horizon is so great that the equinoctial line can scarcely be drawn, because it falls too far from the place of the style. For instance, if the pole's altitude were 89 degrees 30 minutes, its Tangent will be about 1146 of those parts of which the style comprises ten—parts which must be counted downward from the place of the style so that the point of the equinoctial line may be found; and this can hardly be done on a small plane. We shall therefore take the Tangent of the complement of the pole's altitude—namely the Tangent of 0 degrees 30 minutes, which contains about $\frac{8}{100}$ of one tenth, as we said in the Prolegomena—for the reason that from the Tangent 8 nothing can be subtracted. And since $\frac{8}{100}$ of one tenth cannot be taken off with the compass, being $\frac{8}{1000}$ of the whole style (which is divided into only 10 parts, not into 1000), we shall use this device. Since the Tangent 10 is equal to the style, and answers to 45 degrees, we

shall take along the meridian line, from the place of the style downward, a portion equal to the style, and mark its end-point. Then to this Tangent 10 we shall add the Tangent of the aforesaid complement of the pole's altitude—namely $8/100$ of one tenth—and the combined number 10 $8/100$ [of one tenth]—that is, 10 and a little more—we shall transfer from the marked point toward the place of the style, so that a point is found a little above the place of the style, to serve as the centre of the sundial.

And next, the style having been set up at right angles to the meridian line, let the axis of the world be drawn from the centre thus found through the tip of the style; and to this axis let a perpendicular be raised from any point of the meridian remote below the place of the style. And through the assumed point let another perpendicular to the meridian be erected, to serve as a kind of equinoctial line—with respect to a second, smaller style, which is of course dropped perpendicular from the point of the axis onto which the first perpendicular falls upon the meridian. If, then, onto this equinoctial the Tangents of the hours from the little table of the scholium of chapter 1 be transferred, as we taught in chapter 2, No. 3, the straight lines sent out from the centre thus found through these points will indicate the hours from noon and from midnight.

2. After this, if you wish, let there be chosen from table 6 the pole's altitude on the left-hand side, whose horizon—represented by a straight line that makes right angles with the meridian line—can conveniently be described below the place of the style; whose point on the meridian line will be found thus. From the pole's altitude above the horizon of the sundial let the complement of that assumed pole-altitude be subtracted. For the Tangent of the remaining number, carried downward from the place of the style, will give the point on the meridian line through which the chosen horizon is to be drawn perpendicular to the meridian line. For example: if the horizon to be described has a pole-altitude of 50 degrees, we shall subtract its complement of 40 degrees from the given pole-altitude of 89 degrees 30 minutes, and the remaining number being 49 degrees 30 minutes, we shall transfer the Tangent $11 \frac{7}{10}$ downward from the place of the style. For a perpendicular drawn to the meridian line through that end-point will give the chosen horizon of 50 degrees.

3. This horizon having been described, let the hour-points be investigated upon it by means of the Tangents of the complements of the arcs of table 6, as was said in chapter 2, No. 6. For the straight lines sent out from the centre of the sundial, once found, through these points will give the hours from noon and from

midnight—which indeed you will delineate more accurately if you describe several horizons and seek the hour-points upon them.

(conclusion of Chapter VII)

But all these difficulties, which we have set forth in this chapter and the preceding one, have no place if the sundial is constructed by the method of chapter 24 or 25; for there we need neither the centre of the sundial nor the equinoctial line.

CHAPTER VIII. [CAPVT OCTAVVM.]

THE ARCS OF THE SIGNS IN A HORIZONTAL SUNDIAL of the hours from noon and from midnight. [ARCVS SIGNORVM IN HOROLOGIO HORIZontali horarum à merid. & med. noc.]

[Margin: The finding of the points on the hour-lines for the parallels of the Sun at the beginnings of the signs, by means of table 1. ("Inuētio pūctorū in lineis horarijs pro parallelis Solis in signorum initijs per 1. tabulam.")]

1. The arcs of the signs, which the tip of the shadow traces out when the Sun is at the beginnings of the signs, are either hyperbolas, or parabolas, or ellipses, on any plane of a sundial whatever—except on the equinoctial sundial, on which they are circles, as we demonstrated in Book 1 of the *Gnomonics*. These arcs, then, of whatever kind they be, we shall describe by a new and very easy method, on all sundials, from tables 1 and 2. And, in particular, on the horizontal sundial from table 1, thus. Of the portion BG of the meridian line, between the centre of the sundial and the equinoctial line, let there be taken an equal portion BZ in the opposite direction; and through Z let a perpendicular Za be drawn to the meridian line. Then let table 1 be applied, in which are taken the arcs answering to the beginnings of the signs for the several hours in the circle of hour 6—that is, in that line of the hours to which on the left is attached this heading [Circ. hor. 6.], or on the right-hand side the number [6.].

[Margin: With respect to which whole sine the Tangents are to be taken, to be transferred onto hour 6. ("Respectu cuius sinus totius sumēda sint Tangentes in horam 6 trāsferēda.")]

For if you transfer the required Tangents of the complements of those arcs (which you will find beneath the hours, opposite the signs) from the points G and Z onto the straight lines GK and Za, on either side, there will be found the points

through which straight lines drawn from the point B (where the equinoctial line intersects the meridian) will cut the corresponding hour-lines at the beginnings of the signs—that is, at the points through which the arcs of the signs are to be described. For drawing each single straight line there are generally three points: two, indeed, on the straight lines GK and Za, and a third, B; for it is for this use alone that the perpendicular Za has been drawn. And these straight lines, toward the centre G, will give on the hour-lines the points of the northern signs; but the southern signs below the equinoctial line. The Tangents, moreover, are to be taken from a straight line whose part bc is divided into 10 equal parts for the line of hour 6—which part bc (like the rest) must be equal to the interval GD in the sundial of chapter 2, as is clear from what we said at No. 4 of that same chapter.

[Margin: When one and the same straight line exhibits two points on opposite parallels, and when on one and the same. ("Quando eadem recta exhibeat duo puncta in oppositis parallelis, & quando in vno, & eodem.")]

For example: let there be found, at hours 3 and 9, the points of the tropic signs ☿ [Cancer] and ♑ [Capricorn]. Since opposite ☿ and ♑, at the foot of table 1, under hours 3 and 9 in the circle of hour 6, there is found an arc of 31 degrees 35 minutes, we shall take the Tangent of its complement, $16 \frac{3}{10}$ [numeral:?], and transfer it from G and from Z, on both sides, as far as d. For one straight line dBd will give the point ☿ at hour 3 and the point ♑ at hour 9; the other straight line dBd will present at hour 9 the point ☿, and at hour 3 the point ♑. Likewise, since under hour 6 in the circle of hour 6, opposite ☿ and ♑, there is found an arc of 23 degrees 30 minutes, if we transfer the Tangent of its complement, 23 (approximately), from G on both sides, hour 6 will be cut at the points ☿. And so for the rest. But since the straight line drawn out from the point B through the end of the Tangent $22 \frac{2}{10}$ [numeral:?],—which belongs to the complements of the arcs of hours 5 and 7—meets the line of hour 6 too far off from the line of hour 7 from noon and of hour 5 from midnight, so that those hours can scarcely be described on the sundial, we must take the Tangent of the complement of the arc of hours $5\frac{1}{2}$ and $6\frac{1}{2}$, namely $22 \frac{8}{10}$ [numeral:?], approximately; and by it there must be found the points of the parallel ☿ at hours $5\frac{1}{2}$ and $6\frac{1}{2}$ from noon, and likewise at hours $5\frac{1}{2}$ and $6\frac{1}{2}$ from midnight.

[Margin: When one and the same straight line exhibits two points on opposite parallels, and when on one and the same. ("Quando eadem recta exhibeat duo puncta in oppositis parallelis, & quando in vno, & eodem.")]

For the same straight line drawn out from B, through the ends of that Tangent, equally distant from the line of hour 6, cuts across in the parallel ☿, since neither

of them falls below the equinoctial line. For always one and the same straight line sent out from the point B will present either two points—one on the northern parallel and the other on the southern—if it cuts two hour-lines receding in different directions equally from the meridian; or two points on the same northern parallel, on two hour-lines equally distant from the line of hour 6, if it cuts them, as is manifest from table 1. For on it two such hours always have the same arc.

2. The demonstration. The straight lines sent out from the point B, through the ends of the Tangents on the lines GK and Za, represent the great circles of the sphere which, from the intersection of the Meridian with the Equator, are drawn through the hours from noon and from midnight in the parallels of the Sun, since the Tangents transferred from G and Z answer to the complements of the arcs of the circle of hour 6 which the said circles intercept with the Equator. Therefore they will necessarily cut the hour-lines at the points of the parallels of the Sun which answer to them on the sphere, where they are cut by the aforesaid circles.

Now let us also give an example concerning the points of the parallels ♉ [Taurus], ♍ [Virgo], ♏ [Scorpio], and ♐ [Pisces], to be found at hours 3 and 9. The arc, under those hours, opposite the said signs, contains in table 1 sixteen degrees 3 minutes. Its complement's Tangent, about 34 6/10 [numeral:?], transferred onto the straight lines GK and Za on either side, exhibits on each side the points e, from which the straight lines drawn through B cut hours 3 and 9 at the points f of the parallels ♉, ♍, ♏, and ♐. And the same reasoning holds for the rest.

[Margin: That it is enough for the points to be found for the half-parallels of the northern signs. ("Satis esse, ut puncta reperiātur pro semissibus parallelorū borealium.")]

3. Furthermore, it is enough if the aforesaid Tangents are carefully transferred only from G onto the line of hour 6, on one side—the right, say, or the left—and from Z onto the straight line aZa on the opposite side, and the points of the northern parallels only are found, on that side from which the Tangents were transferred onto the line of hour 6. For the points of the northern parallels can be found more accurately than those of the southern, since on the northern parallels the hour-lines are cut less obliquely by the straight lines proceeding from B than on the southern. For from these points we shall easily find similar points on the other side of the meridian line, and also below the equinoctial line, for the opposite southern parallels—which we did also in our *Gnomonics*, Book 2, Proposition 2. And so we shall proceed.

[Margin: The finding of the points for the parallels of the Sun on the meridian line. ("Inuētio pūctorū pro parallelis Solis in linea meridiana.")]

First, on the meridian line let the points of all the parallels be found, thus. Let the declinations of the northern parallels be subtracted from the pole's altitude above your horizon—that is, from the arc of the Meridian between the zenith of your place and the Equator; but let the declinations of the southern parallels be added to that same pole-altitude. For thus will be produced the several distances of the northern parallels from the zenith of the place toward the Equator, and the distances of the southern parallels will be combined from the same zenith. Then, if the Tangents of these distances be taken from the straight line whose segment EF, equal to the style, is divided into 10 parts, and be transferred from C (the place of the style, which answers to the zenith of the place) onto the meridian line, the points will be found through which the parallels are to be described. At an elevation of the pole of 42 degrees the said distances, together with their Tangents, stand as follows:

Horologiorum Nova Descriptio — Chapter VIII (continued)

(Global source pages 661–663 = printed pp. 25–27. Continuation of Cap. VIII, "The arcs of the signs on a horizontal dial for hours from noon and from midnight.")

Diagram. A large horizontal-sundial layout filling nearly the whole page, framed by a rectangular border. From a center (the base of the style, low in the left-center of the figure) a dense fan of straight hour-lines radiates outward; a circle/semicircle (the equinoctial or horizon circle) is drawn about the center, and numerous curved day-arcs (the parallels of the Sun / zodiac signs) cross the hour-lines. Around the border and along the rays are Roman-numeral hour-labels, Arabic degree/hour-arc numbers, zodiac glyphs marking the parallels, and many small cursive point-letters where the arcs cut the hour-lines. The figure is the horizontal dial referred to throughout the surrounding text (latitude 42°).

Readable labels (many small labels are worn or below resolution and are flagged):

- Roman hour-numerals on the rays: V, VI, VII, VIII (upper band); X, XI, XII (lower/right band); IX [?]

- Frame/interior capital letters: **A** (left border, mid-height); **P** (upper-left corner region); **L** (upper edge, center); **N** (right-center); **R** (right side, beside "XI"); **Q** (lower-left corner); **H** (lower area); **K** (lower-left, in "K e VI 23")
- Central cluster of capitals near the style/equinocial region: B, C, D, E, F, G [several individually uncertain — [?]]
- Arabic arc/hour numbers around the outer arcs: 3, 10, 11 [?], 12, 13, 14, 17, 18, 19, 21, 22, 23; and "1", "2", "3" along the lower right
- Half-hour tick labels marked "½" at several rays
- Zodiac glyphs marking the day-parallels (♊, ♋, ♌, ♍, ♎, ♏, ♐, ♑, ♒, ♓, ♈, ♉, ♊, ♋, ♌, ♍, ♎, ♏, ♐, ♑, ♒, ♓) scattered across the arcs — most too small/worn to confirm individually [?]
- Numerous lowercase cursive point-letters (a, b, c, d, e, f, g, i, k, l, m, n, o, p, q, r, u ...) at arc/hour-line intersections — individually unresolvable [?]

Distances of the Sun's parallels from the zenith of the place, together with their Tangents. At latitude 42 degrees. (*Distantiæ parallelorum Solis à vertice loci, vnà cum earum Tangentibus. Ad latitud. grad. 42.*)

Signa (Signs)	♊ (Ca nce r)	♊ ♌ (Gemini / Leo)	♈ ♉ (Taurus / Virgo)	♈ ♎ (Aries / Libra)	♏ ♐ (Pisces / Scorpio)	♑ ♒ (Aquariu s / Sagittari us)	♓ (Cap ricor n)
Distanc es (Distāti æ)	G. 18	G. 21	G. 30	G. 42	G. 53	G. 62	G. 65
Tangen ts (Tāgēte s)	334	399	589	900	1351	1896	2194

But if at any time the declination of a northern parallel is greater than the pole's altitude, then the pole's altitude must be subtracted from that declination, so that the remainder becomes the distance of that parallel from the zenith of the place toward the arctic pole. In that case the Tangent of its distance must be transferred from the place of the style toward the center of the dial, and so on.

The demonstration of this finding of the points depends on what was shown in the problem of chapter 1, number 8, since by means of these Tangents there are cut off from the meridian line straight lines equivalent to the aforesaid distances from the zenith of the place.

[Margin: When the declination of a northern parallel is greater than the pole's altitude — what is to be done. ("Quando declinatio borealis paralleli maior est altitudine poli, quid agendum.")]

4. When the distance of some southern parallel from the zenith of the place turns out to be 90 degrees or more, that parallel cannot be described on the dial, because the Tangent of its distance is infinite. For example, when the pole's altitude is 78 degrees, if the declination of ♊ [Capricorn] — namely 23 degrees 30 minutes — is added to it, the distance from the zenith comes to 91 degrees 30 minutes. Therefore on a horizontal dial the tropic of ♊ [Capricorn], opposite to the tropic of ♋ [Cancer], cannot be described there. And in this case, from the points of the northern parallel found on one side of the meridian line, we shall have to investigate only the points of the same parallel on the other side of the meridian line, as we shall explain in a moment.

[Margin: When a southern parallel cannot be described on a horizontal dial. ("Quando parallelus australis in horologio horizontali describi non possit.")]

5. When the points of all the parallels have been found on the meridian line, as was taught in number 3, and when from the points of any northern parallel found on the hour-lines on one side only of the meridian line — as we taught in number 1 — we must seek the points of the same parallel on the other side of the meridian line as well, and (whenever that parallel can be described on the dial) the points of the opposite southern parallel on both sides of the meridian line, we shall proceed by this route.

(p. 26 — running header: "CAPVT OCTAVVM.")

Onto the portion hG of the meridian line, between the point of the tropic ♋ [Cancer] (for from its points, found on one side of the meridian line, the rest are now to be sought) and the center of the dial, let there be taken an equal portion ig, measured from the point of the tropic ♊ [Capricorn]. Take with the compass the interval of any point found on the tropic ♋, and from G and g, with that same interval, describe three arcs: one from G toward the other side of the meridian line, and two from g toward each side. Then, from i, the point of ♊, at the interval ik, describe an arc cutting the upper one at l; and with the same interval, from h, the point of ♋, describe two others cutting the lower ones also at l. Four points

will now have been found — two belonging to the tropic ☿ and two to the tropic ♄. In the same way we shall proceed for the remaining points of the tropic ☿, even if they do not fall on the hour-lines but lie on the tropic itself as it is described between two of the hours. This you see done at the point ☿, m: from the interval Gm, an arc is described from G toward the other side, and from g two arcs are drawn toward the other three points n. For by the interval Gm the arc described from G, and the arc described from i at the interval im, cut it at n; while the lower ones are also cut at n by two arcs described from h with the same interval, and so on.

[Margin: By what method, from the points of the northern parallels found on one side only of the meridian line, the points of the same parallel are found on the other side, together with the points of the opposite parallels. ("Qua ratio ve ex punctis parallelorū borealiū ex vna tantū parte meridianæ lineæ inuentis reperiātur pūcta eiusdē ex altera parte, vna cum pūctis oppositorū parallelorū.")]

You may also, if you wish, take in place of the points G, g two others equally distant from the points h, i — nearer, however, or farther, as seems convenient — so that the arcs described intersect one another less obliquely, and the points may thereby be found more precisely.

The same procedure is to be kept for the other parallels; only, the points G, g are not to be taken equally distant from the points h, i (the points of ☿ and ♄), but from the points of the other opposite parallels. For example, if part of the parallel of ♈ and ♍ [Taurus and Virgo] had been described through the point o, then, equal to any straight line oq, one would have to take pr, from the point p of the opposite parallel ♎ and ♏ [Scorpio and Pisces], and so on.

This finding of the points on the parallels, from the points of a single parallel described on one side only of the meridian line, was demonstrated by us in book 2 of the Gnomonics, proposition 2. The whole rests on the Conic elements of Apollonius [Apollonius of Perga], since the arcs of opposite parallels are altogether equal to one another, and the arc of each parallel has exactly the same position in the hours after noon as it has in the hours before noon.

[Margin: An easier finding of the points of any parallel. ("Inuētio facilior punctorū cuiusuis paralleli.")]

6. Now if, once the Tangents have been transferred onto the line of hour 6 — from G toward the left, and from Z onto the straight line aZa toward the right — the points of the opposite parallels are found toward the same sides to which the Tangents were transferred, then on the horizontal dial those same points are

carried over easily to the other sides. To do this, transfer the hour-intervals between the equinoctial line and the points of each parallel from the equinoctial line onto the corresponding hour-lines on the other side — that is, onto those hour-lines that recede from the meridian line by an equal amount. For example, since hours 4 and 8 are equally distant from the meridian line, if you transfer the interval of hour 4 (between the equinoctial line and the point $\mathfrak{S}$) onto hour 8, starting from the equinoctial line, you will find the point $\mathfrak{S}$ on hour 8. Likewise, if you carry the interval of hour 2 (between the equinoctial line and the point $\mathfrak{V}$) from the equinoctial line onto hour 10 — which is as far from the meridian line as hour 2 — you will find the point $\mathfrak{V}$ on hour 10, and so on. By this method the left and right parts of any parallel come out exactly alike, which must be attended to with the greatest care in describing the parallels.

[Margin: How the fore-noon and after-noon parts of any parallel come out exactly alike. ("Quo pacto pars ante-meridiana & pomeridiana cuiusuis paralleli simillimæ euadant.")]

But an opposite parallel will be described from any given parallel more precisely by the following method. Suppose the tropic $\mathfrak{V}$ is to be described from the tropic $\mathfrak{S}$. Having found the point i on the meridian, through which the parallel $\mathfrak{V}$ must pass (as was said in number 3), bisect at Aa the segment hi of the meridian lying between the two points h, i of the opposite parallels. For if from any point of the tropic $\mathfrak{S}$ — say from Ae , the point of hour 3 — a straight line Aa, Ac is extended through Aa , and if an interval Aa, Ac is taken equal to the interval Aa, Ae , then the point Ac will lie on the opposite parallel, as Apollonius demonstrated in book 1, proposition 30. And the same procedure holds for the remaining points. This route is very easy and accurate, and it applies in all dials, provided that in them the style-line is taken for the meridian. But so that not so many hidden lines need be drawn, you will do well if first, from Aa , at the interval Aa, Ae , on the opposite side (which is to be judged by eye), a small arc is described, which is then cut by a hidden straight line — namely by laying a ruler on the points Ac, Aa . This is to be understood of the other points of the northern parallels as well.

[Margin: An easy and accurate description of any parallel from its opposite. ("Descriptio cuiusuis paralleli ex suo opposito facilis, & accurata.")]

7. In another way — and indeed a very convenient one — the arcs of the signs can be described by means of the points on the meridian line found from the same table 1, if through those points lines are drawn parallel to the equinoctial line, or perpendicular to the meridian line. For each of these will cut two hours at a time, at the points of the same parallel. We shall carry the matter out by the

following device. From table 1 we shall take the arcs standing opposite each sign under the hours, in the circle of hour 12 — that is, in the row of hours to which this heading is prefixed, [Circ. hor. 12.], or which has this number, [12.], written at its right-hand side. With these same arcs we shall cut off, from the meridian line, portions that begin from the equinoctial line, that is, from the point B. For when perpendiculars to the meridian line — or lines equidistant from the equinoctial line — are drawn through the end-points of these portions, each will cut two hours (namely the two whose arcs have been cut off) at the points of the parallel in question. We shall cut off the said arcs as follows. For the northern parallels, let each arc be subtracted from the pole's altitude above the Horizon, if it can be subtracted, and let the Tangent of the remaining number — taken from the straight line whose segment EF, equal to the style, is divided into 10 particles — be transferred by compass from C, the place of the style, toward the equinoctial line. Or else let the pole's altitude be subtracted from the table-1 arc, if this can be done, and let the Tangent of the remaining number be transferred from the same place of the style toward the center of the dial. But if some arc is found equal to the pole's altitude, then the place of the style C itself will be the end of the table-1 arc. When, however, two hours are more than 6 hours distant from noon, their arc must be reckoned from the Equator below the Horizon; for the arc of the Meridian from the Equator above the Horizon up to the great circle drawn through those hours from the pole of the Meridian is greater than a quadrant, as is clear from the material sphere. Therefore to the complement of that arc — namely to the arc of the Meridian between the arctic pole and the end of the proposed arc — must be added the complement of the pole's altitude — namely the arc of the Meridian between the zenith and the arctic pole — so that the arc of the Meridian from the zenith up to the end of the proposed arc is made up; and the Tangent of the total so formed must be transferred from the place of the style beyond the center of the dial. Finally, for the southern parallels, each table-1 arc must be added to the pole's altitude, and the Tangent of the total so formed must be transferred from C, the place of the style, beyond the equinoctial line.

[Margin: How the arcs of table 1 are transferred onto the meridian line by means of the Tangents. ("Quo pacto arcus 1. tabulæ in meridianā lineam per Tangentes trāsferantur.")]

By way of example: In the circle of hour 12, under hours 1 and 11, opposite ☾ and ♊, there is found an arc of 24 degrees 14 minutes; and taking this away

(p. 27 — running header: "NOVÆ DESCRIPT.")

from the pole's altitude of 42 degrees, 17 degrees 46 minutes remain. Their Tangent, $3 \frac{3}{10}$ [numeral: ?], transferred from C downward, gives a point a little above the point $\mathfrak{S}$, at h, through which a perpendicular drawn to the meridian line will cut hours 1 and 11 at the points $\mathfrak{S}$. But the same arc, 24 degrees 14 minutes, added to the pole's altitude of 42 degrees, makes 66 degrees 14 minutes; and their Tangent, $22 \frac{7}{10}$, transferred from C downward, presents a point below the point $\mathfrak{V}$, at i, through which a perpendicular drawn to the meridian line will cut hours 1 and 11 at the points $\mathfrak{V}$.

So too, the arc of hours 4 and 8 contains 41 degrees 1 minute; and this, subtracted from the pole's altitude of 42 degrees, leaves 0 degrees 59 minutes. The Tangent of this arc, $17 \frac{1}{100}$ [numeral: ?] — that is, nearly one fifth [?] of one of the particles into which EF is divided — presents a point a little below C, the place of the style; and this is better taken by estimation than by compass. But the same arc, 41 degrees 1 minute, added to the pole's altitude of 42 degrees, makes 83 degrees 1 minute, whose Tangent, $81 \frac{5}{10}$ [numeral: ?], will give, below the equinoctial line (if the plane of the dial is large enough), a point through which a perpendicular drawn to the meridian line will give, on hours 4 and 8, the points $\mathfrak{V}$.

Again, the arc of hours 5 and 7 comprises 59 degrees 14 minutes; and if the pole's altitude of 42 degrees is taken from it, 17 degrees 14 minutes remain, whose Tangent, $3 \frac{3}{10}$, gives a point through which a perpendicular drawn to the meridian line will cut hours 5 and 7 at the points $\mathfrak{S}$. But if one of these hours is hour 5 from midnight and the other hour 7 from noon — so that they are more than 6 hours from noon — then the complement of the said arc, namely 30 degrees 46 minutes, must be added to the complement of the pole's altitude, that is, to 48 degrees. For the Tangent of the number so formed, 78 degrees 46 minutes — $50 \frac{7}{10}$ [numeral: ?] and a little more — transferred from C beyond the center G, will give (if the plane of the dial is large enough) a point through which a perpendicular drawn to the meridian line will present, on hours 5 and 7, the points $\mathfrak{S}$. But the same arc, 59 degrees 14 minutes, added to the pole's altitude of 42 degrees, makes an arc of 101 degrees 14 minutes, greater than a quadrant. Therefore its Tangent is infinite, and for that reason the points $\mathfrak{V}$ cannot be found on hours 5 and 7.

Furthermore, the arc of hours $5\frac{1}{2}$ and $6\frac{1}{2}$ comprehends 73 degrees 17 minutes; and when the pole's altitude of 42 degrees is taken away from it, 31 degrees 17 minutes are left, whose Tangent, 6, gives a point through which a perpendicular drawn to the meridian line will cut hour $5\frac{1}{2}$ from noon and hour $6\frac{1}{2}$ from midnight at the points $\mathfrak{S}$. But if the complement of that same arc of 73 degrees 17

minutes — 16 degrees 43 minutes — is added to the complement of the pole's altitude, 48 degrees, the number 64 degrees 43 minutes results, whose Tangent, $21 \frac{1}{10}$ [numeral:?] and a little more, will show a point beyond the center; and if a perpendicular is drawn from it to the meridian line, hours $5\frac{1}{2}$ from midnight and $6\frac{1}{2}$ from noon will be cut at the points $\mathfrak{S}$. Here too the points of the tropic $\mathfrak{V}$ cannot be found, because the arc of 73 degrees 17 minutes, together with the pole's altitude of 42 degrees, makes an arc of 115 degrees 17 minutes, greater than a quadrant. Exactly the same reasoning holds for the other parallels, if the arcs in table 4 opposite the other signs are used.

By this method the points of the parallel $\mathfrak{S}$ cannot be found on the line of hour 6: for if from its arc of 90 degrees the pole's altitude of 42 degrees is taken, 48 degrees remain, whose Tangent, $11 \frac{1}{10}$, gives the point G, through which the perpendicular to the meridian line does not cut the line of hour 6 but coincides with it.

For the rest, the aforesaid perpendiculars to the meridian line will be drawn easily if, once lines parallel to the meridian line have been drawn on both sides, these same Tangents are transferred onto them from the straight line CD, which is drawn through the place of the style at right angles to the meridian line. For thus, for each perpendicular to be drawn, we shall have three points — one on the meridian line, and two on the two lines equidistant from the meridian line.

8. The demonstration of this way of finding the points for the Sun's parallels on the hour-lines is evident. For the plane of the horizontal dial, together with the Equator and with the great circles drawn through the common sections of the Equator with the Horizon (or with the circle of hour 6) and through the hours in the Sun's parallels, produces parallel common sections, as we demonstrated in proposition 18 of book 1 of the Gnomonics. The aforesaid perpendiculars, being equidistant from the equinoctial line, will therefore represent those great circles; and so on the hour-lines they will mark the points through which those same circles are drawn in the Sun's parallels.

Moreover, by means of the same Tangents found in number 7, we shall very conveniently find these same points for the arcs of the signs on the hour-lines, even without drawing those lines parallel to the equinoctial. This is the way: for any given hour and sign, take with the compass the Tangent from the straight line whose segment EF is divided into 10 particles, starting at the beginning of the hour, on this condition — that with the other foot an arc is described touching the line CD (extended on both sides) but not cutting it; this will give the point sought on the hour-line. And no appreciable error will be admitted in this, if careful

diligence is used. If we use this method, we shall not need that immense table 19, computed for many elevations of the pole; rather, for all altitudes of the pole, table 1 will suffice us as a universal table — and not the whole of it, but only its middle row, to which this heading is prefixed, (Circ. horæ 12.). You see clearly, however, that this method is less safe on those hour-lines that are steeply inclined to the equinoctial and lie close to hour 6, because there the straight line CD can be perceptibly touched by several points of those lines through the arcs described at the intervals of the Tangents. On those lines, therefore, the points of the parallels are to be found by rules 1 and 2 of the following scholium, with the help of points already found on the other lines; or by the points found on the line of hour 6, as we taught in number 1 of this chapter; or by the means that will be given in number 10, and so on.

For the rest, we shall transfer these same Tangents onto the hour-lines to find the points of the parallels, even without a compass, in this way. On some thicker paper, such as royal or imperial stock, let the divisions of the line EF be made, as we said at the beginning of chapter 2. Then let the paper be cut so that the side bearing the divisions occupies its edge and serves as a kind of set-square; and let the same divisions be transferred onto another line of the same paper, parallel to the said edge, which (once the superfluous parts are trimmed away) is to occupy the other edge, in such a way that the straight lines joining the numbers 10–10, 20–20, 40–40, and so on are all perpendicular to the said edges of the set-square. For if the perpendicular passing through the numbers 10, or 20, or 30, and so on (as the size of the Tangent requires) is laid against the line CD drawn through the place of the style, and is moved to and fro until the end of the Tangent reaches the proposed hour, that outermost point must be marked as the point of the parallel.

9. But so that you may see the immense usefulness of table 1 — and thereby the marvellous benefit of the problem we demonstrated in chapter 1 — I shall prescribe a method by which the points of any parallel can be investigated, on any hour-line you please, by the arcs of that table reckoned (if you wish) from the line's intersection with the equinoctial line. Suppose, for example, that the point of the parallel γ and η [Taurus and Virgo] is to be found on the line of hour 3, by means of the arc of table 1 reckoned on the line of hour 4, and therefore by a straight line from hour 10 of the Equator (which is six hours distant from hour 4), through the end of that same

[Margin: The application of table 1 to finding the points of the parallels. ("Vsus 1. tabulæ immissus ad puncta parallelorum inuenienda.")]

— through the end of that same arc; and let the line drawn out at hour 4 represent the greatest circle drawn from hour 10 on the Equator through hour 3 in the parallel of γ [Taurus]. To bring this about, from the line of hour 4 (beginning at the equinoctial line), toward the center G, we must cut off an arc of $11^{\circ}54'$ — the arc that is found, opposite the sign γ [Taurus], under hours 3 and 5, in table 1, in the circle of hour 4 — by that same technique taught in the problem of chapter 1. From C, the place of the style, draw a perpendicular C θ to the line of hour 4, and let θu be equal to the interval CX (the line θX being taken equal to the style). This will happen if, with a circle described from G through C and cutting the line of hour 4 at f, an arc f t is taken equal to the arc Cf, and the arc described from G through D — the tip of the style — cuts the produced line Ct at u. For Ct will then be perpendicular to hour 4, and θu will be equal to the interval CX, as was demonstrated in the problem of chapter 1, number 5.

Next, once a straight line has been drawn from u through the intersection of hour 4 with the equinoctial line, describe from u an arc $\beta \gamma$ cutting that line at α . With the arc $\alpha \beta$ taken as $11^{\circ}54'$, and a straight line u β drawn cutting hour 4 at δ , the segment from the equinoctial line up to δ will be $11^{\circ}54'$, as we showed in number 2 of the same problem. Therefore a straight line drawn from hour 10 on the equinoctial line through δ will cut hour 3 at f, the point of γ [Taurus] and ϖ [Virgo]; and when produced it will also cut hour 5 at the point of the same parallel, since hours 3 and 5 have the same arc in table 1. But if the arc $\gamma \alpha$ is likewise taken as $11^{\circ}54'$, the line u γ will cut off, on the same hour 4, at ϵ , the aforesaid arc toward the southern side. Therefore a straight line sent out from hour 10 on the equinoctial line through ϵ will cut hour 3 at f, the point of the parallel of $\mathfrak{M}$ [Scorpio] and)([Pisces], which is opposite to the northern one. The same reasoning holds for the rest.

[Margin: What must be known in order that, by means of Tangents, the points of the parallels can be found in any hour, and by what method it must be done. ("Quid cognoscendū sit, vt per Tāgentes in qualibet hora inueniri possint puncta parallelorū, & qua ratione id fieri debeat.")]

If it were established to how many degrees the segment of hour 4 between θ and the equinoctial line answers, the points δ and ϵ could be found by means of Tangents. For if from this arc the arc of $11^{\circ}54'$ were subtracted, then the Tangent of the remaining number — reckoned with respect to the whole sine u θ (or CX) divided into 10 parts — transferred from θ , would give the point δ . But if to the same arc, terminating at θ , that same arc of $11^{\circ}54'$ were added, the Tangent of the total so formed would indicate to us the point ϵ . How one can find out to how

many degrees the segment of hour 4 between θ and the equinoctial line corresponds, we shall teach how to compute at the end of the little book, in problem 10. Geometrically, however, we shall learn the same thing if the arc $\alpha \beta$ is produced until it cuts the produced line $u C$ at μ . For the degrees contained in the arc $\alpha \mu$ indicate the degrees contained in the segment of hour 4 between θ and the equinoctial line, as we showed in the problem of chapter 1, number 2.

When the parallels of all the signs are wanted, it will be worthwhile to compute, by problem 10 at the end of the little book, the degrees of the segment of each hour-line lying between the equinoctial and the perpendicular drawn from the place of the style, so that the points of all the parallels may be found in any hour by means of Tangents.

Indeed, we shall achieve the same result even if we do not know to how many degrees the segment between the perpendicular and the center G corresponds. For suppose the point of both $\mathfrak{C}$ [Cancer] and $\mathfrak{V}$ [Capricorn] is to be found on the line of hour 3. With Ca drawn perpendicular to the line of hour 3, as far as the circle described through D — so that the center of the circle required in chapter 1 may be had — let the straight line $b c$ be drawn through C , the intersection of hour 3 with the equinoctial, and let a perpendicular $d e$ be raised to it through C . For if from c we transfer onto this perpendicular the tangent of the declination of $\mathfrak{C}$ [Cancer] and $\mathfrak{V}$ [Capricorn], as far as d and e , reckoned with respect to the whole sine $b c$, the lines $b d$ and $b e$ will cut off from hour 3 — beginning at c — the $23^{\circ}30'$ of the declination of $\mathfrak{C}$ [Cancer] and $\mathfrak{V}$ [Capricorn], as we demonstrated in chapter 1; and consequently these same lines $b d$ and $b e$ will cut the hour at the points of $\mathfrak{C}$ [Cancer] and $\mathfrak{V}$ [Capricorn] in the same way. If, on $b e$ produced, $a f$ is taken equal to $a b$, and a perpendicular is raised at any point to the drawn line $f c$, and onto this, on both sides, the tangents of the declinations are transferred (reckoned with respect to the whole sine between f and the said perpendicular), the points will be found through which, if lines are drawn from f , the same hour 3 will be cut at the points of the parallels.

Furthermore, once the points on the meridian for the hours have been found — as we said at the beginning of number 7 — we shall find the points of the Sun's parallels conveniently enough, in any hour, by means of secants, in this way. With respect to a whole sine equal to the segment of the meridian between the center G and the point of the proposed hour, we shall transfer the secant of the angle which the given hour makes with the meridian at the center (this angle being always the complement of the arc of table 6), from the center onto the given hour. For the outermost point will belong to the sought parallel, since the

portion of the hour-line between the center and the parallel is the secant of the said angle reckoned with respect to the said whole sine, as is clear. But if the whole sine is taken equal to the segment of the meridian between B and the same point of the given hour, then the secant of the aforesaid angle must be transferred from the point of the hour on the equinoctial, toward the side to which the said point inclines. For that portion of the hour-line is the secant of that angle with respect to the said whole sine — as is evident if, from the point of the parallel in the given hour, a line parallel to the meridian is dropped. For this line will be equal to the said whole sine, ^a and it will make with the hour-line an angle equal to the one which the meridian makes with the same hour-line.

[Margin: ^a 29.primi (Euclid, *Elements* I.29).]

And this method is easy if an instrument of 100 parts is at hand, on account of the various whole sines. And since several points are to be found on the meridian, so that no confusion may arise among them, it is expedient that on some separate sheet of paper several lines be drawn onto which the points B, G, C are transferred from the meridian. For on each of these a point can be found for any hour, so that the whole sine may serve as the secant. Likewise, for hours 1 & 11, 2 & 10, and 3 & 9, the points of the parallels will also be found exactly, if from the points found on the meridian perpendiculars to that same meridian are drawn with the help of some set-square. For these do not cut the said hours too obliquely; but in the other hours it will be safer to use secants, on account of the oblique intersections of the hours with those perpendiculars. Finally, for hour 6, one must transfer from the center G the tangent of the complement of the declination of the proposed northern parallel, reckoned with respect to the whole sine Gd.

Indeed, it is not necessary that the points be found on the meridian line, or on any other line, in order that whole sines may serve as secants; rather it is enough if, by table 1 and the altitude of the pole, the arcs are investigated whose tangents must be transferred from the place of the style in order to find the said points. For these tangents — in the northern signs subtracted from the tangent of the altitude of the pole, or added to it (according as the arcs in table 1 are subtracted from the altitude of the pole or added to it) — will leave or produce tangents which, transferred onto some line, will from any point give the whole sines to serve as the secants found by table 1 and the altitude of the pole. In the southern signs, from the tangents found by table 1 and the altitude of the pole (as we handed down in number 7), the tangent of the altitude of the pole must always be subtracted, so that the remaining tangents are produced which offer the whole

sines to serve as secants. And the secants, reckoned with respect to the whole sines found in this way, must always be transferred from the equator onto the hour-lines. This method (unless the frequent change of the whole sine seems troublesome to someone — a trouble which, however, the instrument of 100 parts removes, as we said) appears to be most elegant and most reliable.

10. VERY accurately (and this is the method that satisfies me most of all in every sundial), the points of the parallels on the hour-lines will be found from general table 2, by straight lines drawn on the equinoctial line from hour 5 in the afternoon (or 7 after midnight); or from hour 4 in the afternoon (or 8 after midnight); or from hour 3 in the afternoon (or 9 after midnight); or from hour 2 in the afternoon (or 10 after midnight) — through certain definite points of the meridian line. For example, suppose the point is to be found on the meridian line through which the straight line drawn from hour 7 after midnight cuts hour 1 at the point of ♋ [Cancer]. In table 2, under the column of hours to which is prefixed the heading [Ex H.7.à med.noc.] (From hour 7 after midnight), opposite ♋ [Cancer], hour 1 answers to an arc of $22^{\circ}47'$; and its outermost point on the meridian will be found thus. Taking that arc away from the altitude of the pole, 42° , there remains an arc of $19^{\circ}13'$, whose Tangent, $3 \frac{5}{10}$ nearly (reckoned with respect to a whole sine equal to the style), transferred from C, the place of the style, toward the equinoctial, will give the point terminating the aforesaid arc — the point through which a straight line issuing from hour 7 will cut hour 1 at the point of ♋ [Cancer]. But if the same arc of $22^{\circ}47'$ is added to the altitude of the pole, 42° , there will result an arc of $64^{\circ}47'$, whose Tangent, $21 \frac{2}{10}$ and a little more, transferred from C, the place of the style, will exhibit the point through which a straight line sent out from hour 7 after midnight will cut the same hour 1 at the point of ♏ [Capricorn].

[Margin: The accurate method of finding the points for the parallels, from table 2. ("Accuratā ratio inueniendorum punctorum pro parallelis ex 2.tab.")]

Again, suppose the points of ♋ [Cancer] are to be investigated on hours 5 and 3, from hour 4 in the afternoon. On the line [Ex H.4.à mer.] (From hour 4 in the afternoon), under hours 5 and 3, in the row of ♋ [Cancer] and ♏ [Capricorn], the arc $56^{\circ}52'$ answers. If from this the altitude of the pole, 42° , is taken away, there remains an arc of $14^{\circ}52'$, whose Tangent, $2 \frac{6}{10}$ and a little more, transferred from C, the place of the style, toward the center G, will present the point through which a straight line drawn out from hour 4 in the afternoon will cut hours 5 and 3 at the points of ♋ [Cancer]. But if the same arc of $56^{\circ}52'$ is added to the altitude of the pole, there is produced an arc of $98^{\circ}52'$, which cannot be transferred

downward from C so that the points of the same hours 5 and 3 in ♊ [Capricorn] may be found, since its Tangent is infinite. From hour 7 after midnight, however, the point of ♊ [Capricorn] can be found on hour 3. For its arc contains $25^{\circ}52'$, which, added to the altitude of the pole, 42° , makes $67^{\circ}52'$, whose Tangent, $24\frac{5}{10}$ and a little more, transferred from C, will give the point on the meridian through which a straight line sent out from hour 7 after midnight will cut hours 3 and 11 at the points of ♊ [Capricorn]. And so with the rest.

You see, therefore, that the arcs of table 2 are to be cut off from the meridian line, just as the arcs of table 1 were cut off from that same line in number 7. And this method, as I have said, satisfies me most of all — because on the meridian the points are always found in the same way, and one can choose that hour on the equinoctial which will be judged more suitable, so that from it may be drawn the straight line through the point found on the meridian, cutting the given hour at the point of the proposed parallel. We have omitted hour 1 in the afternoon and after midnight in table 2, because the meridian lines are too close together, and therefore the straight lines could be drawn through the points of the meridian from them less accurately — especially since the eight hours from which the straight lines can be drawn are sufficient.

[Margin: Wherein lies the excellence of this method of finding the points. ("In quo consistat præstantia huius rationis inueniendorum punctorū.")]

Now if of the segment of the equinoctial between the assumed hour and the meridian line you take, on the other side, one equal part, or two, or three, or more, in such a way that the straight line between the last point and the assumed hour is a multiple of the aforesaid segment; and if through the last point a perpendicular is drawn to the equinoctial: then onto this perpendicular each Tangent must be transferred which, on the meridian, begins from the equinoctial — twice, or three times, or four times, and so on, according as the straight line between the assumed hour and that last point is double, triple, and so on, of the segment between the assumed hour and the meridian line. For in this way the straight line from the assumed hour, through the point of the said perpendicular, will be drawn more exactly, since it is drawn from a remoter point.

11. WE shall also, and expeditiously, describe those same arcs by means of table 3, which is likewise general. For if, through h, the point of ♋ [Cancer], or through i, the point of ♊ [Capricorn], you draw on the meridian a perpendicular to the meridian (in our sundial, i λ has been drawn through the point of ♊ [Capricorn]), it will represent the greatest circle which, on the sphere, is drawn through the common sections of the Equator and Horizon and through the point of ♋

[Cancer], or of ♑ [Capricorn], on the meridian circle. If onto this straight line you transfer, from h or i, the arcs described in table 3 opposite the hours under the proposed sign (provided that on some straight line you take a number of parts equal to the interval h D or i D — according as the perpendicular to the meridian is drawn through h or through i — and that you divide the first of them, ξ π, into 10 equal parts), you will find the points through which, if straight lines are sent out from B, the hour-lines will be cut at the points of the proposed parallel, just as was said about the line of hour 6. Example: In table 3, opposite hours 3 and 9, under ♋ [Cancer] and ♑ [Capricorn], is found an arc of 32°58', whose Tangent, 6 5/10 nearly (reckoned with respect to the whole sine ξ π of 10 parts), from the point i will give the point λ on both sides. Therefore the straight line B λ will cut hours 3 and 9 at the points of ♋ [Cancer] and ♑ [Capricorn].

[Margin: Another way of finding the points on the parallels, from table 3. ("Inuentio alia punctorum in parallelis ex 3.tabula.")]

Again, in the same table 3, opposite the same hours 3 and 9, under the signs ♉ [Taurus], ♍ [Virgo], ♏ [Scorpio], and ♐ [Pisces], there stands an arc of 54°11', whose Tangent, 13 8/10 and a little more, will give on the straight line i λ the point ρ on both sides. Therefore the straight line B ρ will cut hours 3 and 9 at the points f, of the parallel of ♉ [Taurus], ♍ [Virgo], ♏ [Scorpio], and ♐ [Pisces]. And so with the rest.

Here too, so that for the individual hours we may have three points, another perpendicular to the meridian must be drawn, distant from the point B on the other side of the equinoctial line by as much as the perpendicular drawn through i, or through h, stands from that same point.

12. FINALLY, if from table 9 (if you wish) you take the altitudes of the hours above the Horizon, the Tangents of the complements of those altitudes (reckoned with respect to a whole sine DC equal to the style), transferred from the place of the style, will cut the hours at the points of the parallels.

The reason is that the straight line extended from the place of the style up to the point of any parallel, in any hour, is the Tangent of the complement of the Sun's altitude in that hour above the Horizon. For let the circle of altitude be A B C D, whose center is E; let B H be its common section with the plane of the sundial; and A D the common section of the same circle with the greatest circle to which the sundial is parallel; let the style be E F, and the Sun's altitude A G. Let the Sun's ray G E, passing through the center of the world, meet the plane of the sundial at H, the common section of that section with the sundial. ^a Since, therefore, the angle D E H

is equal to the angle $A E G$ of the Sun's altitude, $F E H$ will be the angle of the complement of the altitude, whose Tangent is $F H$ reckoned with respect to the whole sine $E F$; and the same reasoning holds for the rest.

[Margin: Another way of finding the points to be marked on the parallels, by means of the Tangents of the complements of the Sun's altitudes, from table 9. ("Inuentio alia punctorum in parallelis delineandis per Tangētes complementorum altitudinū Solis ex 9.tabula.")]

[Margin: ^a 15.primi (Euclid, *Elements* I.15).]

Diagram. A circle (the circle of altitude) inscribed within a rectangular frame at the lower right of the page. The circle is $A B C D$ with center E . Along the bottom runs the horizontal line $B H$ (the common section of the altitude-circle with the plane of the sundial), which extends to the right well beyond the circle to reach H . Through the center E runs the horizontal diameter $A D$ (the common section of the circle with the great circle to which the sundial is parallel). From the center E a vertical line $E F$ drops to F on the baseline (the style). A line runs from G , on the upper-left of the circumference, through the center E and continues down to the right to H on the baseline (the Sun's ray $G E$, produced to H).

- A (left, on the horizontal diameter): endpoint of the diameter $A D$
- B (lower left, on circumference and baseline): endpoint of the baseline $B H$
- C (lower right, on circumference): on the baseline
- D (right, on the horizontal diameter): endpoint of the diameter $A D$
- E (center): center of the altitude-circle
- F (bottom center, on baseline): foot of the perpendicular style $E F$
- G (upper left, on circumference): point of the Sun's altitude arc $A G$; the Sun's ray $G E$ begins here
- H (far right, on baseline, outside the circle): where the produced Sun's ray meets the plane of the sundial

CAPVT OCTAVVM.

SCHOLIVM.

[Margin: The same straight line drawn from a point of the Equator cuts two hours at points of the same parallel, or of two opposite parallels. ("Eadē recta ex puncto Æquatoris educta secat duas horas in punctis eiusdē paralleli, vel duorum oppositorū.")]

1. From general tables 1, 2, and 3, it is gathered that any straight line drawn from any hour-point on the Equator cuts, at points of the same parallel, two hours equally distant from the hour that is 6 hours from that hour-point of the Equator; or else it cuts, at points of opposite parallels, two hours receding equally on either side from that same hour-point of the Equator. For the individual arcs of the aforesaid tables answer to two hours each, as will be plain from the way in which they are computed. Excepted, however, are the first and last hours in tables 1 and 2, which stand alone. Thus in table 1 you see that the straight line drawn from B, the point of hour 12 on the Equator, through the point of ☿ [Cancer] at hour 5½ in the afternoon, also cuts hour 6½ in the afternoon at the point of ☿ [Cancer] — these hours 5½ and 6½ being equally distant from hour 6, which is 6 hours from hour 12 assumed on the Equator. By the same reasoning, the straight line sent out from B, through the point of ☿ [Cancer] at hour 5, will cut hour 7 at the point of the same ☿ [Cancer], if the size of the sundial allows it. So too you discern that the straight line drawn from I, the point of hour 7 on the Equator, through the point of ☿ [Cancer] at hour 4, also passes through the point of the same ☿ [Cancer] at hour 10; because hours 4 and 10 are equally distant from hour 1, which is 6 hours from hour 7. In just the same way, finally, you see that the straight line sent out from B, through the point of ☿ [Cancer] at hour 3, cuts hour 9 at the point of ♊ [Capricorn], because hours 3 and 9 recede from hour 12 by an equal interval in opposite directions.

2. But although, as we have said, this is clearly gathered from tables 1, 2, and 3, nevertheless, since this matter has an outstanding and notable use both in finding the points of the parallels and in testing them, I am pleased to demonstrate it geometrically as well by the following theorem.

THEOREMA.

ANY greatest circle drawn through any hour-point assumed on the Equator cuts any parallel at two points of hours equally distant from the hour-circle that is 6 hours from the assumed point; and likewise it cuts any two opposite parallels at points of hours receding equally, in opposite directions, from the assumed point of the Equator.

Let A be the pole of the world; let B C be the Equator; let D E and I K be any two opposite and equal parallels; let A K be any hour-circle cutting the Equator at C, through which let the greatest circle C F G be drawn, cutting the parallel D E at F and G, and the parallel I K at I. Finally, let A B be the hour-circle distant 6 hours from the hour-circle A C — that is, by a quadrant B C — cutting the parallel D E at D, and the greatest circle C G at H. I say that the points F and G are equally distant

from the point D on the parallel D E; likewise that the points F and I are equally distant from the points E and K — that is, that both the arcs D F and D G, and the arcs E F and I K, are equal to one another. For since the greatest circles A B and A C pass through A, the pole of the Equator B C, the Equator B C will in turn pass through the poles of the circles A B and A C, by the scholium to prop. 15, bk. 1 of Theodosius. And since, by the corollary of prop. 16 of the same bk. 1 of Theodosius, the pole of a greatest circle is distant a quadrant from that very circle, and B C is posited as a quadrant, C will be the pole of the greatest circle A B. Since, therefore, the greatest circle C G passes through C, the pole of the greatest circle A B, it will in turn pass — by [prop. 9, bk. 2] — [and] the greatest circle A B [will pass] through the poles of the greatest circle C G. It also passes through A. [By prop. 9] bk. 2 of Theodosius, the segments D F and D G will be equal. Which is the first point. For if some greatest circle passed through C and D, it would not cut the parallel D E, but would touch it at D, by prop. 3, bk. 2 of Theodosius; for then the circle D E and that greatest circle would have their poles on the greatest circle A B, which they would cut at the point D.

[Margin: ^a 28.tertij (Euclid, *Elements* III.28).]

Again, since, by prop. 18, bk. 2 of Theodosius, both the arcs C E and C K, and the arcs C F and C I, are equal, the joined chords E F and I K will, by prop. 3, bk. 3 of the same Theodosius, be equal. ^a Therefore, from equal parallels they will cut off equal arcs, E F and I K. Which is the second point.

And since a straight line drawn, on the equinoctial line, from the hour-point which answers to the point C, through the point of any parallel, represents the greatest circle drawn from the point C, it is clearly established — as we gathered from tables 1, 2, and 3 at the beginning of this scholium.

Diagram. A spherical construction. At the top is the point A (the pole of the world). From A two great-circle (hour-circle) arcs splay downward: one on the left, descending through H to B; the other on the right, descending through C to K. The arc B C at the lower part is the Equator. Two concentric-appearing parallel arcs cross the figure: the upper parallel D E (from D, center, to E, at the right) and the lower parallel I K (from I to K). A further greatest circle C F G runs through C, F, and G.

- A (top): pole of the world
- G (upper left, on circumference): where the greatest circle C F G meets the upper parallel region
- H (upper center): where the hour-circle A B cuts the greatest circle C G

- E (right, on the upper parallel): endpoint of the parallel D E
- F (center-right, just below E): where the greatest circle C F G cuts the parallel D E
- D (center): where the hour-circle A B cuts the parallel D E
- B (lower left-center): foot of the left hour-circle, on the Equator
- C (right): where the hour-circle A K cuts the Equator
- I (lower right): where the greatest circle C F G cuts the parallel I K
- K (bottom right): foot of the right hour-circle, on the parallel I K

[Margin: Three most useful rules for finding and testing, by the hours, the points of the parallels. ("Tres regulæ vtilissimæ ad puncta parallelorū horis inuenienda & examinanda.")]

3. FROM this are derived the following three rules, which contribute very much to both finding the points of the parallels and testing them — namely, whether they have been correctly found or not.

I. REGVLA.

[Margin: Rule 1. ("1.Regula.")]

WHEN in some hour the point of any parallel is given, and it is proposed to investigate from it the point of the same parallel in any other given hour, one must take the hour-point on the equinoctial line that is 6 hours from the hour which holds the middle place between the two given hours. For the straight line sent out through the assumed point on the equinoctial and through the given point on the parallel will pass through the sought point in the other given hour, if it cuts that hour; otherwise it will give, in that hour, the point of the opposite parallel, as is clear from the preceding theorem.

[Margin: By what method the hour that is 6 hours from another given hour is found. ("Qua ratione eruatur hora distas 6 horis ab alia hora data.")]

For example, if the point of ☊ [Cancer] is given at hour 12, and the point of the same ☊ [Cancer] is sought at hour 5. Since hour 2½ is the mean between hours 12 and 5, and hour 8½ is 6 hours from hour 2½ — (the hour that is 6 hours distant from another given hour will be found more quickly than said, [continues]

—continuing Rule I (*I. Regula*), the worked example begun on the previous page:

is distant, if from the given hour one subtracts 6, having first added 12 in case the subtraction cannot otherwise be made; or, alternatively, if one adds 6 to the given

hour, and then adds 12 to the sum, should it be the larger course that is needed. For instance, since in the proposed example the hour distant 6 hours from hour $2\frac{1}{2}$ is sought, add 12 (making $14\frac{1}{2}$) and subtract 6 from that sum; or else add 6 directly to the given hour $2\frac{1}{2}$. (Either way you arrive at hour $8\frac{1}{2}$.) Then a straight line must be drawn from hour $8\frac{1}{2}$ on the equinoctial line through the point of ☿ [Cancer] at hour 12. This line will give the sought point of the same ☿ [Cancer] at hour 5.

So too, if from the same given point of ☿ [Cancer] at hour 12 one seeks the point of the same ☿ [Cancer] at hour 8: since hour 10 is the mean between hours 12 and 8, and hour 4 is distant 6 hours from hour 10, a straight line drawn from hour 4 on the equinoctial line through the point of ☿ [Cancer] at hour 12 will cut hour 8 at the point of the same ☿ [Cancer].

II. REGVLA.

[Margin: Rule 2. ("2. Regula.")]

WHEN the point of any parallel is given at some hour, and it is proposed to investigate from it the point of the *opposite* parallel at any other given hour, one must take the hour-point on the equinoctial line that holds the middle place between the two given hours. For a straight line drawn from the given point of the parallel through that point of the equinoctial line will cut the other given hour at the sought point of the opposite parallel, if it cuts that hour; otherwise it will give, at that hour, the point of the same parallel, as is clear from the preceding theorem.

For example: if from the given point of ☿ [Cancer] at hour 5 (reckoned from noon) one seeks the point of ♊ [Capricorn] at hour 10 (reckoned from midnight) — since from hour 10 up to hour 5 there are counted 7 hours, whose half is $3\frac{1}{2}$, one must take the point between hours 10 and 5 that is distant $3\frac{1}{2}$ hours from either hour 5 or hour 10, which is the point at hour $1\frac{1}{2}$. For a straight line sent out from the point of ☿ [Cancer] given at hour 5, through hour $1\frac{1}{2}$ on the equinoctial line, will cut hour 10 at the point of ♊ [Capricorn].

III. REGVLA.

[Margin: Rule 3. ("3. Regula.")]

WHEN the point of any parallel is given at some hour, together with an hour-point on the equinoctial line, and it is asked at which hour, from these two, the point either of the same parallel or of the opposite one may be found, we proceed

thus. If the point of the *opposite* parallel is to be investigated, one must count off from the given hour on the equinoctial line, in the contrary direction, as many hours as the given hour in the parallel is distant from that same equinoctial hour. For a straight line sent out from the given hour in the parallel through the given hour on the equinoctial line will give, at the counted-off hour, the point of the opposite parallel, if it cuts that hour in the sundial, as is established by the second part of the preceding theorem; otherwise it will cut that same counted hour at the point of the same parallel, as is established by the first part of that theorem. But if the point of the *same* parallel is to be sought, one must take the point distant 6 hours from the given point on the equinoctial line. For a straight line drawn from the point given on the equinoctial line through the given point in the parallel will give the point of the same parallel at that hour which is distant, on the other side, from the point taken on the equinoctial line by just as much as the given point of the parallel is distant from it — provided it cuts that hour, as is manifest from the first part of the preceding theorem; otherwise it will give the point of the opposite parallel at that same hour, as is clear from the second part of the same theorem.

For example. Let the point of ♋ [Cancer] be given at hour 4, and a point given at hour 1 on the equinoctial line. If, then, it is asked at which hour the point of ♏ [Capricorn] may be found from these two given points: since hour 4 stands off 3 hours from hour 1, and hour 10 likewise stands off from that same hour 1 by three hours, a straight line running from hour 4, ♋ [Cancer], through hour 1 on the equinoctial line will give the point of ♏ [Capricorn] at hour 10.

Again, let the point of ♋ [Cancer] be given at hour 3, and a point at hour 10 on the equinoctial line. If it is asked at which hour the point of the same ♋ [Cancer] may be found from the two given points, one must take the point at hour 4, distant 6 hours from the point given at hour 10 on the equinoctial line. For a straight line drawn from this given point at hour 10 through the point of ♋ [Cancer] given at hour 3 will yield the point of the same ♋ [Cancer] at hour 5 — which is distant from the assumed hour 4 by just as much as the given hour 3 is removed from that same hour.

If these are read through with attention, it is incredible how useful they will prove both for finding the points of the parallels precisely and for testing those already found. For, from a single given point of any parallel, nearly all the others will be found, both in the same parallel and in the opposite one, by the three rules above. Thus, if the point of ♋ [Cancer], say, is given at hour 12, from it the point of the same ♋ [Cancer] at hour 6 will be found by the straight line drawn from hour 9 on the equinoctial line through the given point at hour 12, as Rule 1 prescribes.

Likewise the point of ♋ [Cancer] at hour 5, by a straight line sent out from hour 8½ on the equinoctial line through the same point given at hour 12. So too, from the point of ♋ [Cancer] at hour 5 the point of ♏ [Capricorn] at hour 3 will be found, by a straight line drawn from the given point at hour 5 through hour 4 on the equinoctial line; and likewise the point of ♏ [Capricorn] at hour 2, by a straight line drawn from that same point at hour 5 through hour 3½ on the equinoctial line; and so on.

Once the points of the parallels have been found, you will test whether they have been correctly found, by the same rules. [Margin: In what way the found points of the parallels are to be tested. ("Quo modo examinanda sint pūcta parallelorum inuenta.")] For if, say, a straight line drawn from the point at hour 8 into the equinoctial line, through the point of ♋ [Cancer] at hour 12, passes through the point of ♋ [Cancer] at hour 4, this is proof that those two points, at hours 12 and 4, have not been badly found. The same you will say of the point at hour 5 in the parallel of ♋ [Cancer] and the point at hour 10 in the parallel of ♏ [Capricorn], if the straight line joining them passes through hour 1½ on the equinoctial line — from which both given hours, namely 5 and 10, are removed by an equal interval. And so with the rest.

CAPVT IX.

ARCVS SIGNORVM IN HOROLOGIO HORIZONTALI horarum à mer. & med. noc. alio modo.

(The arcs of the signs on a horizontal sundial, for the hours reckoned from noon and from midnight, by another method.)

1. On any line that issues from the center of the sundial — representing, of course, the greatest circle drawn through the poles of the world, even though it marks off neither a whole hour, nor a half, nor a quarter of an hour — we shall find the points of all the parallels geometrically by the following device.

[Margin: Where the computation of the declinations of the points of the ecliptic is taught. ("Vbi doceatur supputatio declinationum punctorum Eclipticæ.")]

Let AB be the meridian line; A the center of the sundial; CD the stylus, perpendicular, at its base C, to the meridian line; AD the axis of the world; BE the equinoctial line; AF the line of hour 6 — and any other line issuing from the center A that cuts the equinoctial line at E. From A, let there be described through

C and D the two circles CF and DG. First let the points of the parallels be found in the meridian line. Having drawn a straight line from D through B, the intersection of the meridian with the equinoctial, and having described from D the circle IHK equal to some quadrant (so that any number of degrees of arc may be transferred onto this circle), let there be counted from H, on either side, the declinations of the Sun at the beginnings of the signs; and let HI be the declination of ♋ [Cancer]; HL that of ♊ [Gemini] and ♌ [Leo]; HM that of ♉ [Taurus] and ♍ [Virgo]; HO that of ♏ [Scorpio] and ♐ [Pisces]; HN that of ♏ [Sagittarius] and ♒ [Aquarius]; and finally HK that of ♐ [Capricorn]. For the hidden straight lines drawn from D through the ends of the declinations — that is, the "rays" of the signs (for so we named those straight lines in the *Gnomonics*) — will cut the meridian at the points of the parallels. How to compute the declination of any point whatever of the ecliptic we shall teach at the end of this little book, in Problem 1. At the beginnings of the signs, however, the declinations, drawn from the table of declinations set down in Chapter 2 of the *Sphere*, stand as follows.

Declinationes principiorum signorum.

(Declinations of the beginnings of the signs.)

	(♈ M)				(♉ M)				(♊ M)				(♋ M)			
Signa	♈ ♌ (G.)	♌	♊ ♍ (G.)	♍	♉ ♏ (G.)	♏	♊ ♐ (G.)	♐	♈ ♒ (G.)	♒	♉ ♑ (G.)	♑	♋ ♒ (G.)	♒	♌ ♑ (G.)	♑
Declinati	0	0	11		3	20		1	23		3		1	23		3
ones					0			2			0		2			0

Diagram. A large horizontal-sundial construction figure enclosed in a square frame. The vertical meridian line AB runs down the middle: S is high on it (top), A is the center of the sundial (middle), C is below A, and B is toward the lower center. Two concentric circles are drawn about A (the circles CF and DG of the text), with the smaller inner circle carrying several close-set labels near the center (among them P, R, and a small point-cluster). To the right of A lies F (on the equinoctial region), and D just below-right of C. To the lower left, E sits on the equinoctial line and, below it, the stacked labels I and L. Sweeping arcs at the left and lower part of the frame carry X (upper left), V (left middle), T (left), M, O, N (lower center), K (lower right), and Z (lower left) — these belong to the circle IHK and the declination arcs, with H low on the meridian side. Toward the right, a second V and the point Y stand near the equinoctial line, and a fan of dotted rays

runs out to a column of small zodiac glyphs marking the signs' parallels (♈, ♉ and others) with small italic letters (d, e, f, m, x) beside them.

- A (center): center of the sundial [centrum horologii]
- B (lower center, on meridian): intersection of meridian with equinoctial
- C (center, below A): base of the stylus CD
- D (center, right of C): upper end / vertex region of the stylus (axis of the world AD)
- E (lower left, on equinoctial line): where a line from A cuts the equinoctial
- F (right of A): endpoint of circle CF
- G (upper left, on circle DG): the sought ray-center point G
- H (lower, meridian side): start-point (0° declination) of circle IHK
- I, L (lower left, stacked): declination points on the circle IHK (arcs HI, HL)
- K (lower right): end-point of the greatest declination arc HK (♊)
- M (lower center): declination point (arc HM)
- N (bottom center): declination point (arc HN)
- O (lower): declination point (arc HO)
- P, R (inner circle, near center): construction points (PG, CP of §2)
- S (top, on meridian): endpoint of the diameter of circle DG
- T (left): point on the outer arc / circle
- V (left middle) and V (right, near equinoctial): endpoints of the perpendicular SV [two "V"-marks appear — see note]
- X (upper left): point on the outer sweeping arc
- Y (right, near equinoctial): where a ray cuts AT beyond the center
- Z (lower left): terminus of a ray beyond the center
- Right-hand ray-cluster: small zodiac glyphs of the signs' parallels (♈, ♉, and further worn glyphs) with small italic letters d, e, f, m, x [several of these small glyphs/letters are not fully legible — [?]]

[Note: numerous small peripheral labels (the inner-circle cluster, the right-hand zodiac-glyph ray labels, and the doubled "V") could not all be resolved with confidence, even under magnification.]

Marginalia beside the demonstration: [Margin: Where the geometric finding of the declinations is handed down, and where in this little book it is treated. ("Inuentio declinationū Geometrica vbi tradita sit, & vbi in hoc libello tradatur.")] [Margin: In what way the points of the parallels in the meridian line are to be found. ("Puncta parallelorū in meridiana linea quo pacto reperiantur.")]

DEMONSTRATION. The practice just described is plain. For if the triangle ADB is imagined to be moved, together with the whole figure of the rays, about AB, until it coincides with the meridian, then DB will be the ray of the Equator, and the other straight lines issuing from D will be the rays of the other signs — so that, produced beyond D, they would cut the celestial meridian in the parallels of the signs. For this reason the rays of the Sun, when it stands in the meridian at the beginnings of the signs, will meet the meridian line at the points exhibited by the straight lines DI, DL, and so on.

In what way, moreover, the declinations of the signs are to be found geometrically, so that through them the rays of the signs may be drawn, we have handed down in Book 1 of the *Gnomonics*, Proposition 1, and in the scholium to Canon 3 of Book 3 of the *Astrolabe*, and in other places; and we shall repeat it briefly in the scholium to Chapter 15, Number 2.

2. Next, let these same points be found on the straight line AE, which cuts the equinoctial line at E. From C, the base of the stylus, let the perpendicular CP be drawn to it; and on CP produced let PG be taken equal to the straight line that would be drawn from D — the vertex of the stylus holding its proper position — to P. This will easily be done if, on the straight line

—a straight line [is taken] equal to the arc CR (between C and the line AE), as far as Q; and, the straight line CQ being joined, let it be produced up to the circle DG. For this line will be perpendicular to AE, and PG will be equal to the straight line drawn from P to the vertex of the stylus, D, holding its proper position, as we demonstrated in Chapter 1, Number 6. Then, having drawn a straight line from G through E — the intersection of the given line AE with the equinoctial — and having described from G a circle equal to the earlier circle IK, let the declinations HI, HL, HM, and so on, be transferred from this circle into that one. For the straight lines from G through the ends of the declinations, sent out, will cut the line AE at the points of the parallels — which I demonstrate thus.

Let the stylus, together with the axis, be understood in its proper position — that is, in the plane of the meridian; and, the straight line AG being drawn, let the triangle AGE be conceived as moved about AE, together with the whole figure of the rays issuing from G, until the point G touches the stylus. (It will necessarily touch it, because the straight line PG, in that motion, always lies in the plane erected through the stylus and drawn through the straight line CG.) [Margin: a. Euclid, *Elements* I.19 ("19. primi").] The point G will necessarily fall onto the point D, because of the equality of the straight lines PG and PD. For if it fell below D, or above, AG would be less or greater than AD or PD. The straight line GE too will

coincide, in that position, with the straight line DE. Since, then, DE is the common section of the Equator and of the greatest circle that produces the line AE on the sundial — because each circle passes through D, the center of the world, and meets the plane of the sundial at the point E — GE too will be, in that position, the ray of the Equator; and therefore the rays of the other signs, from D or from G (which in that position is the same thing), when sent out, will cut the line AE at the points of the parallels. And since these same rays cut the line AE always in the same manner, however the triangle AGE is carried about AE, it is clear that the rays sent out from G cut the line AE at the points of the parallels.

3. Finally, let these same points be sought on the straight line AT of hour 6 — which represents the greatest circle passing through the poles of the world and through the intersections of the horizon with the Equator, and which is parallel to the equinoctial line. [Margin: In what way the points of the parallels on the line of hour 6 are found. ("Puncta parallelorum in linea horæ 6. quo pacto inueniantur.")] Through one or other end of the diameter of the circle DG — say, through S — let a line be drawn with the ray of the Equator. And having described from S, on either side, a circle equal to the circle IK, let the declinations HI, HL, HM, and so on, be transferred from this into it. For the straight lines from S, drawn through the ends of the declinations, will cut the line AT at the points of the parallels — which is demonstrated as follows.

Let a plane drawn through AS and AT be conceived as carried about AT, until the straight line SA coincides with the straight line DA (the triangle ADC being placed in its proper position), and the point S with the point D, because of the equality of the straight lines SA and DA — so that it lies in the plane of the circle of hour 6, since this circle passes through the axis DA and makes, with the plane of the sundial, the straight line AT, parallel to the equinoctial, by Proposition 18 of Book 1 of the *Gnomonics*; because the plane of the sundial is equidistant from the common section of the Equator and the circle of hour 6. [Margin: b. ("19. vnde." — proposition-number and abbreviation uncertain [?]; cf. *Elements* XI, def. 3 cited in the text).] And since the common section of the circle of hour 6 and the Equator is at right angles to the meridian — because each circle is perpendicular to it, passing through the poles — that same common section SV will also, by definition 3 of Book 11 of Euclid, in that stated position (the point S being placed at D) be the ray of the Equator. The rays, then, of the other signs, issuing from D or S in that position, will cut the line AT at the points of the parallels. And since these same rays cut the line AT always in the same manner, however the plane drawn through SA and AT is turned about the line AT, it is evident that the rays sent out from S cut the line AT at the points of the parallels.

That this whole finding of the points, by which the parallels of the Sun are to be described, can be most clearly demonstrated from the problem of Chapter 1 — for since the parallels of the Sun cut, on the sphere, the colures or the meridian, and likewise all the greatest circles drawn through the poles of the world, into arcs, namely, of the declinations, by Proposition 10 of Book 2 of Theodosius; and since, by the practice set out in this chapter, there are cut off from the straight lines AB, AE, AT segments equal to the declinations, as is manifest from the aforesaid problem — it is plainly established that the points of the parallels are rightly found in this way.

4. When a straight line drawn through the center A cuts the equinoctial line — such as the line AE — the point G, from which the rays of the signs are to be drawn out, will be found also by this way. [Margin: Another way of finding the center from which the rays of the signs are to be sent out. ("Alia inuentio centri, è quo radij signorum emittendi sunt.")] From R, the midpoint of the segment AE between the center and the equinoctial, let a circle be described through A, cutting the circumference DG at the point G, which will be what was sought.

For EG will be tangent to the circle DG at G, as is established from what we demonstrated in the scholium to Proposition 31 of Book 3 of Euclid; [Margin: c. Euclid, *Elements* III.18 ("18. tertij").] and therefore the angle AGE will be a right angle. But the angle ADE is likewise a right angle at the top (the stylus DC being placed at right angles to the plane of the sundial), as I shall show. Therefore, since the two sides AG, AE are equal to the two sides AD, AE, and have the right angles G and D equal, subtended by the common side AE; and since each of the remaining angles AEG, AED is less than a right angle, by Corollary 1 of Proposition 17 of Book 1 of Euclid — the bases GE, DE will also (by the scholium to Proposition 48 of Book 1 of Euclid) be equal, and the remaining angles EAG, EAD equal. Therefore, the triangle ADB holding its proper position — so that the straight line DE is drawn up from the height to E — if the triangle AGE is revolved about AE, AG will coincide with the axis AD, and the point G with the point D, because of the equality of the angles EAG, EAD and of the straight lines AG, AD. Hence, as was demonstrated above, the rays sent out from G will cut the line AE at the points of the parallels. That the angle ADE is a right angle I demonstrate thus. Since DE, in that position, is the common section of the Equator and of the circle that makes the hour-section AE, as has been said; and since the axis AD is at right angles to the plane of the Equator — it will be perpendicular also to the straight line DE, which lies in the Equator, by definition 3 of Book 11 of Euclid.

5. But if it should happen that some ray does not cut the straight line drawn out from the center A on the same side where the other rays cut it, that ray will cut the same line on the other side of the center of the sundial. [Margin: What is to be done when not all the rays cut the same line drawn out from the center on the same side. ("Quid fiat, quando nō omnes radij secant eandem rectam ex cētro eductā, ex eadē parte centri.")] Thus, since the ray SX does not cut the line AT on the side toward T, that ray will cut the line AT beyond the center, at Y. For the same reason, if, for example, the ray GZ did not cut the line AE toward the equinoctial line, it would cut it beyond the center A, produced.

6. When, moreover, the center of the sundial is scarcely available — as happens in horizontal sundials of regions that have a small elevation of the pole, such that the circles CF, DG cannot be described from it — the point G, from which the rays are to be sent out, will have to be found by this method. [Margin: When the center of the sundial is not available, what is to be done. ("Quando cētrum horologij nō habetur, quid agendum.")] Having drawn CP perpendicular to AE, let Pa be taken equal to the stylus, and with the interval Ca let the straight line PG be cut off. For the point G will be that from which the rays are to be drawn out, which cut off from AE the declinations of the signs, as is clear from the problem of Chapter 1.

SCHOLIVM.

1. This finding of the points prescribed in this chapter (which is indeed proper to the hours reckoned from noon or from midnight) will be most expeditious if three compasses are at hand, with which the intervals of the declinations HI, HL, HM are once for all taken precisely. [Margin: In what way the practice of this chapter is made easier. ("Quo pacto praxis huius cap. redditur facilior.")] For, having described the hidden circles from D, G, S, and from the other points found in the manner in which the point G was found, which are to be equal to the circle IK,

— in which the intervals of the declinations were taken, then, faster than can be told, the declinations will be transferred onto those points, since those three compasses are kept opened to the same setting throughout.

[Margin: The construction of an instrument for the practical work of this chapter. ("Instrumēti constructio pro praxi huius capituli.")]

2. This same finding will also be made easier if the figure of the rays DIK is drawn separately on thin brass [Orichalcum] or on stiffer paper, and the points I, L, M,

H, O, N, K are pierced most finely, and at the center — the meeting-point of the rays D — a very sharp little pin is fixed, or else the point D itself is likewise pierced. For, on the sundial, once (say) the point G has been found and the hidden straight line GE drawn, if — by means of that little pin or of the hole D — the figure of the rays is set up at G, with the ray of the Equator DH coinciding with the straight line GE, and if some very fine needle is passed through the holes I, L, M, and so on, and the points marked, then the hidden rays of the signs must be drawn through these very points, cutting the hour-line at the points of the parallels. The same figure of the rays must be fixed at the point D, the ray of the Equator DH coinciding with the straight line DB, so that the points of the parallels may be found on the meridian line. And finally the same figure must be fixed at S, the ray of the Equator DH coinciding with the straight line SV — the line equidistant from the 6-o'clock line — so that the same points may be found on the 6-o'clock line.

Diagram. A horizontal-sundial construction (Chapter IX) enclosed in a rectangular frame. A large quarter-circle arc sweeps from the upper left down to the lower part of the frame. Radiating rays (drawn as dotted lines) fan out from the central region, cutting the arc and the hour-lines; a row of zodiac sign-glyphs is set along the rays on the right-hand side. Readable Latin letter-labels:

- X (top left, on the arc)
- V (upper left, on a horizontal line) and V (upper right) — the figure carries two V labels, one on each side
- S (center-top, at the crossing of the vertical and a horizontal line)
- T (left, on the arc)
- A (center of the dial, within a small circle; center of the horologe)
- G (just left of A, within a small circle)
- F (just right of A)
- P, C, R, b (small labels clustered just below A, on the axis)
- E (left of center, on a horizontal line) and a (small, near center)
- B (center, on the lower horizontal line)
- D (center-right)
- I, L (lower left); M, H, O, N, K (descending along the lower left / bottom)
- Z (bottom left)
- Y (upper right, near the zodiac row)

- A row of zodiac sign-glyphs runs down the right-hand rays, with several small lower-case letters (d, f, e, m, x) interspersed. Most of these sign-glyphs will not resolve at this resolution — [?].

[Margin: Another use of the instrument just constructed. ("Instrumēti proxime constructi alius vsus.")]

3. But if, in the figure of the rays DIK, a perpendicular axis AD is drawn to the ray of the Equator DH — extended in both directions, with the superfluous surrounding parts cut away so as not to obstruct — then the instrument will be ready with which we shall obtain the same points of the parallels, even without having the point G together with the straight line GE. For if on the axis the straight line DA is taken from the point D, equal to the axis of the sundial between the center and the tip of the stylus, and its end-point is fixed at the center A of the sundial — whether by some little pin fixed at A, or by a needle passed through the hole A — and the instrument is turned about until the ray of the Equator passes through the intersection of the equinoctial line with the hour-line on which the points are to be sought, then we shall mark the points, as before, through the holes I, L, M, and so on; and straight lines drawn out from G (the point G being likewise marked through its hole) will cut the hour-line at the points of the parallels. Nor does it matter whether the holes of the instrument lie below the point G, toward the hour-line AE, or above it. Yet this will be done more conveniently if, once the point G has been found, the straight line GE is drawn first, so that we may lay the ray of the Equator upon it — lest we be forced to superimpose the ruler on that same ray and turn the instrument about until the ruler passes through the intersection E. But so that the points on the straight line AT, perpendicular to the meridian, may be found, the instrument must be set so that its axis coincides with the meridian line and the ray of the Equator is equidistant from the line AT.

[Margin: By this same method the points of the diurnal arcs are also found, if their rays are drawn out from D. ("Hac eadē via inuientur etiam puncta arcuum diurnorum, si eorū radij ex D, educantur.")]

4. To these rays of the signs you may also, if you like, add the rays of the diurnal arcs of your region — especially those of the 10th and 14th hours, likewise the 8th and 16th, and the 6th and 18th, and finally the 0 and 24 (which we treated in the *Gnomonica*) — so that by them, besides the points of the parallels, points may also be marked on the hour-lines for the hours from sunrise and from sunset that are easily to be described, as we taught in the *Gnomonica*.

[Margin: The finding of the points for the parallels by means of tangents.
("Inuentio punctorum pro parallelis per Tangentes.")]

5. But now, if by Problem 10 at the end of the little book the arc of any circle whatever running from noon or from midnight — the arc between the arctic pole and the vertical circle that stands at right angles to that circle — is computed, we shall find the points of all the parallels on any hour-line most exactly by tangents, in this way. Let the 3-o'clock line from noon be AE. The aforesaid arc, then, will comprise the arc to which corresponds the straight line AP for the latitude of Rome, $38^{\circ}9'$. When this is subtracted from the complement of the declination of ϖ (Cancer), $66^{\circ}30'$, there remains the arc of $28^{\circ}21'$ between P and the parallel ϖ , whose tangent — 5 [numeral:? — stacked fraction not legible], with respect to the whole sine PG — transferred from P, will give on AE the point ϖ . Moreover, in the southern parallels the complement of the found arc AP must be added to the declination of the parallel, so that the arc between P and the proposed parallel may be produced, and so on. In the same way, when the proposed hour lies above the 6-o'clock line AT, the same found arc must be added to the complement of the declination of the northern parallel. Thus, if EA were produced beyond the center A so as to be the 3-o'clock line from midnight, the aforesaid arc of $38^{\circ}9'$, added to the $66^{\circ}30'$ of the complement of the declination of ϖ (Cancer), would make an arc of $104^{\circ}39'$, which is included between P and the tropic of

ϖ (Cancer), and the 3-o'clock line from midnight — which, since it exceeds a quadrant, could not be cut off, and so the point ϖ could not be marked on the 3-o'clock line from midnight. On the 6-o'clock line that arc is nothing, and so the tangent of the complement of the declination of the northern parallel, with respect to the whole sine AD, transferred from A in both directions, will give the points ϖ . But on the meridian line AB the aforesaid arc AC is equal to the complement of the pole's altitude; and when this is subtracted from the complement of the declination of the northern parallel, or when its own complement is added to the declination of the southern parallel, the arc between C and the proposed parallel will be found. And whenever it should happen that the complement of the declination of the northern parallel is less — say, than the found arc AP — this complement must be subtracted from the found arc AP, so that the remaining arc between P and the proposed parallel, toward the center A, may be produced.

There are, in all, five whole sines [required], on account of the five hour-lines distinct from the meridian, together with the line of the sixth hour — a matter that will be no trouble if a hundred-part instrument is at hand. But if you would

rather transfer the tangents from the Equator onto the hour-lines, you must subtract each arc found by Problem 10 from 90° , and take away from the tangent [of the whole] the tangent of the remaining arc — the one previously found, namely the one that was transferred as a perpendicular from the point P. For the remaining tangent, transferred from the Equator toward the center A, will give the point of the northern parallel; and if you likewise take away the tangent of the remaining arc from the tangent to be transferred from P for the southern parallels, the tangent that remains, transferred downward from the Equator, will give the point of the southern parallel.

Furthermore, so that we may not be forced to erect perpendiculars from C (in place of the stylus) to all the hour-lines, and to assume for each one separately the several whole sines, the segments of all the hour-lines between A (the center) and the parallels must be reckoned as tangents with respect to the whole sine CD, equal to the stylus, as we shall teach at the end of the little book in Problem 17. By this reasoning we computed Table 19 for latitude 42° . If from it the tangents are taken under the signs opposite the hours and, with respect to the whole sine CD, are transferred from A, the center of the sundial, onto their proper hour-lines, the points of the parallels will be found most accurately, since no compass cuts any hour-line obliquely. So this method is the most excellent of all, provided that for the given pole-altitude a table similar to our Table 19 has been computed for latitude 42° . For example, in Table 19, under $\mathfrak{S}$ (Cancer), opposite the 3rd hour from noon and the 9th from midnight, is found the tangent 1557 — that is, 15 [numeral:? — stacked fraction; restates as $57/100$] and a little more — which, with respect to the whole sine CD equal to the stylus, transferred from A, will exhibit at the 3rd and 9th hours the points $\mathfrak{S}$; and so for the rest. But if the tangents of the northern parallels of Table 19 are taken from the tangents of the Equator, or if from the tangents of the southern parallels the tangents of the Equator are taken away, there will remain tangents which, transferred from the points on the hour-lines in the Equator onto the hour-lines, will give the points of the parallels, as before.

[Margin: A most excellent finding of the points for the parallels by means of tangents — reckoned with respect to the whole sine equal to the stylus — to be transferred from the center of the sundial. ("Inuentio praestantissima punctorum pro parallelis per Tangentes respectu sinus totius stylo aequalis, ex centro horologij transferendae.")]

CAPVT X.

The arcs of the signs on a horizontal sundial, in yet another way, for the hours from noon and from midnight. (ARCVS SIGNORVM ALIO ITEM MODO in horis à mer. & med. noc. horologij horizontalis.)

1. Let there be, as in the foregoing, the meridian line AB; the center of the sundial A; the axis AD; the stylus DC; the equinoctial line through B, and the 6-o'clock line through A, both perpendicular to the meridian; and the remaining hours drawn out through the points found on the equinoctial. Let there also have been found, on the meridian, the points of the parallels, as was said in Number 1 of the preceding chapter — namely E, ☊; O, ♀ and ♁; P, ☋ and ♎; B, ♍ and ♋; Q, ♌(?) and ♉; R, ♊(?) and ♏; and S, ♏. From these we shall find

Diagram. The horizontal-sundial figure for Chapter X, in a rectangular frame. A large quarter-circle arc runs from the top-left corner down toward the bottom; the meridian AB is the vertical line, with the center A near the top of it and M at its foot. Hour-lines radiate from A and are numbered along the arc and the frame. Readable labels:

- Z (top-left corner, on the arc)
- a, then 6 (small labels on the left edge, below Z); a cursive letter (read as k(?)) in the upper-middle
- N (top, on the meridian, above A) and A (center of the dial)
- G, F, C, E, O, P (small labels descending on the axis just below A)
- I, K, D (a small triangle to the right of A)
- T, L, V (left of center); H (further left, on a horizontal line)
- B (on the meridian, below the center)
- Q, R, S (descending on the meridian toward the foot)
- M (foot of the meridian)
- Hour-numbers along the arc / bottom edge: 7, 6, 5, 4, 3, 2, I (=1), 12 (printed "I 2")

the points of these same parallels on the other hour-lines, in this way. Suppose, for example, that the points of the parallel ☊ (Cancer) are to be found. From its point E, found on the meridian, draw a perpendicular EK to the axis, and cut off EG equal to it — whether toward A or toward B. Then, with a circle described from G at the interval GE, divide its quadrant ET into 6 equal hours, and transfer one of them upward from T. Next, on the straight line BD, take BF equal [to it], toward

[Margin: An ingenious drawing of the parallels. ("Descriptio parallelorum artificiosa.")]

that side on which the point G lies; and from F, through the hours of the circle ET, let hidden straight lines be drawn out. For these, being the answering hour-lines, will cut [the axis] at the points of the parallel $\mathfrak{S}$. So you see that the straight line drawn from F through V — the 4-o'clock line — cuts the 4-o'clock line at L, the point $\mathfrak{S}$, and so on. In just the same way, if a straight line equal [to the perpendicular] is taken on the meridian from the perpendicular drawn from O to the axis at the points Π and $\mathfrak{Q}$, and if from its far end a circle is described through O, likewise cut into hours, and from the same point F straight lines are sent out through the hour-points, the hour-lines will be cut at the points Π and $\mathfrak{Q}$. And so with the rest.

[Margin: The drawing of a larger circle, to be divided into hours, from a center other than the center of the parallel. ("Descriptio circuli maioris in horas diuidendi, ex alio centro, quàm ex centro paralleli.")]

2. But since, as you see, the circle ET is so small — which must be said of the others too, described through O, P, Q, R, S — that scarcely without error can straight lines be drawn from the point F through its points, because of their nearness, we shall describe a circle of some larger size, so that the lines drawn from F through its arcs, similar to the arcs of the circle ET, may also pass through the arcs of the circle ET. We shall find the center and radius of this circle as follows. Take FM as any multiple whatever of FE (in the example it is taken sixfold), and MN an equal multiple of EG; then N will be the center found, and NM the radius. For if a circle is described from N through M and divided into hours, just as the circle ET was divided, the straight lines drawn from F through the hours of this newly described circle will pass through the same hours of the circle ET. But since error may easily be committed in multiplying the straight lines FE and EG, we shall perhaps do it more conveniently, and certainly more accurately, thus. Taking FM of any size whatever, find the fourth proportional MN to the three straight lines FE, EG, FM; then again N will be the center and NM the radius of the circle to be described, as before — all of which I demonstrate in this way.

3. With EH drawn through E, perpendicular to the meridian, let the triangle ABD be conceived in its proper position — that is, in the plane of the meridian, at right angles to the plane of the sundial — and the parallel $\mathfrak{S}$, ET, likewise in its proper situation, so that the radius EG coincides with the straight line EK, and the point G with the point K. Then EH will be the common section of the parallel $\mathfrak{S}$ (passing through KE) and of the plane of the sundial, in the same

[Margin illustration: horizontal-sundial figure repeated. See below.]

Diagram. The same horizontal-sundial figure as fig-p671-1, reprinted on this page beside the continuing text. Same construction and label-set: outer rectangular frame, quarter-circle arc from the top-left (Z) sweeping down; meridian AB vertical (N above A at top; A the center; B below; M at the foot); center A with radiating hour-lines. Readable labels: Z (top-left), a and 6 (left edge), a cursive k[?] and 6 in the upper-middle, N, A, G, F, I, K, D, T, L, V, H, C, E, O, P, B, Q, R, S, M; hour-numbers 7, 6, 5, 4, 3, 2, I (=1), 12 (printed "I 2").

way as the perpendicular drawn through B is the common section of the Equator (passing through DB) and of the same plane of the sundial. [L?] Now let there be drawn from D, the tip of the stylus — that is, from the center of the world — to F the straight line DF, cutting the radius EK of the parallel $\mathfrak{S}$ at I, if through DF and the 4-o'clock line in the circle ET, placed aloft (the straight line EG coinciding, of course, with the straight line EK, and the point G with the point K, so that the parallel makes with the sundial the section EH) — that is, if through the straight line DF and the point V a plane is understood to be drawn, it will make with the sundial a common straight section-line, which will cut the 4-o'clock line at the point $\mathfrak{S}$, since the Sun's ray then, passing through the center of the world D and through the 4-o'clock point $\mathfrak{S}$ at V (the parallel ET keeping the aforesaid position), does not withdraw from that plane. If, therefore, on EH, the common section of the parallel and of the plane of the sundial, a point is found at which it is cut by that common section (which the plane drawn through DF and the point V makes with the sundial), a straight line sent out from F through that point (through which that same plane, and consequently that common section, passes) will give the point $\mathfrak{S}$ on the 4-o'clock line. That point on the straight line EH we shall easily detect. For if a straight line EI equal [to EF] is taken on the meridian up to some point, it plainly follows that the straight line drawn from this point through the point V (the parallel ET lying in the plane of the sundial) cuts the line EH in the same way as it is cut by the straight line from I aloft — the axis and stylus being placed in their proper situation, and the parallel turned about the straight line EH until its center G coincides with the point K — drawn through the same point V; because, when the parallel ET is turned about EH, that point coincides with the point I, owing to the equality of the straight lines. And consequently the straight line drawn from that point through V on the sundial coincides with the straight line likewise drawn from I through V aloft. But since the straight line EF is equal to the straight line EI (because, from the isosceles triangle FBD, the parallel EI cuts off [proportional parts], by the corollary to Proposition 4 of Book 6 of Euclid, the triangle FEI is also isosceles), the straight line FV will lie in the plane of the

sundial — that common section — and will cut the straight line EH at H. Therefore the straight line drawn from F through V, and consequently through a like hour in the circle described through M, will represent that common

that common section; and so it will cut the 4-o'clock line at the point L of the parallel of $\mathfrak{S}$ (Cancer — the summer-solstice parallel, the Tropic of Cancer). The same demonstration holds good for the other hour-lines and for the other parallels as well.

4. That the straight lines drawn from F through the hour-points of the circle ET pass likewise through the corresponding hour-points of the circle described through M is easily shown as follows. The whole NM is the same multiple of the whole GE as FM (cut off from NM) is of FE [?] (cut off from FG) — by the construction it is as great a multiple of it as the whole NM is of the whole GE (Euclid V.5). Consequently the remaining FN will be the same multiple of the remaining FG. And therefore the point F (which stands in place of two centres, in the circles described through M and through E from N and from G) will lie at a like distance from the centres N and G, since it has been shown that FN is to FG as the semidiameter NM is to the semidiameter GE. For this reason, by the scholium to Lemma 21 of Book 1 of the *Astrolabium*, a straight line drawn out from F will cut off similar arcs on the circles described through M and through E from N and from G.

[Margin: What is to be left out in this construction, so that confusion is avoided.]

SCHOLIVM

1. To avoid confusion, it is enough — leaving out the circle ET — to draw only the circle from N through M on the sundial. This drawing of the parallels has no other drawback than that the straight lines coming out from F cut some of the hour-lines too obliquely. In that case great care is needed for the points of intersection to be found correctly; or else the point that has to be found through too oblique an intersection must be tracked down by another route.

[Margin: The drawing of the hour-lines from any parallel whatever.]

2. It follows from what we demonstrated in the *Gnomonices* that, if from G hidden straight lines are drawn through the hour-points of the circle ET — or rather of any other larger circle described from G — cutting the straight line EH in points through which straight lines sent out from A, the centre of

the sundial, will give the hours from noon and from midnight; and this because EK is a certain common section of the Equator and the Meridian, and EH is the equinoctial line falling at right angles onto the meridian with respect to the style set up at K. Hence, if the circles described through E and through M are divided into more equal parts, and from G hidden straight lines are drawn through the parts of the circle ET (or of another larger circle described from G), and through the points where they cut the straight line EH straight lines are drawn from the centre A of the sundial in the manner of hour-lines, then in all cases the points of the parallels will be found, just as was said in the case of the hour-lines; and the parallels themselves will be drawn all the more exactly, the more closely-set the points that are obtained.

[Margin: How the arcs of the signs may be drawn more accurately, by the method set out in this chapter.]

3. It is also convenient to draw by this route, separately, only the [northern] halves of the northern parallels, on one side of the meridian line, on some rather stiff paper. For if they are carefully cut out, so as to make, as it were, curved rulers — either convex or concave, as one prefers — the other halves, and the opposite parallels as well, will easily be drawn, provided the points for them have been found on the meridian line. And for a more accurate drawing, single points will first have to be found for each parallel, points lying far enough from the meridian line that those cut-out halves can be applied without error to their proper points on the meridian line, and, with those distant points also, in such a way that the meridian line drawn upon those halves always coincides exactly with the meridian line of the sundial. In this way we shall easily find, for any given arc, a point on the sundial far removed from the meridian. Once a perpendicular has been drawn from any point N to the meridian, meeting the described arc at h, take on the sundial's meridian a straight line EN equal to [the one taken] from the point through which the arc is to be described; then draw the perpendicular through the endpoint down to the meridian, and transfer the point h onto it: this will be the point sought.

[Margin: That it is enough to draw the halves of the northern parallels.]

[Margin: Certain paper rulers for drawing the parallels.]

[Margin: How the aforesaid rulers can be applied without error.]

4. Moreover, this route can also easily be adapted to the hours from sunrise and sunset, if — in place of the distances of the hours from noon or midnight — one takes, on the circles ET and Ma, the distances of the hours from sunrise or sunset from the Meridian circle. How to compute these distances within each sign we shall teach in the scholium to chapter 15, Number 1. For example, since the 21st hour from sunset, at the beginning of $\mathfrak{E}$, is distant $68^{\circ} 3'$ from the meridian, if this distance is counted from E toward T, or from M toward a, and through the end of the count a straight line is drawn out from F, it will cut the 21st hour from sunset at the point $\mathfrak{E}$; and so for the rest.

[Margin: By what method the drawing of the parallels given in this chapter is adapted to the hours from sunrise and sunset.]

CAPVT XI.

ARCVS SIGNORVM IN HOROLOGIO HORIZONTALI SINE ope, auxilioque linearum horariarum.

(The arcs of the signs on a horizontal sundial without the aid or help of the hour-lines.)

1. In the last place, we can draw the arcs of the signs — indeed, two opposite signs at one and the same operation — without any aid from the hour-lines, by a truly elegant method that depends entirely on the elements of conics. Let there be, then, as in the other cases: the meridian line AB; the axis of the world AD; the centre of the sundial A; the tip of the style D, whose place is at the point onto which the perpendicular dropped from D onto the meridian falls; and the radius of the Equator DB, perpendicular to the axis, so that the equinoctial line has to be drawn through B at right angles to the meridian. From D let two rays of opposite signs be drawn out, if each ray cuts the meridian; or the ray of a single sign only, when only one ray cuts the meridian, or when the arc of only one sign is wanted. Let the two rays of the opposite signs be DC and DC, one above B and the other below. Whatever we prescribe for the one I wish to be understood of the other as well, and for that reason we have set the same letters against both, so that the same demonstration may be adapted to each described arc.

On the ray DC, produced, take any number of equal parts CE, EF, FG, GH, and through the first point E draw EM perpendicular to the axis of the world AD — which is easily done if, on the other ray produced, a segment DM equal [to DE] is

taken; for then the straight line EM will be perpendicular to the axis AD. Let it cut the meridian at Q, and take QP, PO, ON equal to the segment CQ, until as many parts are contained in CN as there are in CH. You will also find these parts if, taking DL, DK, DI equal to the straight lines DF, DG, DH, the hidden straight lines FL, GK, HI are drawn. But because, when there are several parts to be taken in order with the compasses, one may easily go wrong, you will do better to take CH of whatever size, bisect it, then bisect each part again, and so on, so as to obtain 4, or 8, or 16 equal parts, and so forth. Let the same be done on the straight line CN as on CH [i.e. as HI cuts off in N], which HI cuts off perpendicular to the axis AD — a line easily drawn if first DI is taken equal to the straight line DH.

After this, through the points Q, P, O, N let perpendiculars QV, PT, OS, NR be raised to the meridian. These too are easily drawn if a single line RNR, parallel to the meridian line, is set up, along which ef is drawn, and on which, from the point e, straight lines equal to NO, NP, NQ are taken, and so forth.

Finally, from the centre A of the sundial let hidden circles be traced through the points H, G, F, E, cutting the aforesaid perpendiculars at the points R, S, T, V on either side, in such a way that the circle described through the most distant point H cuts the line RN, the one most remote from the point C, and the others cut the others in their order. For through the points R, S, T, V the proposed parallel is to be described.

[Margin: The drawing of two opposite parallels at one operation, even though the hour-lines have not been drawn.]

But so that more points near C may be had, the portions CE, CQ toward C must be subdivided several times. Thus you see, in the figure, that each cut is bisected at X and Z; likewise each of CX, CZ is again bisected at a and b; and through Z and b perpendiculars are drawn, which the arcs described from A through X and a cut at Y and c. In the same way the corresponding portions GH, ON, or FG, PO, or EF, QP can be bisected, as often as it seems useful — that is, whenever the point R lies too far from the point S, or S from T, or T from the point V. Finally, if the parallel is to be carried out further, more parts equal to HG, GF, etc. must be taken beyond H, and just as many equal to NO, OP, etc. beyond N. For if perpendiculars to the meridian are drawn through these, and arcs are described through them from A, other points will be found on these perpendiculars.

2. All this I demonstrate as follows. With the triangle ADC set up in its proper position — that is, in the plane of the Meridian — HDI will be the triangle through the axis in the Cone, whose base is the proposed parallel at right

angles to the axis of the world AD, and whose vertex is at D, the centre of the world, since HDd and IDd are the angles complementary to the declination of the parallel, sloping toward the base of the cone. This triangle is cut through the axis by the plane of the sundial passing through AB, drawn at right angles [to it]; and so a conic section results, whose diameter — or axis — is CN, which I say passes through the points R, S, T, etc.

Diagram. A large rectangular framed construction for drawing the sign-arcs of a horizontal sundial. A vertical meridian line AB runs down the middle of the frame. Near the top-centre lies the cluster of the sundial's centre and style: the points N, A (centre of the sundial), with the small letters d, o and c/C beside them, from which the rays and hour-lines radiate. In the upper-right region a straight ray descends bearing, in order, the capital points I, K, L, M; the same ray reaches the right-hand edge of the frame, where the points M, L, l (small L), I are marked. Dotted arcs (the parallels / conic sections) sweep across both the upper and lower halves of the frame, carrying the repeated series of points R, S, T, V together with F, G, H (upper) and, mirrored below, V, T, S, R with F, G, H, N. Near the centre a small ellipse (the conic section) is drawn with the points c, C, Y and E, P nearby; the meridian continues downward through P, N. Additional readable labels include X and B (right of centre) and the small letters e, f at the left frame edge. D (centre of the world) is the apex from which the construction is projected.

- N, A (top centre): the style-tip / centre of the sundial and neighbouring construction points
- d, o, c / C (top centre, small): auxiliary points at the centre
- I, K, L, M (upper right, descending along a ray): division-points of the ray
- M, L, l, I (right frame edge, stacked): points where the ray/arcs meet the edge
- R, S, T, V (upper, on dotted arcs): points of the parallel above the meridian
- F, G, H (upper left of centre): division-points on the rays
- X (right of centre): bisection point
- B (below centre-right): foot of the equatorial radius DB
- V, T, S, R (lower, on dotted arcs): points of the parallel below the meridian
- F, G, H, N (lower centre): division-points below
- c, C, Y (centre, on the small ellipse): points of the conic section
- E, P (below centre): points on the meridian
- e, f (left frame edge, small): endpoints of the parallel ruler-line ef

- [Several small and duplicated peripheral labels could not be resolved even under magnification.]

That the straight line EM and the remaining lines FL, GK, etc. are perpendicular to the axis AD is established. For since the triangle EDM is isosceles, in which the straight line Dd bisects the angle EDM, Dd will be perpendicular to the base EM, as we demonstrated in the scholium to Proposition 26 of Book 1 of Euclid; and likewise for the rest. Again, that the straight lines EM, FL, GK, HI cut the straight line CN into equal parts as well is plainly established, since they are parallel and therefore cut the straight lines CH, CN proportionally. Finally, that the straight lines drawn from the points of the line ef, corresponding to the points of the straight line NC, are perpendicular to NC is clear, on account of the parallelograms eO, eP, etc.

Now that the point V (and what is said of it is to be said of the other points T, S, R as well) falls on the Conic Section which the plane of the sundial produces — the plane drawn through AB into the cone whose base is the parallel of the Sun and whose vertex is D — this is shown thus. With the triangle through the axis still in its proper position, the straight line VQ will be perpendicular to it (by Definition 4 of Book 11 of Euclid), since it lies in the plane of the sundial perpendicular both to the triangle through the axis and to their common section CN. It therefore coincides with the straight line raised perpendicular from Q to the plane of the triangle through the axis, and which lies in the conic section; so that, produced as far as the conic section — that is, as far as the circumference of the circle of diameter EM, which is parallel to the base of the cone and is likewise at right angles to the triangle through the axis — it meets the conic section of the circle at that same point; inasmuch as this perpendicular is the common section of the circle about the diameter EM and of the conic section. I say, then, that QV is equal to this perpendicular, and hence that the point V likewise lies on the circumference of the conic section. For since the said perpendicular, raised from Q to the triangle through the axis as far as the circumference of the conic section or of the circle about the diameter EM, is a mean proportional between the segments MQ, QE (by the corollary to Proposition 13 of Book 6 of Euclid); and since QV is likewise a mean proportional between the same segments (as I shall show); that perpendicular and QV will be equal, which is what was proposed. That QV is a mean proportional between MQ, QE I prove thus. The rectangle under MQ, QE together with the square on gQ [a] is equal to the square on gE. Adding, then, the common square on gA, the rectangle under MQ, QE together with the squares on gQ, gA [b] — that is, together with the square on QA — will be equal to the squares on gE, gA, that is (drawing the straight line AE), to the square

on AE, that is to the square on AV, since the straight lines AE, AV are equal, [being drawn] from the centre A to the circumference EV. [c] But the square on AV is equal to the squares on QA, QV. Therefore the rectangle under MQ, QE together with the square on QA will be equal to the squares on QA, QV; and, the common square on QA being taken away, the remaining rectangle under MQ, QE will be equal to the remaining square on QV. [d] And so QV is the mean proportional between MQ, QE, which is what was proposed.

[Margin (a): Euclid II.5.] [Margin (b): Euclid I.47.] [Margin (c): Euclid I.47.] [Margin (d): Euclid VI.17.]

SCHOLIUM.

1. Where the sundial has no centre, this construction does not apply, as is evident, since the arcs have to be described from A, the centre of the sundial, in order that the points R, S, T, V of the parallel may be found.

[Margin: Where this construction does not apply.]

2. Furthermore, when the meridian line AB, cutting one side of the triangle through the axis — namely DH — also cuts the other side, ID, produced beyond the vertex D, as happens in our figure, two opposite and equal conic sections are produced, that is, Hyperbolas. But when the same meridian is parallel to the other side, a single section results, a Parabola. And when, finally, it cuts both sides within the triangle through the axis, a single section too results, an Ellipse — as we demonstrated in the *Gnomonices*.
3. To avoid confusion, it is best that only the northern parallels be drawn, and indeed separately, outside the sundial. For if the superfluous parts are cut away, so that only the outer circumferences appear, then with the help of these circumferences — like certain bent rulers — the parallels themselves are easily transferred onto the sundial, even to the points of the southern parallels; especially if certain distant points are first found to which those rulers may be applied, as we said in the scholium to the preceding chapter, Number 3. Or else, if the intervals between A and the points N, O, P, Q are transferred onto the sundial from the centre of the sundial, and through the transferred points perpendiculars are drawn to the meridian, and onto these are transferred also the straight lines NR, OS, PT, etc., then the points of the parallels will be found on the sundial itself.

[Margin: What must be done so that, by this route, the parallels may be drawn on the sundial without confusion.]

CAPVT XII.

ARCVS SIGNORVM IN HOROLOGIO HORIZONTALI hor. à mer. & med.
noc. in quo centrum haberi non potest.

(The arcs of the signs on a horizontal sundial, for the hours from noon and midnight, on which a centre cannot be had.)

1. On a horizontal sundial for a small elevation of the pole, on which a centre can scarcely, or in no way, be had — unless a very distant one, far from the place of the style — the arcs of the signs will be drawn in the way we explained in chapter 8, Number 7. That is: if from the table the arcs are taken opposite any given sign, under the hours in "Circ. hor. 12" — this being on that line of hours which bears the heading "[Circ. hor. 12]," or which on its right-hand side has the number "[12]" written against it — and if with these same arcs we cut off equal portions from the meridian line, all of them beginning from the equinoctial line; then, if straight lines are drawn through the extreme points of these portions perpendicular to the meridian, or equidistant from the equinoctial line, each will cut the two corresponding hours at the points of the proposed parallel. An example may be taken from Number 7 of chapter 8. For the same sundial will serve here, if we imagine that the centre G is not to be had. And the method is the same on every other sundial, however small the elevation of the pole.

[Margin: The drawing of the parallels on a sundial on which the centre does not appear.]

2. We shall draw the same arcs of the signs with ease from the 2nd table, as was handed down in Number 10 of the same chapter 8. Likewise from table 3, as we set out in Number 11 of the same chapter 8. Or (if you wish) by means of the Tangents of the complements of the Sun's altitudes, as we taught there in Number 12.
3. They will also conveniently be drawn by the method which we set out in chapter 9, and by that other one which we set out in chapter 10. What is excluded here, then, is only the method handed down in the preceding chapter 11, and the one by which, in chapter 8, the points on the 6-o'clock line are found — because these two methods necessarily require a centre for the sundial.

[Margin: Which methods of construction do not apply on a sundial that lacks a centre.]

Table 3, the universal one, will also be serviceable here: for, having found on the meridian line the points $\mathfrak{S}$ (Cancer) and $\mathfrak{V}$ (Capricorn), h and i, if perpendiculars to the meridian representing the Ecliptics are raised through them, and the arcs of table 3 are transferred onto these on either side from h and i, with respect to the whole sines hd, id, marking the points on them; then the straight lines sent out from B through these points will cut the hour-lines at the points of the parallels, and so on, just as was said of the 5-o'clock line. And this method can be used on other sundials too, even if the sundial has a centre.

CAPVT XIII.

ARCVS SIGNORVM IN HORIS A MERIDIE, ET MEDIA NOCTE horologii horizontalis, supra quem maxima est altitudo poli.

(The arcs of the signs, for the hours from noon and midnight, on a horizontal sundial above which the altitude of the pole is greatest.)

1. On a horizontal sundial where the elevation of the pole is so great that on it the equinoctial line can scarcely be drawn, we shall draw the arcs of the northern signs — which alone can be delineated on it — by the method which, in the preceding chapter, Number 1, we said was to be sought from Number 7 of chapter 8. For although there is no equinoctial line from which the arcs of table 1, in "circ. horæ 12," are reckoned, nevertheless, because they are to be transferred from the place of the style, as we declared in Number 7 of chapter 8, that method can conveniently be applied. For example: at a pole-altitude of $89^{\circ} 30'$, we must find the point on the meridian through which the perpendicular to it exhibits the points $\mathfrak{S}$ on the 1- and 11-o'clock lines. Under the 1st and 11th hour, in "circ. hor. 12," opposite $\mathfrak{S}$ and $\mathfrak{V}$, the arc found is $24^{\circ} 14'$; and this taken from the pole-altitude of $89^{\circ} 30'$ (to which would be equal the portion of the meridian between the place of the style and the equinoctial line, if it were drawn on the sundial), leaves an arc of $65^{\circ} 16'$, whose Tangent, 21 [fraction: ?], transferred downward from the place of the style — the parts of the line from which the Tangents are to be taken having to be equal to the length of the style, as we said in chapter 2, Number 2 — will give the point through which a perpendicular drawn to the meridian will cut the 1- and 11-o'clock lines at the points $\mathfrak{S}$, and so on.

[Margin: The drawing of the parallels on a sundial on which the equinoctial line does not appear.]

We shall mark the same arcs by means of the Tangents of the complements of the Sun's altitudes, as we wrote in chapter 8, Number 12, if that seems good.

But through the 6-o'clock line, and through tables 2 and 3, nothing will be done here, since we suppose that the point of intersection of the meridian line with the equinoctial line is not to be had — the point from which the lines cutting the hours at the points of the parallels would have to be drawn out.

[Margin: Which methods of construction are excluded here.]

CAPVT XIII (continued)

2. The methods set out in chapters 9 and 11 can very well be applied here, since the centre of the sundial is present. Only this: in order to draw the rays of the signs from the point on the axis where the tip of the style is placed — because we do not have the intersection of the equinoctial line with the meridian, to which the radius of the Equator would have had to be drawn — we shall draw the radius of the Equator from that point perpendicular to the axis, even if it does not cut the equinoctial line; and then, at that same point on the axis, we shall set out the angles of the declinations of the other signs, and so on. So too in chapter 9: to draw out the rays of the signs from the point G once found, we must draw the straight line AG from the centre A, and at G erect a perpendicular to it for the radius of the Equator, and at this same point G set out the angles of the declinations, and so on.

The method explained in chapter 10 has no place here, since it requires the intersection of the meridian with the equinoctial line, so that a perpendicular can be raised to the axis from that point.

If one does not mind computing table 19 for the given elevation of the pole from Problems 10 and 17 at the end of the little book — which is really not at all laborious or difficult — the arcs of the signs will be described most expeditiously by the method we handed down in the scholium to chapter 9, Number 5. For the Tangents of that table, transferred from the centre with respect to the whole sine equal to the style, will indicate the points of the parallels. But where there is no centre, as in the preceding chapter, those Tangents of the northern signs must be subtracted from the Tangents of the Equator; likewise the Tangents of the Equator from the Tangents of the southern signs; and the Tangents that remain

must be carried over into the hours from the hour-points of the equinoctial line, as we advised at the end of the aforesaid scholium to chapter 9.

CAPVT XIII.

HORAE AB ORTV ET OCCASV IN Horologio Horizontali.

(The hours from rising and setting on a horizontal sundial.)

1. The description of the hours from rising and setting on a horizontal sundial is very easy. For, as is gathered from the figure in the scholium to chapter 1, Number 3, the two hours of the following table — which is constructed from that figure — cut each other on the line of hour 24 from rising or setting, on any plane except the plane of a horizontal sundial, on which they are equidistant, as we demonstrated in Book 2 of the *Gnomonice*, Proposition 20, and in the scholium to Proposition 22. If through the points [the construction proceeds as follows]:

Hour 24 from rising or setting cuts, at the same point, two hours of this table on any sundial except the horizontal, on which any two of them are parallel.

[Margin: Which hour from rising or setting, and which from noon or midnight, cut one another at the same point at hour 24 on any sundial, or are parallel to each other on a horizontal one.]

										1		1

H. à mer. vel med. no.	½	1	1	2	2	3	3	4	4	5	5	6
			½		½		½		½		½	
		1		1		1		2		2		2
Horæ ab ortu vel occ.	13	4	15	6	17	8	19	0	21	2	23	4
H. à mer. vel med. noc.	6	7	7	8	8	9	9	1	10	1	11	1
	½		½		½		½	0	½	1	½	2

(Table headers verbatim: "Hours from rising or setting" over "Hours from noon or midnight." The lower value is half the upper number throughout.)

[Margin: Through which points on the equinoctial line the hours from rising or setting are to be drawn on any sundial.]

The hour-points of the equinoctial line, through which the hours from rising and setting must pass, are to be drawn parallel to the hours from noon or midnight that are set down beneath them in this upper table; when this is done, the hours from rising and setting will be described. And through which points on the equinoctial line the hours from rising and setting are to be drawn, this other table shows, which we have excerpted from the same figure of the scholium to chapter 1, Number 3, for whole hours.

The equinoctial line cuts, at the same point, three hours of this table on any plane of a sundial.

											1	1	1
Horæ ab or. vel occ.	1	2	3	4	5	6	7	8	9	0	1	2	
H. à mer. vel med. noc.	7	8	9	1	1	1	1	2	3	4	5	6	
				0	1	2							
Horæ ab or. vel occ.	1	1	1	1	1	1	1	2	2	2	2	2	
	3	4	5	6	7	8	9	0	1	2	3	4	

(Three-row table: an hour from rising/setting 1–12, its corresponding hour from noon/midnight, and an hour from rising/setting 13–24, all meeting at one point.)

[Margin: By what method one may know, from memory, which two hours cut hour 24 at the same point on any sundial, or are parallel on a horizontal sundial.]

[Margin: By what method one may easily know at which hours they cut one another on the equinoctial line.]

These two hours can easily be held in memory — one from rising or setting, the other from noon or midnight — which cut hour 24 at the same point, or are parallel on a horizontal sundial. For such are any two hours, one from rising or setting and the other from noon or midnight, of which the second's number is half the first's number. Thus in the earlier table you see that hour 11 from rising or setting and hour 5½ from noon or midnight occupy the same cell; likewise hour 4 from rising or setting and hour 2 from noon or midnight, and so on. Therefore, given any hour from rising or setting, half its number will give the hour from noon or midnight which, together with it, cuts hour 24 (that is, the horizontal line) at the same point, or is parallel to that hour from rising or setting on a horizontal sundial. And given any hour from noon or midnight, double its number will give the hour from rising or setting which, together with it, cuts hour 24 at the same point — that is, the horizontal line — or is equidistant from that

hour from noon or midnight on a horizontal sundial. This is plainly seen in the earlier table.

With no less ease you will find out which hours from rising or setting cut, at the same point on the equinoctial line, any given hour from noon or midnight. For if to the given hour from noon or midnight you add 6, you will have one of the hours from rising or setting; and if to this you add 12 — or subtract, if it is greater than 12 — the other will be obtained. For instance, if you wish to know which hours from rising or setting cut hour 1 from noon or midnight at the same point on the equinoctial line: add 6, and you will make hour 7 from rising or setting. To this add again 12, and you will make up hour 19 from rising or setting. The hours from rising or setting sought, therefore, are 7 and 19. Suppose also that two hours from rising or setting are to be found which cut hour 8 from noon or midnight at the same point on the equinoctial line. Adding 6 to 8 makes hour 14 from rising or setting; from which, if 12 be taken away, the remaining other hour becomes 2 from rising or setting. But if any hour from rising or setting is proposed, and it is asked which hours it cuts at the same point on the line of the equinoctial: 12 must be added, or (if it is greater) subtracted, in order to have the other hour from rising or setting. And if to the smaller of the two hours from rising or setting found you add 6, you will find the hour from noon or midnight sought. For example, given hour 4 from rising or setting: add 12, and you will make hour 16 from rising or setting. Add 6 to the same hour 4 from rising or setting, which is less than 16, and you will make up hour 10 from noon or midnight. Again, if hour 9 from rising or setting is given: adding 12 makes hour 21 from rising or setting; but taking 6 from hour 9 from rising or setting (which is less than 21), the remainder becomes hour 3 from noon or midnight; and so with the rest. All this stands clear from the later table.

[41] ·

[Margin: The finding of the points on the 6-o'clock line for drawing the hours from rising or setting.]

To draw easily — through that point of the equinoctial line through which a given hour from rising or setting must be drawn — a line parallel to any hour-line from noon or midnight, the line which must be equidistant from that hour from noon or midnight, we shall use this device. On the meridian take a portion BZ equal to the portion BG, and through Z draw to the meridian a hidden perpendicular Ze, on which the points are to be marked where it is cut by the hour-lines from noon or midnight. Or indeed, if perhaps the hour-lines have not been drawn, then, with Z ω drawn perpendicular to the axis, let the hour-points on Ze be found by means

of the Tangents, with respect to the whole sine $Z\omega$ divided into 10 parts, just as on the equinoctial line. For Ze is likewise an equinoctial line with respect to a style let fall from ω perpendicularly to the meridian.

Diagram. A large horizontal-sundial construction enclosed in a rectangular frame. The meridian runs vertically down the left border; a horizontal line runs from the point **A** (upper left, on the meridian) rightward through the centre **G**, from which the ordinary hour-lines and the declination-lines radiate. A large semicircle (the horizon) is struck within the frame. Superimposed are the ordinary hour-lines (solid) labelled with Roman numerals, the Babylonian/Italian hour-lines "from rising and setting" (mostly the fainter/dotted lines) labelled with Arabic numerals 1–24, and the parallels of declination marked with zodiac-sign glyphs. The construction points **B**, **Z**, **e**, ω (with **aa**, **bb** on the line Ze), **H**, **K**, **O**, **P**, **L** appear around the figure. The engraving is extremely dense and many peripheral labels do not resolve at the available resolution; those legible are listed below.

- Frame: rectangular border; meridian = left vertical edge.
- **A** (upper left, on meridian): construction point, left end of line AG .
- **G** (centre, on line AG): centre of the sundial; origin of the radiating hour- and declination-lines.
- **B**, **Z** (right / centre-right, on the meridian portion): points defining $BZ = BG$.
- **e** (right, on line Ze): end of the hidden perpendicular Ze .
- ω (upper right): foot of the auxiliary style; $Z\omega$ perpendicular to the axis.
- **aa**, **bb** (right region, on/near Ze): hour-points on the line Ze .
- **H** (right, on the horizontal line): construction point.
- **K**, **O** (lower left corner region): construction points.
- **P**, **L** (top edge, left of centre): hour-line labels.
- Ordinary hour-lines (Roman, reading across the top / sides): VI, VII, VIII, XI, XII, I, II, V [several further Roman labels illegible — [?]].
- Babylonian/Italian hour-lines (Arabic): 3, 10, 12, 13, 14, 16, 17, 18, 19, 21, 22, 23 legible at various positions [remaining values 1–24 not all separately resolvable — [?]].
- Zodiac-sign glyphs marking the parallels of declination: Υ (Aries) and ϖ (Taurus) legible; several further glyphs ($\varrho/\mathfrak{M}/\mathfrak{V}$ region) present but not securely resolved — [?].

[More than two peripheral labels are flagged [?]:**]

DEINDE: Then, placing one foot of the compass on the hour-point of the equinoctial line through which the proposed hour from rising or setting must be

drawn (this point the upper, second table will supply), extend the other foot to the point of that hour from noon or midnight to which the proposed hour from rising or setting is parallel (this point the first table will show). Transfer this interval onto the 6-o'clock line from the centre of the sundial, G, and onto the line Ze from the point of the same hour from noon or midnight, toward the same side toward which it was transferred onto the 6-o'clock line. For a straight line drawn through the first hour-point of the equinoctial line and through the other two points on the straight lines Ge and Ze will be parallel [Margin: ^a Euclid I.33] to the line

[42] ·

of the hour-line from noon or midnight drawn through the second hour-point of the same equinoctial line. Moreover, the said interval must always be transferred, on the 6-o'clock line, to the side opposite the point through which the hour from noon or midnight is drawn — namely, to the left side of the meridian line, if that point occupies the right side of the same meridian line, and the reverse.

But let us now illustrate the description of the hours from rising or setting by examples. Hour 23, by the first table of this chapter, is equidistant from hour 11½, and passes, by the second table, along the equinoctial line through hour 5. We shall transfer the interval taken between hour 5 and hour 11½ on the equinoctial line onto the 6-o'clock line, from G, up to the point 23; and onto the line Ze, from aa (the point of hour 11½), up to bb. For the straight line bb–23, passing through hour 5 on the equinoctial line, will be hour 23, and will be equidistant from hour 11½. By the same reasoning hour 22 will pass through hour 4 on the equinoctial, and will be equidistant from hour 11. Hour 21, then, will be drawn through hour 3, parallel to hour 10½; and hour 20 through hour 2, parallel to hour 10; and hour 19 through hour 1, parallel to hour 9½. Likewise hour 18 through hour 12, parallel to hour 9.

[Margin: The description of the hours from setting, from 23 through 22, 21, and so on down to 13; and of the hours from rising, from 2 up to 12.]

Diagram. A second, near-identical horizontal-sundial construction, the companion to the figure on the preceding page. The same elements recur: the rectangular frame, the meridian down the left edge, the centre **G** with radiating hour- and declination-lines, the horizon semicircle, the ordinary hour-lines (Roman), the Babylonian/Italian hour-lines 1–24 (Arabic), and the zodiac-marked parallels of declination, with construction points **A, G, B, Z, e, ω, aa, bb, H, K, O, P,**

L, δ. As on the previous page the label-density exceeds what resolves cleanly; legible labels are listed.

- Frame, meridian (left edge), centre G, horizon semicircle — as in fig-p677-1.
- A (upper left, on meridian); B, Z, e, ω, aa, bb (right region, on/near line Ze); H (right, on horizontal line); K, O (lower left); P, L (top edge).
- Ordinary hour-lines (Roman): VI, VII, VIII, XI, XII, I, II, V legible [others [?]].
- Babylonian/Italian hour-lines (Arabic): 10, 12, 14, and 13–23 region legible in part [not all separately resolvable — [?]].
- Zodiac glyphs marking parallels of declination: ♈ (Aries), ♉ (Taurus) legible; δ-like and further glyphs at the lower right present but unresolved — [?].

[More than two peripheral labels are flagged [?]:**]

PER eadem: Through the same points of the 6-o'clock line the hours 17, 16, 15, 14, 13 must be drawn in reverse order. For from the figure of the scholium to chapter 1, Number 3, it is gathered that any two hours from rising or setting, equally distant on either side from hour 6 [i.e. from the 6-o'clock line] from noon or midnight, cut the 6-o'clock line at the same point — such as 17 and 19; likewise 16 and 20, as well as 15 and 21; and moreover 14 and 22, and 13 and 23. Therefore hour 17 must be drawn through hour 11 from noon or midnight on the equinoctial, and through hour 19 on the 6-o'clock line. Hour 16 through hour 10 from noon or midnight on the equinoctial, and through hour 20 on the 6-o'clock line. Hour 15 through hour 9 from noon or midnight on the equinoctial, and through hour 21 on the 6-o'clock line. Hour 14 through hour 8 from noon or midnight, and through hour 22 on the 6-o'clock line. And hour 13 through hour 7 on the equinoctial, and through hour 23 on the 6-o'clock line.

There is no different method for describing the hours from rising. For hour 1 from rising must be drawn through hour 7 from noon or midnight on the equinoctial, equidistant from hour $\frac{1}{2}$ from noon. And hour 2 from rising through hour 8 on the equinoctial, parallel to hour 1 from noon, and so on, as is gathered from the two tables above.

(Chapter XIII continues.)

[Margin: Another, convenient way of finding the points on the 6-o'clock line for drawing the hours from rising or setting.]

These same intervals, transferred from **G** onto the line of hour 6, will be exhibited by the distances between **Q** (taking the straight line **BQ** equal to the interval **BD**)

and the hours 5, 4, 3, 2, and so on, on the equinoctial line. For, as is established from the table of Chapter 3, Number 3, the point of hour $11\frac{1}{2}$ on the equinoctial is found by the distance between **Q** and hour 5; hour 11, by the distance between **Q** and hour 4; and so on. From this it follows that the interval between **Q** and hour 5 on the equinoctial — since it is equal to the portion of the equinoctial between hours 5 and $11\frac{1}{2}$ — is equal to the portion of the line of hour 6 between **G** and point 23. And so with the rest.

For you will always find that the interval between **Q** and the hour on the equinoctial through which some hour from rising or setting must pass (as prescribed by the later table of this chapter) is equal to the interval between that same hour on the equinoctial and that other hour from which the hour from rising or setting must be equidistant (as prescribed by the earlier table of the same chapter). For example, the interval between **Q** and hour 13 from rising or setting is equal to the interval between the same hour 7 and hour $6\frac{1}{2}$, from which hour 13 must be equidistant; and this because the point of hour $6\frac{1}{2}$ is found from the interval between **Q** and hour 7, as is established from the table set out in Number 3, Chapter 3. The same reasoning holds for the rest.

And in this way the points of all the whole hours from rising or setting will be found on hour 6, even though the points of the half-hours have not been marked on the equinoctial. But if the points of the half-hours have been marked, then by means of them the points of the half-hours from rising or setting will be found on hour 6, even though the quarter-hours on the equinoctial, from which they must be equidistant, have not been drawn. Finally, if the points of the quarter-hours have been impressed on the equinoctial, then by means of them the points of the quarter-hours from rising or setting will be found on hour 6, even though the eighth-parts of the hours on the equinoctial, from which they must be equidistant, have not been found — which is worth noting.

[Margin: The drawing of hour 12 from rising or setting, together with the other hours from setting that precede it, and the others from rising that follow it.]

Hour 12 from rising or setting must be drawn parallel to the equinoctial line — or perpendicular to the meridian — through the point that bisects the portion of the meridian **BG** lying between the equinoctial and the center of the dial, as we shall demonstrate. Hour 11 must be drawn through hour 5 on the equinoctial (as is clear from the later table of this chapter) and through the point of hour 6 by which hour 1 from rising is drawn; and this point is found by the interval between hours $\frac{1}{2}$ and 7 on the equinoctial, transferred from **G** to the right onto the line of hour 6 — because hours 11 and 1 from rising or setting cut hour 6 at

the same point, as is evident from the figure of the scholium to Chapter 1, Number 3. Hour 10 must be drawn through hour 4 on the equinoctial, and through the point of hour 6 through which hour 2 from rising passes; and this is found by the interval between hours 1 and 8 on the equinoctial. And so on, if more hours can be drawn above your horizon.

This is not difficult, if the said figure of the scholium to Chapter 1, Number 3, is considered carefully and attentively, together with the later table of this chapter. The same, understood in a certain proportion, is also to be grasped for hours 13, 14, 15, and so on, from rising. For hour 13 from rising must be drawn through hour 7 on the equinoctial, and through hour 23 from setting on hour 6, and so on, as is plain from the same later table of this chapter and from the same figure of the scholium to Chapter 1, Number 3.

*2. That hour 12 must be drawn through the midpoint of the straight line **GB**, perpendicular to the meridian, I demonstrate as follows. Let an analemma be described, in which the meridian is **AEF**; the axis of the world **ID**; the diameter of the equator **HD**; the vertical diameter **ED** — on which, produced, let **DC** be taken equal to the style [gnomon] — and through **C** let **GB** be drawn perpendicular to **EC**, which the axis cuts at **G**, and the diameter of the equator at **B**. Let arc **IK** also be taken equal to arc **IF**; and, the straight line **FK** being joined, let the straight line **KD** be drawn, cutting **GB** at **L**. By what we demonstrated in Book 2 of the Gnomonics, the center of the horizontal dial will be **G**; and through **B** the equinoctial line must be drawn perpendicular to the meridian **GB**. **FK** is the diameter of the greatest circle of perpetual apparition, and **KD** the diameter of the circle of hour 12 from rising or setting, cutting the meridian at the point **L**, through which the line of hour 12 must be drawn perpendicular to the meridian **GB**. I say that **GB** is bisected at **L**.*

*For since the angles **FDI** and **KDI** are equal [a], and angle **FDI** is equal to angle **DGL** [b], and angle **KDI** to angle **GDL** [c], the angles **DGL** and **GDL** will also be equal, and therefore [d] the straight lines **LD** and **LG** will be equal. Again, since **HI** is a quadrant, the two remaining arcs **IF** and **HA** — out of the semicircle — will each be equal to a single quadrant, and hence to the quadrant **HI**; and, the equal arcs **IF** and **IK** being subtracted, the remaining arcs **HA** and **HK** will be equal. Therefore [e] the angles **ADH** and **KDH** will be equal. But [f] angle **ADH** is equal to angle **DBL**, and [g] angle **KDH** to angle **BDL**. Therefore the angles **DBL** and **BDL** will also be equal; and consequently [h] the straight lines **LD** and **LB** will be equal. But **LG** was equal to the same **LD**. Therefore **LG** and **LB** are equal to one another. Which was to be shown.*

[Margin: Proof citations for the demonstration — a) *Elements* III.27; b) *Elements* I.29; c) *Elements* I.15; d) *Elements* I.6; e) *Elements* III.27; f) *Elements* I.29; g) *Elements* I.15; h) *Elements* I.6.]

Diagram. An analemma construction set within a rectangular frame. A semicircle stands on the horizontal diameter **A–D–F** (the meridian **AEF**), with **A** at the left end, **D** at the center, and **F** at the right end. Radiating from the center **D** to the arc are lines to the labelled points **H** (upper left), **E** (top), **K** (upper right), and **I** (right). The vertical diameter **ED** runs from **E** at the top down through **D**; produced below **D** it reaches **C** on a lower horizontal line. That lower line **GB** (perpendicular to **EC** at **C**) carries, left to right, the points **G**, **L**, **C**, **B**.

- A (left end of horizontal diameter): terminus of meridian
- D (center): center of the figure; center of dial construction
- F (right end of horizontal diameter): terminus of meridian
- E (top of arc): top of vertical diameter ED
- H (upper-left of arc): terminus of equator-diameter HD
- K (upper-right of arc): arc IK laid off equal to arc IF
- I (right of arc): terminus of axis of the world ID
- C (on lower line, below D): DC taken equal to the style
- G (left end of lower line GB): center of the horizontal dial
- L (on GB between G and C): where KD cuts GB (bisection point)
- B (right end of lower line GB): where the equator-diameter meets GB

3. In Chapter 19, Number 9, you will find the method by which, if you please, a point can be found — for any hour from rising or setting — on any hour from noon or midnight; and hence the method by which the points for the hours from rising or setting can be sought on the line of hour 6, even if the intervals of the equinoctial line (spoken of in Number 1 of this chapter) are not transferred onto hour 6, as we shall say there.

[Margin: Where another way of finding the points on the line of hour 6 for the hours from rising or setting is given.]

4. Also, by the distances of the hours from rising or setting from the meridian, their points in the tropics can, if you wish, be found, as we shall make plain in the following chapter, Number 4.

[Margin: Where the finding of the points in the tropics for the hours from rising or setting is taught.]

CAPVT XV.

ARCVS SIGNORVM IN HORIS AB OR. VEL occ. horologij horizontalis.

(The arcs of the signs in the hours from rising or setting of the horizontal dial.)

1. Although it may seem superfluous to teach how the arcs of the signs are to be drawn in the hours from rising or setting — since we have already drawn them in the hours from noon or midnight, so that they can readily be transferred onto a dial of the hours from rising or setting (for these will cut the hours from rising or setting at the points of those same arcs of the signs; or, if only the tropics are wanted, and if they have already been drawn through the hours from noon or midnight, the hours from rising or setting need not be produced beyond the outermost arcs, which belong to ♋ [Cancer] and ♎ [Capricorn]) — nevertheless, for the benefit of

students, it is worth prescribing here certain methods by which the points of the arcs of the signs may be found in the hours from rising or setting, even if they had not been found in the hours from noon or midnight. I shall propose several methods, since for certain hours one is more convenient than another, as practice will teach you. Let this, then, be the first way.

[Margin: The finding of the points of any parallel whatever in the hours from rising or setting, from Table 7, computed for latitude 42°.]

From Table 7, which has been computed for latitude 42° for the whole hours (how anyone may, by his own effort, compute another table for any elevation whatever, we shall show at the end of this little work, in Problem 12; for it did not seem good to compute more, lest the book should swell too much) — take the complements of the arcs of the hours from rising or setting, set opposite the sign presented, and their tangents with respect to a whole sine of 10 (these are to be taken from the straight line whose portion **bc**, standing for the line of hour 6, has been divided into 10 parts); and let them be transferred from **G** and **Z**, in opposite directions, onto the line of hour 6 and the line **Ze**, marking the points on them. For the straight lines drawn from **B** through these points will cut the hours from rising or setting at the points of the proposed parallel.

For example: let the point of ♎ [Capricorn] on hour 21 be sought. This arc contains 49°19', and so its complement is 40°41', whose tangent — $8 \frac{6}{10}$, approximately — will give the points **cc** on the lines **GL** and **Ze**. The straight line **ccBcc**, therefore, will cut hour 21 at the point of ♎. The tangents are to be transferred to the opposite sides of the lines **GL** and **Ze** in such a way that the

lines drawn from **B** and extended through those points can cut the proposed hours at the sought points of the parallels — which will not be difficult to judge. Namely, for the afternoon hours of the southern parallels and for the morning hours of the northern parallels, transfer from **G** toward the right and from **Z** toward the left; the opposite is to be understood for the morning hours of the southern parallels and the afternoon hours of the northern parallels.

You also have an example in the point of $\mathfrak{S}$ [Cancer] on hour 12. For this arc comprises $25^{\circ}18'$, and therefore its complement is $64^{\circ}42'$, whose tangent — $21\frac{1}{10}$ — presents the points **dd** on the lines **GL** and **Ze**. The straight line **ddBdd**, therefore, will cut hour 12 at the point of $\mathfrak{S}$. And so with the rest. I bring forward no more examples, lest the figure be obscured by so great a multitude of lines — especially since this method does not differ from the one given in Chapter 8, Number 1, except that here Table 7 is to be used, but there Table 1.

[Margin: The finding of the points of any parallel whatever in the hours from rising or setting, from Table 8, computed for latitude 42° .]

2. A second method rests on Table 8, and does not differ from the manner we set out in Chapter 8, Number 7. For by Table 8 we shall find, on the meridian line, points through which — if lines parallel to the equinoctial line are drawn — the several hours from rising or setting will be cut at the points of the parallels; just as there, from Table 1, points were found through which straight lines parallel to the equinoctial line cut the hours from noon or midnight, each line, that is, cutting two hours. This Table 8, however, has been computed only for latitude 42° , for the whole hours. But if anyone wants similar tables for other latitudes, he will find the way of computing them at the end of the book, in Problem 12.

In order to find the points of the parallels in the hours from rising or setting for any elevation of the pole, we have computed the following general table, by Problem 12 placed at the end of the book. It contains the arcs of the meridian intercepted, at the beginnings of the signs, between the equator and the great circles that are drawn — from the intersection of the equator with the horizon, or with the 6-o'clock circle from noon or midnight — through the hours from noon and their minutes: that is, if the hours are taken at the top of the table and the minutes on the left side. For if the hours are taken at the foot of the table, and the minutes on the right side, the same arcs will be had on the 6-o'clock circle, intercepted at the beginnings of the signs, between the equator and the great circles that are drawn — from the intersection of the equator with the meridian — through the hours from noon and their minutes.

But in order to fit this table to the hours from rising or setting in any region, the distances of those hours from the meridian circle must first be found, as I shall teach below; and the hours of these distances are to be taken at the top of the table, the minutes on the left side. For in the common corner you will find the arcs of the meridian by which the points of the parallels will be found in the hours from rising or setting, as we taught in Number 7, Chapter 8, and reminded in Number 2 of this chapter. For example: at latitude 42° , the distance of hour 21 from setting is distant from noon by 4h32m, at the beginning of $\mathfrak{S}$ [Cancer], to which, in the following table, there corresponds an arc of $49^\circ 15'$. And when the pole's altitude of 42° is subtracted, there remains an arc of $7^\circ 15'$, whose tangent — $1 \frac{2}{10}$ and a little more — transferred upward from **C**, will give a point on the meridian; and if a line parallel to the equinoctial is drawn through this point, hour 21 will be cut at the point of $\mathfrak{S}$. And so with the rest. So that you may know how to proceed in the other hours — especially when they are more than 6 hours from noon — consult Number 7, Chapter 8. How the said arcs may be more accurately drawn out of the table by proportional parts, we shall teach in Practice 6, Number 4, excerpted there.

Moreover, by these same tangents we shall very conveniently find these same points of the parallels of the Sun, even if we do not draw the lines parallel to the equinoctial or perpendicular to the meridian, as was said in Number 8, Chapter 8 — in this way, namely. Let the tangent for any hour and sign be taken with the compass from the straight line whose portion **EF**, at the beginning of Chapter 2, was divided into 10 parts. For this tangent — if one foot of the compass is placed on the given hour, on the condition that the arc drawn by the other foot touches, but does not cut, the line **CD** extended both ways — will give on the hour-line the sought point of the parallel. Nor will any notable error be admitted in this matter, if careful diligence is applied.

Only this method will be less reliable on those hour-lines that are too obliquely inclined to the equinoctial, because the line **CD** can be touched appreciably at several points of those lines by the arcs drawn at the intervals of the tangents. For this reason, on those lines the points of the parallels must be found either by Rules 1 and 2 of the scholium to Chapter 8, with the help of points found on other lines; or by the points on the line of hour 6 found from the same following table, as was taught in Number 1, Chapter 8; or else by the means we shall write of in Number 3 of this Chapter 15 — namely, by the distances of the hours from noon, found in degrees and minutes.

Indeed, even without a compass we shall very opportunely transfer these same tangents onto the hour-lines for finding the points of the parallels, in this way. On some rather stiff paper — such as royal or imperial paper — let the divisions of the line **EF** be made, as we said at the beginning of Chapter 2. Then let the paper be cut so that the side containing the divisions occupies its edge and serves as a kind of ruler; and let the same divisions be transferred to some line of the same paper parallel to the aforesaid edge, which (once the superfluous parts are cut away) occupies the other edge — so that the straight lines joining the numbers 10, 20, 30, 40, and so on are all perpendicular to the two aforesaid edges, so that a rectangular parallelogram is made, divided into several parts by parallel lines. For if that perpendicular which is drawn through the number 10, or 20, or 30, and so on (as the magnitude of the tangent requires) is applied to the line **CD** drawn through the position of the style — by moving the ruler back and forth until the end of the tangent marked on the little line **EF** reaches the proposed hour — that endpoint must be marked as the point of the parallel. And this method, as you see, is common also to the hours from noon and midnight.

And if other similar rulers are made for taking the tangents on the equinoctial line, or on the line of hour 6, or on the other lines, as was taught in Chapter 2, all the tangents will be transferred onto them, without a compass, most exactly — provided each ruler is applied to its proper line, and so on.

Now the distances that the hours from rising or setting have from noon will easily be found from the semidiurnal arcs. For the semidiurnal arc gives the distance of hour 24. And if you subtract one hour, you will have the distance of hour 23, and so on. But when one hour can no longer be subtracted, one must take the complement of the last distance found — the complement, I mean, to 60 minutes — for the distance of the next hour before noon; and if to this you add one hour, you will produce the distance of the preceding hour, and so on. For example: at latitude 42° , at the beginning of ♋ [Cancer], the distance of hour 17 from setting is found to be 0h32m. Therefore hour 16 is distant before noon by 0h28m, while hour 15 has a distance of 1h28m; and so with the rest. Likewise, if you subtract one hour from the semidiurnal arc, you will make the remainder the distance of hour 1 from rising, and so on.

Furthermore, you will obtain the semidiurnal arc in hours and minutes if you divide the semidiurnal arc in degrees — from Table 4, computed at the end of the book — by 15, to get the hours; and assign to each of the remaining degrees 4 minutes of one hour, and to each minute of the degrees 4 seconds of one hour. These seconds may be omitted when they do not exceed 30; but when they do

exceed 30, one whole minute must be taken for them. For example: at latitude 42°, at the beginning of ♉ [Taurus] and ♍ [Virgo], the semidiurnal arc in Table 4 contains 100°33′. Dividing the 100 degrees by 15 yields 6 hours, with 10 degrees left over, which multiplied by 4 give 40 minutes. Finally, 33 multiplied by 4 gives 132 seconds, which divided by 60 make 2 minutes, with 12 seconds left over, which are to be neglected. The whole semidiurnal arc, therefore, contains 6h42m. And so with the rest.

THERE NOW FOLLOWS THE AFOREMENTIONED TABLE.

(The announced table is not printed on this leaf; the rest of the page is blank, with only show-through of the table on the following leaf visible. The table itself falls on the next page.)

The Table Foretold (Table 18 of the meridian arcs)

[Table] Top title, verbatim: *"Arcus Meridiani inter Æquatorem, & circulos maximos ex intersectione Æquatoris cum Horizonte per horas à meridie earumque minuta ductos, intercepti."* — The arcs of the meridian intercepted between the equator and the greatest circles that are drawn, for the hours from noon and their minutes, through the intersection of the equator with the horizon.

This is a double-entry table. Each of the three panels on the page is one hour reckoned from noon (top labels **hor. 0**, **hor. 1**, **hor. 2**); the same body read from the bottom serves the complementary hours (bottom labels, printed inverted: **hor. 5**, **hor. 4**, **hor. 3**), under the foot-title: *"Arcus circuli horæ 6. inter Æquatorem & maximos circulos ex intersectione Æquatoris cum Meridiano per horas à meridie earumque minuta ductos, intercepti."* — The arcs of the hour-6 circle intercepted between the equator and the greatest circles drawn, for the hours from noon and their minutes, through the intersection of the equator with the meridian.

In every panel the left index column (0–60, the minutes read downward) heads the panel's hour; the right column ("min.", 60–0, read upward) heads the foot-hour. The three value columns are each headed by a tetrad of zodiac signs sharing the same declination; each cell is printed as **G. M.** (degrees, minutes). Column headings (verbatim glyph groups): ♈ ♉ | ♊ ♋ ≈ ♌ | ♍ ♎ ♏ ♐.

Page 46 — hour 0 (foot: hour 5)

Table 18, continued — hours 3, 4, 5

[Table] Same title as p. 46 (*"Arcus Meridiani inter Æquatorem, & circulos maximos ..."*). Top labels **hor. 3**, **hor. 4**, **hor. 5**; the same body read from the foot serves **hor. 2**, **hor. 1**, **hor. 0** (foot-title as before). Column headings as on p. 46: ☾ ♄ | ♂ ♀ ☿ | ♄ ☿ ♀ ♀; each cell "G. M."

[Foot-title: Arcus circ. hor. 6. inter Æquatorē & maximos circ. ex intersectione Æquatoris cū Meridia. &c.]

Chapter 15 (continued)

[Margin: Finding the points of any parallel in the hours from rising or setting, from the distances from the meridian.]

3. A third method is drawn from the distances of the hours from noon — distances whose computation I shall teach in the scholium to this chapter, Note 1. It runs as follows. Take the tangent of the distance of any hour, reckoned to a whole sine of 10, laid off on the straight line whose portion MN — equal to the

line BD — has been divided into 10 parts for the equinoctial line; and transfer it onto the equinoctial line, before or after noon according as the distance falls before or after noon. For a straight line drawn out from G, the centre of the dial, through the end of this tangent will cut the hour proposed at the point of the parallel proposed. When the tangent cannot be transferred onto the equinoctial line, it must instead be transferred onto the line VS, laid off on the straight line whose portion [?] — divided into 10 parts — is equal to the line ST. Likewise, when the distance is greater than a quadrant, one must transfer the tangent of its complement up to 180° , from B or from S, into the opposite direction, so that a straight line from its endpoint through G can cut the given hour at the point sought.

By way of example. The distance of hour 21 from setting, in ♋ [Cancer], comprises $68^\circ 3'$, whose tangent $24 \frac{7}{10}$ gives the point *ee* on the equinoctial. The straight line G–*ee*, therefore, will cut hour 21 at the point of ♋ . Again, the distance of the same hour 21 in ♏ [Capricorn] contains $21^\circ 57'$, whose tangent 4 yields on the equinoctial the point 11, through which a straight line drawn out from G will cut hour 21 at the point of ♏ . Once more, the distance of hour 11 from setting, in ♋ , has $81^\circ 57'$, whose tangent $70 \frac{7}{10}$ — reckoned to the whole sine ST, transferred onto SV — gives the point *ff*; and the straight line G–*ff* will cut hour 11 at the point of ♋ . Finally, the distance of hour 23 from setting, in ♋ , is $98^\circ 3'$, greater than a quadrant; subtracted from 180° it leaves $81^\circ 57'$, whose tangent $70 \frac{7}{10}$ — reckoned to the whole sine ST — gives on the line SV the point *ff*, and the straight line *ff*–G, produced, cuts hour 23 at the point of ♋ .

[Margin: An easier finding of the points of parallels in the hours from rising or setting, from Table 18, by the arcs of the Horizon.]

But by Table 18 — through the arcs of the horizon between the meridian (on the southern side) and the greatest circles that pass through the poles of the world and through the whole hours from rising or setting and their halves, drawn at the beginnings of the signs in the manner of hour-circles from noon and midnight — we find the points of the parallels in the hours from rising or setting far more easily, if we count those arcs, in the circle described from G, the centre of the dial, from the meridian line toward the right or the left, according as the hours are before noon or after noon. For the straight lines sent out from G, the centre of the dial, through the ends of these arcs (which do not differ from those we said just now must be drawn through the points found on the equinoctial by the distances of the hours from noon) will cut the hours from rising or setting at the points of the parallels, since they stand for those greatest circles which are drawn through

the poles of the world — just as the earlier lines did, drawn out through the ends of the tangents that correspond to the distances of the hours from the meridian. For example: since the arc of hour 23 in $\mathfrak{S}$, from setting, contains in Table 18 $101^{\circ} 57'$, if we count it from the meridian line toward the left — that is, $11^{\circ} 56'$ beyond the line of hour 6 (having of course taken away the 90° that lie between the meridian and hour 6 in the circle) — the straight line from G, drawn through the end of that arc, will cut hour 23 at the point of $\mathfrak{S}$. And so with the rest. The construction of this Table 18 is given at the end of the little book, in Problem 9, from which anyone may build a similar one by his own effort for a given elevation of the pole.

Now this method by the arcs of the horizon of Table 18 is the most convenient, because when the distance of some hour from rising or setting from the meridian cannot be taken on the equinoctial, nothing prevents the arc of that same hour from being taken on the circle described from G.

[Margin: A very close approximation, and how it is done by tangents.]

Now indeed, if — as I shall show at the end of the little book in Problem 17, and as I explained in the scholium to Chapter 9, Note 5 — the segments of the straight lines drawn from G, the centre of the dial, through the ends of the arcs of the horizon out to the parallels are reduced to tangents equal to the style with respect to the whole sine, then on those same straight lines the points of the parallels will be found by means of those tangents. And these points can be found even if the hours from rising or setting have not yet been drawn. Once these points have been carefully found in the tropics $\mathfrak{S}$ and $\mathfrak{V}$, the hours from rising or setting must be drawn through them. I set down no example, both because the thing itself is easy from what was said in the scholium to Chapter 9, Note 5, and because time did not allow me to compute a table for the hours from rising or setting like Table 19 computed for the hours from noon and midnight. You will therefore compute it by your own effort from Problems 10 and 17 at the end of the little book.

[Margin: Finding the points for the hours from rising or setting in the tropics, or in the other parallels, by means of the distances from the meridian.]

4. Furthermore, if the arcs of $\mathfrak{S}$ and $\mathfrak{V}$ have been drawn in the hours from noon and midnight — as was handed down in Chapters 8, 9, and 10, or as we taught in Chapter 11 — we shall find, by an extremely easy method, the points in them, by the aid of the aforesaid distances or of the arcs of Table 18, through which the lines of the hours from rising or setting are to be drawn. This method fits every plane of dials, and is the most convenient for drawing certain of the hours from

rising or setting on declining dials. For instance, if we seek the point in the tropic of $\mathfrak{S}$ through which hour 11 from setting is to be drawn, we shall take its distance from $81^{\circ} 57'$; for the tangent of this, $70 \frac{7}{10}$ — reckoned to the whole sine ST, on the line SV (because reckoned to the whole sine BD it runs out too far on the equinoctial) — will give the point *ff*, and the straight line G–*ff* will cut the tropic of $\mathfrak{S}$ at the point through which hour 11 is to be drawn. And because that same hour 11 must also be drawn through hour 5 from noon or midnight on the equinoctial, hour 11 from setting will be described through hour 5 on the equinoctial and through the point found in the tropic of $\mathfrak{S}$, even if in hour 6 no other point is found. And the same method holds for the rest. In no other way will the points of these same hours be found in the other parallels drawn on the dial, whenever there is need and the matter requires it. By like reasoning, if we compute the arc of $78^{\circ} 4'$ from Table 18 — which corresponds to hour 11 from setting in $\mathfrak{S}$ — in the circle described from G, from the meridian line toward the right, then the straight line from G passing through the end of this arc will cut the tropic of $\mathfrak{S}$ at the same point of hour 11 from setting. And so with the rest.

[Margin: Finding the points in the hours from rising or setting for the parallels, by the tangents of the complements of the Sun's altitudes.]

5. By yet another way, too, you will find the points of the parallels in these same hours from rising or setting, if from Table 10 you take the complements of the Sun's altitudes, and transfer their tangents from the position of the style — reckoned to the whole sine DC, equal to the style — onto the corresponding hours. For these will cut the hours at the points of the parallels, as we showed in Chapter 8, Note 12.

[Margin: Finding the points of all the parallels in the hours from rising or setting, by the rising amplitudes (ortive latitudes).]

6. Besides, we shall find the points of the parallels in the hours from rising or setting by the rising or setting amplitudes — a method proper to the hours from rising or setting — in this way. Having prepared a figure of the rays of the rising amplitudes, in the manner of the figure of the rays of the signs of the Zodiac (as I shall teach in the scholium, Note 2), draw from the position of the style a perpendicular to the hour-line on which the points of the parallels are to be investigated; and from the point where the hour-line cuts it, take on that same hour-line a straight length equal to the style; and along that perpendicular, from the same point of intersection, take an interval equal to the distance between the far end of this style and the position of the style; and finally, from the far endpoint of this interval draw a hidden straight line through the intersection of

the given hour with the equinoctial, and describe from that same endpoint an arc of a circle equal to the circle on which the rising amplitudes are marked. For if into this arc, from the straight line drawn through its centre and the equinoctial point, the arcs of the rising amplitudes are transferred, they will cut

the straight lines drawn from the same centre and extended through these amplitudes will cut the given hour-line at the points of the parallels.

For example: in the figure of Chapter 9, let the line d–e be given as drawn, which is hour 2 from rising; and to it, from C (the position of the style), let the perpendicular C–d be drawn, and let d–e be taken equal to the style CD; and by the interval C–e let d–b be cut off, on whichever side you please. Finally, from b as centre, draw the straight line b–f through the intersection of hour 2 from rising with the equinoctial; and, having described the circle g–h, transfer onto it, from the straight line b–f, the rising amplitudes on both sides. For the straight lines drawn from b as centre through the ends of the amplitudes will cut hour 2 from rising at the points of the parallels. And the same reasoning holds for the rest.

Demonstration. The arcs of the hour-circles from rising or setting (among which the horizon too is counted, since it is the circle of hour 24) touch the two greatest of the parallels — of those always visible and of those always hidden — as we demonstrated in the *Gnomonics*, Book 1, Proposition 10. Therefore, by Proposition 13 of Book 2 of Theodosius [Theodosius, *Sphaerica* II.13], the arcs of these same circles between the equator and any parallel are equal. Since, then, the arc of the horizon between the equator and any parallel measures the rising amplitude of that parallel, the arcs of the other circles will measure the same amplitude. And so, since — as we showed in the problem of Chapter 1 — the straight lines drawn from b through the rising amplitudes on the circle g–h cut off from the hour-line d–e those same amplitudes, it is clearly established that the points of the parallels have been rightly found.

[Margin: Another way of finding the points for the parallels in the hours from rising or setting.]

7. Finally, the points of the parallels in the hours from rising or setting will be found by the methods handed down in the scholium of Chapter 10, Note 4.

SCHOLIUM

[Margin: How the distances of the hours from rising or setting from the meridian are computed.]

1. The distances from the meridian which the hours from rising or setting have, at any elevation of the pole, will be found in any parallel of the Sun by this method. From Table 4, take the semidiurnal arc of the proposed parallel, in degrees and minutes, computed for the given altitude of the pole. Then, since the semidiurnal arc indicates the distance of hour 24 from rising or setting from the meridian, if we subtract 15 degrees from it, there will remain the distance of hour 23 from setting and of hour 1 from rising. From this, if we again take away 15 degrees, we shall have the distance of hour 22 from setting and of hour 2 from rising. And, proceeding thus in succession, we shall find the distances of the other hours — observing, however, this rule: when 15 degrees cannot be subtracted from the distance last found, then let that distance last found be taken away from 15 degrees. For thus there will remain the distance of the following hour on the other side of the meridian. And if 15 degrees are added to this, the distance of the next following hour will result; and so on in succession, until a number is produced greater than the semidiurnal arc, which will indicate the distance of an hour lying below the horizon, of which therefore no account is to be taken. When, however, we need the distances of the hours below the horizon, we shall obtain them by the continuous addition of 15 degrees to the distance of the hour which either falls on the horizon or is nearest to it.

[Margin: How the distance from the meridian of any hour from rising or setting may be found, even though the distances of the other hours are not available.]

Therefore, given any hour from rising: if you subtract its distance from hour 24 (when this is less than the semidiurnal arc) from the semidiurnal arc, you will make the remainder the distance of the given hour from the meridian before noon. But if you take the semidiurnal arc away from the distance which that hour has from hour 24 (when it is greater than the semidiurnal arc), you will leave the distance of that given hour from the meridian after noon. The contrary is to be understood of any hour given from setting. For if you take its distance from hour 24 away from the semidiurnal arc, there will remain the distance of that given hour from the meridian after noon; but if the semidiurnal arc is subtracted from the distance which that hour has from hour 24, the remainder will be its distance from the meridian before noon. By this method the following table has been computed for latitude 42 degrees.

The hour from rising and from setting: distances from the meridian at the beginnings of the signs

Upper panel (each cell is degrees° minutes'; "G." = degrees, "M." = minutes):

[Margin: How it may be known from the table of distances which hour from rising or setting is before noon or after noon. — How the distances of the halves and quarters of the hours are drawn from the table above. — How the declinations of the points of the ecliptic are found geometrically.]

In this table you see that the distance of hour 24 from rising or setting is always equal to the semidiurnal arc in every sign; and from this distance the rest arise by the continuous subtraction of 15 degrees, until a number smaller than 15 degrees is reached. For then that number, smaller than 15 degrees, is subtracted from 15 degrees, so that the remainder becomes the hour's distance on the other side of the meridian; and from this, finally, all the others are generated by the continuous addition of 15 degrees. Thus, in any sign, the hour of this table which first turns up with a distance smaller than 15 degrees is placed — together with all the preceding hours — on one side of the meridian, namely the eastern side if the hours are counted from rising, but the western side if from setting; while the remaining hours that follow lie on the other side of the meridian.

And although the table above contains only the distances of the whole hours, still from these the distances of the halves and quarters of the intermediate hours will also easily be known: namely, for one-quarter add or subtract $3^{\circ} 45'$, for one-half $7^{\circ} 30'$, and for three-quarters $11^{\circ} 15'$, from the preceding distance, according as the distances increase or decrease. For example, in ♋ [Cancer], hour $3\frac{1}{2}$ from rising will be distant from the meridian $60^{\circ} 33'$; but hour $19\frac{3}{4}$ [?] from setting will be distant from the meridian $49^{\circ} 18'$; and so with the rest.

Diagram. A large geometric construction (framed) for finding, by ruler and compass, the declinations of the signs and their rising/setting amplitudes, described in Note 2 below. The figure combines an upper declination construction and a lower amplitude construction sharing the horizontal base-line C–R–A. Readable labels and positions:

- A (right edge, mid-height): centre of the outer construction; right end of the horizontal line C–A
- C (left end of the horizontal line): centre of the inner semicircle BD
- R (centre of the horizontal line C–A)
- B (top-right, on the arc): top end of the vertical diameter of the semicircle
- D (right/lower edge): lower end of that diameter
- E (upper centre, on the arc): point where the pole-altitude complement is marked; joined to A
- H (just below E, macron over it): foot of the perpendicular F–H to E–A

- F (left, on the arc): endpoint of the maximum-declination arc E–F
- G (top, right of K): auxiliary point for setting the perpendicular (arc E–G = arc E–F)
- K (upper-left, on the arc): endpoint of the divided semicircle I–F–K
- I (right-centre, on the arc): other endpoint of that semicircle
- L (left, below N): division point (arc K–L)
- M (centre-low): division point (arc I–M)
- N (left, below K): division point (arc F–N)
- O (centre, below H): division point (arc F–O)
- P (inner left-centre): declination point on arc E–F
- Q [?] (inner, near P, on a dotted line): second declination point on arc E–F
- S (lower centre): point on the circle found via $R-S \parallel B-D$
- T (right edge, mid-low): foot of perpendicular S–T to B–D; centre of the lower semicircle V–S–X
- V (right edge, below A): endpoint of the lower semicircle
- X (bottom-right corner): other endpoint of the lower semicircle
- Y [?] (lower-right, inside): division point (arc V–Y)
- Z [?] (near S—a region): division point (arc X–Z) — label not clearly resolved
- a [?] (α -like, lower-right inside): division point (arc S–a)
- b [?] (bottom centre): division point (arc S–b)
- c [?] (small, right of S): amplitude point on arc D–S
- d [?] (small, right-below S): amplitude point on arc D–S

[Margin: Where the computation of the declinations is taught. — How the rising or setting amplitudes of the points of the ecliptic are investigated geometrically.]

2. The declinations, moreover, of the signs, and their rising and setting amplitudes, we shall determine geometrically by this method. From A, having described the semicircle BD, and having drawn in it the diameter BD cut at right angles by the radius CA, let there be counted from point C the complement of the pole's altitude — or from point B the pole's altitude itself — up to E; and let the radius of the equator EA be joined. Then, the Sun's maximum declination of $23^{\circ} 30'$ having been computed, let a line be drawn from E to F, and from F a perpendicular FH to EA — which will easily be done if EG is taken equal to the arc EF and a ruler is laid to the points F, G. From H also, through F, let the semicircle IFK be described and divided into 6 equal parts — which too will easily be done if, with the same radius FH, the arcs KL, IM, FN, FO are cut off. For the straight lines LM, NO will cut the arc EF at the declination points P, Q; so that the

arc EF is the declination of ♋ [Cancer] and ♑ [Capricorn]; EP the declination of ♊ [Gemini], ♌ [Leo], and ♐ [Sagittarius], ♒ [Aquarius]; EQ the declination of ♉ [Taurus], ♍ [Virgo], and ♏ [Scorpio], ♓ [Pisces]. And the straight lines AE, AQ, AP, AF are the radii of the signs — as was handed down in the *Gnomonics*, Book 1, Proposition 1, and in Book 1 of the *Astrolabe*, Lemma 19, and in the scholium on Canon 3 of Book 3 of the same.

We shall also teach how to compute the declination of any point of the ecliptic, at the end of this booklet, in Problem 1, so that it may be transferred from E onto the circumference BC [?], or onto other circles, whenever the matter requires.

After this, FR having been drawn parallel to EA and cutting the diameter of the horizon CA at R, let RS be drawn through R parallel to BD, cutting the circle at S. (This point S will also be found if from D the rising amplitude of ♋ [Cancer] or ♑ [Capricorn] is counted, which at the pole's altitude of 42 degrees amounts to 32° 27' — and how to compute this for every altitude of the pole we shall teach at the end of the booklet, in Problem 3.) Then, ST having been drawn perpendicular to BD, let the semicircle VSX be described from T through S; and this being divided into 6 equal parts (which will easily be done if, with the same interval of the radius ST, the arcs VY, XZ, Sa, Sb are cut off), let the straight lines YZ, ab be joined, which will cut the arc DS at the rising or setting amplitudes: so that DS is the amplitude of ♋ [Cancer] and ♑ [Capricorn]; Dc the amplitude of ♊ [Gemini], ♌ [Leo], and ♐ [Sagittarius], ♒ [Aquarius]; Dd the amplitude of ♉ [Taurus], ♍ [Virgo], and ♏ [Scorpio], ♓ [Pisces] — as we demonstrated in Book 3 of the *Astrolabe*, in the scholium on Canon 6. And the straight lines AD, Ad, Ac, AS will be the radii of these same amplitudes.

By the same method we shall find the declination and the rising or setting amplitude of any point of the ecliptic, if — for the arc of the ecliptic between that point and the beginning of ♋ [Cancer] or ♑ [Capricorn] (whichever, of course, is nearer) — similar arcs are taken on the circles IFK, VSX, beginning from the points F and S, and through their ends lines are drawn parallel to the straight lines AK, AX.

We shall also teach how to compute the rising or setting amplitude [latitudo ortiua, occidua] of any point of the ecliptic, at the end of the booklet in Problem 3, so that it may be transferred from D onto the circumference DC, or onto other circles where needed. And these rising amplitudes, computed at the beginnings of the signs for various elevations of the pole, we shall set out in Table 5.

[Margin: The same straight line drawn from a point on the equinoctial cuts two hours from rising or setting, equally distant from that point, of opposite parallels. — By this method the points of the parallels in the hours from rising or setting are to be examined.]

3. Moreover, just as we said in the scholium of Chapter 8, Note 1 — that one and the same straight line drawn through any hour on the equinoctial cuts two hours from noon and from midnight, equally distant on either side from that hour, at the points of two opposite parallels — so too the same thing happens in the hours from rising or setting. For a straight line drawn, say, through hour 22 on the equinoctial, cutting hour 23 at the point of $\mathfrak{S}$ [Cancer], will cut hour 21 at the point of $\mathfrak{V}$ [Capricorn]. And a straight line drawn through hour 20 on the equinoctial, cutting the same hour 23 at the point of $\mathfrak{S}$, will cut hour 17 at the point of $\mathfrak{V}$. Finally, a straight line drawn through hour $16\frac{1}{2}$ on the equinoctial, cutting hour 12 at the point of $\mathfrak{S}$, will cut hour 21 at the point of $\mathfrak{V}$ — because hour 12 and hour 21 are each distant $4\frac{1}{2}$ hours on either side from hour $16\frac{1}{2}$. And by this method you will be able to test almost all the points of the parallels that have been found: namely, whether any two points of opposite parallels correspond to each other by a straight line drawn on the equinoctial through an hour equally distant from the hours of those points.

This is briefly demonstrated as follows. Let AB be the equator, and CD, EF two opposite parallels. Through point G of the equator let the circle of any hour from setting be drawn, cutting the parallels at H, I. Through the two points A, B likewise, equally distant from G, let two other hour-circles from setting pass, CAE and DBF. Finally, through D, G let a great circle be drawn, which I say passes through E. Likewise let a great circle be described through C, G, which I assert passes through F. For the circle DG will cut —

— for the circle DG will cut the parallel EF at E. And since, by Proposition 18 of Book 2 of Theodosius [*Sphaerica* II.18], the arcs GD, GE are equal, as are GH, GI, the connecting straight lines DH, EI will be equal, by Proposition 3 of Book 3 of the same. [a] Therefore, from the equal parallels the lines DH, EI will cut off equal arcs. Since, then, by Proposition 13 of Book 2 of the same, the four hour-spaces CH, HD, EI, IF are equal — being of course similar to the equal arcs AG, GB (because, by Proposition 15 of Book 1 of our *Gnomonics*, the hour-circles from rising or setting touch the same greatest parallel of the always-visible stars) — the circle DG will necessarily pass through E. And by the same reasoning we shall show that the circle CG passes through F, which is what was proposed. And since a straight line sent out from any hour-point on the equinoctial through a point of

any parallel reproduces the great circle drawn from G, it is clearly established, that which we concluded at the beginning of this Note 3.

[Margin: a — [Theodosius] III.28.]

Diagram. A square framed figure illustrating the demonstration of Note 3. A horizontal line (the equator AB) runs through the middle, with two opposite parallels arching above and below it, and several hour-circle arcs crossing them. Readable labels:

- C (upper left): left end of the upper parallel CD
- H (top centre): intersection of the hour-circle through G with the upper parallel
- D (upper right): right end of the upper parallel CD
- A (mid-left, on the equator): point on the equator
- G (centre, on the equator): the hour-point through which the hour-circle passes
- B (mid-right, on the equator): point on the equator
- E (lower left): left end of the lower parallel EF
- I (bottom centre): intersection of the hour-circle through G with the lower parallel
- F (lower right): right end of the lower parallel EF

4. But now, if in that dial which we described in Chapter 6 — where, because of the too-small elevation of the pole, its centre can scarcely be obtained — someone wishes to lay out the hours from rising or setting, then lines must be drawn through the hour-points of the equinoctial line (through which, according to the prescription of Table 2 of Chapter 14, they must pass), parallel to those hours from noon or midnight which, in Table 1 of the same chapter, correspond to the hours from rising or setting — even if no other points are found on the line of hour 6 from noon or midnight (since it is not present) through which they should be drawn.

[Margin: The hours from rising or setting in a dial where the centre is not available. — That the hours from rising or setting have no place throughout the whole year in a region where the pole's altitude is greater than $66^{\circ} 30'$.]

5. But in a dial which has so great an elevation of the pole that it cannot admit an equinoctial line — as was described in Chapter 7 — there is no reason for anyone to want the hours from rising or setting in it, since they cannot be had: for they touch the greatest parallels of the always-visible and of the always-hidden stars,

as we demonstrated in the *Gnomonics*, so that the hour-lines cannot indicate the hours from rising or setting throughout the whole year, wherever the pole's altitude is greater than $66^{\circ} 30'$. They will have to be drawn only at a pole-elevation which does not exceed $66^{\circ} 30'$ — which will not be difficult. For since in such a dial the equinoctial line can conveniently be drawn (the tangent of the pole-altitude $66^{\circ} 30'$ — which is the greatest of all those at which the hours from rising or setting are of use throughout the whole year — contains only about 23 [?] parts, so that they can easily be transferred downward from the position of the style to find the point through which the equinoctial line, perpendicular to the meridian, is to be drawn), the lines of the hours from rising or setting are to be drawn through its hour-points (through which, by the prescription of Table 2 of Chapter 14, they must pass), equidistant from those hours from noon and midnight which, in Table 1 of the same chapter, correspond to the hours from rising or setting — as we explained at the beginning of the said Chapter 14.

LEMMA

To extend a straight line, without error, through two points however close together.

This is Lemma 11 of Book 1 of our *Astrolabe*, which we worked out and demonstrated by various methods. But since not infrequently we need it in this booklet — especially in what follows — it is worth briefly repeating its first construction here. Let then a straight line be extended through two points, A, B. From A as centre, through B, let a circle be described, from which two equal arcs BC, BD are cut off, whether at the same interval AB or at a greater or smaller one. Then from C, D let two arcs be drawn on either side, at such an interval that they may conveniently intersect each other at E and F. For the straight line AE will pass through B, as was demonstrated in the *Astrolabe*. And by the same reasoning the straight line AF will pass through B — so that the four points F, A, B, E lie on one straight line. But if the line AE must be produced further, let another circle be described from A through E, from which again two equal arcs EG, EH are cut off; and from G, H let two arcs be drawn cutting each other at I. For the straight line AI will pass through the points B, E, F, as we showed in the same place. And in this way one may proceed as far as one pleases.

[Margin: A most elegant construction for drawing a straight line through two points however close together.]

Diagram. A framed figure for the Lemma. A horizontal straight line carries, from left to right, the points F, A, B, E, I; pairs of compass-arcs intersect above and below the line to fix the collinear points. Readable labels:

- F (left, below/on the line): intersection point on the extended line
- A (left-centre, on the line): first given point / circle centre
- B (centre, on the line): second given point
- E (right-centre, on the line): far intersection point
- I (right, on the line): further intersection point of the produced line
- C (top, above A–B): upper arc-intersection near the first circle
- D (bottom, below A–B): lower arc-intersection near the first circle
- G (top, above E): upper arc-intersection near the second circle
- H (bottom, below E): lower arc-intersection near the second circle

CAPUT XVI

The hours from noon and from midnight on a plane which is equidistant from [parallel to] some vertical declining from the prime vertical — that is, on the plane of some declining wall that is perpendicular to the horizon.

1. Now that the matters concerning the horizontal dial have been dispatched, there follow the vertical or mural dials, in which nothing new will have to be taught; rather, nearly everything hitherto handed down is to be transferred here, with a few changes. In this place, however, we shall treat only of dials declining from the meridian, so that the multitude [of...]

[Margin: Why only dials declining from the meridian are treated here.]

[Margin: The horizontal line.]

so as to avoid too great a multitude of precepts. For from the delineations produced beyond the horizontal line we shall derive the dials declining toward the north, as we shall teach in the scholium of chapter 19.

Let, then, a straight line AB be drawn in any way, to serve as the horizontal line; on it let the position of the style, C, be chosen, and let a straight line CD be erected, equal to the style. Now on any straight line take as many segments as you please, each equal to the style CD, and divide the first segment CD into 10 equal parts. From that line take the Tangent of the wall's declination, 30 degrees — (for we suppose the plane, or wall, to decline from the meridian toward the east by 30 degrees; how that declination is to be investigated we shall teach in chapter 22) — namely about $5 \frac{7}{10}$ [parts]; and transfer it from C, the position of the style, toward the right if the plane inclines from the meridian toward the east, as ours does, but toward the left if toward the west, as far as B. Likewise transfer the Tangent of 60 degrees, the complement of the declination, which is a little more

than $17 \frac{3}{10}$, from the same position of the style C into the opposite direction, as far as A.

[Margin: A geometric finding of the points through which the meridian line must be drawn, and also the equinoctial, which is the line of the 6th hour. The center of the dial.]

These points B and A may also, if you like, be found geometrically as follows. From D describe a circle HGI, and toward the right take an arc GH equal to the declination, 30 degrees — (since we suppose our plane to decline from the meridian toward the east by 30 degrees; for the said arc of declination must be taken toward the left if the plane inclines toward the west) — and in the opposite direction an arc GI equal to the complement of the declination, namely 60 degrees in our example. For the hidden [construction] lines DH, DI will cut the horizontal in the points B, A. Through B the meridian EBF must be drawn, perpendicular to the horizontal; while through A must be drawn both the equinoctial line and the line of the 6th hour, as we demonstrated in the scholium to Proposition 1 of Book 3 of the *Gnomonics*.

2. Next let the Tangent of the pole's altitude, 42 degrees — namely 9, reckoned relative to the whole sine DB — be transferred along the meridian from B as far as E; and the Tangent of the complement of the same pole-altitude, namely $11 \frac{1}{10}$, as far as F. And E will be the center of the dial, and F the point through which the equinoctial is to be drawn from the point A already found; for the pole is distant from the horizon AB, along the meridian, by the altitude of the pole, while the equator [is distant] by its complement.

The points E and F will likewise be found geometrically if BR is taken equal to the straight line DB, and from R a circle is described, in which, from the straight line RA upward, the pole's altitude, 42 degrees, is counted off. For the straight line drawn from R through the end of the pole count will give the center E. And if in the same circle the complement of the pole's altitude is counted off downward, the straight line extended from R through the end of the count will give the point F — so that the straight line AF is the equinoctial line.

[Margin: The equinoctial line.]

For conceive the triangle DBC to be moved about BC until it stands at right angles to the plane of the dial — that is, until it lies in the plane of the horizon. Likewise [conceive] the triangle ERF to be moved about EF until the point R coincides with the point D, and the straight line RB with the straight line DB; for in that motion the line RB does not depart from the plane of the horizon, and it is equal to the

line DB, existing in the same plane. In that position RE, forming with RB (or with DB, which is the same) the angle of the pole's altitude, will be the axis of the world: for in that position the triangle REF lies in the plane of the meridian, which is then drawn through the lines DB, EF, and therefore also through RB, EF. The axis RE therefore meets the meridian line at E, the pole of the world — that is, at the center of the dial. And since the axis is at right angles to the equator, and therefore perpendicular to the common section of the equator and the meridian; and since RF is perpendicular to the axis, because the angle ERF, standing on the quadrant, is a right angle: RF will be the common section of the equator and the meridian, seeing that RF lies in the plane of the meridian perpendicular to the axis, and the equator passes through R, or D, the center of the world, and makes (as has been said) with the meridian a section forming right angles with the axis ER. The equator therefore meets the plane of the dial at F; and consequently the straight line drawn through A and F will be the equinoctial line.

This, however, can be proved more easily. For since BE is the Tangent of the angle ERB, the pole's altitude, and BF the Tangent of its complement, namely of the angle FRB, reckoned relative to the whole sine RB, RE will fall entirely upon the pole, or center of the dial, and RF [?] upon the point of the equator.

[Margin: The equinoctial line, another way.]

The same equinoctial line may be drawn, if you like, in this way: first, by Problem 6 at the end of the booklet, compute the arc of the declining plane between the horizon and the equator, which in our example is 29 degrees 3 minutes. For if from A a circle is described, in which this arc of 29 degrees 3 minutes is counted off downward from the straight line AB, the straight line sent out from A through the end of the count will give the equinoctial, which — if no error has been made — will pass entirely through F, the point found before.

For while the triangle DBC still remains in its proper position (so that D is at the center of the world), let the horizon and the equator be drawn through the straight line DA, and let them form, in the vertical to which the plane of the dial is parallel, [Margin: a — Euclid XI.16] straight lines parallel to the straight lines they form in the plane of the dial. [Margin: b — Euclid XI.10] The angle which those lines make in the said vertical at the center of the world will be equal to the angle which these make in the plane of the dial at A. Since, therefore, that angle at the center of the world stands upon the arc of that vertical lying between the horizon and the equator, and the angle BAF in the plane of the dial stands, by construction, upon a similar arc, this angle BAF will be equal to that one; and therefore AB, AF will be the common sections of the horizon and the equator.

[Margin: The style-line.]

3. The style-line — that is, the common section of the plane of the dial and of its own meridian — must be drawn from the center E, perpendicular to the equinoctial line, as we showed in the *Gnomonics*; such is EK, which necessarily passes (if no error has been made) through C, the position of the style, because the proper meridian of the dial passes at right angles through DC, the erected style, and through the center E.

[Margin: In what way the style-line may be drawn precisely. The pole's altitude above the declining plane.]

But if, in the first place, after the center E has been found, the style-line is drawn through C (which will be drawn more precisely if, taking a straight line EN equal to EB, a parallel to AB is drawn through N, on which NO is taken equal to BC; for thus, through the three points O, E, C, the style-line will be extended more accurately — and the same line may also, by the Lemma we set before this chapter, be drawn precisely through the two points E, C alone) — then at C let a perpendicular CZ be erected, equal to the style; the straight line EZ will be the axis of the world, and ZEC the angle of the pole's altitude above the plane of the dial; while the straight line ZK, perpendicular to the axis, will be the common section of the equator and of the proper meridian, meeting the style-line at the point K, through which the equinoctial line is to be drawn. All this has been shown in the *Gnomonics*.

[Margin: The style-line, another way. The equinoctial line, another way. The style-line, another way.]

Since the angle BEC is equal to the angle CAK — because the two remaining angles B, C in the triangle BCE are equal to the two remaining angles K, C in the triangle KCA — if the equinoctial line AF has been drawn first, the style-line will be conveniently drawn by making the angle FEK equal to the angle BAF. Or, if the style-line EC has been described first, we shall easily draw the equinoctial line by making BAF equal to the angle BEC. Or indeed, if from E a circle is described (if you please), in which, from the meridian line toward the side of the style, the arc computed by Problem 6 at the end of the booklet is counted off — (that is, the arc of the declining plane between the horizon and the equator, which is equal to the arc of the same plane between its proper meridian and the meridian of the horizon, and which we said in our example contains 29 degrees 3 minutes) — the straight line sent out from E through the end of the count will be the style-line.

This will be demonstrated in the same manner in which it was shown in Number 2 that the straight line AF is the equinoctial line.

[Margin: The line of the 6th hour.]

4. The line of the 6th hour will be the straight line EA, drawn through the center E and the point A. It may also be drawn in this way, if you like. By Problem 8 at the end of the booklet, find the arc of the declining plane between the meridian of the horizon and the circle of the 6th hour; or between the horizon and the same circle of the 6th hour, which is the complement of the former. In our example the former arc contains 65 degrees 46 minutes, the latter 24 degrees 14 minutes.

[Margin: The line of the 6th hour, another way. The line of the 6th hour, another way.]

For if from E a circle is described, in which the former arc is counted off from the meridian line toward A, the straight line drawn from E through the end of the count will give the line of the 6th hour, which will pass entirely through A if no error has been made. Or if from A a circle is described, in which the latter arc is counted off from the horizontal line AB toward E, the straight line drawn from A through the end of the count will give the same line of the 6th hour, which will necessarily pass through the center E, unless an error has been made. Both will likewise be demonstrated, as was said of the equinoctial line in Number 3.

Diagram. A large, very dense full-page dialling-construction figure occupying most of the page, enclosed in a heavy rectangular frame. It shows the complete construction of a declining vertical (mural) dial for latitude 42° and 30° declination, developed in the surrounding text: the horizontal line AB, the meridian EBF, the equinoctial AF, the style-line EK, the line of the 6th hour EA, and the full pencil of hour-lines radiating from the two centers (E, the dial center, and A). A great many solid and dotted construction lines cross the field; numerous compass-arcs and dotted auxiliary squares/perpendiculars (the alternative constructions of Numbers 2–4) are overlaid. Below the main construction are four separate graduated scale-bars used to lay off the tangent-distances.

Readable labels (capital construction points):

- E: principal dial center (upper-center), where most hour-lines converge; the meridian-scale mark "Num.100" stands beside it
- D: just below/left of E

- A: on the horizontal line (lower-center), the second pencil-center of hour-lines
- B: on the horizontal line, right of A
- C: at the far left, on the lowest scale
- Q: far left, on a horizontal line
- N: center (near E)
- R: upper-center
- M: upper-right
- K, F, L: cluster right of center
- H, I, G: right side
- X, Y: a dotted auxiliary square near center-left
- Z: near center
- S, T, V: upper-left, dotted auxiliary construction

Hour-line numerals labelling the radiating lines around the rim: 4, 4½, 5, 5½, 6, 6½, 7, 7½, 8, 9, 10, 11, 12, 1, 2, 2½, 3, 3½. Numerous lowercase letters (z, u, g, r, i, h, e, k, d, l, m, q [?]) mark hour-line endpoints around the border; several are too small/overlapped to resolve individually [?].

The four scale-bars at the foot, each a graduated ruler numbered 10 · 20 · 30 · 40 · 50 · 60 with endpoint letters (C, D, B, K, N, A, L):

- "Pro horiz. et lin. styli" [For the horizontal and the style-line]
- "Pro mer." [For the meridian]
- "Pro æquin." [For the equinoctial]
- "Pro Vert" [For the vertical]

[Many peripheral labels, both the lowercase hour-line endpoints and the small hour-numerals, are at or below the resolution of the scan and could not be individually confirmed.]

[Margin: The line of the 6th hour, another way.]

When the point A can scarcely be obtained, because of its excessive distance from the point C — which happens when the angle of declination BDC is very small, and the angle CDA, of the complement of the declination, very large — then, although we can draw the line of the 6th hour by means of the arc of which we spoke just now, we shall nevertheless draw the same line without it, by this method. At R erect a perpendicular to AB, from which cut off RS equal to BE; make the angle VST [equal to] the complement of the declination, and set the

straight line ST equal to the straight line SR; and finally through T draw TV parallel to AB, cutting RS produced at V. For the straight line drawn from V through E will give the 6th hour, so that it passes through the point A, if that can be obtained on the dial.

[Margin: In which case the style-line must be drawn first, and then the equinoctial.]

That it may be drawn more accurately when the point A is not available, we shall take on SE produced a straight line EX equal to ES; and, having erected at X a perpendicular XY to EX, we shall take the straight line XY equal to the straight line SV. For thus, through the three points V, E, Y, the line of the 6th hour VE will be drawn more precisely. And in this case the style-line must be drawn first, as we said in Number 3, so that from F a perpendicular can be drawn to it for the equinoctial line.

[Margin: c — Euclid VI.4]

Let this be the demonstration of that construction. The triangles ADB (for, to demonstrate this, let us suppose that we have the point A) and TVS are equiangular, since the angles T, V are right angles, and the angles B, S are equal to the complement of the declination. Therefore, as AB is to BD — that is, to BR, or to ES — so is ST — that is, RS, or BE — to SV. And, alternately, as AB is to BE, so is ES to SV. Wherefore, since the triangles ABE, ESV have their sides about the angles B, S proportional, and are so composed at the angle E that the homologous sides...

[Margin: a — Euclid VI.32]

AB, ES and BE, SV are parallel, the straight lines AE, VE will make one straight line; and consequently the straight line VE, produced, will fall upon the point A — that is, it will give the line of the 6th hour, which we said was to be drawn from E through A.

[Margin: The line of the 6th hour, another way.]

We shall also very conveniently describe the line of the 6th hour by the means which we shall set out in chapter 17, Number 1.

5. Now that the horizontal line has been drawn, together with the meridian, the equinoctial, the style-line, and the line of the 6th hour — the points B, A, E, F having been found by means of the Tangents, as we taught at the outset in Numbers 1 and 2, setting aside the other geometric methods which we employed (unless you wish to use them for a more precise construction) — let us proceed to

describe the hours. In the first place we shall set out the method that requires the distances of the hours from the equinoctial line: of these, the former are derived from the sixth table, but the latter from the inclination of the meridian of the horizon to the meridian of the declining plane, as we shall presently teach. Then we shall describe the hours on the declining plane without their distances from the style-line: so that this latter method may suffice, even if the sixth table had not been computed for all elevations of the pole, and the aforesaid inclination of the meridians were unknown.

[Margin: How the distances of the hours on the horizontal, from the position of the style, are elicited from the sixth table, on a plane declining from the meridian toward the east.]

For the former method, then, a certain little table must be constructed from the complements of the arcs of the horizon that belong, in the left-hand column, to the given pole-altitude of the sixth table, in this way. To the complements of the arcs of the hours after noon, if the dial declines from the meridian toward the east, let the declination of the dial be added; but from the complements of the arcs of the hours before noon let the same wall-declination be subtracted, or the complements themselves [subtracted] from the wall-declination — the smaller number, that is, from the greater. And finally, when an hour before the 6th hour from midnight is to be given, let the complement of the wall's declination be added to its arc — not to its complement. For thus will be produced, or made up, the remaining distances of the hours from the position of the style on the horizontal line.

[Margin: Which distances belong to the left of the style, and which to the right, on a wall declining from the meridian toward the east.]

Now when the wall's declination has been subtracted from the said complements, or when the complement of the wall's declination has been added to the horizontal arcs themselves, the distances of those hours will belong to the left of the style's position; but when the aforesaid complements of the arcs have been taken from the wall's declination, or added [to it], the distances of the hours will be generated toward the right of the style's position.

[Margin: How the distances of the hours on the horizontal line, from the position of the style, are gathered from the sixth table, on a plane declining from the meridian toward the west.]

But if the dial declines from the meridian toward the west, let the contrary be done. For to the complements of the arcs of the hours before noon the wall's

declination must be added; while from the complements of the arcs of the hours after noon the wall's declination must be taken away, or the complements themselves [taken] from the wall-declination — the smaller number, that is, from the greater; and finally, when an hour after the 6th hour from noon is to be given, the complement of the wall's declination must be added to its arc, not to its complement. For thus will be produced, or made up, the remaining distances of the hours from the position of the style on the horizontal line.

[Margin: Which distances look toward the left of the style, and which toward the right, on a wall declining from the meridian toward the west.]

And if indeed the wall's declination has been added to the complements of the arcs, or when the said complements have been subtracted from the wall-declination, the distances of those hours will belong to the left of the style's position; but when the wall's declination has been subtracted from the complements of the arcs, or the complement of the wall's declination has been added to the arcs themselves, the distances will look toward the right of the style's position.

For example: the complement of the arc of the 1st hour from noon, at latitude 42 degrees, contains in the sixth table 10 degrees 10 minutes. If, then, the wall's declination of 30 degrees is added — our dial declining from the meridian toward the east — the distance from the position of the style toward the right becomes 40 degrees 10 minutes, for the 1st hour from noon. Likewise, the complement of the arc of the 8th hour from midnight is 49 degrees 13 minutes. If, then, the wall's declination of 30 degrees is taken away, the remaining distance from the position of the style toward the left becomes 19 degrees 13 minutes. Again, the complement of the arc of the 11th hour from midnight is 10 degrees 10 minutes; and when this is subtracted from the wall's declination of 30 degrees, there remains the distance from the position of the style toward the right of 19 degrees 50 minutes, for the 11th hour from midnight. Finally, the arc of the 5th hour from midnight (which is before the 6th hour) contains 21 degrees 49 minutes. When the complement of the wall's declination, namely 60 degrees, is added, the distance from the position of the style toward the left becomes 81 degrees 49 minutes. And so with the rest.

By this method we have constructed the following little table for our dial declining from the meridian toward the east by 30 degrees, at latitude 42 degrees. Now when any distance found is greater than a quadrant, it is not placed in the table, because its hour-distance does not fall on the horizontal line. But in that case its complement to 180 degrees must be carried over to the opposite side, by

means of its tangent. The point so found will belong to the hour to be counted from noon, if the one that was sought — and which does not fall on the horizontal line — was counted from midnight, and vice versa.

Table of the hour-distances from the position of the style on the horizontal line, when the dial declines from the meridian toward the east. For latitude 42 degrees. [*Tabella distantiarum horariarum à loco styli in horizontali linea, quando horologium declinat à mer. in ortum. Ad latitudinem grad. 42.*]

Hours from midnight (G. = degrees, M. = minutes):

Hour	5	5½	6	6½	7	7½	8	8½
G.	81	71	60	48	38	28	19	11
M.	49	8	0	52	11	14	13	5

To the left of the style. [*Ad sinistram styli.*]

Hours from midnight — and (last column) from noon (G. = degrees, M. = minutes):

Hour	9	9½	10	10½	11	11½	12	½ (from noon)
G.	3	2	8	14	19	24	30	35
M.	47	51	53	30	50	58	0	2

To the left | To the right of the style. [*Ad sinist. | Ad dextram styli.*]

CAPVT XVI. (continued)

(Declining vertical / mural dials — continued from the preceding page.)

Table (concluded from the preceding page): hour-distances from the position of the style on the horizontal line, for a dial declining from the meridian toward the east by 30 degrees, at latitude 42 degrees

Hours from noon [*Horæ à mer.*] (G. = degrees, M. = minutes):

Hour	1	1½	2	2½	3	3½	4	4½
G.	40	45	51	57	63	71	79	88
M.	10	30	7	9	47	5	13	14

To the right of the style. [*Ad dextram styli.*]

These distances are exactly the same in a dial declining from the meridian toward the west; but the hours must be changed into their complements to 12, and those that were previously reckoned from midnight must now be reckoned from noon, and vice versa. Likewise, the distances that inclined toward the left of the position of the style will now lie toward the right, and vice versa. Thus, just as in our dial the 10th hour from midnight stands 8 degrees 53 minutes to the right of the position of the style, so in a dial declining from the meridian toward the west, at the same latitude of 42 degrees, the 2nd hour from noon likewise stands 8 degrees 53 minutes to the left of the position of the style — and so with the rest.

[Margin: How the aforesaid distances are fitted to a plane declining from the meridian toward the west by 30 degrees.]

This little table can also very conveniently be constructed from the arcs of the sixth table — not, however, from their complements — in this way. For a dial declining from the meridian toward the east, the hour-arcs of the sixth table after the 6th hour are to be subtracted from the complement of the wall's declination, wherever such subtraction is possible; whereas the arcs of the hours before the sixth are to be added to that same complement of the declination — for so are produced the arcs whose tangents are to be transferred to the left of the style. But when, for the hours after the 6th, the arcs in the sixth table are greater than the complement of the declination, then the complement of the declination is to be subtracted from those arcs; and if the hours after noon are being counted, the wall's declination itself is to be added to the complements of the sixth-table arcs — for so are produced the arcs whose tangents are to be transferred to the right of the style. The opposite is to be done in a dial declining from the meridian toward the west.

[Margin: How the hour-points on the horizontal line are found by means of the tangents.]

6. Now if you transfer the tangents of these distances — taken with respect to the whole sine DC, that is, of the style — from the position of the style C onto the horizontal line, to the left or to the right as the table directs, and likewise from the point O in the opposite direction along the straight line O N: three points will be found for drawing each single hour-line. One of these lies on the horizontal line, another on the straight line O N, and the third is E, the center of the dial. And so the straight lines drawn out from E, the center of the dial, through the hour-points on the straight lines A B and N O once found, will be the hour-lines. Of these, the ones that lie to the left with respect to the meridian line, as we face the dial, belong to the hours

reckoned from midnight; those to the right belong to the hours reckoned from noon — provided, of course, that the dial declines from the meridian toward the east or west. For in dials declining toward the north the reverse must be understood.

[Margin: Which hour-lines belong to the hours reckoned from midnight and which to the hours reckoned from noon.]

Just as, in the upper table, the distances of the whole and half hours were found, so too the distances of the quarter-hours can be found, if anyone wants them, from that same sixth table of horizontal arcs.

To find conveniently the points of the 9th and $9\frac{1}{2}$ hours — whose tangents are very small — one should add the tangent of the 9th hour, namely 66, to CB, the tangent of the wall's declination, which for us is 30 degrees, that is, 577; so that the composite tangent becomes 643 — that is, reduced to tenth-parts, a little more than 6 $\frac{1}{10}$. For this, transferred from the point B, will give the point of the 9th hour. Likewise the tangent of the $9\frac{1}{2}$ hour, which is 50, is to be subtracted from CB, the tangent of the wall's declination — that is, from 577 — so that the remainder becomes the tangent 527, that is, roughly 5 $\frac{1}{10}$; and this, transferred from B, will give the point of the $9\frac{1}{2}$ hour. This device is always to be used whenever some tangent is too small: namely, we either add it to the larger tangent on the other side of the style, or subtract it from the larger one on the same side, and so on, as was done with the tangents of the 9th and $9\frac{1}{2}$ hours. This is just what we noted in Chapter 2, Number 2 as well [recte: monuimus].

[Margin: What to do with the hours lying only a little from the line of the style, whose tangents are too small.]

7. If the tangents of the arcs of the verticals, from the sixth table taken with respect to the whole sine D A, drawn out for the given latitude of 42 degrees on the right-hand side, are transferred from A on both sides onto the vertical line — which is drawn through A parallel to the meridian line — we shall likewise have the hour-points on the vertical line, through which the hour-lines described a little earlier must pass, if no error has been made.

[Margin: The vertical line, and how the hour-points are found on it by means of the tangents.]

8. Again, to find the hour-points on the equinoctial line, another table must be constructed from the distances of the hours from the meridian, which we

set out in the table of the scholium to Chapter 1, in exactly the same way as the previous one was made. Only, in place of the plane's declination of 30 degrees, whose tangent is C B, one must take the inclination of the meridian of the horizon to the proper meridian of the declining wall — which is found by Problem 5 at the end of this little book, and in our example amounts to 40 degrees 48 minutes, whose tangent is KF with respect to the whole sine KZ. And in place of the sixth table, the table of the scholium to Chapter 1 is to be used, from which the arcs themselves are to be taken, not their complements as there. For example: the 5th hour from midnight is distant from the meridian — that is, from the point F — by 105 degrees. (For whenever an hour from midnight falls before the 6th hour, or an hour from noon after the 6th, one must take the complement, up to 180 degrees, of that distance found in the table of the scholium to Chapter 1.) Now, subtracting the 40 degrees 48 minutes of the inclination of the meridians, there remain 64 degrees 12 minutes for the distance of the 5th hour from midnight, which it has to the left of the line of the style. And so with the rest. This, then, is how the table stands.

[Margin: The distances of the hours on the equinoctial line from the line of the style; how they are found on a declining plane.]

Table of the hour-distances from the line of the style on the equinoctial [line], for latitude 42 degrees, when the declination of the plane amounts to 30 degrees

[*Tabella distantiarum hor. à lin. styli in æquinociali, ad latit. gr. 42. quando declinatio plani continet gr. 30.*]

First block — Hours from midnight [*Horæ à med. noc.*] (G. = degrees, M. = minutes):

Hour	3½	4	4½	5	5½	6	6½	7
G.	86	79	71	64	56	49	41	34
M.	42	12	42	12	42	12	42	12

To the left of the line of the style. [*Ad sinistram lineæ styli.*]

Second block — Hours from midnight [*Horæ à med. noc.*] (G. = degrees, M. = minutes):

Hour	7½	8	8½	9	9½	10	10½	11
G.	26	19	11	4	3	10	18	25
M.	42	12	42	12	18	48	18	48

To the left of the line of the style (hours 7½–9) | To the right of the line of the style (hours 9½–11). [*Ad sinistr. lin. styli.* | *Ad dextram lin. styli.*]

Third block — Hours from noon [*Horæ à mer.*] (G. = degrees, M. = minutes):

Hour	11½	12	½	1	1½	2	2½	3
G.	33	40	48	55	63	70	78	85
M.	18	48	18	48	18	48	18	48

To the right of the line of the style. [*Ad dextram lineæ styli.*]

The construction of this table is somewhat easier than that of the previous one, since it is enough to find the distances of two hours on either side of the line of the style — the two nearest ones. For if to these distances you keep adding continuously 3 degrees 45 minutes, or 7 degrees 30 minutes, or 15 degrees 0 minutes — according as the table proceeds by quarter-hours, half-hours, or whole hours — the distances of the other hours will also be found.

[Margin: How the nearest distances are fitted to a plane declining from the meridian toward the west by 30 degrees.]

These distances too are entirely the same in a dial declining from the meridian toward the west, provided you change the hours of the nearest table into their complements to 12 and reckon them from noon where the hours were being computed from midnight, and vice versa; and provided, likewise, that they now incline toward the right where the hours were tending toward the left, and the reverse.

[Margin: How the hour-points on the equinoctial are found by means of the tangents.]

And so, if the tangents of the distances of the nearest table — taken with respect to the whole sine ZK — are transferred onto the equinoctial from the line of the style, that is, from the point K, to the left or to the right as the table directs, we shall once again have the hour-points on the equinoctial line, through which the hour-lines described above will also pass, unless an error has been made.

9. But we shall draw the hour-lines with great exactness, even without the distances of the hours on the horizontal line from the position of the style, and without the distances on the equinoctial line from the line of the style, provided the lines of the 3rd and 9th hours have first been drawn with the utmost care. This is done as follows. Through B, drawn perpendicular to DBH, let there be e f; and from B, to the axis ER, let there also be raised the perpendicular Bd. On e f let two segments B e, Bf be taken, equal to Bd. For the straight lines D e, Df will cut the horizon at the points of the 9th and 3rd hours; and if through these, straight lines are extended out from E, the center of the dial, they will be drawn as the lines of the 9th and 3rd hours. And to draw these more accurately, one should use the Lemma set before this Chapter 16, because the points of the 9th and 3rd hours found on the horizontal line are only a little distant from the point E.

[Margin: An elegant way of laying out a declining dial without the sixth table and without the inclination of the meridians. How the lines of the 3rd and 9th hours are drawn without the tangents.]

Or else: on the straight line BD, extended below B, let two or three segments equal to DB be taken; and through the outermost point let a perpendicular to DB, or a parallel to e f, be raised. This will give the straight line Bd, transferred twice or three times over into that perpendicular — yielding other points for the 3rd and 9th hours, and so on.

That the straight lines D e, Df cut the horizontal line at the points of the 9th and 3rd hours will become clear thus. In Number 2 we demonstrated that, if the triangle BCD — or rather the whole plane through that triangle, together with the straight line e f, drawn about BC — is moved until it stands perpendicular to the plane of the dial and lies in the horizon, the straight line DBH will be the meridian line in the horizon, that is, the common section of the horizon and the meridian, passing in that position through the straight lines DB, BE. Likewise, if the triangle BER is revolved about B E until the straight line BR coincides with the straight line BD, and the point R with the point D, it will lie in the plane of the meridian along the straight lines DB, BE thus drawn; and the straight line R E, making at D with the meridian line of the horizon DB the angle of the pole's elevation, will be the axis of the world. Since, then, in that position the perpendicular e f raised through B stands as the equinoctial line in a horizontal dial, and the perpendicular Bd raised from B — the intersection of that same equinoctial with the meridian — to the axis, will be the common section of the equator and the meridian: therefore, as was demonstrated in Chapter 3, Number 1, once B e, Bf are taken equal to Bd, the points e and f will be

the points of the 9th and 3rd hours in the horizontal dial whose center is D. The straight lines D e, Df, therefore, are the lines of the 9th and 3rd hours in the horizontal dial, meeting the plane of the declining dial at the points of those same hours on the horizontal line. And it is evident that the straight lines D e, Df cut the horizontal line always in the same manner, even if the plane D e f be turned about BC.

From which it follows that, if e f be extended as far as one pleases, the points of the other hours too can be found on it — just as was done in the equinoctial line of the horizontal dial in Chapter 2, Number 3, namely by taking the tangents with respect to the whole sine Bd, and by cutting off from that same Bd, out of the straight line DBH, a segment equal to it, beginning at the point B so as to have it as the center of the equator, so that then, by Chapters 2 and 3, the hour-points may be found on e f. In just the same way we shall find the points of these same hours on the perpendicular which we directed above to be raised at D B extended, if the same tangents are taken with respect—

—to the whole sine Bd, and transferred, doubled or tripled and so on, into the said perpendicular, according as the portion DB was doubled or tripled, and so forth. By the same reasoning, so that these same points may be found by Chapter 3, one must take from the point of the straight line dBH through which the perpendicular is drawn — upward or downward — the straight line B d, doubled or tripled and so on, so that the center of the equator may be had with respect to that perpendicular, standing as the equinoctial line. And when, through the points found on e f, hidden straight lines are drawn out from D, the horizontal line will be cut at the hour-points; so that the hour-points on the horizontal line are found without the aid of the sixth table, by means of which they were found long ago above.

Diagram. A large rectangular construction figure filling most of the page, laying out the hour-lines of the declining dial by the tangent method of §9 (the "elegant delineation without the sixth table"). Within the frame a dense web of straight hour-lines crosses at several centers, with a semicircular arc (the equinoctial/hour-circle) sweeping through the middle; dotted lines mark auxiliary constructions. The periphery and the interiors of the radiating pencils are labelled with the hour numbers 1–12 and the intervening halves ($\frac{1}{2}$, $1\frac{1}{2}$, $2\frac{1}{2}$, $3\frac{1}{2}$, $4\frac{1}{2}$, $5\frac{1}{2}$, $6\frac{1}{2}$, $7\frac{1}{2}$, $8\frac{1}{2}$, $9\frac{1}{2}$, $10\frac{1}{2}$, $11\frac{1}{2}$). Readable letter-labels of construction points include the capitals A, B, C, D, E, F, G, H, I, K, L, M, N, O, Q, R, S, T, V, X, Y, Z and the small italic letters a, b, c, d, e, i, m, n, r, u, w, y; E lies near the upper central node and A near the lower central node of the crossing pencils. Because of

the density and the many rotated glyphs, the exact placement of a number of interior labels cannot be resolved with certainty — see the QA note.

At the lower left, four graduated scale-lines run horizontally across the foot of the figure, each captioned:

- **Pro horiz. et lin. styli** ("For the horizontal and the line of the style") — running between the points C and D, graduated 10, 20, 30 ... (to about 60).
- **Pro mer.** ("For the meridian") — running between the points D and B, graduated.
- **Pro æquin.** ("For the equinoctial") — running from K to N, graduated.
- **Pro vert.** ("For the vertical") — running between the points b, L and A, graduated.

Indeed, if — with respect to the whole sine DB — the complements of the arcs of the sixth table are transferred from B onto e f, points will be found on e f through which the straight lines drawn from D will cut the horizontal line at the same hours; because those straight lines take off from the horizontal line the arcs of the said complements, as we showed at the end of Chapter 1. And if, on DB extended, another point farther from D be taken, and through it a perpendicular to d B be raised, the tangents of the complements of those same arcs of the sixth table can be transferred onto it, with respect to the whole sine that lies between D and the said perpendicular. So too, if through A, a perpendicular to DA be raised, and onto it, from A on both sides, the tangents of the very arcs of the sixth table themselves — not of their complements — be transferred with respect to the whole sine D A, points will be found on it through which the straight lines emitted from D will cut the horizontal line at the hours; because, as we showed at the end of Chapter 1, those lines cut off from the horizontal line segments corresponding to the said arcs. And this method must be used whenever the wall's declination is unknown in degrees and minutes.

Furthermore, if on the line of the style a segment K a be taken equal to the straight line KZ, and a F be drawn, and to it at F a perpendicular be raised; and if finally onto this perpendicular, from F on both sides, the tangents of the hours from the table of the scholium to Chapter 1 be transferred with respect to the whole sine from F: then points will be found on it through which the straight lines emitted from a will cut off, from the equinoctial AF, portions corresponding to the arcs of the hours of the said table — as is clear from what was demonstrated at the end of Chapter 1. And this method too we shall use whenever the inclination of the meridians is unknown.

[Margin: Accurate finding and varied placing of the hour-points on straight lines that are equidistant from (parallel to) the meridian lines and the line of hour 6 [?], without the aid of a table; and of the distances from the styles in the horizontal, and from the line of the style in the equinoctial line. [?]]

10. Once the lines of hours 9 and 3 have been carefully drawn, draw PM parallel to the line of hour 6, EA (the line we drew in no. 4), cutting the meridian EF at L; PM will be bisected at L, as we showed in Chapter 4, since hours 9 and 3 are six hours apart and hour 12 lies midway between them. On this straight line PM, then, the hour-points will be found, as we taught in Chapter 3. For if a perpendicular Lb is raised to it, equal to LP or LM, and from b the line PM (extended) is cut on both sides at the interval PM, the points of hours 8 and 4 will be found. A third part of L4 (or L8), namely L2 (or L10), will give hour 2 (or 10). The remaining hours are then found from the table of no. 3, Chapter 3.

The same points on PM will be found if from b an arc g h is described and divided into hours. This is easily done: with the same radius b g, cut off an arc g h spanning four hours; then, drawing a straight line from b to the point P and cutting the arc at i, mark off on arc h i and arc g i three equal parts. For the straight lines emitted from b through the points of division will cut LP at the hour-points, which must then be transferred from L towards M.

Finally, these same points on PM, extended indefinitely, are found by means of the Tangents of 15° , 30° , 45° , and so on — taken with respect to the whole sine bL and transferred from L to either side — as we said in Chapter 4, no. 10.

We shall proceed in no other way with the straight line PQ, which is drawn parallel to the meridian line in any position. (We drew it through A, so that it coincides with the vertical.) For this line too is bisected between hours 9 and 3 by the line of hour 6. Indeed, if PQ has been drawn through A so as to represent the prime vertical, it will be worth while to take from the 6th table, in the right-hand column opposite the pole's altitude, the arc under hours 3 and 9 — in our example $53^\circ 23'$. For if you take its Tangent, about 13[?] and a little more, divide it (with respect to the whole sine DA) into 10 equal parts, and transfer it from A on both sides, you will find the points P and Q through which hours 3 and 9 must be drawn — points which must necessarily pass through those found on the horizontal line, if no error has been made. And by the same method you will find the points of the other hours on the line PQ from the 6th table, as we wrote above in no. 7. If, then, from the point of intersection a perpendicular A a is raised to PQ, equal to half of AP or AQ (in our example the straight line A a is the same as

the horizontal), and from a the line PQ (extended) is cut on both sides at the interval PQ, the points of hours 10 and 2 will be found, four hours distant from the point of hour 6; and a third part of that same line A10, namely A8, will give hour 8, which lies two hours from A, the point of hour 6. From this the other hours are found from table 1 of no. 9, Chapter 4.

The same hour-points on PQ are found if from a an arc is described and divided into hours, and so on.

Or, if into it there are transferred from A on both sides the Tangents of 15° , 30° , 45° , and so on — with respect to the whole sine a A — for the whole hours, and so on, just as was done in Chapter 2, no. 3, for the equinoctial line of the horizontal sundial.

CAPVT XVII.

The hours from noon and from midnight on a declining plane, where either the point of hour 6 on the horizontal line, or the centre of the sundial, or both points, or the point of the meridian on that same horizontal line — together with all the rest [omnibus? [?]] of the sundial — can be had only most inconveniently.

[Margin: When the point of hour 6 is not available on the horizontal line, what to do.]

When the point A on the horizontal line, through which the line of hour 6 must be drawn, cannot conveniently be had — which happens when the plane of the sundial deviates only slightly from the prime vertical, because then the complement of the wall's declination falls only a little short of 90° , and so the straight line DI cuts the horizontal too far off, and its Tangent CA spans more parts than the size of the sundial allows — when, I say, the point A can scarcely be had, we lay out the sundial as follows. Having found the points B, E, F as we explained in the preceding chapter, nos. 1 and 2, draw the line of the style [linea styli] EC; this will be drawn more accurately if the Lemma placed before Chapter 16 is employed. Or, if you prefer, in an arc described from E count off the arc of the plane between its own meridian and the meridian of the horizon, found by Problem 6 at the end of the booklet, and so on, as was done in the preceding chapter, no. 3. Then from F raise a perpendicular to the line of the style, to serve as the equinoctial line, even though it does not meet the horizontal — since the point A is assumed to be unavailable. Or, if you prefer, at F construct with the

meridian an angle equal to the complement of the angle BEC, that is, equal to the angle BCE. For the straight line making this angle will be the equinoctial line.

[Margin: A fine way of describing the hour[-line] even when the point on the horizontal line of the sundial is not available. [?]]

After this, having drawn the lines of hours 9 and 3 as was stated in no. 9 of the preceding chapter, from any point l of hour 9 draw a line l m parallel to the meridian, cutting hour 3 at m. For l m, bisected at n, gives (by the straight line E n) hour 6, even though it does not cut the horizontal — because the line of hour 6, lying midway between hours 9 and 3, bisects the line l m (which is parallel to the meridian), since hour 6 is six hours distant from the line of hour 12, as was demonstrated in Chapter 4, no. 6. And in this way the line of hour 6 can be drawn in any sundial, provided hours 3 and 9 have first been drawn, even if the point where it cuts the horizontal is very far off. This line of hour 6 can also easily be drawn, if you wish, by counting off in an arc described from E, from the meridian line, the arc of the plane between the meridian and the circle of hour 6, found by Problem 8 at the end of the booklet, as was done in no. 4 of the preceding chapter. The rest is completed as was set out in the preceding chapter, especially in no. 10 — namely by drawing p q parallel to the line of hour 6. For this too will be bisected at r. Accordingly, on the straight lines l m and p q the hour-points will be found, just as in no. 10 of the preceding chapter they were found on the lines PQ and PM.

[Margin: When the centre is not available in the sundial, what to do.]

2. When, however, the points B and A have indeed been found on the sundial conveniently enough — whether by Tangents or by the arcs GH and GI of the wall's declination and of its complement, as was done in no. 1 of the preceding chapter — but the centre G of the sundial can be located only with difficulty (which happens when the pole-altitude of the region is very great, even though the declination of the plane is moderate), the point F must be found by the Tangent of the complement of the given pole-altitude, as was stated in no. 2 of the preceding chapter, and in addition the equinoctial line AF must be drawn. This will be drawn more accurately by the Lemma before Chapter 16. Or, if you like, by Problem 6 at the end of the booklet: reckon the arc of the plane between the horizon and the equator, and count it off downward from the horizontal line in an arc described from A, and so on. At a pole-altitude of 80° , with the declination set at 30° , this arc contains $5^{\circ}2'$. The point F will be found

[Margin: [?]¹⁵. primi [?] (uncertain marginal reference)]

as well if — drawing the straight line RE through an arc of the pole-altitude described from R (although it does not meet the meridian except at a very remote place) — a perpendicular RF is drawn to RE, cutting the meridian at F.

Next, to the equinoctial AF a perpendicular CK must be drawn through C, the place of the style, to serve as the line of the style, even though the centre E of the sundial is unavailable. Or indeed, if you prefer, in an arc described from C count off, from the horizontal line on the side of A towards F, the complement of the arc of the declining plane between its own meridian and the meridian of the horizon — which arc is computed by Problem 6 at the end of the booklet and, at the aforesaid pole-altitude and declination, contains $5^{\circ}2'$, while its complement is $84^{\circ}58'$. For the straight line making this angle will be the line of the style, since the angle ACK is equal to the angle BCE, which is the complement of the angle BEC — as it would be if the point E were present. Or indeed, in the same arc count off, from the straight line CG towards A, the arc itself of $5^{\circ}2'$.

The line of hour 6 will likewise be drawn if, in an arc described from A, one counts off upward from the horizontal line the arc of the declining plane between the horizon and the circle of hour 6, found by Problem 8 at the end of the booklet, and so on. At the said pole-altitude and declination this arc contains $70^{\circ}34'$.

Once the lines of the style and of hour 6 have been drawn, we shall proceed to describe the other hours as follows. Since we do not have the centre of the sundial, we shall draw from C, the place of the style, a perpendicular CZ to the line of the style, equal to the style; and to KZ (the common section of the equator with its own meridian), joined to it, we shall raise another perpendicular Z f, which will represent the axis of the world — even though we do not have the point where it cuts the meridian line BF. Then, taking any point t on the line of the style, raise a perpendicular t s to the axis, to serve as a new common section of the equator with its own meridian; and [raise], perpendicular to the line of the style through t [and Ct], a line to serve as a new equinoctial line. Now if — the inclination of the proper meridian to the meridian of the horizon having been found by Problem 5 at the end of the booklet, which (with the pole-altitude set at 80° and the declination at 30° , as before) contains $30^{\circ}23'$ — the hour-points are found on each equinoctial by Tangents, with respect to the whole sines KZ and t f, as was stated in no. 8 of the preceding chapter, then the hour-lines must be drawn through the corresponding hour-points on each equinoctial, even though the centre in which they ought to meet does not appear. It is not necessary to find the hour-points on the horizontal line, because at the aforesaid pole-altitude the

horizontal lies too close to the equinoctial line AF — as is clear if a sundial is constructed for that altitude of 80° and declination of 30° .

[Margin: When neither point A nor E is available, what to do. [?]]

3. But when both points A and E cannot easily be had (which happens when the pole-altitude is very great and the wall's declination very small), the point B must be found by the Tangent of the wall's declination, and the point F by the Tangent of the complement of the pole-altitude. Then through C the line of the style must be drawn, by means of an arc described from C and counted from the line CG towards A — the arc, namely, that is interposed between the horizon and the equator, or between the meridian of the horizon and the proper meridian of the declining plane, and which, by Problem 6 at the end of the booklet, at a pole-altitude of [numeral:?] and a declination of 4° , contains $7^\circ 1'$. To this line of the style a perpendicular must be raised from F, to serve as the equinoctial line. Or indeed, if you please, in an arc described from F towards A count off from the meridian the complement of the aforesaid arc (the one, that is, that lies between the meridian of the horizon and the equator), and at the end of the counting draw the equinoctial line, and to it raise a perpendicular from C for the line of the style. Everything else is to be carried out as we said just above in no. 2. But hour 6 cannot be drawn, since its point is found neither on the horizontal nor on the meridian line, and therefore not on the equinoctial line either, which does not cut the horizontal except at the point of hour 6 — assumed to be unavailable. The inclination of the proper meridian to the meridian of the horizon contains $35^\circ 23'$, by Problem 5 at the end of the booklet.

[Margin: When neither the point B of the meridian line nor the centre of the sundial is available, what to do. [?]]

4. When, finally, the point B of the meridian line — and therefore also the centre of the sundial — cannot conveniently be had (which usually happens when the declination of the plane is very great), the point A must be found, through which the equinoctial line too must be drawn, by means of an arc described from A that is interposed in the plane between the horizon and the equator. By Problem 6 at the end of the booklet, if the plane declines from south towards east by 89° , this arc is found to span $48^\circ 0'$, a little less, at latitude 42° . Then the same arc must be counted off from the straight line CG towards A in a circle described from C, and at the end of the counting the line of the style CK must be drawn. Or indeed, from

C a perpendicular must be raised to the equinoctial, to serve as the line of the style. Likewise, through A the line of hour 6 must be drawn, by means of an arc described from A that is interposed in the plane between the horizon and the circle of hour 6. At a pole-altitude of 42° , with the sundial's declination from south towards east set at 89° , this arc is found by Problem 8 at the end of the booklet to span $42^\circ 0'$, a little less. Everything else is to be completed as stated in no. 2. The inclination of the proper meridian to the meridian of the horizon (by which, namely, the hour-distances from the line of the style are to be elicited, as was set out in the preceding chapter, no. 8), at a pole-altitude of 42° and a declination of 89° , is found by Problem 5 at the end of the booklet to be $89^\circ 20'$.

[Margin: A more convenient method in the aforesaid four cases.]

5. But in the aforesaid four cases we shall also proceed very conveniently as follows. Let the style be continually bisected until the last part, near the place of the style, is so small that — taking it for the style — the three points A, B, E can conveniently be found, by the methods set out in Chapter 16, and so the whole sundial can be described. For if this sundial is enlarged according to the size of the given style — that is, if all its intervals are multiplied as many times as the style's subdivision was carried out, as will be taught in Chapter 23 — the sundial that was to be described will be described, even if some of its points cannot be found because of their too great distance from the place of the style. But all these difficulties will be removed if the sundial is described by the method of Chapter 24 or 25, as will be stated in the scholium to Chapter 25, no. 3.

CAPVT XVIII.

The arcs of the signs in the hours from noon and from midnight of a declining sundial.

[Margin: The description of the arcs of the signs on a declining sundial, by points on the line of hours from noon and from midnight. [?]]

The arcs of the signs are described on a declining sundial just as on a horizontal one. For if in table 1 one takes the arcs corresponding to the beginnings of the signs for the individual hours in the circle of hour 12 — that is, in the line of hours to which the title [Circ. hor. 12.] is written on the left, or the number [12.] on the right side — and if by these same arcs equal portions are cut off from the meridian line, beginning at the equinoctial line, then the straight lines emitted from A through the endpoints of these portions will give, on the corresponding

hour-lines, points parallel to the one set out. Now we shall cut off the aforesaid arcs from the meridian line as follows. For the southern parallels (which in mural sundials are contained between the equinoctial and the centre E), let the arc of any hour be subtracted from the complement of the pole-altitude above the region's horizon, if it can be subtracted; and let the Tangent of the remaining number — on the straight line whose portion DB was divided in the preceding chapter into 10 equal parts for the meridian line — be transferred, taken with the compass, from B towards the equinoctial. Or let the complement of the pole-altitude be subtracted from the arc of table 1, if it can be done, and let the Tangent of the remaining number be transferred from the same point B towards the centre of the sundial. But if some arc is found equal to the complement of the pole-altitude, the point B itself will be the endpoint of that arc. When, however, two hours have a greater distance from noon than 6 hours — as does hour 5 from midnight and 7 from noon — the pole-altitude must be added to the complement of those hours' arc, and the Tangent of the sum must be transferred from B beyond the centre E of the sundial, as was stated in Chapter 8, no. 7. Finally, for the northern parallels, any arc of table 1 must be added to the complement of the pole-altitude, and the Tangent of the sum transferred from B beyond the equinoctial. But if the sum exceeds a quadrant, that hour's point cannot be found on the meridian. In that case the hour's point must be found on the northern parallel by the 2nd rule of the scholium to Chapter 8 — namely, from some point opposite the southern parallel already found. This must also be done whenever some point is too far removed from the horizontal line, so that it cannot be marked on the sundial.

For example: in the circle of hour 12, in table 1, under hours 3 and 9, opposite ♋ [Cancer] and ♑ [Capricorn], there is found an arc of $31^{\circ}35'$. Subtracting this from the complement of the pole-altitude — that is, from 48° , to which the portion BF corresponds — $16^{\circ}25'$ remains. Its Tangent, about 3 (with respect to the whole sine BD, which serves the meridian), transferred downward from B, gives the point H, through which the straight line drawn from A will cut hours 3 and 9 at the points of the tropic ♋. But the same arc of $31^{\circ}35'$, added to the complement of the pole-altitude, 48° , makes $79^{\circ}35'$, whose Tangent, about 54[?], transferred from B, will give a point on the meridian through which the straight line emitted from A will cut hour 9 at the point ♎, and hour 3 from midnight at the point ♑ — since it cannot cut hour 3 from noon. In our example, moreover, that point on the meridian could not be marked because of the narrowness of the space. So we shall find the point ♎ on hour 9 by the straight line drawn from the point ♑ (found on hour 3 from noon) through the point F. And the point of hour 3 from midnight we shall find by the straight line drawn from this point ♎ (now found

on hour 9) through the point A, as the 2nd rule of the scholium to Chapter 8 directs.

Next, the arc of hours 5 and 7 spans $59^{\circ}14'$. If from it the complement of the pole-altitude, 48° , is subtracted, $11^{\circ}14'$ remains, whose Tangent, about 2, transferred upward from B, gives the point I, through which the straight line emitted from A cuts hour 7 from midnight at the point $\mathfrak{V}$, and hour 5 from midnight at the point $\mathfrak{S}$ — since hour 5 from noon does not cut it.

Likewise, the arc of hour $5\frac{1}{2}$ from midnight and $6\frac{1}{2}$ from noon contains $73^{\circ}17'$, whose complement is $16^{\circ}43'$. If the pole-altitude 42° (to which the portion BE corresponds) is added — since the aforesaid hours have a greater distance from noon than hour 6 — the arc becomes $58^{\circ}43'$, whose Tangent, about 16[?], transferred from B beyond the centre E, will give the point L; and the hidden straight line AL will cut hour $5\frac{1}{2}$ from midnight at the point $\mathfrak{V}$, and, produced, will cut hour $6\frac{1}{2}$ from midnight at the point $\mathfrak{S}$ — since it does not cut hour $6\frac{1}{2}$ from noon.

So too, since the arc of hour 12 contains $23^{\circ}30'$, if it is subtracted from 48° and added to the same, arcs of $24^{\circ}30'$ and $71^{\circ}30'$ result, whose Tangents — 4[?], a little more, and 29[?], about — will give the points O and M of the parallels $\mathfrak{V}$ and $\mathfrak{S}$.

But since the points of certain hours cannot be marked on the meridian line, because they are removed too far from the point B, we shall find other points on the line of hour 6, through which, if hidden straight lines are emitted from E, the hours will again be cut at the points of the parallels. We shall proceed as follows. From C, the place of the style, raise a perpendicular CNP to the line of hour 6; and, taking a straight line N a equal to the style, cut off NP equal to the interval C a. Then, on any straight line, taking as many segments as you like equal to that same C a — with an interval equal to C a — divide the first C a into 10 equal parts. Then, having found the arc of the circle of hour 6 between the pole E and the vertical perpendicular and that same circle (which the straight line CNP represents), and which in our sundial, by Problem 10 at the end of the booklet, spans $37^{\circ}51'$, we shall subtract from the meridian line the arc of the plane between the meridian and the circle of hour 6 (found by Problem 8 at the end of the booklet) — that is, from $52^{\circ}9'$ — the arcs of table 1 corresponding to the hours in the line of the circle of hour 6, which is the topmost; or [we shall subtract] the very complement of the arc $52^{\circ}9'$ from the aforesaid arcs of table 1 — namely the smaller numbers from the larger, for the southern signs; and the Tangents of the remaining arcs, taken on the straight line C a, we shall transfer from the point N onto the line of hour 6 — downward, indeed, if the arcs have been subtracted

from the said complement, but upward if the complement has been subtracted from the arcs. For the northern parallels, on the other hand, the arcs of table 1 corresponding to the hours in the circle of hour 6 are to be added to the aforesaid complement.

But when the Tangents to be transferred onto the meridian line are too long, we shall proceed as follows. Cutting the portion AB of the horizontal line in half, we shall draw through the point of division a line perpendicular to the horizontal; for if into this there are carried the halves of the Tangents that were to be transferred onto the meridian, the points will be found through which the straight lines drawn from A will indicate the parallels' points on the hour-lines. And if in this perpendicular some points still stand too far from the horizontal, the portion between A and the said perpendicular must again be cut in half, and through the point of division another perpendicular to the horizontal must be raised. For if into this there are transferred the quarter parts of the Tangents that were to be transferred onto the meridian, the points will be found through which the straight lines emitted from A will cut the hour-lines at the points of the parallels.

When the Tangents are to be transferred from N beyond the centre of the sundial — as happens in some hours from noon in the parallel ♎, namely in hours 1 and 2 — the complement of any arc of table 1 corresponding to the hours in the circle of hour 6 must be added to the arc of the circle of hour 6 between the pole and the point N, that is, in our example, to $37^{\circ}51'$, provided the resulting arc does not exceed 90° ; otherwise, to the complement of the said arc EN one must add the arc of any hour from table 1, and the Tangent must be transferred from N towards the equinoctial. The very position of the hour-lines will readily show whether the Tangents are to be transferred beyond the centre E, or rather towards the equinoctial line.

For example: the arc of hours 1 and 11 in the circle of hour 6 contains $59^{\circ}14'$. If the complement of the arc EN (I mean the arc to which the portion EN is equivalent) — that is, $52^{\circ}9'$ — is subtracted, there remains an arc of $7^{\circ}5'$, whose Tangent, 1 [fraction:?] (a little more), transferred from N toward E, will give a point through which a straight line drawn from F will cut hour 11 at the point ♎ [Capricorn], and consequently also hour 1 at the point ♋ [Cancer]. But if the complement of the aforesaid arc of table 1 — containing $30^{\circ}46'$ — is added to the arc EN of $37^{\circ}51'$, the arc becomes $68^{\circ}37'$, whose Tangent, 25 [fraction:?] (a little more), will give, beyond the centre, the point S; and the straight line FS will cut

hour 1 at the point ♊ [Capricorn], and consequently hour 11 at the point ♋ [Cancer].

Again, the arc of hours 5 and 7 in the circle of hour 6 contains $24^{\circ}14'$. If the arc of the segment NA, $52^{\circ}9'$, is added, the arc becomes $76^{\circ}23'$, whose Tangent, 41 [fraction:?] (nearly), will give the point T; and the straight line FT will cut hour 7 at the point ♋ [Cancer], and, produced toward T, would also cut hour 5 at another point ♋. But if you subtract the same arc, $24^{\circ}14'$, from the arc of the segment NA, $52^{\circ}9'$, there remains an arc of $27^{\circ}55'$, whose Tangent, 5 [fraction:?] (nearly), will give a point through which a straight line drawn from F will cut hours 5 and 7 at the points ♊ [Capricorn].

Finally, the arc of hour 6 contains $23^{\circ}30'$; added to the arc of the segment NA, $52^{\circ}9'$, it makes an arc of $75^{\circ}39'$, whose Tangent, 39, will give the point V, in hour 6, for the tropic ♋ [Cancer].

3. Without Tangents, the points on the line of hour 6 can also be found — as was shown in the problem of chapter 1 — in this way. Having drawn the perpendicular CN and found the point P (as we said at the beginning of Number 2), let a hidden straight line PA be drawn, and from P let the circle QR be described. For if in it the arc of any hour of table 1 in the circle of hour 6 is counted from the point Q — to the left, indeed, for the northern signs, but to the right for the southern — and through the end of the count a hidden straight line is emitted from P, the line of hour 6 will be cut at a point through which a straight line from F will cut the proposed hour at the point of the given parallel. For example, the arc of hour 6 is $23^{\circ}30'$; let it be counted from the point Q in both directions, as far as R and X. For the straight lines PR, PX will cut hour 6 at the points V, e, ♋ [Cancer], and ♊ [Capricorn]. Likewise the arc of hours 5 and 7 in the parallel of ♉ [Taurus] and ♍ [Virgo], and also of ♏ [Scorpio; glyph worn, [?]] and ♐ ([♋ Pisces], is $11^{\circ}54'$; counted from the point Q leftward as far as d, the straight line Pd will cut hour 6 at the point b, and the straight line Fb will cut hours 5 and 7 at the points f, f of the parallels ♉ [Taurus] and ♍ [Virgo].

Diagram. A large, extremely dense construction figure for a declining sundial, filling most of the page within a heavy rectangular border. A sheaf of straight hour-lines radiates from a principal node near the upper-left interior (labelled 3) and from a second principal centre lower in the figure (near the point labelled A); superimposed on these are dotted (hidden/occult) construction lines, several arcs of the parallels of the signs, and a set of graduated tangent scale-bars along the right margin. Because the engraving is packed with intersecting lines and many

labels are minute and overprinted, only the clearly legible labels are transcribed; a large number of interior point-letters cannot be resolved.

- Left margin, hour-lines (read top-to-bottom): 6, 7, 8, 9, 10, 11, 12
- Upper interior radiating lines: also numbered 1, 2, 3, 4, 5
- Top edge and upper-right, hour-lines (morning / after-sunrise): 17, 18, 19, 20, 21, 22, 23, 24
- Additional line-numbers near the lower interior: 4½, 5, 23, 24
- Right margin: several vertical graduated tangent scale-bars headed with letters (legible column heads include C, C, C and, to their left, E, λ, ψ), with tick-labels 10, 20, 30, 40, 50
- Legible interior point-letters: A (lower principal centre), E, F, K, L, M, N, O, P, Q, R, S, T, V, X, and the Greek α (alpha, appearing near the point A and again — doubled, αα — up near hour-line 24)
- Numerous further interior point-letters and short labels are illegible [several labels [?]]

[Margin: The drawing of the arcs of the signs by means of points on the line of hour 6 and on the meridian, found without Tangents.]

When the same arc is counted from the point Q toward the right as far as h, the straight line Ph will cut hour 6 a little below a, at a point through which a straight line issuing from F will cut the same hours 5 and 7 at the points g, g of the parallels ℳ [Scorpio; glyph worn, [?]] and)([Pisces].

In no other way are the points found on the meridian line, if — with an interval Bm taken equal to BD, up to the tip of the style, on whichever side you prefer — a hidden straight line is drawn from m through F. For if from m a circle is described, in which the arcs of table 1 in the circle of hour 12 are counted on both sides from the line mF, the straight lines emitted from m through the ends of these arcs will cut the meridian at points through which straight lines extended from A will cut the hours at the points of the parallels.

4. But most conveniently the arcs of the signs will be drawn by the method we set out in chapter 8, Number 7 — especially in sundials in which either the meridian line (and therefore the centre), or the point A of hour 6, is not available on the horizontal line. The matter will be carried out as follows. Let us conceive the style-line CK to be the meridian of some horizontal sundial, and C the zenith of the place. On either side of the style-line let hour-lines be drawn, fifteen degrees apart from one another, like the hour-lines in a horizontal sundial, as was taught in chapters 2, 3, and 4 — so that

the two nearest lines on either side stand for hours 1 and 11, the next two for hours 2 and 10, the next two for hours 3 and 9 (such are the lines k p, n q), and so on for the rest. The Tangents are to be taken on the equinoctial (when the said lines are to be drawn by means of them) with respect to the whole sine KZ, in the sundial of the preceding chapter, so that points fifteen degrees apart from one another are found.

Then, by Problem 4 at the end of the booklet, let the elevation of the pole above the declining plane be found, which in our example contains $40^{\circ}4'$. Once it is found, let there be cut off from the style-line — as [one would] from the meridian — the arcs of table 1 corresponding to the hours in the circle of hour 12, exactly as we taught in chapter 8, Number 7, and so on. This will be understood from the following two examples. From the little table of the scholium of chapter 1 let the Tangent of hours 3 and 9 be taken — namely 10 — on the line KZ of the preceding chapter, which is assigned to the equinoctial line, and let it be transferred from K on both sides as far as r and s, in the figure of this chapter. For the hidden straight lines Er, Es will stand for the lines 9 and 3. And since in table 1, under hours 3 and 9, on the line of the circle of hour 12, opposite $\mathfrak{C}$ [Cancer] and $\mathfrak{C}$ [Capricorn], is found an arc of $31^{\circ}35'$ — which, if it is subtracted from $40^{\circ}4'$ (the elevation of the pole above our declining plane, to which the segment CK corresponds, as is clear from the figure of the preceding chapter), leaves an arc of $8^{\circ}29'$, whose Tangent, 1 $\frac{1}{2}$ (nearly), transferred downward from the point C, will give a point through which, if a line k n parallel to the equinoctial is drawn, the straight lines Et, Es will be cut at the points k, n for $\mathfrak{C}$ [Capricorn]. And if the same arc, $31^{\circ}35'$, is added to the aforesaid elevation of the pole, $40^{\circ}4'$, an arc of $71^{\circ}39'$ is produced, whose Tangent, 30 $\frac{1}{2}$ (a little more), transferred downward from C, will give a point through which [a line drawn parallel to the equinoctial] will cut the straight lines Er, Es at the points p, q for $\mathfrak{C}$ [Cancer]. And the same reasoning holds for the rest.

If, then, through the points found on the hidden lines (as [one finds] the hour-points of a horizontal sundial) the parallels of the Sun are drawn correspondingly, these will cut the hour-lines of the declining sundial at the points of those same parallels. But in order that the northern parallels be drawn more exactly, points on the hidden lines of the half-hours and quarter-hours must also be found for them, so that more numerous points may be had.

5. But even without knowledge of the elevation of the pole above the declining plane, the arcs of the signs can also be drawn with ease — provided the centre of the sundial is available — by the method we

prescribed in chapter 8, Number 1, from table 1: namely, if for the line of hour 6 a line parallel to the equinoctial itself is drawn through E, the centre of the sundial, standing for the line of hour 6 with respect to the lines which at the beginning of this Number 4 we directed to be drawn; and onto it are transferred the complements of the arcs drawn in table 1 opposite the signs, under the hours in the circle of hour 6 (which line stands for the line of hour 6). For if from K, through the points marked on that parallel line, hidden straight lines are drawn, those hidden lines will be cut — like the hour-lines of a horizontal sundial, which at the beginning of this Number 4 we said were to be drawn — at the points of the arcs of the signs, and so on.

It is also enough here if only the southern parallels are drawn; for from these the opposite northern ones will be drawn, as was said in chapter 8, Numbers 3, 4, 5, and 6 — especially by the method we prescribed at the end of Number 6 of chapter 8. For if, for example, the segment of the proper meridian line — that is, of the style-line $t u$ — between the tropics ♊ [Capricorn] and ♋ [Cancer] (the points t, u of the opposite parallels will be found by Tangents, as we taught in chapter 8, Number 3, if for the elevation of the pole above the Horizon one takes the elevation of the pole above the declining plane, which by Problem 4 at the end of the booklet is found to contain $40^{\circ}4'$; or, if you prefer, geometrically: if in the sundial of chapter 16, at the axis EZ , the angles of declination are set up at Z — that is, if from Z the radii of the signs are emitted on either side of the radius of the Equator ZK , for these will cut the style-line at the points of the parallels, as we showed in chapter 9, Number 1) — is bisected at Y ; and from any point of the tropic ♊ [Capricorn], say from ϵ [epsilon], the point of hour 5, a straight line $\epsilon Y \beta$ is extended through Y , and an interval $Y \beta$ equal to the interval $Y \epsilon$ is cut off, the point β [beta] will fall on the tropic ♋ [Cancer] — which was demonstrated by Apollonius [of Perga], Book 1, Proposition 30. And so for the rest. But you will do well if first, from Y , at the interval $Y \epsilon$, a small arc is drawn on the opposite side, which is then cut at a point by the hidden straight line ϵY , and so on. For in this way the confusion of the hidden lines will be avoided, as was said at the end of Number 6 of chapter 8.

6. But the easiest method of all is taken from table 2, by which points are found on the meridian line; through these you will cut the hours at the points of the parallels — whether from hour 2 after noon on the equinoctial, or hour 10 after midnight; or from hour 9, 8, or 7 after midnight; or from hour 3, 4, or 5 after noon (with respect, of course, to whichever hour you found the points on the meridian from table 2) — as

was explained in chapter 8, Number 10. For example, if from hour 10 after midnight, on the equinoctial, the point ♊ [Capricorn] is to be found at hour 3 after noon, you will find in table 2, under hours 3 and 5, on the line headed *From hour 10 after midnight*, opposite ♊ [Capricorn], an arc of $12^{\circ}41'$. When this is subtracted from the complement of the elevation of the pole above the Horizon (to which the segment BF is equivalent), there remains an arc of $35^{\circ}19'$. If, then, you transfer its Tangent — which is 7, with respect to the whole sine BD divided into 10 parts — downward from B, you will find a point through which a straight line issued from F will cut hour 3 after noon at the point ♊ [Capricorn], and hour 5 after midnight at the point ♋ [Cancer]. And so with the others.

And this method is very convenient if in the sundial there are drawn lines equally distant on either side from the style-line, like the hour-lines in a horizontal sundial, and if the elevation of the pole above the declining plane is found, as was said in Number 4. For example, in the sundial of this chapter, once the straight lines n q, k p are drawn — the former being hour 3 after noon, the latter hour 9 after midnight (if the style-line were the meridian) — in table 2, on the line headed *From hour 3 after noon*, under hour 9, opposite ♊ [Capricorn], is found an arc of $17^{\circ}5'$. Subtracting this from the elevation of the pole above the plane — namely from $40^{\circ}4'$ — leaves $22^{\circ}59'$, whose Tangent, 4 [fraction:?] (a little more), transferred from C, in place of the style, onto the style-line, will give a point through which a straight line issued from the point f [s] will cut the line k p at the point k of the parallel ♊ [Capricorn], and so on.

[Margin: Another drawing of the arcs of the signs, most convenient, especially in sundials in which either the meridian line, or the point of hour 6, is not available on the horizontal line.]

[Margin: The immediately preceding drawing of the arcs of the signs, without knowledge of the pole above the declining plane.]

[Margin: How the drawing of the northern arcs of the signs is to be made from the southern ones.]

[Margin: The drawing of the parallels from table 2 — the easiest of all.]

7. From table 3 the same arcs of the signs will be laid out, if — once the straight lines AM, AO are drawn (of which the former represents the Ecliptic with its beginning ♋ [Cancer] placed on the Meridian above the Horizon, the latter the Ecliptic with its beginning ♊ [Capricorn] placed on the Meridian above the Horizon) — by Problem 14 at the end of the booklet

one seeks the arc of the Ecliptic between the Meridian and the great circle that is drawn perpendicular from the pole of the declining plane to the Ecliptic; which perpendicular is represented by the line $C\delta$ [C-delta] on the straight line AM, and by $C\gamma$ [C-gamma] on the straight line AO. In our example, the segment $M\delta$ contains $61^{\circ}12'$, while the segment $O\gamma$ contains $32^{\circ}24'$. For on the straight line AM we shall chiefly find the points through which straight lines drawn from F will cut the hour-lines at the points of the northern parallels; but on the straight line AO, the points for the southern parallels — although either of the two suffices, as we shall say in practice. We shall therefore proceed in this way. Let the arcs of table 3 in the hours after midnight be subtracted from the arcs to which the segments $M\delta$, $O\gamma$ correspond — that is, from $61^{\circ}12'$, or from $32^{\circ}24'$; or, conversely, these arcs from those, namely the smaller numbers from the larger. But the same arcs of table 3 in the hours after noon are to be added to the arc of the straight line $M\delta$ or $O\gamma$. For the Tangents of the arcs that remain, or that are made up, transferred from δ or γ onto the straight line AM or AO, will give points through which straight lines issuing from F will cut the hours at the points of the parallels. The Tangents, moreover, are to be taken on the straight line $C\delta$ or $C\gamma$, which are equal to the intervals δC , γC , the straight lines $\delta\epsilon$ and $\gamma\lambda$ being taken equal to the style. Likewise these same Tangents are always to be transferred from δ or γ toward the right, except when the arcs themselves are subtracted from $M\delta$ or $O\gamma$ out of the arcs of table 3.

For example, the arc of hour 10 after midnight, in table 3, with beginning $\mathfrak{C}$ [Cancer] and $\mathfrak{M}$ [Capricorn], contains $24^{\circ}38'$; and in the parallel of $\mathfrak{C}$ [Cancer], with the Ecliptic represented by the straight line AM, it inclines toward the hours before noon, as is clear from the material sphere. Subtracting it, then, from $61^{\circ}12'$, there remain $36^{\circ}34'$, whose Tangent, 7 [fraction:?] (a little more), transferred from δ toward M, shows a point through which a straight line extended from F cuts hour 10 at the point $\mathfrak{C}$ [Cancer], and hour 2 at the point $\mathfrak{M}$ [Capricorn]. The same arc, $24^{\circ}38'$, added to $61^{\circ}12'$, makes $85^{\circ}50'$, whose Tangent, 137 [fraction:?] (a little more), transferred from δ toward M, would show a point — if the plane were so large — through which a straight line issued from F would cut hour 10 at the point $\mathfrak{M}$ [Capricorn]. This point in $\mathfrak{M}$ [Capricorn] we shall find more conveniently by means of the straight line AO. For subtracting the said arc, $24^{\circ}38'$, from $32^{\circ}24'$ — to which the segment γO is equivalent — there remain $7^{\circ}46'$, whose Tangent, 1 [fraction:?] (a little more), transferred from γ , offers a point nearer O, through which a straight line issued from F will cut hour 10 at the point $\mathfrak{M}$ [Capricorn]. But if you wish to find the point $\mathfrak{C}$ [Cancer] on hour 10 by

means of the straight line AO, the aforesaid arc, $24^{\circ}38'$, is to be added to $32^{\circ}24'$, because in the Ecliptic represented by the straight line AO that arc inclines toward the afternoon hours, as is clear from the material sphere. For the arcs joined make $57^{\circ}2'$, whose Tangent, 15 [fraction: ?], transferred from γ , [gives a point through which] a straight line issued from F cuts hour 10 at the point $\mathfrak{S}$ [Cancer]. And so for the rest. But this method is more convenient and easier in a horizontal sundial; and therefore it may with very good reason be left aside here.

It will, however, be most convenient if the hidden hour-lines are drawn as in a horizontal sundial, as we taught at the beginning of Number 4; for then the Ecliptic will have to be drawn perpendicular to the style-line through the point $\mathfrak{S}$ [Cancer] or $\mathfrak{V}$ [Capricorn], which point is to be found on the style-line from the elevation of the pole above the declining plane — just as, in a horizontal sundial, we taught that it was to be found on the meridian line from the elevation of the pole above the horizon.

8. If, by Problem 15 at the end of the booklet, the altitudes of the Sun above the declining plane are computed, the Tangents of their complements — taken from the place of the style (which is the whole sine of those Tangents) — will cut, at the hours after noon or after midnight, at the points of the parallels, as was shown in chapter 8, Number 12.
9. Moreover, everything that was set out in the scholium of chapter 8 and in chapters 9, 10, and 11 is to be applied here. Only, for the meridian line, the style-line is here to be understood. For in this way we shall draw the parallels of the Sun by several methods, and shall be able to examine whether they have been correctly drawn or not — especially by the three rules of the scholium of chapter 8. But in the method of chapter 10, the circle ET (or Ma) will have to be divided not into hours, but into any number of equal parts; and through those parts straight lines are to be emitted from G, cutting the straight line EH at points through which, finally, straight lines are to be drawn from A, the centre of the sundial, like the hour-lines, as we taught in the scholium of chapter 10, Number 2. For on these will be found the points of the signs, by means of straight lines issued from F through the points of division of the circle ET (or Ma).
10. Finally, we shall point out yet another way of investigating the points of the parallels, in the scholium of the following chapter, Number 4, from certain arcs of the Horizon and of the Vertical.

11. By almost the same methods, the arcs of the signs in the sundial of chapter 17 — where either one of the points A, B, E, or two of them, are not available — can be drawn, as is evident.

[Margin: The drawing of the arcs of the signs from table 3.]

[Margin: The drawing of the parallels by the altitudes of the Sun. Here are to be applied chapters 9, 10, 11, and the scholium of chapter 8.]

[Margin: Where another drawing of the parallels is treated.]

CAPVT XIX.

THE HOURS FROM SUNRISE AND SUNSET ON A DECLINING SUNDIAL.

1. There is almost no difficulty in laying out the hours from sunrise and sunset on a declining sundial. For from table 2 of chapter 14 the points of the hours after noon or after midnight on the equinoctial line will be known, through which the hours from sunrise and sunset are to be drawn; while from table 1 of the same chapter we shall understand through which points of the hours after noon or after midnight on the horizontal line those same hour-lines from sunrise or sunset must pass. For since the horizontal line is the line of hour 24, the hours from sunrise and sunset laid out in that table 1 will pass through those hours after noon or after midnight on the line of hour 24 which are written beneath them.

For example: hour 18 from sunset passes through hour 12 after noon or after midnight on the equinoctial line, as is clear from table 2 of chapter 14; likewise through hour 9 after noon or after midnight on the horizontal line, as appears from table 1 of the same chapter 14. Therefore a straight line through hour 12 on the equinoctial and through hour 9 on the horizontal line, extended, will give the line of hour 18 from sunset. In the same way you will find from the same tables that hour 19 is to be drawn through hour 1 after noon or after midnight on the equinoctial, and through hour $9\frac{1}{2}$ after noon or after midnight on the horizontal; and hour 11 from sunset through hour 5 after noon or after midnight on the equinoctial, and through hour $5\frac{1}{2}$ after noon or after midnight on the horizontal line. And so for the rest — although, for drawing a single hour from sunset or sunrise, it is enough to have recourse to those two tables of chapter 14. For the other hours will be drawn through the following or preceding points of the whole hours on the equi[noctial...]

[Margin: The drawing of the hours from sunrise and sunset on a declining sundial.]

on the equinoctial line, but the points of the half-hours on the horizontal line — so that the hours from sunrise or sunset with even numbers are drawn through the whole hours on the horizontal, and those with odd numbers through the half-hours. Thus you see that, after hour 11 from sunset — which is drawn through hour 5 from noon or midnight on the equinoctial and through hour $5\frac{1}{2}$ on the horizontal — hour 12 is drawn through hour 6 on the equinoctial and through hour 6 on the horizontal (and here these two points coincide in one, so that a different point will have to be found afterwards through which hour 12 is to be drawn). Hour 13 is drawn through hour 7 on the equinoctial and through hour $6\frac{1}{2}$ on the horizontal; hour 14 through hour 8 on the equinoctial and through hour 7 on the horizontal; and so with the rest. In just the same way hour 1 from sunrise will be drawn through hour 7 on the equinoctial and through hour $\frac{1}{2}$ on the horizontal; hour 2 from sunrise through hour 8 on the equinoctial and through hour 1 on the horizontal; and so on.

Diagram. A large declining sundial [horologium declinans] enclosed in a rectangular frame, illustrating the layout of the hours from sunrise and sunset treated in this chapter. From a node in the central-left region of the plate a very dense pencil of straight hour-lines radiates outward; around the whole rim the sunrise/sunset hour-lines are numbered from 1 to 24 (both ends of many lines carry their hour-number). Two principal long reference lines cross the figure — the equinoctial line and the horizontal line — and dotted lines trace the construction of the parallels/tropics (the circles $\pi \mu \rho$ construction of §2). Along the inside of the right-hand edge run several parallel vertical graduated scales carrying the numeric divisions 10, 20, 30, 40, 50, used as the tangent/sine scales for transferring the tabulated values.

The plate carries several dozen point-labels: Latin capitals (A at the dial-centre, together with B, C, D, E, F, G, H, I, L, M and compound labels of the form A-c, A-d, A-f, A-g, A-h, A-k, A-m, A-o), and many Greek minuscules (among them α , β , γ , δ , λ , μ , π , ρ , ψ). Readable border hour-numbers include, going around: 24, 23, 22, 21, 20, 19, 18, 17, 12 (right side and top); 6, 7, 8, 9, 10, 11, 12, 1, 2, 3 (left side); and 4, $4\frac{1}{2}$, 5, 6, 23, 24 (lower part). Because the interior is extremely dense and most of the small point-labels do not resolve cleanly at this resolution, the great majority of the interior letters cannot be committed with confidence.

[Margin: When the two points of some hour from sunrise or sunset are too close together, or when only one point is available, what is to be done.]

2. Now some hours from sunrise or sunset have two points — one on the equinoctial and the other on the horizontal — through which they are to be

drawn, and these lie so close together that they can scarcely be drawn without error. Such, in our example, are hours 11, 13, 14, 15, 16, and so on. Others have only a single point, as does hour 12, whose point is at the intersection of the equinoctial with the horizontal, and hour 21, which has only its point at hour $10\frac{1}{2}$ on the horizontal line. We shall settle the matter with sufficient exactness in this way. When only two points are available, we shall find another two, or even more (if we please), for the same hour, by means of the lemma that precedes chapter 16 — whose procedure for hour 14 from sunset we shall adapt to our sundial, so that the same may also be done for the other hours. For if from point g — that is, from the point of hour 7 on the horizontal line, through which hour 14 is to be drawn — through point μ , the point of hour 8 on the equinoctial, through which the same hour 14 must also pass, a circle $\pi \mu \rho$ is described; and if in it, from μ , two equal arcs $\mu \pi$ and $\mu \rho$ are cut off at any interval; and if from π and ρ , at any interval whatever, two arcs are described both upward and downward, meeting each other at ξ (we took the arcs $\mu \pi$, $\mu \rho$ at the interval of the radius $g \mu$): then μg — that is, hour 14 — will pass through these four points ξ , μ , g , ξ [?]. And so with the rest.

3. When, however, only a single point is available, one must have recourse to the figure of the scholium of chapter 1, number 3. For, once the hours that have two points have been drawn, as has been said, we shall take one of them, whichever seems more convenient — such as hour 20, for drawing hour 12. And since, as is clear from the said figure, hour 12 from sunset and hour 4

from noon or midnight intersect each other at hour 20 (because hours 12 and 20 from sunrise or sunset are, in that figure, equally distant from hour 4 from noon or midnight), we shall draw hour 12 through A and through point $A-c$, where hour 4 from noon or midnight intersects hour 20. And if from $A-c$, and through A , a circle is described, and the rest is carried out as we said of hour 14 by the lemma proposed before chapter 16, a third point will be found below A for the same hour 12. Again, for hour 21 we shall take hour 11 from sunset; and since hours 11 and 21 intersect each other at hour 4 from noon or midnight — as is gathered from the same figure of the scholium of chapter 1, number 3 — we shall draw hour 21 through the point of hour $10\frac{1}{2}$ from noon or midnight on the horizontal line (as the aforesaid figure, or table 1 of chapter 14, requires), and through point $A-d$, where hour 4 from noon or midnight intersects hour 11 from sunset. Had you instead taken hour 12 from sunset, you would have found that hour 21 must be drawn through the point where hour $4\frac{1}{2}$ from noon or midnight

intersects hour 12 from sunset. And in this way, from that figure of the scholium of chapter 1, number 3, several points can be found for the same hour — which is a most useful thing for testing whether the hour-lines have been accurately drawn or not. For if several points correspond to one another, it is proof that the lines have been drawn most accurately.

[Margin: A fine way of testing the hours from sunrise or sunset by means of the figure of the scholium of chapter 1, number 3.]

We shall also, and with easy effort, draw hours of this kind — those that have two points too close together, or only one — in the following way, provided the tropics have first been drawn. On the tropic of Capricorn [φ , the winter tropic] take the point of some hour that is distant by 2, 4, 6, or 8 hours from the one we wish to draw. For from this point, if we draw a concealed straight line to the hour on the equinoctial that is distant from the same hour to be drawn by 1, 2, 3, or 4 hours — namely by half the assumed distance — the tropic of Cancer [ϑ , the summer tropic] will be cut at the point through which the sought hour is to be drawn. Thus, if hour 12, which has only the single point A, is to be drawn, we shall take the point of hour 22 on the tropic of Capricorn (for the more remote the point taken, the more accurately the point for the hour to be drawn will be found); then, if from this point we draw a straight line to hour 17 on the equinoctial, which holds the middle place between 12 and 22, the tropic of Cancer will be cut at the point of hour 12. The same will be found by a straight line drawn from hour 14 on the tropic of Capricorn through hour 13 on the equinoctial, and so on.

[Margin: Hour 12 from sunset, by another method.]

3. But hour 12 from sunset (if you please) we shall also draw most exactly by means of the arc of the declining plane comprehended between the horizon and the circle of hour 12, which — by problem 8 at the end of the little book — contains, in our sundial, 78 degrees 8 minutes. (The line of hour 12 slopes toward the meridian above the horizontal line whenever the said arc is less than a quadrant; for when it is a quadrant, the line is parallel to the meridian, as at latitude 45 degrees; and finally, when it is greater than a quadrant, as at a latitude greater than 45 degrees, it slopes toward the meridian below the horizontal line.) For if from A a circle is described toward the parts of B, and in it, upward from the horizontal line, the said arc of 78 degrees 8 minutes is counted, then a straight line from A extended through the end of the count will give the line of hour 12 from sunset. On it, hours 18, 19, 20, 21, 22, 23 from sunset are to be drawn, through hours 3, $3\frac{1}{2}$, 4, $4\frac{1}{2}$, 5, $5\frac{1}{2}$ from noon or midnight; and hours 1, 2, 3,

4, 5, 6 from sunrise are to be drawn through hours $6\frac{1}{2}$, 7, $7\frac{1}{2}$, 8, $8\frac{1}{2}$, 9 from noon or midnight — as is established from the figure mentioned above, in the scholium of chapter 1, number 3.

In our sundial, moreover, hour 12 does not answer exactly to the aforesaid arc of 78 degrees 8 minutes, because it was cut somewhat carelessly in the wooden figure. Nor should this trouble you: it is enough that the sundial be drawn exactly if the precepts handed down are duly observed, even if the printed figure answers, in certain lines, less accurately to those same precepts.

Now, in order to free the studios from the trouble they would have in searching out, from the figure of the scholium of chapter 1, number 3, through which points the hours from sunrise or sunset are to be drawn, we have gathered together below, in the notes to the new description of sundials, several little tables, which together with those of chapter 14 can suffice for laying out the hours from sunrise or sunset in any sundial whatever — a matter of which we thought the reader ought to be advised.

[Margin: Finding the points, in the tropics, for the hours from sunrise or sunset by their distances from the meridian.]

Once the tropics of Cancer and Capricorn have been drawn on the sundial, the points of the hours from sunrise or sunset are very conveniently found on them by the distances of those hours from the meridian, which you will find, for latitude 42 degrees, in the scholium of chapter 15, number 1 — as we set out in the same chapter 15, number 4. Let it be required, for example, to draw line 12 from sunrise or sunset. Since the distance of hour 12, in the table of the scholium of chapter 15, contains 113 degrees 3 minutes on the tropic of Capricorn, then if the inclination of the meridians — that is, the segment FK, 40 degrees 48 minutes — is subtracted, there remain 72 degrees 15 minutes for the distance of hour 12 from the line of the style; and its tangent, $31\frac{4}{5}$ [?], transferred onto the equinoctial line from K toward the left, will give the point at which a straight line drawn from E will cut the tropic of Capricorn, at the point through which hour 12 is to be drawn, as you see in the example. Again, since the distance of the same hour 12 on the tropic of Cancer, in the same table of the scholium of chapter 15, comprehends 66 degrees 57 minutes, and 40 degrees 48 minutes being subtracted, there remain 26 degrees 9 minutes, whose tangent, 4 [+ fractional part: numeral: ?], transferred onto the equinoctial from K toward the left, will offer the point through which a straight line sent out from E will cut the tropic of Cancer, at hour 12 from sunrise or sunset, as is plain in the example. Therefore a straight line drawn through A and the two points found on the tropics will give

the line of hour 12 from sunrise or sunset. And the procedure is the same for the rest.

[Margin: Finding the points for the hours from sunrise or sunset at any hour whatever from noon or midnight.]

4. From table 13 we shall find the points of the diurnal arcs at any proposed hour from noon or midnight, through which the hours from sunrise or sunset are to be drawn, in this way. By however many hours the given hour from noon or midnight is distant from the meridian (this distance is to be counted from the twelfth hour of noon in retrograde order if the given hour is from midnight, but in direct order if from noon — thus hour 5 from midnight is distant from the meridian by 7 hours, namely by the complement of 5 up to 12, as appears here: 11, 10, 9, 8, 7, 6, 5; whereas hour 5 from noon is distant from the meridian by 5 hours, as appears here: 1, 2, 3, 4, 5): by so many hours from sunrise or sunset count on, after that hour from sunrise or sunset for which the point of the diurnal arc at the given hour from noon or midnight is sought. For in this way the counting will be terminated at that hour from sunrise or sunset which makes the meridian [i.e., at noon]. And this counting is to be made in direct order if the given hour from noon or midnight belongs to the hours after midnight; but in retrograde order if it belongs to the hours after noon. Then see by how many hours the hour from sunrise or sunset at which the counting ended is distant from hour 24, and double that number: for so you will have the diurnal arc that cuts the given hour from noon or midnight at the proposed hour from sunrise or sunset. Of this diurnal arc take from table 13 the declination, opposite the altitude of your pole: for this — if the diurnal arc is less than 12 hours — subtracted from the quadrant, will give the remaining distance, at the given hour from noon or midnight, of the given hour from sunrise or sunset from the antarctic pole, that is, from the centre of the sundial; but if the diurnal arc is greater than 12 hours, the same declination added to the quadrant will make the aforesaid distance; and if, finally, the diurnal arc is of 12 hours, that distance is equal to the quadrant. This distance you will cut off from the given hour from noon or midnight thus: with a perpendicular drawn from C, the place of the style, to the given hour, let it be found by problem 10 at the end of the little book how great is the arc of the circle of the given hour between the pole and that perpendicular. For this arc is to be subtracted from the found distance, or conversely the distance from

that arc (the smaller number, of course, from the greater) when the said perpendicular falls on the side of the given hour from noon or midnight. For when it falls on the opposite side, the aforesaid arc must always be added to the found distance. For thus will be produced the arc whose tangent, transferred from the point at which the perpendicular cuts the given hour into the given hour, will give the endpoint of the found distance, through which, namely, the proposed hour from sunrise or sunset is to be drawn. And the whole sine [sinus totus] of that tangent, to be divided into 10 equal parts, must be equal to the interval which, between C, the place of the style, and the endpoint of the straight line that is taken in the given hour from noon or midnight from the point of the perpendicular of that line, is reckoned equal to the style.

An example will make the matter plainer. Let it be required, at hour 4 from noon or midnight, to find the point of hour 11 from sunset. The perpendicular C ϕ falls on the side of hour 4 from midnight, and the segment E ϕ contains 12 degrees 34 minutes, by problem 10 at the end of the little book. And since hour 4 from midnight is distant 8 hours from the meridian — namely by the complement up to 12 — if from hour 11 we count 8 hours in this manner, 12, 13, 14, 15, 16, 17, 18, 19, the counting will terminate at hour 19 of noon, which is distant 5 hours from 24. This number 5, doubled, gives the diurnal arc of hour 10, whose declination in table 13, at latitude 42 degrees, contains 16 degrees 2 minutes; these being taken from 90 degrees, there remain 73 degrees 58 minutes, for the distance of hour 11 from sunrise or sunset from the centre of the sundial at hour 4 from midnight. If from this distance the segment E ϕ , 12 degrees 34 minutes, is subtracted, there remains an arc of 61 degrees 24 minutes, whose tangent with respect to the whole sine C ζ [?] ($\phi \zeta$ being taken equal to the style), 18 [+ fractional part: numeral: ?] a little more, will give point A-d — transferred from ϕ — for hour 11 from sunrise or sunset.

Let it also be required, at hour 4 from noon, to investigate the point for hour 23. The perpendicular C ϕ does not fall on hour 4 from noon, but on hour 4 from midnight, and the segment E ϕ comprehends 12 degrees 34 minutes. And since hour 4 from noon is 4 hours from the meridian, and from 23 four hours are counted in retrograde up to 19 in this way, 22, 21, 20, 19 — which are 5 hours — from 19 up to 24 we fall again into the diurnal arc of hour 10, whose declination 16 degrees 2 minutes, taken from 90, leaves 73 degrees 58 minutes; and if to these the segment E ϕ , 12 degrees 24 minutes [?], is added, the distance of hour 23 from point ϕ becomes 86 degrees 22 minutes [?], whose tangent, about $157\frac{1}{2}$, will give at hour 4 from noon the most remote point through which hour 23 is to be drawn.

Let it also be required, at the same hour 4 from noon, to inquire after the point of hour 22. And since from 22 four hours are counted in retrograde up to 18, and there are six hours from 18 up to 24, we shall have the diurnal arc of hour 12, whose declination is 0 degrees 0 minutes; and therefore the distance of hour 22 from the centre, at hour 4 from noon, contains a quadrant, or 90 degrees. When the arc of 12 degrees 24 minutes is added, an arc of 102 degrees 24 minutes results, which cannot be cut off from hour 4 from noon, since it exceeds the quadrant. Hence the point of hour 22 must be found at hour 4 from midnight, by the tangent about $45\frac{1}{2}$, of the arc 77 degrees 36 minutes, which is left when 102 degrees 24 minutes are taken from 180, or when 12 degrees 24 minutes are subtracted from 90. Indeed, whenever we fall into the diurnal arc of hour 12, the proposed hour from sunrise or sunset must be drawn through the intersection of the given hour from noon or midnight with the equinoctial. Since, then, in our example hour 4 from noon does not cut the equinoctial, hour 22 must be drawn through hour 4 from midnight on the equinoctial. And in this way, whenever the arc found last, after the addition or subtraction of the arc between the centre and the perpendicular, is greater than the quadrant, the point will be found not in the given hour, but in the opposite one.

So too, at hour 4 from midnight, for hour 21 there will be found point A-d, the same that was found for hour 11. For if after 21 we count eight hours, 22, 23, 24, 1, 2, 3, 4, 5, we shall fall again into the diurnal arc of hour 10, because there are five hours from 24 up to 5, at which the counting stopped, and so on.

In the same way, at any other hour from noon or midnight, the points of the hours from sunrise or sunset will be found, if from the place of the style a perpendicular is raised to that hour, and the segment between the centre of the sundial and that perpendicular is investigated, and so on. At hour 5 from midnight, the segment between E and the perpendicular CD contains 27 degrees 22 minutes. And the whole sine, to be divided into 10 equal parts, must be equal to the interval C ϕ , the straight line D ϕ being taken equal to the style, and so on.

Let it again be required, at hour 12 from midnight, to inquire after the point of hour $16\frac{1}{2}$ from sunrise or sunset. Since hour 12 from midnight is in no way distant from the meridian — because at it noon occurs — nothing will need to be counted after hour $16\frac{1}{2}$. But since from $16\frac{1}{2}$ up to 24 there are reckoned $7\frac{1}{2}$ hours, which, doubled, exhibit the diurnal arc of 15 hours, its declination, 23 degrees 2 minutes, must be added to the quadrant (because the diurnal arc of hour 15 is greater than 12 hours), so that the distance of hour $16\frac{1}{2}$ from the centre E is made up to 113 degrees 2 minutes. From these, if the segment BE, 42

degrees, which the perpendicular CB cuts off, is subtracted, there remains an arc of 71 degrees 2 minutes, whose tangent, 29, with respect to the whole sine BD, transferred from B, will indicate point A-f, through which hour $16\frac{1}{2}$ is to be drawn.

Now if, at hour 12 from noon, the point of hour 12 from sunrise or sunset is to be found: since hour 12 from noon is distant 12 hours from the meridian, and there are, from 12, the hours from sunrise or sunset counted in retrograde up to 24, namely 12 hours, as appears here, 11, 10, 9, 8, 7, 6, 5, 4, 3, 2, 1, 24, and hour 24 is in no way distant from 24, we shall have the diurnal arc of hour 0, whose declination is 48 degrees; this, taken away from the quadrant, leaves 42 degrees for the distance of hour 12 from sunrise or sunset from the centre E. If to this is added the segment BE, 42 degrees (because the perpendicular CB falls on the opposite hour, namely on 12 from midnight), an arc of 84 degrees will be made up, whose tangent, 95 [+ fractional part: numeral: ?] a little more, transferred from B toward E, will give the most remote point through which hour 12 from sunrise or sunset is to be drawn — provided, however, that the plane of the sundial is large enough to receive that point.

Finally, at hour 12 from midnight, let the point of hour $16\frac{3}{4}$ be sought. Since up to 24 there are reckoned $7\frac{1}{4}$ hours, we fall into the diurnal arc of hour $14\frac{1}{2}$, whose declination 19 degrees 39 minutes, added to the quadrant, makes the distance of hour $16\frac{3}{4}$ from the centre E to be 109 degrees 39 minutes. From this, if the segment BE, 42 degrees, is subtracted, there remains an arc of 67 degrees 39 minutes, whose tangent, 24 [+ fractional part: numeral: ?] a little more, will offer point A-g of hour $16\frac{3}{4}$ at hour 12 from midnight. And so with the rest. On the line of hour 12 from noon or midnight the finding of the points for the hours from sunrise or sunset is easier and quicker, because the perpendicular CB has already been drawn to it, and it is established that the segment BE is equal to the altitude of the pole above the horizon — so that there is no need to seek it by problem 10.

5. But once the diurnal arc has been found, which cuts the given hour from midnight at the proposed hour from sunrise or sunset, as was handed down at the beginning of number 4, we shall find that point of section without tangents, even if the segment between the centre and the perpendicular drawn from the place of the style to the given hour from noon or midnight is unknown, in this manner. Let it be required, for example, to find at hour 4 from midnight the point of hours 11 and 21 from sunrise or sunset. Since hour 4 from

Horologiorum Nova Descriptio — Cap. XIX (continued)

(continuing §5, from the catchword "med.")

midnight is 8 hours from noon. If 8 is added to 21, they make 29; taking away 24, there remain 5, which doubled produce a diurnal arc of 10 hours, whose declination — from table 13, at latitude 42 degrees — is 16 degrees 2 minutes. You will find the same diurnal arc if you add 8 to hour 11: for you will produce hour 19, which is 5 hours from 24, and 5 hours doubled produce a diurnal arc of 10 hours. Therefore, once the perpendicular $C\oplus$ has been drawn to hour 4 from midnight, and the line $\oplus$ -Ab taken at an interval equal to $C\oplus$ (the line $\oplus$ - $\oplus$ having first been set down equal to the style), let a straight line be drawn from Ab to hour 4 from midnight on the equinoctial; and from it, on the circle described from Ab, let the aforesaid declination of 16 degrees 2 minutes be counted off toward the line of hour 5. For the straight line issuing from Ab through the end-point of the counting will cut hour 5 at the sought point Ad, as is established from the problem of chapter 1. And so with the rest.

[Margin: Finding the points for the hours from sunrise or sunset, at a given hour from noon or midnight, without tangents.]

But if the given hour from noon or midnight does not cut the equinoctial, one must take the complement of the declination of the diurnal arc found, and proceed as you will presently hear. For example, if at hour 5 from noon the point of hour 6 from sunrise is to be found: since hour 5 from noon is 5 hours from the meridian, and from hour 6 counting backwards down to 1 there are likewise 5 hours, and hour 1 is 1 hour from 24, we shall have a diurnal arc of 2 hours, whose declination at latitude 42 degrees is 47 degrees 1 minute, and whose complement is 42 degrees 59 minutes. Therefore, once CD has been drawn perpendicular to the line of hour 5 from noon — which falls on the opposite side, that is, on hour 5 from midnight — and the line D-Aa taken at an interval equal to $C\bullet$ (the line D- $\bullet$ having first been set down equal to the style), let a concealed straight line Aa-E be drawn from Aa through E, the centre of the dial, from which the complement of the declination is to be reckoned; and from it, on the circle described from Aa, let the complement of the declination — which we said was 42 degrees 59 minutes — be counted off toward hour 5 from noon. The straight line extended from Aa through the end-point of the counting will cut hour 5 from noon at the point Ah, through which hour 6 must pass. And so with the rest.

But we shall teach this same finding otherwise, and most easily, at number 8, where it will need to be carefully noted and learned.

[Margin: The finding explained shortly, where it is taught more easily.]

6. Finally, by means of the diurnal arcs we shall also neatly find, among the hours from noon or midnight, the points for the hours from sunrise or sunset. Those diurnal arcs which embrace fewer than 12 hours — or at any rate cut the horizontal line in at least one point — we shall lay out by this method, even if we do not know their declinations. Observe how many hours before or after noon any given hour-point taken on the horizontal line is distant. For this point lies on the diurnal arc which those hours before or after noon, doubled, produce; and from this point, by the first rule of the scholium of chapter 8, you will find all the other points of that same diurnal arc in the remaining hours. Or else, given any diurnal arc, consider at which hour from noon or midnight the Sun rises or sets upon it. For the point of that hour, found on the horizontal line, lies on the diurnal arc. Thus, since on the diurnal arc of 6 hours the Sun rises at hour 9 from midnight and sets at hour 3 from noon, the said diurnal arc will pass both through hour 9 from midnight and through hour 3 from noon on the horizontal line. Therefore, from each of the two points, again by the first rule of the scholium of chapter 8, you will find the other points of that same diurnal arc in the remaining hours, in this way. Since hours 3 and 2 from noon are equally distant from hour $2\frac{1}{2}$, which is 6 hours from hour $8\frac{1}{2}$ from midnight, if you draw a concealed straight line from hour $8\frac{1}{2}$ from midnight on the equinoctial through hour 3 on the horizontal, you will cut hour 2 from noon at a point of the diurnal arc of 6 hours, as is established from the first rule of the scholium of chapter 8. Likewise a concealed line from hour 8 from midnight on the equinoctial, through hour 3 on the horizontal, will cut hour 1 from noon at a point of the same diurnal arc of 6 hours — because hour 8 from midnight is 6 hours from hour 2 from noon, which holds the middle place between hours 3 and 1 from noon. This point at hour 1 from noon will likewise be found by a concealed line drawn from hour $7\frac{1}{2}$ from midnight on the equinoctial through the point of the said arc at hour 2 from noon. Again, a straight line drawn from hour 9 from midnight on the equinoctial through the point of the said arc at hour 2 from noon will cut hour 4 from noon at a point of the same arc. The same will also be done by a line drawn from hour $9\frac{1}{2}$ on the equinoctial through hour 3 on the horizontal. And so on in succession.

[Margin: Finding the points, among the hours from noon or midnight, through which a proposed diurnal arc is to be laid out, even if its declination is unknown.]

Through the point of hour 9 from midnight on the horizontal, too, you will find in the same way the points of that same diurnal arc of 6 hours in the other hours. For a straight line drawn from hour $5\frac{1}{2}$ from midnight on the equinoctial through hour 9 on the horizontal will cut hour 2 at a point of the said arc, because hour $5\frac{1}{2}$ is 6 hours from hour $11\frac{1}{2}$, and this hour $11\frac{1}{2}$ holds the middle place between hour 9 from midnight and hour 2 from noon. So too a line from hour 5 from midnight on the equinoctial, through the same hour 9 on the horizontal, will cut hour 1 from noon at a point of the same diurnal arc. Finally, if a point of the same diurnal arc of 6 hours is to be found at any proposed hour — say at hour 4 from midnight — one must take the hour midway between the given hours 4 and 9, which is $6\frac{1}{2}$. For a straight line from hour $\frac{1}{2}$ on the equinoctial, which is 6 hours from $6\frac{1}{2}$, drawn through hour 9 on the horizontal, will cut hour 4 from midnight at the sought point. But if on neither side is there found on the equinoctial an hour 6 hours distant from that middle hour, a point of the same arc must first be found at some other hour, and then through that point the point at the proposed hour must be sought. For instance, if through the point of hour 9 on the horizontal a point of the diurnal arc of 6 hours is to be sought at hour 10: since on the equinoctial no hour-point is 6 hours distant from hour $9\frac{1}{2}$, which is the middle between 9 and 10, we shall take, for example, hour 4 on the equinoctial, from which hour 10 recedes by 6 hours. Therefore a straight line drawn from hour 4 on the equinoctial through hour 9 will cut, on the horizontal, hour 11 at a point of the diurnal arc of 6 hours, since hours 9 and 11 are equally distant from 10. And if now through hour $4\frac{1}{2}$ on the equinoctial a line is drawn through the point found at hour 11, the proposed hour 10 will be cut at the sought point, because hour $10\frac{1}{2}$, midway between 11 and 10, is 6 hours from $4\frac{1}{2}$. And so on.

[Margin: A general rule for finding the points of a proposed diurnal arc at a given hour from noon or midnight.]

Through point B, of hour 12, on the horizontal, the points of the diurnal arc of hour 0 will be found in the other hours. The points of the diurnal arc of 4 hours are found through the points of hours 10 and 2 on the horizontal; the points of the diurnal arc of 8 hours, through the points of hours 8 and 4 on the horizontal; likewise the points of the diurnal arc of 10 hours, through the single point of hour 7 from midnight, since the point of hour 5 from noon is not available on the horizontal. Finally, through the point of hour $5\frac{1}{2}$ from midnight on the horizontal the points of the diurnal arc of 13 hours will be investigated, and so on.

Moreover, from the points of any southern diurnal arc, the points of the northern diurnal arc that is its counterpart — the one which together with it completes 24 hours — will likewise be found, by the second rule of the scholium of chapter 8, if need be. Thus from the points of the diurnal arc of 10 hours you will find the points of the diurnal arc of 14 hours; and from the points of the diurnal arcs of 8, 6, 4, and 2 hours you will find the points of the diurnal arcs of 16, 18, 20, and 22 hours, if it can conveniently be done — because arcs of this kind are sometimes too far distant from the Tropic of Cancer [☿] for their points to be easily obtained.

[Margin: How the northern diurnal arcs are described from their opposite southern ones.]

7. Now, to teach the laying-out of the hours from sunrise or sunset by means of the diurnal arcs: it will not be difficult to recognize through which point of any diurnal arc a proposed hour from sunrise or sunset should be drawn. Beginning on the dial from that hour after noon at which the Sun sets — or at which the diurnal arc cuts the horizontal line on the western side — let a count be made from hour 24 through the hours from noon and midnight, up to the proposed hour from sunrise or sunset. For through that hour from noon or midnight at which the count ends, the proposed hour from sunrise or sunset must be drawn on the diurnal arc taken. For example, suppose hour 20 from sunrise or sunset is proposed, and it is asked through which point of the diurnal arc of 6 hours it should be drawn. Since hour 20 is 4 hours from 24 — that is, from hour 3 from noon, through which that diurnal arc passes (as appears here: 24, 23, 22, 21, 20) — hour 20 must be drawn through the point of that arc at hour 11 from midnight, since hour 11 too is 4 hours from hour 3 (as appears here: 3, 2, 1, 12, 11). So that hour 24 answers to hour 3, hour 23 to hour 2, hour 22 to hour 1, hour 21 to hour 12, and hour 20 to hour 11. The same point will be found if, beginning from the hour at which the Sun rises, the count is made through the hours from noon or midnight — starting from that hour from midnight at which the Sun rises, or at which the diurnal arc intersects the horizontal line on the eastern side — up to the proposed hour from sunrise or sunset. As in the given example: since the Sun rises at hour 9 from midnight, or hour 18 from sunset, and hour 20 is 2 hours from hour 18 toward the west, the point of hour 11 from midnight must be taken, likewise 2 hours after hour 9 from midnight at which the Sun rises. For in this way hour 18 answers to hour 9, hour 19 to hour 10, and hour 20 to hour 11. In the same way you will find that hour 1 from sunrise or sunset must be drawn on the same arc through the point of hour 4 from noon, since hour 1 from sunrise

or sunset is precisely 1 hour from 24 toward the west, just as hour 4 is from hour 3. Likewise you will recognize that hour 21 must be drawn on the diurnal arc of 10 hours through hour 2 from noon, because both 21 from 24 and 2 from noon are 3 hours from 5 toward the east. Finally you will perceive that, on the diurnal arc of hour 0, which touches the horizontal line at B — the point of hour 12 from midnight — hour 23 must be drawn through hour 11 from midnight (because hour 23 precedes hour 24, when the Sun sets, by one hour, just as hour 11 from midnight precedes hour 12, when the Sun sets, by one hour), and hour 22 through 10, and hour 21 through 9, and so on; likewise hour 1 from sunrise through 1 from noon, hour 2 through 2, and so on.

[Margin: The laying-out of the hours from sunrise or sunset by means of the diurnal arcs.]

Therefore, if one carefully observes at which hour from noon the Sun sets and at which hour from midnight it rises, one will recognize without difficulty to which hour from noon or from midnight a proposed hour from sunrise or sunset corresponds, on any diurnal arc. For to the former hour there corresponds hour 24 from sunset, and the hour from sunrise that closes the diurnal arc; while to the latter hour there corresponds the hour from sunset that ends the nocturnal arc, and hour 24 from sunrise. From these the other corresponding hours are to be derived.

Here too it is worth observing that any hour from sunrise or sunset, on any diurnal arc which it cuts twice, passes through two hours which are as many hours apart from each other as are contained in that same diurnal arc, or in the nocturnal arc which together with it completes 24 hours. Thus you see that hour 21, on the diurnal arc of 10 hours, passes through hour 2 from noon and through hour 4 from midnight. Likewise hour 23 passes through hour 4 from noon and hour 6 from midnight. Again, on the diurnal arc of 6 hours, hour 23 is drawn through hour 2 from noon and hour 8 from midnight. But on the horizontal dial you will find that hour 13 from sunrise or sunset cuts the diurnal arc of 14 hours at hour 8 from midnight and hour 6 from noon, which are 10 hours apart from each other (as many, that is, as are contained in the nocturnal arc of 10 hours), and so on. Only on the diurnal arc of hour 0 do the several hours from sunrise or sunset touch that arc each at a single point only.

[Margin: How any hour from sunrise or sunset passes through two hours from noon or midnight on any diurnal or nocturnal arc, and which they are.]

Therefore, since (for example) hour 23 must be drawn through hour 4 from noon on the diurnal arc of 10 hours, but the point of hour 4 is not included on our dial, it will have to be drawn through hour 6 from midnight, which is 10 hours from hour 4 from noon. And the same reasoning is to be applied to the rest.

[Margin: A most elegant way of finding the point at any hour from noon or midnight, for any hour from sunrise or sunset.]

8. But since in this place we have dealt with the finding of the points through which the diurnal arcs are to be laid out, it is worth setting out a most convenient way of finding, at any hour from noon or midnight, the point for any hour from sunrise or sunset — a method which itself depends entirely on finding the point of any diurnal arc at any hour from noon or midnight. The matter stands thus. Once the diurnal arc has been found which cuts the given hour from noon or midnight at the proposed hour from sunrise or sunset (as we taught at the beginning of number 4 of this chapter), the point of that diurnal arc at the given hour from noon or midnight must be found by the first rule which we handed down in the scholium of chapter 8, number 3; for through that point the hour from sunrise or sunset must be drawn.

For example, suppose at hour 5 from midnight one must find the point through which hour 18 from sunrise or sunset is to be drawn. Since hour 5 from midnight is 7 hours from noon, we shall count from the given hour 18, in direct order (as we said in number 4), 7 hours down to 1, in this way: 19, 20, 21, 22, 23, 24, 1. And since hour 1 is 1 hour from 24, which doubled gives a diurnal arc of 2 hours, hour 18 from sunrise or sunset must be drawn through the point of this arc at hour 5 from midnight. We shall find it thus. The diurnal arc of 2 hours passes through hours 11 and 1 on the horizontal line, since on it the Sun rises at hour 11 from midnight and sets at hour 1 from noon. And since between hours 11 and 5 from midnight the middle is hour 8 from midnight, from which hour 2 from noon is 6 hours distant, if from the point of hour 2 from noon on the equinoctial a straight line is drawn through the point of hour 11 on the horizontal, hour 5 from midnight will be cut at the point of the diurnal arc of 2 hours through which hour 18 from sunrise or sunset is to be drawn.

But if perchance the point of hour 2 from noon cannot conveniently be had on the equinoctial, we shall take, for example, the point of hour $1\frac{1}{2}$, from which hour $7\frac{1}{2}$ is 6 hours distant. And since hours 11 and 4 are equally distant from hour $7\frac{1}{2}$ (each being $3\frac{1}{2}$ hours away), a straight line drawn from the point of hour $1\frac{1}{2}$ on the equinoctial through the point of hour 11 on the horizontal will

give the point of the diurnal arc of 2 hours at hour 4 from midnight. Now between hours 4 and 5 from midnight the middle is hour $4\frac{1}{2}$, from which hour $10\frac{1}{2}$ is 6 hours distant. If, therefore, from the point of hour $10\frac{1}{2}$ on the equinoctial a straight line is drawn through the point found at hour 4, hour 5 from midnight will be cut at the sought point of the same diurnal arc. And in this way, for the most part by a second operation, the sought point will always be found, if it was not found in the first.

Again, suppose at hour 4 from noon a point is to be found for hour 21 from sunrise or sunset. Since, counting 4 hours back from 21 in retrograde order (as was said in number 4), the count ends at hour 17 (thus: 20, 19, 18, 17), which is 7 hours from 24, we fall upon the diurnal arc of 14 hours — which hour 4 from noon cannot cut, as is evident. We shall therefore take hour 4 from midnight; and since this is 8 hours from noon, by counting 8 hours from 21 in direct order we shall arrive at hour 5 (thus: 22, 23, 24, 1, 2, 3, 4, 5), which is 5 hours from 24. We therefore fall upon the diurnal arc of 10 hours. And since this arc runs through hour 7 from midnight on the horizontal line, and hour $5\frac{1}{2}$ is the middle between 4 and 7, if from the point of hour $11\frac{1}{2}$ on the equinoctial — this hour $11\frac{1}{2}$ being 6 hours from that middle hour between 4 and 7,

that is, from hour $5\frac{1}{2}$ — a straight line is drawn through the point of hour 7 on the horizontal, hour 4 from midnight will be cut at a point of the diurnal arc of 10 hours, through which hour 21 must be drawn. And the same reasoning holds for the rest. This method is most excellent, since it does not require any whole diurnal arc in order to lay out a given hour from sunrise or sunset; rather, at any hour from noon or midnight it seeks the point for the proposed hour from sunrise or sunset, and at the same time discovers to which diurnal arc that point belongs, as is clear from what has been said.

9. All these things apply also to the horizontal dial: only, the point of the diurnal arc found must be sought on the meridian line, by means of the declination of that arc taken from table 13 — just as, on the meridian line of the horizontal dial, we investigated the points of the Sun's parallels by their declinations in chapter 8, number 3. For example: let the point for hour 11 from sunrise or sunset be sought at hour 7 from midnight. Since hour 7 from midnight is 5 hours from noon, we shall count 5 hours after 11, down to 16 (which is 8 hours from 24). We therefore fall upon the diurnal arc of 16 hours, whose declination, from table 13, is 29 degrees 3 minutes. This, subtracted from the pole's altitude of 42 degrees, leaves 12 degrees 57 minutes, whose tangent, about $2\frac{3}{10}$, transferred downward

from C, the place of the style, will give the point of the diurnal arc of 16 hours. From this we shall find the point of the same arc at hour 7 from midnight in this way. Since hour $9\frac{1}{2}$ is the middle between hours 7 and 12, a straight line from the point of hour $3\frac{1}{2}$ on the equinoctial — which is 6 hours from the point of hour $9\frac{1}{2}$ — through the point found on the meridian, will give, at hour 7, the point of the diurnal arc of 16 hours for hour 11 from sunrise or sunset, and so on.

[Margin: Application of what has just been said about the diurnal arcs to the horizontal dial.]

But if we wished to seek the point for the same hour 11 from sunrise or sunset at hour 7 from noon, we should labour in vain. For by counting 7 hours back from 11 we fall upon hour 4, and thus upon the diurnal arc of 8 hours — which, since it lies below the equinoctial line, hour 7 from noon cannot cut. Therefore the point for hour 11 must be sought at hour 7 from midnight, as we did.

Therefore, if a diurnal arc is found, as we taught in number 4, through whose point at hour 6 the given hour from sunrise or sunset must be drawn, we shall transfer the tangent of the complement of its declination from the centre of the dial onto hour 6, so as to have on it the point through which that same given hour from sunrise or sunset must pass. For example: let hour 14 from sunrise or sunset be given. Since hour 6 from noon is 6 hours from the meridian, we shall count back six hours from 14 down to 8, thus: 13, 12, 11, 10, 9, 8. And since hour 8 is 8 hours from 24, we shall double 8 to obtain the diurnal arc of 16 hours, whose declination at latitude 42 degrees is found in table 13 to be 29 degrees 3 minutes. If, then, we transfer the tangent of its complement from G, the centre of the horizontal dial, onto hour 6, we shall find the point for hour 14, and hence also for hour 22. This is what, in this place, we undertook to teach in chapter 14, number 3.

SCHOLIVM

1. Thus far we have handed down precepts for laying out only those dials that decline from the south, whether toward the east or toward the west; of those that decline from the north, toward east or west, we have said nothing at all, so as not to overwhelm the minds of students with a multitude of precepts. But if anyone wishes to lay out a dial facing north, it is enough for him to lay out, by the foregoing precepts, a south-facing dial of equal declination but in the opposite direction: that is, if he wants a dial declining from the north toward the east, let him draw one declining from

the south toward the west; and if he wants one declining from the north toward the west, let him construct one declining from the south toward the east. For the lines of this dial, extended beyond the horizontal line — yet so that they do not run beyond the Tropic of Capricorn [♊] — will yield the desired northern dial, provided that the portion of the dial cut off by the horizontal line, enclosed between that same horizontal line and the Tropic of Capricorn, is so inverted that the horizontal line takes the upper place, and the part which, when we face the dial, is then on our right becomes the left, and vice versa; which will happen if the same lines exactly coincide. For if this portion is drawn on the opposite face of the plane, so that the lines are drawn exactly opposite to the lines and set down so that the horizontal line holds the upper place, the northern dial proposed will have been made. But the segments of the arcs of the northern signs will belong to the southern signs, and those of the southern signs to the northern.

[Margin: How a dial declining from the north is derived from one declining from the south.]

2. It will not be difficult, moreover, to judge which hours in the northern dial (that is, the part cut off by the horizontal line) are to be counted from noon or from midnight, or from sunrise or sunset. For the hours which in the southern dial are counted from midnight are to be counted, in the northern dial, from noon, and vice versa. But as regards the hours from sunrise or sunset, let this rule be held. The hours from sunrise or sunset whose lines, extended, first touch the diurnal arc of hour 0 or 24 (if it were drawn) before they cut the Tropic of Capricorn [♊] of the northern dial — which will most often happen when they cut the meridian line before the horizontal — are also to be counted from sunrise or sunset, keeping, that is, the same denomination. But the hours whose extended lines cut the Tropic of Capricorn of the northern dial before they touch the diurnal arc of hour 0 or 24 — which will most often happen when they cut the horizontal line before the meridian — will take the opposite denomination: so that the hours counted from sunrise in the southern dial must be reckoned from sunset in the northern, and vice versa. But it is enough to make the judgement about hour 24 alone; for from it all the others will easily be distinguished. For example, since in our southern dial the segment of the horizontal line to the right of the meridian (I call "the right part" that which is on our right when we face the dial, whereas the part inclining to the left indicates hour 24 from sunrise) belongs to hour 24 from sunset, we shall make our inference about the rest from both cases. For since the portion of

hour 24 from sunset, extended toward the left, touches the diurnal arc of hour 0 at B before it reaches the tropic, the segment of the horizontal line toward the left will likewise, in the northern dial, look toward hour 24 from sunset; and therefore hours 23, 22, 21, 20, etc., immediately preceding hour 24 from sunset, are also to be counted from sunset, and accordingly the remaining hours extended from sunset, such as 11, 12, 13, 14, etc., will look toward the hours from sunrise. Again, since the portion of hour 24 from sunrise in the same southern dial, extended toward the right, touches the same diurnal arc of hour 0 at B before it reaches the tropic (which, in planes declining but little from the prime vertical, also cuts the horizontal line on the other side), the segment of the horizontal line toward the right will likewise, in the northern dial, belong to hour 24 from sunrise; and therefore hours 1, 2, 3, 4, etc., immediately following hour 24 from sunrise, are also to be reckoned from sunrise, and consequently the other hours extended from sunset, such as 9, 10, 11, etc., will belong to the hours from sunset. All of which we have demonstrated in the *Gnomonica*.

[Margin: Which hours in the northern dial are to be counted from noon and which from midnight; likewise which are to be reckoned from sunset and which from sunrise.]

3. Now, if anyone wishes to lay out the arcs of the signs among the hours from sunrise or sunset, taking no account of the hours from noon and midnight, he will be able to do it by almost the same means by which we accomplished it in chapter 15 for the horizontal dial. For from table 7, computed for latitude 42 degrees, there will be found, on the line of hour 6 from noon or midnight, the points through which straight lines drawn from F, the intersection of the equinoctial with the meridian, will cut the hours from sunrise or sunset at the points of the parallels — as we explained in chapter 18, number 2, concerning the hours from noon and midnight.

[Margin: A manifold finding of the points for the Sun's parallels, among the hours from sunrise or sunset, without the hours from noon or midnight.]

CAPVT XIX. (continued)

Likewise, from table 8, computed for the same latitude, the points on the meridian line will be found through which — if straight lines are sent out from A, the intersection of the equinoctial with the horizontal, — the hours from sunrise or sunset will be cut at the points of the parallels. These points on the meridian

line are found in this way. For the southern parallels, let each arc of table 8 be subtracted from the complement of the altitude of the pole above the horizon, if it can be subtracted; and let the tangent of the remaining degrees be carried from B, the intersection of the meridian with the horizontal, into the meridian line toward the equinoctial. Or else let the complement of the altitude of the pole be taken away from any arc of table 8, if that can be done, and let the tangent of the remaining degrees be carried from the same point B toward the centre of the dial. But if some arc is found to equal the complement of the altitude of the pole, the point in question will be B itself, the endpoint of the arc of table 8.

Whenever, however, some hour is more than six hours distant from noon (as, for example, is hour 13 in Capricorn ♑), its arc must be reckoned from the point of the equator below the horizon, as was said at chapter 8, number 7. Therefore the altitude of the pole must be added to its complement, and the tangent of the combined number carried from B beyond the centre. For the northern parallels, by contrast, each arc of table 8 must be added to the complement of the altitude of the pole, and the tangent of the combined number carried from B beyond the equinoctial line. And if the combined number should happen to be greater than a quadrant, it must be subtracted from 180 degrees, and the tangent of the remaining number carried from B toward the centre. Whenever, moreover, the points for the proposed parallel are found only with difficulty at certain hours, those points must be found by the second rule of the scholium of chapter 8, from the points of the opposite parallel, as was said at chapter 18, number 1.

Thirdly, the points of the parallels in the hours from sunrise or sunset can be found by their distances from the meridian, or by the arcs of the horizon of table 18, as was taught at chapter 15, number 3. For example, the distance from the meridian of hour 11 in Capricorn ♑ from sunset contains $128^{\circ}3'$. Now, with the inclination of the meridians, $40^{\circ}48'$, subtracted, there will remain $87^{\circ}15'$. Their tangent, $208 \frac{2}{10}$ (approximately), carried from K beyond A, will place a point on the equinoctial (if the plane is capable of it) through which a straight line drawn from E will cut hour 11 at the point Capricorn ♑. Again, in table 18, the arc of the horizon of the same hour 11 from sunset embraces $139^{\circ}27'$, which must be counted from B beyond A. Therefore, with the wall's declination of 30° taken away, there remain $109^{\circ}27'$, which cannot be cut off from the horizontal line — the start having been made at aC, the place of the style — since they exceed a quadrant. Therefore we shall take their complement up to 180, namely $70^{\circ}33'$, and carry its tangent, $28 \frac{3}{10}$, from C beyond B. For a straight line drawn through its endpoint and through E, extended, will cut hour 11 at the point Capricorn ♑. And in this manner, whenever some arc cannot be cut off on one side, its

complement to 180 must be cut off on the other side, and so on. Likewise, whenever the distance of some hour from sunrise or sunset cannot be taken on the equinoctial, the arc of the horizon of the same hour can generally be taken from table 18, and conversely. This is what happens in the next example.

Fourthly, the same result is obtained if, by problem 15 at the end of the little book, the altitudes of the Sun above the declining plane are computed for the hours from sunrise or sunset. For the tangents of the complements of those same altitudes, taken from the place of the style (which is the whole sine of those tangents), will cut the hours from sunrise or sunset at the points of the parallels, as was shown at chapter 8, number 12.

Fifthly and lastly, we shall accomplish the same by the rising and setting amplitudes for the latitude of the place in which the dial is described, as was explained at chapter 13, number 6.

4. Finally, I should like to add here another most convenient way of describing the parallels of the Sun on a declining dial, both for the hours from noon and midnight and for the hours from sunrise and sunset, by means of the arc of the horizon and of the vertical, which are computed in tables 14, 15 and 16, 17 from problem 12 at the end of the little book for latitude 42 degrees. For, for the forenoon hours of the northern parallels and the afternoon hours of the southern, let the wall's declination be added to the arcs of the said tables; but for the afternoon hours of the northern parallels and the forenoon hours of the southern, let the arcs of the same tables be subtracted from the wall's declination, or the wall's declination be subtracted from them — according, that is, as they are less than or greater than the wall's declination. Then let the tangents of these combined arcs, or of the remaining ones, be carried from the place of the style into the horizontal line, to the right or the left, as the case requires (which will not be hard to determine): the straight lines drawn from F, the intersection of the equinoctial line with the meridian, through the endpoints of the tangents laid off, will cut the hours at the points of the parallels. In the same way, if the tangents of the arcs of the vertical circle from the same tables are carried into the vertical line — which is to be drawn through A perpendicular to the horizontal — upward or downward from A, as the case demands, the straight lines drawn from F through the ends of the tangents so carried will likewise cut the same hours at the points of the parallels. I give no example of this matter, since it is clear of itself.

[Margin: The description of the parallels in the hours both from noon and midnight and from sunrise and sunset, on a declining dial, by means of the arc of the horizon and of the vertical, computed for the given latitude.]

5. To this may also be adapted what we wrote at number 1 of the scholium of chapter 8 and at number 3 of the scholium of chapter 15: namely, that one and the same straight line, drawn through any hour on the equinoctial, cuts two hours — as much from noon and midnight as from sunrise and sunset — whose points are equally distant on the equinoctial from the first assumed hour, at the points of two opposite parallels.

[Margin: That any straight line drawn through any hour-point on the equinoctial cuts two hours at the points of opposite parallels.]

CAPVT XX.

DE HOROLOGIO, QVOD VERTICALI CIRCVLO PRIMARIO ÆQVIDISTAT.

(On the dial that is parallel to the prime vertical circle.)

1. On a plane that is parallel to the prime vertical, the hours from noon and midnight are described as on a horizontal dial, but the hours from sunrise and sunset as on a declining dial. Only, in order that the centre may be found, one must carry into the meridian line, from the place of the style upward, the tangent of the altitude of the pole — not the tangent of the complement of the altitude of the pole, as on a horizontal dial — and downward the tangent of the complement of the altitude of the pole, so that the point may be found through which the equinoctial line is to be drawn. Moreover, the hour-lines to the right of the meridian belong to the hours from noon, and those to the left to the hours from midnight, in the reverse order, that is, from the horizontal dial.

For if a vertical dial is to be constructed, for example, for latitude 48° , let the dial of chapter 2 be inspected (so that we are not forced to construct a new figure), in which the place of the style is at C and its length is CD. Having drawn through C the two straight lines AB, cutting each other at right angles at C, of which AB represents the meridian and CD the horizontal, let there be carried from C upward the tangent of the altitude of the pole, $11 \frac{1}{10}$, for latitude 48° (with respect to the whole sine CD divided into 10 equal parts) as far as G; and downward the tangent of the complement of the altitude of the pole, 9, as far as B. For G will be the centre of the dial, and the straight line H B I, perpendicular to the meridian A B, will be the equinoctial line. Now if, from

the little table of the scholium of chapter 1, the tangents of the arcs by which the hours are distant from the meridian toward noon or midnight are carried into the equinoctial from point B (with respect to the whole sine BD), marking points on both sides on the equinoctial itself, then the straight lines drawn from G through these points will indicate the hours from noon and midnight — in such a way that the hours from midnight fall on our left when we face the dial, and the hours from noon on our right; that is, to the hour-lines are ascribed the complements of the hours of the horizontal dial, up to 12: namely, hour 1 is called 11, and 9 is called 3, and so on. For the horizontal dial constructed for latitude 42° is a vertical dial for latitude 48° , if that interchange of the hours, of which we spoke, is made — as far as concerns the hours from noon and midnight.

2. By the tangents of the complements of the arcs, taken in table 6 opposite the altitude of the pole 48° in the left-hand column, or 42° in the right (since at latitude 48° the pole is raised above the vertical by 42°), you will find, if you please, other hour-points on the horizontal line CD. And so that the hour-lines may be drawn more exactly, the points of the equinoctial line must be carried into the straight line O P parallel to the equinoctial, the straight line G A being set equal to G B, as was done at chapter 2 for the horizontal dial.

Thus the altitude of the pole above the horizon must be taken in the left-hand column, and its complement — that is, the altitude of the pole above the vertical — in the right. Therefore, if a vertical dial is constructed for latitude 42° , one must take 42° in the left-hand column, or 48° in the right.

To this, finally, are to be referred all the other methods that we set out at chapters 2, 3, 4, and 5: provided that into a circle described from the centre of the dial you carry the arcs of table 6, opposite the altitude of the pole in the left-hand column, above the vertical of your own region — that is, above the plane of your dial — as in our example, opposite 42° , yet so that those arcs have their beginning on the line of hour 6.

3. Concerning the arcs of the signs nothing new need be prescribed here: only be mindful that the segment of the meridian line CB, between the place of the style and the equinoctial line, contains the degrees of the complement of the altitude of the pole of your region, and the segment CG the degrees of the altitude of the pole. Likewise, that the arcs of the southern signs incline from the equinoctial line toward the centre of the dial, and so forth.

4. Finally, the hours from sunrise and sunset are described as on a declining dial, by means of the same points of the equinoctial line and of the horizontal which the two little tables of chapter 14 supply us; and by other means too, if you please, which we prescribed at chapter 19, the same hours from sunrise and sunset can be laid out.

CAPVT XXI.

DE HOROLOGIO MERIDIANO.

(On the meridian dial.)

1. Let a straight line A B be drawn in any way for the horizontal line, and from any point A of it, taken for the place of the style, let a circle B C be described — to the right, indeed, in an eastern dial, but to the left in a western one — in which, from point D downward, let the complement of the altitude of the pole be numbered as far as C. For the straight line A C will be the equinoctial line; and to it, having drawn through A the perpendicular A D, for hour 6, let the length of the style A D be taken on it. Then, having taken on any straight line as many segments as you please equal to the style A D, let the first of them, A D, be cut into 10 equal parts.

If, by the aid of the tangents, you wish to draw the equinoctial line and the axis, you will proceed thus. On the horizontal line take any portion you like from point A toward B, and through its endpoint erect a perpendicular to the horizontal. Then, that portion having been divided into 10 equal parts, the tangent of the complement of the altitude of the pole, namely $11 \frac{6}{10}$ [recte: $11 \frac{1}{10}$? — astronomically the 42° dial's complement (48°) gives $11 \frac{1}{10}$; numerator glyph best-reads 6], carried into the said perpendicular downward, will give the point through which the equinoctial is to be drawn from A. But the tangent of the altitude of the pole, namely 9, carried into the same perpendicular upward, will give the point through which the axis of the world must be drawn from A. These tangents must be taken with respect to that portion which we said was to be assumed on the horizontal, divided into 10 parts, in the manner of a whole sine.

Now if, from the little table of the scholium of chapter 1, the tangents of all the hours from noon and midnight are carried in order from point A into the equinoctial line on both sides, in each dial, the hour-points will be found on each equinoctial line. But since here the line of hour 6, A D, stands in place of the meridian line of the horizontal dial, the points nearest to A will belong to hours 7 and 5, the next to hours 8 and 4, and so on — as the numbers on the equinoctial

line indicate; just as on the horizontal dial the points nearest to point B belong to hours 1 and 11, and the next to hours 2 and 10, and so on.

[Margin: The construction of the meridian dial.]

The same hour-points will be found from what was handed down at chapter 3. For the straight line A D, laid off on both sides from A, exhibits the points of hours 3 and 9. If, therefore, at the interval between hours 3 and 9 the equinoctial line is cut from D, the points of hours 4 and 10 will be had; and if the portions of the equinoctial line between A and hours 2 and 10 are cut into 3 equal parts, the third parts of these, beginning from A, will give hours 4 and 8. But the interval between D and hour 10 or 2, carried on the equinoctial from point 10, will give hours 11 and 5; and from point 2, it will exhibit hours 1 and 7, and so on. Since, moreover, as was shown in the *Gnomonica*, the hour-lines on a meridian dial are parallel and perpendicular to the equinoctial, if through the points found perpendiculars to the equinoctial (or parallels to A D) are drawn, the hours from noon and midnight will be described. These perpendiculars, or parallels, will easily be drawn if in each dial there is drawn a line E F, or G H, parallel to the equinoctial line, and into it the hour-points are carried, the beginning being made from the line of hour 6, A D, and so forth.

[Margin: The finding of the hour-points from noon and midnight.]

[Margin: The finding of the hour-points on the equinoctial.]

[Margin: In what way the lines of the hours from noon and midnight are drawn on the meridian dial.]

2. The arcs of the signs will be described thus. From table 1 let the arcs of the signs be taken under the hours in the topmost line, to which the title [Circ. hor. 6.] is prefixed, and let their tangents be carried from A into the line of hour 6 on both sides. For in this way, if through the endpoints of these tangents lines parallel to the equinoctial line are drawn, the corresponding hours will be cut at the points of the parallels of the Sun. For example: the arc of hours 1 and 11 in the parallel of Cancer ☿ and Capricorn ♑ contains $59^{\circ}14'$, whose

[Margin: The description of the arcs of the signs on the meridian dial.]

tangent, $16 \frac{8}{10}$ (approximately), will give on each side the point I, on the line of hour 6. Therefore the straight line I K, parallel to the equinoctial, will cut hours 1 and 11 at K, the points of the parallels Cancer ☿ and Capricorn ♑. And so with the

rest. Furthermore, the arcs below the equinoctial line belong to the northern signs, but those above the equinoctial to the southern.

Since, moreover, if the straight lines A I are taken equal to L K, in hours 1 and 11 the straight line I K is parallel to the equinoctial line, it will be enough — in order that the points of the parallels may be found — for the tangents of the arcs of table 1 to be carried into the corresponding hour-lines. For example, so that the points Cancer ☿ and Capricorn ♑ may be had in hours 1 and 11, the tangent 16 8/10 (approximately) of the arc 59°14', under hours 1 and 11 of the topmost line of table 1, will have to be carried from the points L, L of hours 1 and 11 on both sides as far as K. For through the points K the parallels Cancer ☿ and Capricorn ♑ will pass. And so with the rest.

Diagram. A large rectangular meridian-dial (*horologium meridianum*) construction, occupying most of the page, enclosed by a heavy rectangular border with a semicircular arc (the bounding circle B C) sweeping through it. A dense web of hour-lines and sign-parallels crosses the field, with a graduated declination/altitude scale down the left edge and the words for the eastern and western faces lettered along the right side.

Readable labels:

- **A** (upper left, at the head of the left-edge scale): the place of the style.
- **D** (left edge, just below A): the top of the hour-6 / style line.
- **B** (top center and again bottom center): endpoints of the bounding circle B C / the meridian line A B.
- Left-edge graduated scale (reading downward, degrees): **10, 20, 30, 40, 50, 60, 70, 80** — with additional numerals **18, 19, 20** near the top of the frame.
- "**Occidentale**" (Western) — lettered vertically in the upper-right quadrant.
- "**Orientale**" (Eastern) — lettered vertically in the lower-right quadrant.
- Hour numerals ranged along the arc / margins: **24, 18, 12, 6** (and a further **9** near the top left).
- Interior point-letters (crossings of hour-lines and parallels), as far as legible: **K** (recurring at several intersections), **H, I, L, M** (M appearing twice, upper-right and lower-right), **E, F, G** (in the lower crowded region).

Several interior point-letters and the small hour-numerals sit within a very dense line-crossing region and do not resolve individually, even under magnification; more than two labels are uncertain.

That the parallels drawn through the points of the line of hour 6 cut the hour-lines at the points of the parallels is evident, since they represent the great circles drawn out through the hours in the parallels from the intersection of the Equator with the Meridian, cutting the circle of hour 6 in the degrees whose tangents have been carried into hour 6. For the common sections of these great circles and of the plane of the meridian dial are parallel — by proposition 18 of book 1 of our *Gnomonices* — to the equinoctial line, since those circles (the Equator and the Meridian, to which the dial is parallel) have the same common section.

3. In order that the hours from sunrise and sunset may be described, the lines of hours 6 and 18 from sunrise or sunset must first be drawn. Hour 6, indeed, must be drawn through the point of the line of hour 24, or of the horizontal, where it is intersected by hour 3 from noon or midnight — namely through point G, as is evident from the earlier little table of chapter 14. And since (as we demonstrated in the scholium of proposition 22 of book 1 of the *Gnomonica*) the lines of hours 6 and 18 from sunrise or sunset are parallel to the equinoctial line on a meridian dial, the straight line G H, equidistant from the equinoctial, will be the line of hour 6 from sunrise or sunset. In the same way the straight line E F, drawn parallel to the same equinoctial through point E, where hour 9 from noon or midnight intersects the horizontal line, will give hour 18 from sunrise or sunset, as is evident from the same earlier little table of chapter 14.

[Margin: The description of hours 6 and 18 from sunrise or sunset.]

Once hours 6 and 18 from sunrise or sunset are described, the other hours from sunrise or sunset are laid out with no trouble by the aid of the two little tables of chapter 14. For from those little tables you will learn through which hour-points, both on the equinoctial

[Margin: The description of all the hours from sunrise or sunset.]

in the equinoctial line, and which ones in the horizontal line, they are to be drawn. Likewise, from the figure of the scholium of chapter 1, number 3, you will understand through which hour-points on hours 6 and 18 from sunrise or sunset they are to be described. For example: from the later little table of chapter 14 it is established that hour 20 from sunrise or sunset must be drawn through hour 2 from noon or midnight on the equinoctial line. From the earlier table, on the other hand, it is clear that the same hour 20 from sunrise or sunset must be drawn through hour 10 from noon or midnight on the horizontal line of hour 24; likewise through hour 7 from noon or midnight on the line of hour 18 from

sunrise or sunset; and finally through hour 1 from noon or midnight on the line of hour 6 from sunrise or sunset — as is evident from the figure of the scholium of chapter 1, number 3. And so four points are obtained through which hour 20 from sunrise or sunset must be drawn.

In the same way, hour 4 from sunrise or sunset must be drawn through hour 10 from noon or midnight on the equinoctial, through hour 2 on the horizontal, through hour 11 on the line of hour 18 from sunrise or sunset, and through hour 5 on the line of hour 6 from sunrise or sunset. Likewise hour 2 from sunrise or sunset is drawn through hour 8 on the equinoctial, through hour 1 on the horizontal, through hour 10 on the line of hour 18 from sunrise or sunset, and through hour 4 on the line of hour 6 from sunrise or sunset. Hour 9 from sunrise or sunset, however, is drawn through hour 3 on the equinoctial, through hour $4\frac{1}{2}$ on the horizontal, through hour $1\frac{1}{2}$ on the line of hour 18 from sunrise or sunset, and through hour $7\frac{1}{2}$ on the line of hour 6 from sunrise or sunset — as appears in the figure. And so on for the rest.

Once some one hour from sunrise or sunset has been drawn through the points found from the table of chapter 14 and from the figure of the scholium of chapter 1, number 3, the others will be drawn without any trouble through the neighbouring points on either side: taking the points of the whole hours on the equinoctial line, but the points of the half-hours on the lines of hours 24, 18, and 6.

If, on the circle B C, the doubled altitude of the pole is counted upward as far as M, the straight line A M will give hour 12 from sunrise or sunset; because the straight line B M, if it were drawn, would be the diameter of the largest of the parallels that are always visible, which the circle of hour 12 from sunrise or sunset touches at M.

SCHOLIUM.

We have described so far, then, on plane surfaces — as we proposed at the outset, on the horizontal and on any vertical whatever — all the kinds of equal hours, namely the hours counted both from noon and midnight and from sunrise and sunset. But of the unequal hours [horae inaequales], of which each single day comprises twelve, we have written nothing at all. For although we did lay them out on every plane in our *Gnomonica*, following Ptolemy in this and most of the other weighty authors who set the same hours out on sundials, nevertheless — since they cannot be drawn by straight lines (for, as I demonstrated in the *Astrolabe*, book 2, Lemma 39, there cannot be great circles dividing the diurnal

arcs of the several parallels into twelve equal parts, which is nevertheless required if those straight lines are to be the common sections of those circles and of the plane of the sundial) — it seemed best not to describe them again here.

[Margin: Why nothing is prescribed in this little book about describing the unequal hours.]

I admit that those straight lines differ little from the true unequal hours, because of the small distance of the tropics from the Equator, especially where the altitude of the pole is less than 45 degrees; and that they may be drawn through the twelfth-parts of the tropics, or of other parallels lying not far from the tropics. This is because, as we demonstrated in the scholium of proposition 10, book 1 of the *Gnomonica*, the same great circles passing through the hours of the Equator and through the unequal hours of any northern diurnal arc (that is, through its twelfth-parts) pass also through the unequal hours of the opposite southern diurnal arc. Therefore anyone who wants the unequal hours will be able to describe them by the methods we have handed down in the *Gnomonica*.

Yet it will also be permissible to describe the same hours by tangents [per Tangentes], as follows. Let the diurnal arcs of ♋ [Cancer, the tropic of Cancer] and ♑ [Capricorn, the tropic of Capricorn], reduced to degrees and minutes, be divided by 12, so that the quotients indicate how many degrees one unequal hour in Cancer and in Capricorn contains. These degrees doubled will give the magnitude of two hours, tripled of three, and so on. If, then, the tangents of the unequal hours of Cancer are carried over onto the equinoctial line — as we said of the hours from noon and midnight in chapters 2, 16, and 21 — the straight lines drawn from the centre of the sundial through the ends of the tangents will give the points of the unequal hours on the tropic of Cancer. On a meridian dial, however, where there is no centre, perpendiculars to the equinoctial will yield the same points. In just the same way the points of the same unequal hours on the tropic of Capricorn will be found, and so forth. If, then, the points of the corresponding hours are joined by straight lines — which will necessarily pass through the hour-points on the equinoctial — the unequal hours will have been described.

[Margin: How the description of unequal-hour dials, of meridian dials, and of the ascending signs is carried out by tangents.]

Indeed, by tangents it will also be possible to investigate on the equinoctial line the points through which the meridians of places are to be drawn, provided their distances from the meridian of your own place have first been investigated.

Finally, by the same method, using tangents, we shall find on the equinoctial and on the tropics the points through which the ascending signs are to be drawn, if the four little tables of proposition 9, book 1 of our *Gnomonica* are employed.

By tangents this same hour 12 will be drawn as follows. On the axis, between B and M, let any portion whatever be taken and divided into 10 equal parts; and at the end of the portion taken, toward M, let a perpendicular to the axis be raised. For the tangent of the altitude of the pole, reckoned with respect to that portion as the whole sine [sinus totius] — namely 9 — carried over onto that perpendicular, will give the point through which hour 12 must be drawn from A.

CAPVT XXII.

DE INVENTIONE LINEAE MERIDIANAE, declinationisque murorum, atque horologiorum ac styli collocatione.

(On finding the meridian line, the declination of walls, and the placing of sundials and of the style.)

1. Let the analemma of the proposed region be described — that is, let the meridian be A B C D, from centre E, in which let the common section of the Horizon and the Meridian be B D; the common section of the primary Vertical and of the same Meridian, A C; the common section of the same Meridian and of the Equator, F G, taking the two arcs A F, C G equal to the altitude of the pole; and finally the common section of the same Meridian and of the parallel of the Sun on the day on which the meridian line is sought, H I, taking the two arcs F H, G I equal to the declination the Sun has on that day. These arcs are to be taken toward A when the Sun is northern, but toward B when it is southern.

[Margin: Finding the meridian line.]

2. Intending, then, to find the meridian line on any day, observe on a plane that is equidistant from the Horizon...

Page 74 — CAPVT XXII (continued)

the shadow of some fine, freely hanging thread. For this purpose I usually employ an instrument, such as you see drawn at the foot of the figure, in which the set-square [norma] C D E is fixed at right angles to the flat rule A B, along the straight line D I, parallel to the two sides of the rule, so that the side D H of the set-square stands like a gnomon perpendicular to the Horizon, or like a freely hanging

thread, when the rule A B is placed upon a plane parallel to the Horizon. For in this way, with easy labour, we shall mark — without any perceptible error — two points along the length of the shadow's tip cast by the side H D.

[Margin: An instrument for observing shadows, most convenient in place of a gnomon.]

But if on the set-square's rule C D, which is raised above the Horizon, a line F G is drawn parallel to the side D H, and a hole is made near the point G, such that a round plumb hung by a fine thread from the hole F can swing freely in it, then this same instrument will be very convenient for examining any proposed plane, to see whether or not it is equidistant from the Horizon. For when the thread F G grazes the rule C D and coincides with the straight line F G, the plane on which the rule A B is set will be equidistant from the Horizon.

Diagram. A large composite construction filling most of the page. It combines three elements:

1. **The analemma (meridian circle)** — a large circle A B C D about centre E, with the horizon-diameter B D, the vertical-diameter A C, the equator-line F G, and the parallel of the Sun H I, together with the auxiliary construction points K, L, M, N, O, P, Q and the sun-parallel points G, I on the rim. A is at the top, B at the left, D at the right of the rim; the interior is densely crossed by the meridian, equator, parallel, and the construction lines K L, M O, N O.
2. **The shadow-observing instrument** at the lower left — a right-angled set-square (norma C D E) fixed to a flat rule (regula A B), with the upright side D H acting as a gnomon and a plumb-bob hanging on a thread from the hole F (labelled $\bigcirc$ F); base points A, D, G, H visible, the plumb shown as a small shaded disc at G.
3. **Five small circles** showing the meridian-line angle-constructions: one at the upper left (labels A, D, C, B, E, K), one at the upper right (labels B, D, C, A, E, L), and a row of three below (each with D at top, C at centre, A and B at the sides, E at the foot).

Readable labels by region:

- **Upper-left small circle:** A (left), D (top), C (centre), B (right), E (lower), K (foot).
- **Upper-right small circle:** B (top left), D (top right), C (centre), A (lower right), E (lower), L (foot).

- **Large analemma rim:** A (top), B (left), D (right), K (upper left, twice), H (upper), L (right), I (lower right), G (lower), Q (lower left), C (lower).
- **Large analemma interior (crowded):** E (centre), O (below centre, twice), P (lower, twice), and a cluster of N and M labels (repeated, upper-middle) marking successive crossings of the construction lines. Several of these interior N/M/O/P labels sit in a very dense crossing region and cannot be individually resolved with confidence [?].
- **Instrument (lower left):** H (top), G (top right of upright), F (hole, $\bigcirc$ F), A (foot left), G (plumb), D (foot).
- **Lower row of three small circles:** each labelled D (top), A and B (sides), C (centre), E (foot); A appears twice on each.

More than two interior labels of the analemma are uncertain.

Now let two points A, B, a little apart from each other, be marked along the length of the shadow's tip cast by the side D H, or at the middle of the breadth of the shadow which the freely hanging thread casts — as in the five small circles — and through them let the straight line A B be extended. This will be the common section of the plane equidistant from the Horizon and of the vertical circle which at the time of observation passes through the centre of the Sun. Once the shadow has been observed, let the Sun's altitude be taken without delay, by a quadrant or some other instrument. I say "without delay" because it is expedient that the Sun's altitude be observed immediately after the two points A, B have been marked in the shadow, before the straight line A B is drawn through them — lest there be danger in delay, since through the Sun's daily motion the shadow is continually changing, the Sun at once stands in a different vertical, and consequently the shadow cast by the instrument changes.

Next, in the analemma, with the observed altitude of the Sun computed, from B and D as far as K and L let the straight line K L be drawn. This will be the common section of the Meridian and of the parallel to the Horizon then passing through the centre of the Sun, and it will cut the vertical diameter at M, and the diameter of the Sun's parallel H I at N. Then, with the semicircle K O L described about K L from M, let a perpendicular to K L — or a line N O parallel to A C — be drawn from N, cutting the circumference K O L at the point O, and to that point let the straight line M O be drawn.

Page 75 — NOVAE DESCRIPT.

If, then, the point N falls between K and M — as happens on all southern parallels, but on northern ones when the Sun is beyond the primary Vertical —

and the observation is made before noon, we shall set at the centre C (from which, some magnitude having been assumed on the shadow-line A B, a circle of any size whatever is described) an angle A C D equal to the acute angle K M O, measured from sunrise toward the south, that is, from A, the eastern point, toward the southern parts D — as is seen in the small circle uppermost at the left. (Through carelessness it has come about that this angle A C D, like the following ones, has not been made equal to the angle K M O; it should nevertheless be understood to be equal.) But if the observation is made after noon, we shall make the angle A C D equal to the same K M O, measured from sunset toward the south — that is, from A, the western point, toward the southern parts D — as appears in the small circle which is the first of the three lower ones.

But if the point N falls upon the point M — whether the observation is made before or after noon — we shall draw to A B, through the centre C, the perpendicular D E, as is plain in the small circle which is the middle one of the three lower ones.

If, finally, the point N lies between L and M — as happens on northern parallels, when the Sun is on the near side of the primary Vertical, after sunrise and before its setting — and the observation is made before noon, we shall make an angle A C E equal to the acute angle L M O, measured from sunrise toward the north, that is, from A, the eastern point, toward the northern parts E — as is manifest in the small circle which is the last of the three lower ones. But if the observation is made after noon, we shall set an angle A C E equal to the same angle L M O, measured from sunset toward the north — that is, from A, the western point, toward the northern parts E — as may be seen in the small circle which occupies the uppermost place at the right. For always the straight line D E, forming the said angle with the shadow-line A B, will be the meridian line.

[Margin: The meridian line.]

But if at any time the Sun's altitude, counted from B, ends at H, the Sun will be, at the moment of observation, in the Meridian circle itself, and will have its greatest altitude for that day; and therefore the shadow-line itself will be the meridian — all of which is plain from what we have demonstrated in the *Gnomonica*.

Without the aid of a quadrant divided into 90 degrees, everything can be accomplished in the analemma by tangents. For if a perpendicular is raised at E D, and the straight line between it and the centre E is divided, as the whole sine, into ten equal parts, then the tangent of the complement of the altitude of the pole, reckoned with respect to that whole sine, must be carried downward onto it,

marking a point on it. For through this point and through the centre E the diameter of the Equator must be extended. And if the tangent of the number compounded from the northern declination of the Sun and the complement of the altitude of the pole is carried over onto the same line, and from its end a hidden straight line is drawn through E, the point G will be found, through which the diameter of the northern parallel must be drawn. If the Sun is southern, the declination must be subtracted from the complement of the altitude of the pole, and the tangent of the remaining number carried over, and so on. Finally, if the tangent of the Sun's altitude is carried upward onto the same perpendicular, and from its end a straight line is extended through E, the point K will be found, through which the diameter of the parallel to the Horizon must be drawn. If all these things are rightly weighed, we shall never need a quadrant divided into degrees, but shall accomplish everything by tangents alone.

3. I say nothing about finding the meridian line by a magnetized needle [per acum Magnete illitam], because it is exceedingly deceptive, since in very few places does that needle point straight from north to south. Add to this that even if it were known how much it deviates from the true meridian line, I would still not think it should be trusted, because, on account of various external hindrances, it seems to decline more at one time than at another.

[Margin: A magnet-rubbed needle is deceptive for indicating the meridian line.]

The method here set out is also to be preferred to that common procedure which we explained in the *Sphere*, when we treated of the Meridian. This is because the tip of the shadow is not easily discerned on a plane, and it is inconvenient to observe the shadow twice in one day — once before noon, and again after noon, as is prescribed there — since it often happens that at the very hour after noon at which the shadow's tip should be observed, some cloud covers the Sun, and so the morning observation is made in vain. Neither of these difficulties is necessary in the method handed down here, but it is enough to observe the shadow-line and the Sun's altitude once only, and that in a very short time, as is clear.

[Margin: The finding of the meridian line explained here is preferred to the finding handed down in the *Sphere*.]

4. Indeed, if it can conveniently be done, it is enough to note carefully the tip of the shadow of the style H D, even if the Sun's altitude is not taken — provided that the point on the plane be accurately marked which lies directly beneath the straight line on the side of the set-square D H, that is,

beneath the vertex of the style; so that of course the interval between this point and the tip of the shadow, that is, the length of the shadow, can be taken with compasses without error. For if in the analemma a straight line E P is taken equal to the style H D, or to any other you may perhaps be using, and on the perpendicular P Q a straight line equal to the length of the shadow — that is, to the interval between the place of the style and the tip of the shadow — then the straight line Q E, extended to the circumference, will give the Sun's altitude D L, as is plain from what has been demonstrated in our *Gnomonica*. But in this observation it is necessary that the plane be most exactly equidistant from the Horizon, and that the tip of the shadow be marked with the utmost care and diligence.

[Margin: How the Sun's altitude is elicited in the analemma from the length of the shadow of any style.]

5. In order that the declination of the wall on which the sundial is to be built may be found, we shall use this other instrument, in which let there be a perfectly flat board A B (the longer it is, the more exactly will its side A C — which must be perfectly straight — examine the flat surface of the wall; or else, if the board A B is not long enough, some longer and perfectly straight rule must be fixed beneath the board, so that its end corresponds exactly to the end of the board), and on it let a straight line I K be drawn parallel to the side A C. On the side A C, too, let two rules of uniform thickness C D, E F be fixed, forming right angles with the plane A B; and to these let another rule G H be fitted, parallel to the side C E.

[Margin: An instrument for investigating the declinations of walls.]

When this instrument has been applied to the wall by means of two small pins which, fixed in the wall, support the rule G H, so that the plane A B is equidistant from the Horizon — which will be tested by plumb-line and level — then... (For this purpose, in one of the rules, as in C D, a hole may be made near...)

[Margin: How the declination of a wall is detected.]

Diagram. The wall-declination instrument, drawn in perspective. A flat rectangular board (the tabula A B) is shown as a slab, with two upright rules rising from its far side and a cross-rule joining them, plus a plumb-line hanging from the upper right. Readable labels:

- F (top of the left upright), D (top of the right upright).
- H (left end of the cross-rule), G (right end of the cross-rule).

- A (near left front corner of the board), E and M and C (along the front edge, left to centre), K (right front corner).
- I (lower left corner of the board), L (at the foot, near a small drawn arc), B (lower right corner).
- A plumb-bob hangs on a thread from near D (shown as a small shaded disc suspended within the right upright).

The line I K runs across the board parallel to the front edge A C; a short arc is drawn near M, C, L. No labels flagged uncertain.

(The passage below continues Cap. XXII from the previous page — the finding of the meridian line and of a wall's declination — and runs to the foot of §7, where Cap. XXIII begins.)

[Margin: In which direction the proposed wall declines, and by what method this is discovered.]

near the point C, so that a round plumb, hung by a fine thread from the hole a and caught up on it, can swing freely there, the straight line drawn from a through the centre of the hole being extended parallel to the ends of the rule C D. For when the thread grazes the rule C D and coincides with that straight line drawn from a through the centre of the hole, the plane A B will be equidistant from the Horizon. Then, when the Sun lights the wall, find the meridian line L M, which cuts the straight line I K — the line equidistant from the side A E — at M. If, therefore, the angles at M are right angles, the wall will have no declination but will be parallel to the prime vertical. But if the angles at M are not right angles, the acute angle I M L will show the complement of the declination from the vertical: so that the arc of a circle described from M and contained between I M and M L will hold the degrees of the wall's declination from the meridian, while its complement gives the degrees of declination from the prime vertical. Moreover, toward whichever quarter of the world the obtuse angle K M L points, in that direction the proposed wall will decline — from the south, if the wall faces south (that is, if it is lit by the Sun at noon); but from the north, if it faces north (that is, if it is not lit at noon).

For example, with the wall facing south: if, when we turn to face the instrument applied to the wall, the acute angle stands to our left and the obtuse to our right, the wall will decline from south toward east; but toward west if the acute angle is set to our right and the obtuse to our left. The exact opposite is to be understood when the wall faces north. For with the acute angle set to our left, the wall will

decline from north toward west; and from north toward east if the acute angle is found to our right.

But if the wall is nearly aligned with the meridian, so that it is hard to judge whether it faces south or north — for when it recedes further from the meridian the matter has no difficulty, since one can observe daily around noon whether or not it is lit by the Sun — then the meridian line found on the tablet A B will show us nicely whether it faces south or north, and whether it declines toward east or west. For when that line meets the wall toward the north (one must, after all, know more or less where east, west, south, and north lie — which a needle rubbed with a magnet will readily show), the wall will decline from south toward west if it faces west, but toward east if it looks upon the rising Sun. But when the meridian line meets the wall toward the south, the wall will decline from north — toward west if it faces west, but toward east if it faces east. We have written more on this matter both in Book 1 of the *Gnomonics*, Proposition 23, and in the little book *On the Construction and Use of the Instrument for Sundials*, Chapter 20. But let this suffice.

[Margin: The placing of any sundial in its proper position.]

6. In order that a horizontal sundial may indicate the hours correctly, it must be set equidistant from the Horizon in such a way that its meridian line is parallel to the meridian line found on some other neighbouring plane. This will hold only when the shadow of the style on the sundial makes the same angle with the meridian as the shadow of the side D H — of the upper set-square placed above the meridian line found — makes with that found meridian.

Wall sundials, on the other hand, will have their proper position when the horizontal line occupies the upper place on the walls and stands parallel to the Horizon. And a line parallel to the Horizon is easily drawn on any wall by means of the level and the plumb.

[Margin: What position the style ought to have.]

7. Finally, the style too will have its proper position in its own place when it stands perpendicular to the plane of the sundial. It will be perpendicular to the sundial when, a circle having been described from its foot, the same span of the compasses reaches the vertex of the style from three points of the circumference. On this you will find more in Book 4 of the *Gnomonics*, Proposition 12. On walls, however, since the style is longer, it is not necessary that it be perpendicular to the plane of the sundial; it may be

fixed at any point outside its proper place, provided that its vertex touches the extreme point of the length of the proper style issuing from its proper place and making right angles with the sundial. This is done if at the style's proper place a set-square perpendicular to the sundial is set up, on which the length of the style has been marked. For when the vertex of the style fixed in the wall touches the end of this length, it is to be made fast and the set-square removed. Then indeed the vertex of the style will have obtained its proper position.

CAPVT XXIII.

How a wall sundial drawn on paper is to be transferred to the wall for any magnitude of style whatever.

1. Suppose, for example, that a declining sundial, constructed as in Chapters 17, 18, and 19 — for a wall declining 30° from south toward east in the Roman Horizon — is to be transferred to the wall for a given magnitude of style, one that is tenfold the style C D of the aforesaid sundial. On the horizontal line take two points aa and γγ [doubled-letter auxiliary points], anywhere, and at them erect two perpendiculars aa–ββ and γγ–δδ. Again, making aa–ββ and γγ–δδ equal, join the straight line δδ–ββ, which will be parallel to the horizontal. Finally let the hour-lines that do not cut this straight line be produced until they cut it.

[Margin: prop. 33 of Book 1 (Euclid I.33).]

2. Next, on the wall draw a horizontal line by means of the plumb and level, and choose on it the place of the style, from which the interval C B between the style and the meridian is to be laid off ten times toward the same side on which the sundial's meridian stood. For if from the extreme point so transferred a perpendicular is dropped to the Horizon, it will be the meridian on the horizontal line; and if on it the portion of the meridian B F is likewise taken ten times downward, the point will be found through which the equinoctial is to be drawn on the wall. And if the interval C A on the horizontal line — between the style and the equinoctial — is transferred ten times from the proper place of the style onto the horizontal of the wall, a second point will be had through which the equinoctial is to be extended on the wall.

After this, transfer in the same way, ten times, the intervals C–aa and C–γγ onto the horizontal of the wall, and from their ends drop perpendiculars, onto which

the intervals $aa-\beta\beta$ and $\gamma\gamma-\delta\delta$ are likewise to be transferred ten times. The same is to be done with the interval $B-[\text{?}]$ [a doubled auxiliary point, small and worn; further confirms it does NOT read " $\epsilon\epsilon$ " — possibly $\delta\delta$, unresolved], and a straight line drawn through the extreme points, corresponding to the straight line $\delta\delta-\beta\beta$,

3. Now if, whether from the meridian line or from the perpendiculars $aa-\beta\beta$ and $\gamma\gamma-\delta\delta$, all the hour-intervals are taken — both on the horizontal line and on the straight line $\delta\delta-\beta\beta$ and on the equinoctial — and transferred ten times onto the wall from the corresponding lines to the corresponding lines, the points will be found on the wall through which the hours are to be drawn.
4. Lastly, if the intervals of the hour-lines between the arcs of the signs of the sundial and the equinoctial or horizontal line are transferred ten times onto the corresponding hour-lines on the wall, from the equinoctial or horizontal line, the points will be found through which the arcs of the signs are to be traced on the wall. Once these are marked, all the rest outside the tropics is to be cut away as superfluous.

[Margin: A further usefulness of this teaching, for certain declining sundials.]

5. By this same art any sundial whatever — even a horizontal one — may be reduced to a larger or smaller form, namely if all its intervals are increased or diminished as many times as the style is taken larger or smaller. This is most useful for declining sundials, in which one cannot conveniently obtain the point of the sixth hour on the horizontal line, or the centre of the sundial, or both points, or the point of the meridian line on that same horizontal line together with the centre of the sundial: that is, if first a sundial is constructed small enough for all those things to be found in it, and this is then enlarged for the given magnitude of style, as we advised in Chapter 17, Number 5. From this enlarged one it must afterward be transferred to the wall, and not from that former small one, lest errors be committed if the intervals are increased as many times as that tiny style requires. But this whole difficulty will be removed if the sundial is drawn by the method of Chapter 24 or 25, as will be taught in the scholium to Chapter 25, Number 3.

CAPVT XIV. [recte: XXIV]

By what method a sundial — whether horizontal or on a wall — is to be constructed for a given latitude of place, from the horizontal circumferences of the Sun and the altitudes of the Sun above the Horizon at that same place, when these have been computed.

1. In the scholium to Chapter 10 of Book 6 of the *Gnomonics* we taught by what art declining sundials can be drawn from the altitudes of the Sun above the Horizon and from the horizontal circumferences, which elsewhere we have called the "latitudes of the shadows." Therefore, that this little work may be complete in every respect, I am glad to append the same device here, by way of appendix — yet much more clearly and plainly than in the *Gnomonics*, since we are going to explain it by tangent lines, as we did the preceding methods; and in the following chapter we shall also carry it out geometrically. This appendix will be like a whole self-contained treatise on the drawing of sundials, so that anyone may rest content with it alone, even if he has learned nothing of what we have written hitherto — provided only that he first computes, by Problems 15 and 16 at the end of the little book, the tables of the Sun's altitudes and of the horizontal circumferences for the latitude of the place in which the sundials are drawn, both for whole hours and for halves and quarters of hours, if these segments of the hours too are wanted. Nor will it be troublesome to make such tables once for all, since they are small and can be adapted to every declination of walls in the same region. We have computed these tables for the Roman Horizon, above which the pole is raised 42° , both for whole hours from noon and midnight, and for whole hours from east and west; and they occupy places 9, 10, 11, and 12 among the tables. Had time permitted, I would gladly have computed tables for other elevations of the pole, to free students of this labour.

[Margin: The horizontal, meridian, and equinoctial lines.]

2. Suppose, then, that there is to be drawn a sundial of the hours declining from west, that is, from south toward east 30° — the same as above. The horizontal line A B having been drawn, and the place of the style C D chosen on it at C (perpendicular to the horizontal), set out the Tangent $5 \frac{7}{8}$ [?] (approximately), owed to the 30° of the wall's declination, with respect to the whole sine C D divided into 10 parts, from C as far as B — to the right if the plane declines from south toward east (as ours does) or from north

toward west; but to the left if it turns aside from south toward west or from north toward east. For the straight line B E, perpendicular to A B, will be the meridian line. Likewise, in the opposite direction transfer the Tangent $17 \frac{3}{8}$ of the complement of the declination, which comprises 60° , from C as far as A. For through A the equinoctial and vertical line is to be drawn; so that, of the sundial declining from south, the part from A toward B is southern, while the part from A in the opposite direction is northern — since the shadow of the style is cast into the former when the Sun deviates from the vertical toward the south, but into the latter when it withdraws toward the north; just as the portion of that same sundial toward the right of the meridian is western, the shadows being cast into it when the Sun is past noon, while the rest, toward the left, is eastern, for the contrary reason. But in a sundial declining from the north, the northern part slopes from A toward B, the southern in the opposite direction; and the eastern portion lies from the meridian toward the right, the western toward the left.

[Margin: The southern and northern part, and likewise the western and eastern, in a declining sundial. [?]]

3. Next, from the 12th table of horizontal circumferences investigate, on the horizontal line, the distances of the hours from the place of the style C as far as the vertical circles drawn through each hour from the west at the beginnings of the signs, in this way.

[Margin: The distances of the hours from the place of the style on the horizontal line — how they are investigated in a sundial declining from south toward east. [?]]

In a sundial declining from south toward east: when the horizontal circumference is eastern B, add to it the complement of the sundial's declination; but when the horizontal circumference is eastern A and less than the complement of the declination, subtract it from the complement of the declination. For in this way either the whole, or the remaining, sought distance will be produced, to be counted from the place of the style toward the left. But when the circumference is eastern A and greater than the complement of the declination, subtract the complement of the declination from it, so that the remaining distance is to be counted from the place of the style toward the right. And when the circumference is eastern A, add to its complement the distance to be counted; and finally, when the circumference is western B, both that distance and the circumference of the quadrant, 90° , are to be added. For the sought

distance will always be made up, likewise to be counted from the place of the style toward the right.

[Margin: The distances of the hours from the style on the horizontal line — how they are investigated in a sundial declining toward west. [?]]

4. But in a sundial declining from north toward west: when the horizontal circumference is western A, add to it the complement of the wall's declination; but when it is western B and less than the complement of the declination, subtract it from the complement of the declination. For thus there will always be produced, either the whole or the remaining, sought distance, to be counted from the style toward the left. But when the circumference is western B and greater than the

complement of the declination, subtract from it the complement of the declination, so that the remaining distance is to be counted from the style toward the right. And when the circumference is western B, add to its complement the wall's declination and the circumference of the quadrant, 90° . For in this way there will always be found the sought distance, likewise to be counted from the style toward the right.

[Margin: The distances of the hours from the style on the horizontal line — how they are found in a sundial declining toward west (from north toward west). [?]]

5. Further, in a sundial declining from south toward west: when the circumference of the 12th table is western B, the complement of the wall's declination is to be added; but when the circumference is western A and less than the complement of the declination, it is to be subtracted from the complement of the declination. For thus the sought distance will be produced, to be counted from the style toward the right. But when the circumference is western A and greater than the complement of the declination, the complement of the declination is to be taken from it, so that the remaining distance sought is to be counted from the style toward the left. And when the circumference is eastern A, the declination itself is to be added to its complement; and finally, when the circumference is eastern B, both the distance and the circumference of 90° are to be added. For the whole, or the remaining, distance we seek will always be made up, to be counted from the style toward the left.

[Margin: The distances of the hours from the style on the horizontal line — how they are found in a sundial declining from north toward east. [?]]

6. Finally, in a sundial declining from north toward east: when the circumference is eastern A, the complement of the declination is to be added to it; but when it is eastern A [recte: eastern B?] and less than the complement of the declination, it is to be taken from the complement, so that the sought distance is had from the style toward the right. But when the circumference is eastern B and greater than the complement of the wall's declination, this complement is to be taken from the circumference, so that the remaining desired distance is counted from the style toward the left. And when the circumference is western B, the wall's declination itself is to be added to its complement; and finally, when the circumference is western A, both the wall's declination and the circumference of 90° are to be joined to it. For in this way there will always be had the sought distance, to be counted from the style toward the left.

Example. In our sundial declining from south toward east 30° : since the circumference of the 10th hour from the west, in ♋ [Cancer], is $22^\circ 9'$ eastern B, we shall add the complement of the declination, namely 60° , and make the distance $82^\circ 9'$, to be counted from the style toward the left. Again, since the circumference of the 14th hour from the west, in ♈ [Aries] and ♎ [Libra], is $21^\circ 7'$ eastern A, less than the complement of the declination, we shall subtract it from the complement of the declination — that is, from 60° — so that a distance of $38^\circ 53'$ is left, to be counted from the style leftward. Again, since the 23rd hour, in ♑ [Capricorn], has the circumference $43^\circ 3'$ western A, we shall add to its complement — that is, to $46^\circ 57'$ — the wall's declination, 30° , so as to make the distance $76^\circ 57'$, to be counted rightward.

But in the sundial declining from north toward west, which is drawn on the opposite face of the plane: since the circumference of the 20th hour from the west, in ♋ [Cancer], is $5^\circ 41'$ western A, we shall add to it the complement of the declination, namely 60° , and make up a distance of $65^\circ 41'$, to be counted from the style toward the left. And the same reasoning holds for the rest. But if the distance is found greater than a quadrant, that hour does not fall on the proposed plane but on the opposite face. Thus in this same northern sundial, the circumference of the 19th hour from the west, in ♋ [Cancer], is $18^\circ 17'$ western A; if to its complement, $71^\circ 43'$, the 30° of the wall's declination are added, a distance of $101^\circ 43'$ is made, greater than a quadrant. Therefore the 19th hour from the west, in Cancer, cannot be had on the said sundial. So too, since in the southern sundial the circumference of the 9th hour from the west, in ♋ [Cancer], is $31^\circ 43'$ eastern B, if to it be added 60° , the complement of the declination, a distance of $91^\circ 43'$ is made, exceeding a quadrant. Therefore the 9th hour cannot be drawn in

the southern sundial. By like reasoning, since the circumference of the 21st hour from the west, in ♋ [Cancer], is $4^{\circ}32'$ [?] western B, if to it be added both the wall's declination, 30° , and the quadrant, 90° , a distance of $124^{\circ}42'$ is made, which cannot be taken from the place of the style.

But if at some point the distance is found a little less than a quadrant, that hour will scarcely fall on the plane, unless it is very large. Thus in the northern sundial, since the circumference of the 19th hour from the west, in ♊ [Gemini] and ♌ [Leo], is $26^{\circ}17'$ [printed "nim.17"; recte min.17] western A, if the complement of the wall's declination, 60° , be added to it, a distance of $86^{\circ}17'$ is made, which can scarcely be taken from the style toward the left. And so of the rest.

[Margin: Which hour does not fall on the plane of the sundial.]

[Margin: Which hour scarcely falls on the plane of the sundial.]

[Margin: The drawing of a sundial declining from south toward east, from the horizontal circumferences and the altitudes of the Sun.]

7. These things having been rightly set forth and understood, the drawing of the hours will not be difficult. To this end, with the greatest care let an equilateral triangle A B C be described, whose base B C, cut into 10 equal parts, sends straight lines from A to the points of division; and upon A C let another equilateral triangle A C D be built, so that D C is parallel and equal to A B, as was done in the scholium to Chapter 1. Then, with the interval D B, take in the triangle the equals A E, A F, D G; and, the straight line E F G having been drawn, take off from E F any number of equals: F 10 : 10, 20 : 20, 30, etc. For if the Tangent of the complement of the pole's altitude, $11\frac{1}{8}$, taken on the straight line E F, is transferred onto the meridian from B as far as E — downward indeed in the southern sundial, but upward in the northern — it will give A E, the equinoctial line. And that this may be drawn without error through the two points A, E, an arc must be described, A through E, and equal arcs cut off (whether with the same interval A E or a different one), E I, E m; and then from I, m two other arcs must be described, with any interval, cutting each other at n, so that three points A, E, n are had for drawing the equinoctial line — just as the Lemma before Chapter 16 prescribes.

Now if, for example, the 11th hour from the west is to be drawn in the southern sundial, three points must be found: one in ♋ [Cancer], another in ♈ [Aries] and ♎ [Libra], and a third in ♐ [Capricorn], in this manner. The circumference of the

11th hour from the west, in ♋ [Cancer], is found in the 12th table to be $13^{\circ}3'$ eastern B. If, then, as was said in Number 3, the complement of the wall's declination — namely 60° — is added to it, a distance of $73^{\circ}3'$ is produced, to be counted from the style toward the left. Its Tangent, $32 \frac{7}{8}$, transferred from C, gives the point R, through which the Vertical drawn through the Sun then passes, and cuts off the horizontal circumference A R as northern. Then, with R S drawn perpendicular to A B (which is easily done: if, through any point F of the meridian line, a perpendicular F X is drawn, take F H equal to B C; for the same Tangent C R, transferred from H as far as X, gives the straight line R X perpendicular to A B, etc.) — if from it be cut off the length of the shadow R S, which the Tangent $3 \frac{7}{8}$ gives, approximately, with respect to the whole sine D R, corresponding to the Sun's altitude of $21^{\circ}14'$ (which the Sun has in ♋ [Cancer] at the 11th hour from the west, as appears from the 10th table), the point S will be found, for the 11th hour in ♋ [Cancer]. This Tangent, moreover, is found in the triangle A B C if, with the interval B C, equals A H, A I, D K are taken, and the straight line H I K drawn; for thus H I will be equal to the interval D R, etc.

Again, the circumference of the 11th hour from the west, in ♈ [Aries] and ♎ [Libra], is found in the same 12th table to be $10^{\circ}10'$ eastern B. The complement of the declination — that is, 60° — being added, a distance of $70^{\circ}10'$ is made, whose Tangent $27 \frac{7}{8}$ [or $27\frac{3}{4}$?], a little more, transferred from C toward the left, gives the point I, and from F the point G. And the straight line G I will cut the equinoctial at K, at the 11th hour from the west.

(Continuation of Cap. XXIV — the worked example of laying out a horizontal/mural declining dial from the tabulated horizontal circumferences and the Sun's altitudes.)

Finally, the circumference of the 11th hour from the west, in ♑ [Capricorn], is found in the 12th table already cited to be eastern (Or.) B, $8^{\circ}28'$. When, therefore, the complement of the declination — that is, 60° — is added, a distance of $66^{\circ}28'$ results. Its Tangent, nearly 23, transferred from C, H toward the left, will give the points T, Y and the straight line YT; and this will be the Vertical through which the Sun then passes. And since, in the 10th table, the Sun's altitude at the 11th hour in ♑ [Capricorn], which lies below the Horizon, contains $43^{\circ}23'$: if its Tangent — about 9 [fraction: ?], nearly, with respect to the whole sine DT — is taken in the triangle on the straight line LM (the straight lines AL, AM, DN having been cut off equal to the interval DT, etc.) and transferred upward from T (for the portion of the dial above the horizontal line represents the underground part) as far as V, then V will be the point of the 11th hour from the west in ♑. The straight

line SKV, therefore, will give the whole 11th hour from the west. And in the same way the remaining hours are drawn.

You have an example in the point N, of the 13th hour from the west in the equinoctial. For its circumference, eastern (Or.) A, $10^{\circ}10'$, subtracted from 60° — namely the complement of the declination — leaves a distance of $49^{\circ}50'$, whose Tangent, 11 [fraction: ?], a little more, gives the points L, M and the straight line L, M, which cuts the equinoctial at N, the point of the 13th hour. By the same reasoning, since the horizontal circumference of the 20th hour in Υ [Aries], or ♎ [Libra], is western (Occ.) A, $49^{\circ}13'$, we shall add to it its complement — as we said in Number 3 — that is, to $40^{\circ}47'$ [we add] the wall's declination, 30° , so that a distance of $70^{\circ}47'$ is made, whose Tangent, nearly 28 [fraction: ?], transferred from C, H toward the right, presents the points O, P and the straight line OP, [and] the point Q, of the 20th hour from the west in the equinoctial. For to find the points in the equinoctial there is no need of the Sun's altitudes; they are found conveniently enough from the Sun's horizontal circumferences alone, as was done in the points K, N, Q.

When the point of some hour in ♋ [Cancer] cannot be found, its point must be sought in some other sign. Thus you see that at the 18th hour from the west the point b was found in ♊ [Gemini] and ♌ [Leo]. For its circumference, in the 12th table, is western (Occ.) A, $47^{\circ}12'$; and if to its complement, $42^{\circ}48'$, the declination 30° is added — as we said in Number 3 — a distance of $72^{\circ}48'$ results. Its Tangent, 32 [fraction: ?], from C toward the right, gives the point Z; and the Tangent, about 19 [fraction: ?] with respect to the whole sine DZ, carried into the triangle, corresponding to the Sun's altitude of $62^{\circ}46'$ at the 18th hour from the west in ♊ and ♌ (as is clear from the 10th table), gives the point b. By the same reasoning, for the 19th hour ♉ [Taurus] and ♍ [Virgo] the point a was found. Likewise for the 21st hour ♏ [Scorpio] and ♓ [Pisces], the point d; and for the 22nd hour ♐ [Sagittarius] and ♒ [Aquarius], the point e. But since this point is very close to the point ♑ [Capricorn], we described from the point ♑ , through e, an arc, from which, with the same interval, we cut off the arcs e f, e g; and from f, g [we described]

Diagram. A large rectangular framed construction showing the worked example of the declining dial, comprising two dials one above the other, separated by a horizontal line: the upper is labelled **Australe** [Southern], the lower **Boreale** [Northern, engraved vertically]. Across the very top runs a graduated tangent-scale ruler with tick-marks and the numbers **10, 20, 30, 40, 50, 60, 70**, above

which stand small zodiac glyphs; it is captioned **Pro horizontali fin.** [i.e. "for the horizontal line/sine"].

Legible labels in the **upper (Australe)** portion:

- On the main horizontal (style/base) line, left to right: **R, A, L, C, B, D** (D at upper right)
- **V** — apex of a set of dotted vertical lines, above the base line at left
- **K** — on an oblique line at upper left
- **I, T** — just below A; **II, S** and **12** below at left; then **13, 14, 15**, a small **m**, and **16** descending toward the centre
- **N** — below L
- **E** — the central node at which many straight lines converge (foot of the style)
- Descending toward the lower right, along oblique lines and dotted verticals: **O, Z** (tops of dotted verticals), **24, 23, 22** (the last two with small cross/star intersection marks), **21**, a small **n**, **20, P, Q**
- Scattered zodiac glyphs beside individual lines (Π , ϱ , Υ , $\triangle$ region)

Legible labels in the **lower (Boreale)** portion:

- A horizontal line carrying **X, G, Y, M** (left) and **H, F** (right)
- **I, A, N, M, K, L, G** among the arcs and oblique lines
- descending numbers **24, 23, 22, 21, 19, 18, 17** and a small **b**
- **D, E, B, C** toward the right; zodiac glyphs ($\varnothing$, $\mathbb{M}$, Π , Υ region) beside the lines

[Margin: Description of a dial declining from the North toward the West.]

two other arcs cutting each other in h, so that three points may be had for the line of the 22nd hour, according to the prescription of the Lemma before Chapter 16 — which must always be done whenever only two points are had that lie very close to one another; as you see was done in the northern dial, which declines from the north toward the west.

For, at the 20th hour, besides the point $\varnothing$ [Cancer], we find also the point K in Π [Gemini] and ϱ [Leo]; and for the 21st hour the point L in $\varnothing$ [Taurus] and $\mathbb{M}$ [Virgo]; and at the 22nd hour, again, the point M, in $\varnothing$ and $\mathbb{M}$. And finally, for the 23rd hour, the point N in the equinoctial; and we described the arcs of which we have spoken, so that the hour-lines might be drawn more accurately, and so forth.

Lastly, in the southern dial we drew the 23rd hour through its point found in ♊ [Capricorn], and through the 11th hour on the equinoctial line — which is 12 hours distant from it — so as not to be compelled to seek another of its points in the parallel of ♐ [Sagittarius] and ♒ [Aquarius].

[Margin: What is to be done in any declining dial, so that the distances of the hours from the style may be found.]

8. The whole business, therefore, as you see, consists in finding the distances that the hours have from the style, along the horizontal line up to the Verticals, for the hours in any sign; and this finding, from what has been said, is not difficult. For if we have before us a dial declining from the south toward the east, we must go back to what we wrote in Number 3. But if one declining from the north toward the west is to be described, [we go back] to what was said in Number 4. And if a dial declining from the south toward the west is to be described, we must consult what we said in Number 5. If, finally, one declining from the north toward the east is wanted, we must apply what was set forth in Number 6.
9. But should we not wish to undertake a labor so great and difficult, we shall find the Tangents of the Sun's altitudes described in the 10th table, taken with respect to the whole sine CD; so that it will not be necessary to employ the equilateral triangle, and so forth. We shall proceed thus. Once the distance of any hour from the place of the style has been found, let its Secant be taken, the whole sine being set at 1000, which suffices for the present business. *And let it be arranged that, as the whole sine is to the Tangent of the Sun's altitude of that same hour, so the Secant of the found distance of that same hour is to a fourth term; and the Tangent of that same altitude will be found, in parts of the whole sine CD.* For example: the circumference of the 18th hour from the west, in ♊ [Gemini] and ♌ [Leo], is western (Occ.) A, 47°12'. If, then, as we taught in Number 3, we add to its complement — that is, to 42°48' — the wall's declination, 30°, we shall make a distance of 72°48', to be counted from the style toward the right, so that the point Z is found and the Vertical Z b is drawn. Let it be, then, as 1000 — that is, as the whole sine DZ — is to 1943, the Tangent of the Sun's altitude 62°46' (which is due at the 18th hour from the west in ♊ and ♌, by the 10th table; for the straight line DZ, drawn, is the whole sine with respect to the Tangent Zb, as is plain, if the style CD is set perpendicular to the dial), so is 3382, the Secant of the found distance 72°48' — that is, so is the Secant DZ with respect to the whole sine CD (with respect to which the straight line

DZ is the Secant of the aforesaid distance, whose Tangent is CZ) — to a fourth term; and the Tangent Zb will be found, of 6571 parts with respect to the whole sine CD, that is, 65 71/100 [the last two figures, 71, being of course removed]. This Tangent, taken from the straight line CD which we divided for the horizontal line, and transferred from Z onto the straight line Zb, will exhibit the point b, of the 18th hour in Π and ϱ . And so of the rest. But here, look, are the distances from the style and the Tangents of the Sun's altitudes with respect to the whole sine CD, computed for the hours from the west at latitude 42°, at the beginnings of the signs ϖ [Cancer]: γ [Aries], $\varnothing$ [Libra]: and $\var�$ [Capricorn], from which the next two dials have been constructed.

Diagram. The equilateral-triangle tangent-scale device used in the construction. From the apex **A** at the top, a fan of straight lines descends to the base. The base runs from **B** (left) to **C** (right) and is graduated **9 8 7 6 5 4 3 2 1** (reading from B toward C). Just below the apex a horizontal line crosses the fan through **E** (left) and **F**; produced to the right it passes to **G** and carries the tangent scale **10 20 30 40**, with **D** at the upper right (the oblique right side D–C). Two further horizontal lines cross the fan lower down through **L** and **M**, and through **H** and **I**; **N** and **K** lie on the right side (D–C) where the scale lines meet it.

Table — Pro horologio australi [For the southern dial]. Hours from the west (Horæ ab occ.); for each sign-group, the Distance from the style (Distantiæ à stylo, in degrees G. and minutes M.) and the Tangent of the altitude (Tangentes altitud.). The middle group serves both γ [Aries] and $\varnothing$ [Libra] (equinox).

10. It is not to be overlooked, moreover, that if the horizontal circumferences and the Sun's altitudes are at hand, together with the adjoining little tables, a declining dial can — for a given size of style — be painted directly on a wall, even if it has not first been drawn on paper to be afterward transferred to the wall enlarged for the given style; which I leave to the Reader's judgment.

11. In exactly the same way, from the 11th table of horizontal circumferences and the 9th table of the Sun's altitudes, [the hour-lines] will be described for the hours from the morning-side and from midnight, as is evident.

12. In no other way, by means of these same horizontal circumferences and the Sun's altitudes, will the primary Vertical dial, and the Meridian dial, and likewise the horizontal one, be constructed, provided one observes what we shall now say. In the southern Vertical dial the Eastern part inclines from the meridian line toward the left, and the Western toward the right. Further, the whole dial [continues]

[Margin: Description of the primary Vertical dial from the horizontal circumferences, etc.]

is the southern dial. Therefore the distances of the hours from the style are equal to the complements of the horizontal circumferences. But in the northern vertical dial the eastern part reaches to the right and the western to the left; and the whole is a northern dial. Hence the distances of the hours are likewise equal to the complements of the horizontal circumferences.

In the eastern meridian dial the northern part slopes from the style toward the left, and the southern toward the right; and the whole is an eastern dial. In the western one, by contrast, the northern part reaches to the right and the southern to the left; and the whole is a western dial. For this reason the horizontal circumferences are also the distances of the hours from the style.

[Margin: The description of the horizontal dial from the horizontal circumferences, etc. The description of the meridian dial from the horizontal circumferences, etc.]

Finally, in the horizontal dial the eastern part is placed to the right of the meridian line and the western to the left — when we turn to face the dial — so that the style slopes toward the south. And if a vertical line is drawn through the position of the style, perpendicular to the meridian line, the northern part will slope toward the south and the southern toward the north. From this vertical line the horizontal circumferences are to be reckoned in the circle described from the position of the style. Indeed, if a perpendicular is drawn to the vertical line, the tangents of the horizontal circumferences can be transferred onto it with respect to the whole sine [the radius], provided the portion of the vertical line between C (the position of the style) and the said perpendicular is set equal to that whole sine. When, however, the horizontal circumferences are too great, the perpendicular must be drawn through a point nearer the position of the style, so that the tangents can be transferred onto it, with respect to a smaller whole sine. But for the Sun's altitudes their complements are to be taken from tables 9 and 10, and the tangents of these — with respect to a whole sine equal to the style — are to be transferred onto the vertical lines, all of which are drawn from the position of the style through the horizontal circumferences marked in the said circle, so that the hour-points may be found, and so on.

CAPVT XXV.

HOROLOGIA EX CIRCVMFERENTIIS TANTUM MODO HORIZONTALIBUS, & ALTITUDINIBUS SOLIS SUPRA HORIZONTEM.

[Dials from the horizontal circumferences alone, and the altitudes of the Sun above the horizon.]

Since perhaps a geometrical laying-out of dials pleases most people more than the one worked out by us up to now through the numbers of the tangent lines, I think it will be worth my while if, in this last chapter, I show geometrically, by means of the Analemma, how — from the Sun's horizontal circumferences and its altitudes above the horizon — both horizontal and mural dials may be constructed. This is the same thing that in the preceding chapter we also handed down by means of the Tangents.

[Margin: Construction of the Analemma.]

1. First, then, in order to find the horizontal circumferences and the altitudes of the Sun above the horizon: let ABCD be the meridian, with centre E. Draw two diameters cutting each other at right angles, A C and B D, of which let B D be the common section of the horizon and the meridian, and A C the common section of the vertical circle and the same meridian. Let there be four arcs, D F, A H, B G, and C I, equal to the elevation of the pole; and the drawn straight line F G will be the axis of the world, and H I the diameter of the Equator. From the points H and I let there be cut off on either side the arcs of the declinations which, in the scholium of chapter 15, number 2, we investigated for the beginnings of the [zodiacal] signs; and let the diameters of the parallels be drawn, as you see in the figure. And since the axis F G — by the scholium of proposition 27, book 3, of Euclid — bisects all the diameters of the parallels (as it also bisects the arcs which they cut off), let there be described, for example, from the point P, where the diameter of the parallel of $\mathfrak{S}$ [Cancer] is divided by the axis, about the diameter of $\mathfrak{S}$, K L, the tropic of $\mathfrak{S}$, namely K N, L O; and from the point M, where the same diameter of the horizon cuts the diameter K L, let there be erected perpendicular to K L the line N M O, the common section of the horizon and of the parallel of $\mathfrak{S}$, so that N K O is the diurnal arc of $\mathfrak{S}$ and N L O the nocturnal arc; while both N K and O K are the semidiurnal arc, and both N L and O L the seminocturnal. But if the circle K N L O be taken for

the tropic of ♊ [Capricorn] — F being taken, of course, for the antarctic pole and G for the arctic — then N L O will be the diurnal arc of ♊, and N K O the nocturnal arc, and so on.

[Margin: In what way the division of the hours is made in the Analemma.]

2. Next, if the horizontal circumferences and the Sun's altitudes are to be sought for the hours from noon and from midnight, the parallel must be divided into 24 equal hours, beginning from the point of noon K, or from the point of midnight L; and the hours into half-hours, and the half-hours into quarters of an hour, if you wish. But if the hours are proposed from sunrise or sunset, the same parallel must be divided into 24 hours, beginning from the point N of the horizon, at which the Sun rises or sets, so that the first point of division from N toward K belongs to hour 1 from sunrise and hour 23 from sunset in the tropic of ♋; the next to hour 2 from sunrise and hour 22 from sunset; and so on in succession. Again, let the first point from N toward L be understood to look to hour 1 from sunrise and hour 23 from sunset in the tropic of ♊; the next point to hour 2 from sunrise and hour 22 from sunset, and so on, as the numbers in the figure indicate. For the inner ones belong to the hours from sunrise, and the outer to the hours from sunset.
3. After this, from the hour-points hidden perpendiculars are to be dropped to the diameter of the parallel, and their intersections with the diameter are to be marked. These perpendiculars will easily be drawn with the aid of some accurately made set-square. For if one of its sides is made to coincide with the diameter K L, and the other passes through any hour-point whatever, this other side will indicate the perpendicular, and its intersection with the diameter K L. Or indeed, when the hours from sunrise or from sunset are not equally distant from noon, if the interval between K and any hour on the arc K N is transferred from K onto the arc K O — marking a point on it — then the straight line drawn from this point to the assumed hour will be perpendicular to K L. Thus you see that K 22 is equal to the interval K Q, and that the straight line Q 22 is perpendicular and cuts K L at the point 22. In the same way, from the hour-points on the arc K O there are dropped

perpendiculars to K L, if their intervals are carried over from K onto the arc K N, and so on. Furthermore, the same points of the diameter K L belong to the hours from sunrise, if the numbers are changed into their complements up to 24. Thus the point of hour 21 from sunset will also be the point of hour 3 from sunrise; and

the point of hour 10 from sunset will look to hour 14 from sunrise, and so on. In no other way will the other parallels, described about their own diameters, be distributed into hours, if from the intersections of their diameters with the diameter of the horizon B D perpendicular lines are erected to those diameters, for the common sections of the parallels and the horizon. And the same is to be said of the Equator described about its diameter H I, such as is ABCD, whose common section with the horizon is F E G.

[Margin: The finding of the horizontal circumference.]

4. When these things have been duly carried out, if through the point of any hour on the diameter of a parallel — for instance, through the point of hour 22 on the diameter of ☿ — a perpendicular R S is drawn to the diameter of the horizon B D, and from it R T is cut off equal to the interval intercepted between the point of the assumed hour 22 and the same hour 22 on the circumference of the parallel, then the straight line

Diagram. A large square frame enclosing the analemma of Chapter XXV. Within it is the meridian circle labelled **A** (top), **B** (left), **C** (bottom), **D** (right), with centre **E**. Through the centre run the two perpendicular diameters **A C** (vertical, common section of the vertical circle and meridian) and **B D** (horizontal, common section of the horizon and meridian); the oblique diameter **F G** is the axis of the world (F upper-right, G lower-left) and **H I** the diameter of the Equator (H upper-left, I right). Superimposed are the parallels of the tropics with their divided diameter **K L**, the perpendicular common-section chord **N ...O** (points **N**, **O**), and the dividing point **M** on B D and **P** on the axis. The construction points **Q** (lower-left), **R** (near centre, "fR"), the vertical-line points **X**, **Y**, **Z** and lower-case **c**, **e**, **f** appear near the centre; a point **V** and hour-arc terminus stand near the top. Around the rim run two concentric series of hour-numbers 1–24 (inner = hours from sunrise, outer = hours from sunset) written along the parallel-arcs, together with the twelve zodiac glyphs marking the signs; on the upper-left rim ♊ [Pisces], ♋ [Aquarius] and neighbouring signs are legible, and on the lower/right rim ♏ [Scorpio], ♐ [Sagittarius], ♑ [Capricorn], ♌ [Leo], ♍ [Virgo] can be made out.

- A (top of circle): apex of vertical diameter A C
- B (left of circle): left end of horizontal diameter B D
- C (bottom of circle): foot of vertical diameter A C
- D (right of circle): right end of horizontal diameter B D
- E (centre): centre of the meridian

- F (upper right on circle), G (lower left on circle): ends of the axis of the world F G
- H (upper left), I (right): ends of the Equator's diameter H I
- K (upper left area), L (lower right): ends of the divided parallel-diameter K L
- M (on B D, right of centre): where the horizon-diameter cuts K L
- N, O: ends of the common-section chord N M O of horizon and parallel
- P: point where the axis divides the $\mathfrak{S}$ diameter
- Q (lower left): hour-construction point (K Q = K 22)
- R (near centre): foot of perpendicular R S / R T
- V (near top): terminus of horizontal circumference A V
- X, Y, Z (near centre): perpendicular-line points
- c, e, f (near centre); a, b, d (near centre): lower-case construction points
- Hour-numbers 1–24 (two series) and zodiac glyphs around the rim: individually too small to resolve cell-by-cell; several legible as noted [numeral:?] for the remainder
- One label near the top read as "T"/"V" is uncertain [?]

E V, sent out from the centre of the world through T, cuts off the horizontal circumference A V of the assumed hour 22 — the circumference, that is, which on the horizon is intercepted between the primary vertical and the vertical circle that passes through the Sun set on the parallel at the said hour; which we demonstrated in book 6 of the *Gnomonics*, chapters 3 and 5. In the same way, through the point 22 in $\mathfrak{V}$ the perpendicular Z a has been drawn, and from it Z b has been cut off equal to the interval between the said point 22 and the point 22 on the circumference of $\mathfrak{V}$. Finally the straight line E b cuts off the horizontal circumference C d for hour 22 in $\mathfrak{V}$; and so with the rest.

Again, if through the same point of hour 22 on the diameter of $\mathfrak{S}$ a perpendicular X Y is drawn to A C, the diameter of the vertical circle, then D Y will be the altitude of the Sun for hour 22 in $\mathfrak{S}$. By like reasoning e f, a perpendicular to A C passing through the point of hour 22 in $\mathfrak{V}$, cuts off D f, the altitude of the Sun for hour 22 in $\mathfrak{V}$ — as we showed in book 6 of the *Gnomonics*, chapters 3 and 5. Moreover we shall draw the aforesaid perpendiculars with no trouble, if one side of the set-square is made to coincide with the diameter B D or A C, and the other passes through the hour-point on the diameter of the parallel. Likewise, if a compass is extended from M — the intersection of the parallel's diameter with the horizon's diameter — as far as the assumed hour 22 on the circumference of the parallel, then, swept round, it will cut the circle ABCD at the point S (or a),

onto which the said perpendicular to the horizon falls. But if the same compass is extended from c — the intersection of the parallel's diameter with the vertical's diameter — as far as the same point of hour 22 on the circumference of the parallel, then, swept round, it will cut the circle ABCD at the point Y (or f), onto which the perpendicular to the vertical falls; both of which we demonstrated in book 6 of the *Gnomonics*, chapter 4. And so the Sun's altitude will be found by means of the interval c 22, even if the perpendicular X Y or e f is not drawn.

[Margin: The finding of the Sun's altitude.]

5. Furthermore, all the horizontal circumferences of the hours from sunset that lie between N and K (or L) are western; those of the hours between O and K (or L) are eastern. The contrary is to be said of the hours from sunrise. Again, all the circumferences of the southern parallels are southern; but of the northern parallels, the horizontal circumferences of those hours whose points lie between the meridian and the point c — the intersection of the parallel's diameter with the vertical — are southern, while those hours whose points fall in the segment c M, between the vertical and the horizon, are northern.

[Margin: Which horizontal circumferences are eastern or western; likewise which are southern or northern.]

[Margin: What is to be done so that the horizontal circumferences and the Sun's altitudes may be investigated without confusion of lines. The arrangement of the horizontal circumferences and the Sun's altitudes in the figure proposed.]

Now, so that the horizontal circumferences and the altitudes of the Sun may be investigated for the hours of all the parallels, four Analemmas will have to be described: in the first of which, about the diameter of $\mathfrak{S}$, let the parallel of $\mathfrak{S}$ be described; in the second, about the diameter of $\mathfrak{II}$ [Gemini] and $\mathfrak{Q}$, the parallel of $\mathfrak{II}$ and $\mathfrak{Q}$; in the third, about the diameter of $\mathfrak{V}$ [Taurus] and $\mathfrak{M}$, the parallel of $\mathfrak{V}$ and $\mathfrak{M}$; while in the fourth let the circle ABCD itself be taken for the parallel of $\mathfrak{V}$ [Aries] and $\mathfrak{L}$ [Libra]. For by this method all confusion of circles, lines, and points will be avoided. And of any northern parallel that portion which the common section of it with the horizon cuts off can be taken for the opposite southern parallel, so that we are not forced to build three other Analemmas — just as, in the upper Analemma, the portion N L O represents the diurnal arc of $\mathfrak{V}$, since it is altogether equal to the portion which the common section of the parallel of $\mathfrak{V}$ with the horizon cuts off from the parallel of $\mathfrak{V}$, as is plain.

In the following figure we have set out the horizontal circumferences and the altitudes of the Sun for the hours from sunset in ☿, ♊, and ♈ and ♎, found for latitude 42 degrees in this order. In the topmost, or first, arc (now all the arcs are described to the interval of the semidiameter of the meridian of the Analemma) the horizontal circumferences of ☿ take their beginning from the point A, and the upper numbers belong to the eastern, or forenoon, hours — and to the left indeed the southern circumferences are drawn, and to the right the northern — while the lower numbers look to the western, or afternoon, hours, of which again the left are southern and the right northern.

Diagram. Within a square frame, a set of five nested quarter-circle arcs (a quadrant-fan) springs from a common corner, each arc graduated with hour-numbers and captioned in curved lettering. Reading the arc-captions from the outermost inward, they alternate "**Circumf. horizont.**" (horizontal circumference) and "**Altitudines Solis**" (altitudes of the Sun); the outer arcs terminate in the zodiac glyph ☿ **[Cancer]**, the middle pair in ♊ **[Capricorn]**, and the innermost carries ♈ **[Aries]** & ♎ **[Libra]** ("Circūf. horiz."). The arc-beginnings are lettered along the right-hand edge **A** (first/top arc), **B** (second), **C** (third), **D** (fourth), **E** (fifth). At the lower part of the frame is the gnomon construction: a right-triangle/square with corners **A** (upper right), **G** (upper left), and **E, F, C, D** along the base with **H** at the lower-left foot, forming the shadow triangle for the dial. The arcs are graduated with hour-numbers running roughly 1–24 (legible values along them include...14, 15, 16, 17, 18, 19, 20, 21, 22, 23, 24...); the individual graduations are too small to resolve every cell.

- A (top-right, first arc / and upper-right corner of the gnomon square): start of the ☿ horizontal-circumference arc
- B (second arc start): start of the ☿ altitude arc
- C (third arc start): start of the ♊ horizontal-circumference arc
- D (fourth arc start): start of the ♊ altitude arc
- E (fifth arc start / and lower-left of gnomon square): start of the ♈ & ♎ arc
- F, G, H: corners of the gnomon/shadow construction at the base
- Arc-captions "Circumf. horizont." and "Altitudines Solis" repeated, each ending in its zodiac glyph
- Hour-graduation numbers along each arc: partially legible; individual values [numeral:~] where not resolvable

In the second arc, from the point B, begin the arcs of the Sun's altitudes in ☿, and the hours to the left are forenoon, but to the right afternoon.

In the third arc the horizontal circumferences of ♎ have their beginning at the point C, as in the first, and are all southern.

In the fourth arc the altitudes of the Sun in ♎ begin from the point D, as in the second.

In the fifth and last arc the circumferences beginning to the left from the point E are the horizontal circumferences of ♊ and ♍, while the arcs of the Sun's altitudes proceed from the point E toward the right. And the upper hours indeed are forenoon, the lower afternoon. And these circumferences and altitudes of ♋, ♎, and ♊, ♍ are enough for laying out a dial, unless one desires to draw the arcs of all the signs. For then the horizontal circumferences and the altitudes of the Sun in the other signs will also have to be sought.

Moreover, we shall also teach how to investigate the horizontal circumferences and the altitudes of the Sun with almost no trouble, from the horizontal and the meridian dial, in the following scholium, number 4.

[Margin: The horizontal line.]

6. Let there be, then, a dial to be constructed, for the hours from sunset, declining from the meridian toward the east by 30 degrees, concerning which [we spoke] above. Having drawn the horizontal line A B, and having chosen the position C of the style, let the perpendicular L K be drawn through C to A B, and let C D be equal to the style. From D describe the circle E F G H, equal to the meridian of the Analemma, that is, to the interval of the arcs of the preceding figure. Then, the declination of 30 degrees having been counted from the point K as far as E, toward the right — because the plane declines from the meridian toward the east (if it declined from the meridian toward the west, the declination would have to be counted toward the left) — let the diameter G D E be drawn, which the diameter F D H cuts at right angles. G E will be the common section of the meridian and the hori-

and of the horizon; while FH is the common section of the vertical circle and the horizon — as is evident, if the circle EFGH is carried around AB until it stands perpendicular to the plane of the dial and so comes to lie in the plane of the horizon, exactly as we demonstrated in the scholium to proposition 1 of *Gnomonics* Book 3. EHG will then be the eastern semicircle of the horizon, and EFG the western; likewise FGH will be the southern semicircle and FEH the northern, as is clear. Therefore through B the meridian line BI is to be drawn, perpendicular to the horizontal line; and through A the equinoctial line is to be

drawn in the following way. Taking BM equal to BD itself, describe from M the circle NO. For once the arc NO, [equal to] the altitude of the equator — that is, to the complement of the pole's altitude — has been taken, the hidden straight line MO will cut the meridian at the point I, through which the equinoctial line is to be drawn from A. And so that it might be drawn more exactly, we employed the Lemma demonstrated before chapter 16: that is, from I, through A, we described a circle, and with the same interval marked two points on it, one on each side of the point A, from which two pairs of arcs intersecting each other were drawn, both toward I and on the opposite side. For through these two points of intersection, and through A and I, the equinoctial line is to be drawn. That it must be drawn through I, I demonstrate as follows.

[Margin: The meridian line.]

[Margin: The equinoctial line.]

Suppose the circle EFGH placed in its proper position, so that D coincides with the center of the world. If the plane of the circle NO, together with the semidiameter MN, is imagined to be turned about BI, the point M will fall upon D, the center of the world, because the straight lines BD and BM are equal; and the plane of the circle NO will coincide with the meridian drawn through DB. Since, then, NMO is the angle of the equator's altitude, which the radius of the equator makes at the center of the world (where the point M has been placed) with the horizon, or with the meridian line DS: MO in that position will be the radius of the equator meeting the meridian at I, and so on.

Now let the hour to be drawn be, for example, hour 17. From the horizontal circumference of hour 17 in ☿ [Cancer], taken from the first arc, let FP be taken equal to it, since it is western and southern; and let the hidden straight line PD be drawn, cutting the horizontal

Diagram. A large declining-dial construction of the Analemma type, enclosed in a rectangular frame (the plane of the dial). Within it is a great circle EFGH (the horizon/meridian circle of the Analemma), crossed by a horizontal diameter and a near-vertical diameter, with a dense fan of hour-lines and dotted altitude/circumference arcs radiating into the lower-right quadrant. The right and lower edges of the frame carry the hour-line numbers 17–24. This same figure is reprinted on the facing page (p. 722). Because the figure is exceptionally crowded and many small labels overlap the ruled and dotted lines, several labels cannot be resolved with certainty**

Readable labels (position → content):

- G (upper left, on the circle)
- ♂ [Taurus glyph] (top, on the circle, with a dotted radius)
- L (top center)
- a (top, just right of L)
- F (upper left, interior, dotted line) — a second F appears at the lower left
- H (upper right, on the circle)
- q (right of H, on a dotted line)
- P (right, on a dotted line)
- D (upper-center interior, an intersection point)
- Horizontal diameter, left → right: S, N, A (center), r, d, f [long-s / f], B, R, M, X
- γ [Aries glyph, on a dotted line, lower left of A] [?]
- 11 (lower left), then the descending series 12, 13, 14, 15, 16 curving down through the center
- c, m, e (small letters just below B / center)
- I (interior, right of center — a major point)
- Q (right, on a curved line)
- Right-edge hour numbers, top → bottom: 24 [followed by a small zodiac glyph, ♈?] [?], 23, 22, 21, 20
- O, b, K (lower left, near the circle)
- h (bottom center)
- E (lower right, on the circle)
- Z (lower right, on a dotted line)
- Bottom edge, left → right: S, V, T, 17, 18, 19

line at R. And so that this line may be drawn more exactly, one should take the opposite arc HQ, equal to the arc FP — which must be done for all the circumferences. Next let RT be dropped perpendicular to the horizontal line. To do this more readily, draw ST parallel to the horizontal line; for if RS is taken from BR equal to ST, then RS, drawn to the horizontal line, will be perpendicular to it — which likewise must be done in the other cases. This straight line RT is the common section of the plane of the dial and of the vertical circle that passes through the center of the Sun at hour 17. After this, let RX be taken from RD equal to it, and from X describe the circle YZ with a radius equal to the semidiameters of the arcs of the preceding figure. For if in it the arc YZ is taken equal to the arc of the Sun's altitude in the second arc, the hidden straight line XZ will cut the vertical RT at V, the point of hour 17 in ☉.

For suppose the horizon EFGH placed in its proper position. If the circle YZ, together with the semidiameter XY, is imagined to be turned about RT, the point X will fall upon D, the center of the world, because the straight lines RX and RD are equal; and the plane of the circle YZ will coincide with the vertical circle drawn through the Sun. Since, then, YXZ is the angle of the Sun's altitude, which the Sun's radius makes at the center of the world (where the point X has been placed) with the horizon, or with the straight line DR — the common section of the horizon with the vertical circle drawn through the Sun: XZ in that position will be the radius of the Sun meeting the straight line RT at the point V.

The point of the same hour in ♊ [Capricorn] is found in just the same way. For if from the third

arc of the preceding figure — the arc which is forenoon and southern — an equal arc Ha is taken, and to it the opposite arc Fb, then the hidden straight line ab will cut the horizontal line at the point d, and the perpendicular de will represent the vertical circle that is then drawn through the Sun. Then, having taken the straight line dm equal to dD, describe from m the circle np with a radius equal to the semidiameter of the Analemma, and in it take the arc np equal to the arc of the Sun's altitude at hour 17 in ♊, in the fourth arc of the preceding figure. For the straight line pm, hidden, will cut the vertical de at e, the point in ♊ — which will be demonstrated in the same way as was said of the point V in ♉. For here too the angle nmp, or dme, is the angle of the Sun's altitude. And so the Sun's altitude must always be cut off above the horizontal line when the circle is not described toward the vertical line of the proposed hour, but below the horizontal line when it is described toward that vertical line — as was done in the circle YZ.

Finally, for the same hour 17, we shall find the point on the equinoctial line if, from the horizontal circumference of hour 17 in ♈ [Aries] or ♎ [Libra], drawn from the fifth arc of the preceding figure — the arc which is forenoon and southern —

Diagram. The **same** declining-dial Analemma construction as on p. 721, reprinted so it can be seen while reading either side of the leaf. The labels are identical (great circle EFGH within a rectangular frame; horizontal and near-vertical diameters; a fan of hour-lines and dotted altitude/circumference arcs into the lower-right quadrant; hour numbers 17–24 along the right and lower edges; letter-labels G, ☿, L, a, F, H, q, P, D, S, N, A, r, d, f, B, R, M, X, c, m, e, I, Q, O, b, K, h, E, Z, V, T and the numeric series 11–16). Same crowding and the same unresolved labels as fig-p721-1 (see the parsing note there).

there is taken an equal arc Hg, and opposite to it Fh. For the hidden straight line gh will cut the horizontal line at the point f, through which the perpendicular to that same horizontal line will cut the equinoctial line at l, the point of hour 17. Here there is no need of the Sun's altitude, except when the equinoctial line cannot be drawn without those altitudes, as we shall prescribe in the following scholium, number 3. The straight line therefore passing through the three found points e, l, V will indicate hour 17 from the west.

In exactly the same manner the other hours will be drawn. In those hours, however, that have only two points — such as 18, 19, and 20, which have no point in ☿ — the Lemma set before chapter 16 must be employed when those two points lie very close to each other, so that the hour-lines may be drawn more accurately, as you see was done in hour 18. But when in some hours only a single point is obtained — such as 11, 21, 22, 23 (for hour 12 also has the point A) — other points must be sought on the horizontal line by means of the rising latitudes [latitudines ortiuas], in the following way. Since, when the Sun rises at hour 11, the day contains 13 hours (because from 11 up to 24 there are counted 13 hours), we shall count out on the Analemma the declination of the diurnal arc of 13 hours (in the following scholium we shall find these declinations geometrically for any latitude of place), from the points H, I toward ☿, as far as gh; and we shall draw the diameter of its parallel gh, cutting the diameter of the horizon at i. For the perpendicular ik will cut off the rising amplitude [amplitudo ortiua] Ak, as we demonstrated in *Astrolabium* Book 3, in the scholium to Canon 6. If, then, we cut off from this amplitude-arc Ak — which is northern, because the diurnal arc exceeds 12 hours — an equal arc Hq, and opposite to it Fr, the hidden straight line qr will cut the horizontal line at f, the point of hour 11 — namely at the point of the rising latitude of the diurnal arc of 13 hours. And so for the rest. For example, to find the point on the horizontal line for hour 23, one must take the declination of the diurnal arc of one hour, since then the Sun rises at hour 23 and sets at hour 24, which is southern; and from it the southern rising latitude is likewise to be investigated, and so on. Instead of the points of the rising latitudes on the horizontal line, the point for any hour may be sought on a nearby parallel: thus for hour 11 the point ♉ [Taurus] and ♍ [Virgo] may be looked up; while for hour 13 the point ♌ [Leo] [?] and ♒ [Aquarius], and so with the others. Once this is found, the Lemma demonstrated before chapter 16 is to be applied.

[Margin: When only two points, or only one, are had for the hours to be drawn — what is to be done.]

Indeed, we shall find that same point for a given hour on the horizontal line still more easily by way of the hours from noon and from midnight. For if a point is found on the horizontal line for the hour from noon or from midnight that is the half of the given hour from sunrise or sunset, that hour must be drawn through the said point: thus for hour 11 from the west one must look up the point of the astronomical hour $5\frac{1}{2}$; for hour 23, the point of hour $11\frac{1}{2}$; for hour 22, the point of hour 11, and so on.

Nay more, since every hour-circle from sunrise or sunset, and the horizon — which is the hour-circle of hour 24 — cut each other mutually on the hour-circle from noon or midnight whose number is the half of that hour from sunrise or sunset (as is evident from the figure of the scholium of chapter 1, number 3, and as we demonstrated in *Gnomonics* Book 1, propositions 17 and 20), it comes about that the rising or setting amplitude of any hour from sunrise or sunset does not differ from the arc of the horizon of that hour from noon or midnight which is its half. Since, then, the lines of the hours from noon and midnight are described in the horizontal dial (chapter 2) by means of the arcs of the horizon of table 6, transferred onto a circle described from the center G, as we showed in chapter 5: the arc of that circle between the line of hour 6 and any hour-line will be equal to twice the amplitude of the hour from noon or midnight — as the arc between hour 6 and $5\frac{1}{2}$ will be the amplitude of hour 11, and likewise of hour 13, and so with the rest. Therefore, if the hours from noon and midnight are carefully described in the horizontal dial together with the half-hours, they will contain at the center G, together with hour 6, the angles of the rising or setting latitudes which the hours from sunrise or sunset make on the horizon — a thing indeed well worth noting. And so, if the amplitude of some hour from sunrise or sunset is wanted in degrees, one must take from table 6 the arc of the horizon of that hour which is the half of the given hour from sunrise or sunset.

7. But if in the dial itself you do not wish to describe so many circles for the Sun's altitudes, lest confusion arise, we have for that purpose described in the preceding figure the quadrant ABC, to the radius of the semidiameter of the Analemma. For if in this quadrant one cuts off the arc of the altitude of any hour, beginning at B, and from A toward B cuts off a straight line equal to the interval in the dial between D and the vertical line of the proposed hour; and if from the endpoint of this cut-off line a perpendicular to AB is erected (which will be done easily if DE is drawn parallel to AB and the same cut-off line is transferred onto it): then the straight line drawn from A through the endpoint of the altitude will cut off, from that perpendicular, the length of the shadow, which is to be transferred in the dial onto the

vertical line of the given hour. For example: let BF be taken equal to the arc of the Sun's altitude at hour 17 in $\mathfrak{S}$, and let AG be cut off equal to the straight line RD. Then the perpendicular GH will cut off from the straight line AF the length of the shadow, which, transferred onto the vertical RT, will yield the point V of hour 17 in $\mathfrak{S}$. And so with the rest. You have another example in hour 23 in $\mathfrak{V}$. But if some straight line issuing from the center A cuts the perpendicular to AB too obliquely — as nearly happens in finding the point of hour 17 in $\mathfrak{S}$ — it will be expedient to investigate that point by means of the Tangents, as was set forth in the preceding chapter.

8. Concerning the dial that is parallel to the prime vertical, to the meridian, and to the horizontal, exactly the same must be said as we wrote in the preceding chapter. For they will be described here in the same way as there.

SCHOLIVM.

1. The **declinations** of the diurnal arcs, which we need in order to find through them the rising latitudes of the hours from sunrise or sunset on the horizontal line — as we said at the end of number 6 of this chapter — we shall explore geometrically in this way. Having described from A an arc of a circle CD to any interval whatever (though you will do well to make the interval equal to the semidiameter of the Analemma), and having drawn the straight line AB as the radius of the equator — that is, as the radius of the diurnal arc of 12 hours — let there be taken on each side the arcs BC and BD equal to the complement of the pole's altitude. Then let the straight line CD be drawn; by the scholium to proposition 27 of Euclid Book 3 it will be cut in two by the straight line AB at E; and from E, to the interval EC or ED, a circle described [and divided] into 48 equal parts. Then, if the points of division are joined two by two in equal measure — from C, or from D — by hidden straight lines, CD will be cut at points through which from A the radii of the diurnal arcs are to be sent out: so that AD is the radius of the diurnal arc of hour 0, the one next to it the radius of the diurnal arc of hour 1, the following the radius of the diurnal arc of hour 2, and so on in succession up to AC, the radius of the diurnal arc of hour 24.

[Margin: The radii of the diurnal arcs.]

And the **arcs** of the circle CBD, contained between AB — the diurnal radius of hour 12, or the radius of the equator — and the aforesaid radii, measure the declinations of the parallels of the Sun which those radii represent; that is, of the

parallels whose diurnal arcs above the horizon embrace as many hours as are inscribed on each of the radii. All of which are demonstrated geometrically at the end of our *Gnomonices*.

[Margin: The declinations of the diurnal arcs.]

2. And so you see that, if once, with all diligence applied, for a given altitude of the pole the horizontal circumferences and the Sun's altitudes are found — which is really not very laborious — then any declining dial whatever can be described by an agreeable operation, whether it declines from south toward east or toward west, or from north toward west or east, by however many degrees.
3. For the rest: by means of the horizontal circumferences and the Sun's altitudes — whether these are found geometrically, as we have taught in this chapter, or by numbers, as will be taught at the end of the booklet in problems 15 and 16 — declining dials will be described with almost no trouble, even those in which either the point of hour 6 on the horizontal line, or the center of the dial, or both points, or finally the point of the meridian line (and hence the center of the dial), cannot conveniently be obtained — dials which we did indeed treat in chapter 17. The only thing to be taught briefly here is by what method the equinoctial line is to be drawn in them, which will be done thus. In the upper dial let there be the horizontal line AB and the style CD, perpendicular to it at C. Let the angle CDB of the declination from south toward east be supposed so small that its complementary angle CDF is so large that the straight line DF cannot, because of the narrowness of the space, cut the horizontal line at the point through which the equinoctial line would have to be drawn. Whether or not the center of the dial can be obtained makes no difference. Taking BM equal to BD, and having described the circle NO from M, let the arc NO be equal to the complement of the pole's altitude. For the hidden straight line MO will cut the meridian at the point I, through which the equinoctial line must be drawn. But since the other point A, through which the same line is to be drawn, is supposed not to be had, some other point must be found through which it may be extended, in this way. Since the point I belongs to hour 18, we shall take another, preceding hour — for example, hour 17 — and of its horizontal circumference, which is eastern and southern, we shall take the equals Hg, Fh. For the hidden straight line gh will cut the horizontal line at the point f, through which the perpendicular straight line fl will represent the vertical circle that is drawn through hour 17 on the

equator. If, then, by means of the Sun's altitude in the same hour 17 the point *l* on the equator is found — just as the points *V* and *e* of the same hour [were found] by the Sun's altitudes in $\mathfrak{S}$,

[Margin: Declining dials, which we treated in chapter 17, are described with no trouble by means of the horizontal circumferences and the Sun's altitudes.]

If, then, by means of the Sun's altitude in the same hour 17 the point *l* on the equator is found — just as the points *V* and *e* of the same hour were found by the Sun's altitudes in $\mathfrak{S}$ [Cancer] and $\mathfrak{V}$ [Capricorn] — the equinoctial line must be drawn through the points *I*, *l*; and so that it may be drawn more precisely, one should employ the lemma before chapter 16. In no other way can other points, more distant from *I*, be found through which the equinoctial line is to be drawn, if one wishes.

Next, let us imagine the angle *CDB* to be so large (the declination of the plane from south toward east being, that is, very great) that the straight line *DB* cannot cut the horizontal line in the dial, and consequently the meridian line cannot be drawn, nor even the point *I* found through which the equinoctial line would be drawn. Let there therefore again be found the point *l* of some hour — namely of hour 17, with the Sun in the Equator, as has been explained — or of another hour before noon. For the straight line *A l* will be the equinoctial.

But should it happen that the meridian line can indeed be drawn on the dial, yet the point *I* — through which the equinoctial line must be drawn — lies too far from the point *B*, then a point of the equinoctial line for some hour after 12, which is drawn through *A*, must also be found, or even several points, and so on. Everything else will be completed as this chapter has taught. The operation itself will nicely reveal which hours' points are contained on the dial, and which hours' points cannot be drawn.

Diagram. A square-framed sundial figure (horologium) for the declining-dial construction of this chapter. Within the frame a large circle is drawn, graduated with degree-tick marks along its upper arc. Straight hour-lines radiate as a fan from the point *C* toward hour-division marks numbered around the rim. A horizontal line runs from *C* at the left through the center *E* to *D* at the right; a vertical line rises through *A* (at the top, on the circle, with a short line/style projecting above it) and descends through *E* to *B* below. Several dotted perpendicular lines are also shown.

- *A* (top, on the circle, with a vertical line rising above it): apex point of the meridian/style

- C (left, on the horizontal diameter): point from which the hour-lines radiate
- D (right, on the horizontal diameter): endpoint of the horizontal line
- E (center of the horizontal line CD): center point
- B (below E, on the vertical line): foot point
- Hour-division numerals around the rim: down the left side, 24[?], 23, 22, 21, 20, 19, 18; along the bottom (left to right), 17, 16[?], 15, 14[?], 13, 12, 11, 10, 9, 8; up the right side, 0, 1, 2, 3, 4, 5, 6, 7

This same result will be achieved by means of the tangents, as we taught in chapter 24, since the distances of the hours from the position of the style can be found from the wall's declination, even if the meridian line does not appear on the dial, as is evident.

[Margin: Finding the horizontal circumferences and the Sun's altitudes from the horizontal dial.]

4. Nor do I wish it to escape the studious reader that the horizontal circumferences and the Sun's altitudes — if he does not wish to investigate them by the analemma, as this chapter 25 has taught (so that he need not distribute the Sun's parallels among the hours and raise so many perpendiculars; for in this matter, unless the utmost diligence is applied, one may easily err) — can be found by a very easy method. This is so, provided that beforehand, with the greatest care, a horizontal dial is constructed for the given altitude of the pole, with all the arcs of the signs, as we taught in chapters 2, 3, 4, 8, 9, 10, 11, and 14 — which is not difficult; and certainly, in my judgment, far easier and safer than employing so many divisions and perpendiculars to investigate the horizontal circumferences and the Sun's altitudes by the analemma. For from this dial one will find the horizontal circumferences and the Sun's altitudes by this easy and agreeable method. From the position of the style in the horizontal dial, let a circle of any size be described, representing the horizon. Then from the same position of the style — that is, from the center of the horizons — let hidden straight lines be sent out through the points of the parallels (or of the arcs of the signs) at which they cut the hour-lines. For the arcs of the described circle enclosed between the straight line CD — which is drawn through the style perpendicular to the meridian and represents the prime vertical [*verticalis primarius*] — and those hidden straight lines are the horizontal circumferences, since they are the widths of the shadows.

For example: if, in the dial of chapter 14, a hidden straight line is drawn from C to the intersection of hour 23 with the parallel ☿ [Cancer], then the arc of the circle described from C, enclosed between this hidden line and the vertical line CD, will be the horizontal circumference of hour 23 in ☿ — western and northern.

[Margin: Which part is northern, southern, eastern, and western in the horizontal dial.]

For in the horizontal dial the portion that inclines from the vertical line CD toward the center is northern, since the shadows are cast into it when the Sun is on the near side of the vertical; but the other portion, toward the equinoctial line, is southern. Likewise, the portion that the meridian line cuts off toward the afternoon hours is western, because the shadows fall into it when the Sun is in the west; while the other portion, toward the forenoon hours, is eastern. And by this same method you will find the horizontal circumferences of all the hours in each of the Sun's parallels, even in the Equator itself, if from C hidden straight lines are drawn out through the hour-points on the equinoctial line, and so on.

The Sun's altitudes will be examined in this way. When a straight line AB of any length has been drawn, let a perpendicular AC be raised to it, equal to the style of the horizontal dial; and from C let a circle EIF of any size be described, in which let a diameter EF be drawn parallel to the straight line AB. Then, in the horizontal dial, take the interval between C (the position of the style) and any hour in the parallel ☿ [Cancer], or ♊ [Capricorn], or ♈ [Aries] and ♎ [Libra], or finally in the parallel of any other sign — that is, the length of the shadow of any hour — and transfer it onto the straight line AB from the point A of this figure. For a straight line drawn from the endpoint of the transferred interval to the center C will cut off from the circle EIF the arc of the Sun's altitude — proceeding upward from the point E, but downward from the point F [Margin (a): Elements III.27] — so that there is no need to extend the lines beyond the center C, but it is enough to produce them as far as the center. For, proceeding downward from the point F, they cut off arcs equal to the arcs of the altitudes that extend upward from E, on account of the angles at the vertex C, which [Margin (b): Elements I.15]

are equal. For example, the straight line AB is equal to the interval between C (the position of the style) and hour 22 in ♊ [Capricorn], on the horizontal dial. Therefore the Sun's altitude at that hour is the arc ED, or FG. Likewise, the straight line AK is equal to the interval between C and the same hour 22 in ☿ [Cancer], and the Sun's altitude is the arc EH, or FO. Moreover, the straight line AM is equal to the interval between C and the same hour 22 in ♈ [Aries] or ♎ [Libra], and the Sun's altitude is the arc EI, or FL; and so with the rest.

Diagram. A wide rectangular figure for finding the Sun's altitudes from the horizontal shadow-lengths. A large circle (EIF) is drawn with its center at C; the horizontal diameter runs from E at the left through C to F at the right. From the point A at the bottom, shadow-lengths are laid off along the base line, and straight lines drawn from their endpoints to the center C cut the circle at the altitude points. On the left, the points D, H, I are marked on the circle above E (with I highest); on the right, the points G, O, L are marked on the circle below F.

- I, H, D (left, stacked above E on the circle): altitude points measured upward from E
- E (left end of the horizontal diameter)
- C (center of the figure, on the horizontal diameter): the vertex/center of the style
- N, F (upper right, on/near the circle): F is the right end of the horizontal diameter
- Q (right, below the horizontal line): intersection point of NP with BC
- G (right, on the circle below F): altitude point
- o (small circle, right, near L): [label as printed]
- L (right, on the circle, lowest): altitude point measured downward from F
- A (bottom center, below C): origin of the shadow-lengths
- P, M, K, B (along the base line, left to right toward the right corner): endpoints of shadow-lengths / construction points
- Zodiac glyphs ♈ [Aries], ♋ [Cancer], ♏ [Capricorn] with the numeral 22 (set along the hour-22 verticals near K, B)

With this figure constructed — that is, with straight lines drawn from the endpoints of the shadows on the line AB to the center C — you can use it in place of the quadrant ABC described in the figure of number 7 of this chapter 25. For suppose that onto the straight lines AB and EF there are transferred, from A and from C, the intervals between the vertex of the style of the declining dial and the verticals of the hours on the horizontal line — which are found by means of the horizontal circumferences, as was explained in number 6 of this chapter — and that their endpoints are joined by straight lines. Then the segments of those lines enclosed between EF and the altitude-lines of the hours (which, namely, are drawn from the endpoints of the shadows on the line AB to the center C) are transferred onto the vertical lines of the dial, and the hour-points on the dial will have been found. Thus there is no need to construct another figure, or to draw many arcs on the dial itself onto which the altitudes are transferred, as was done above — a procedure that inevitably breeds great confusion. For example: if in

the next figure CN and AP are taken equal to the interval, in the dial of this chapter 25, between D and the vertical of hour 22 in ♊ [Capricorn], then the straight line NP will cut the straight line BC of the altitude of hour 22 in ♊ at Q; and the line NQ, transferred from the horizontal line to the vertical of the same hour 22 in ♊, will give the point of hour 22 in ♊, and so on. And in this way that huge multitude of arcs on the dial will easily be avoided.

And so that we may also avoid the confusion of the multitude of lines in the next figure, it will not be amiss to build several figures — in the first of which the altitudes of the hours of one parallel are found, in the second the altitudes of the hours of another parallel, and so on in succession — which I leave to the skill and industry of the studious reader.

[Margin: By what method the horizontal circumferences and the Sun's altitudes are drawn out from the meridian dial.]

The same horizontal circumferences and the Sun's altitudes can very conveniently be investigated from the meridian dial, whose description is very easy, and in which the points of the parallels at the hours from noon and from midnight are found most exactly by means of the tangents of the arcs of the first universal table transferred onto the hour-lines, as we said in chapter 21, number 2. For if, in the meridian dial of chapter 21, a perpendicular is raised through A to the horizontal — which will be the common section of the plane of the dial and of the prime vertical, as we demonstrated in the *Gnomonics*, book 2, proposition 28 — and on it, upward, a straight line equal to the style is taken, and from its endpoint a circle is described, this circle will be the horizon, if it is turned about the horizontal line until it stands perpendicular to the dial. And a straight line drawn through the center of that circle, parallel to the horizontal, will be the common section of the horizon and the meridian. Now if from any hour-point a perpendicular is raised to the horizontal, it will represent the vertical passing through the said hour in the proposed parallel. And a straight line extended from the point where the said perpendicular cuts the horizontal, through the center of the circle just described, will cut off from that circle the horizontal circumference — to be counted from the prime vertical, which the perpendicular raised to the horizontal through A expresses — since that straight line is the common section of the horizon and of the vertical passing through the Sun at that hour, as is evident if the horizon is conceived in its proper position, set up together with the dial. Finally, take on the horizontal a straight line equal to the interval between the center of the aforesaid circle and the perpendicular drawn in the horizontal from the given hour-point to the horizontal, and from its endpoint describe an

arc; then a straight line extended from its center through the given hour-point will cut off the arc of the Sun's altitude enclosed between the horizontal and that extended line, and so on.

[Margin: That from a horizontal dial [thus constructed] all declining dials of the same latitude of place can be constructed.]

And so you see that, for any latitude of place, from a horizontal or meridian dial alone, skillfully constructed, all declining dials can be described — a truly excellent matter, and one worthy to be thoroughly learned with special study.

[Margin: An easier way to find the hour-points, by means of the tangents of the arcs of table 6, than the one explained in chapter 2, number 5.]

But so that a horizontal dial may be described most precisely with the arcs of the signs, we have computed table 19 for several altitudes of the pole, so that by means of it the points of the Sun's parallels on the hour-lines may be found from the center of the dial, as we taught in the scholium of chapter 9, number 5.

Likewise, for the same reason, by means of problem 10 at the end of the booklet, we have computed — for very many altitudes of the pole as well — the segments of the hour-lines between the center and the perpendiculars that are drawn to them from the position of the style. For from the points of the perpendiculars the points of the Sun's parallels can also be accurately found, as we handed down in the same scholium, especially if the use of that equilateral triangle is added, which we constructed in the scholium of chapter 1, and whose use we explained in chapter 24, number 7.

5. Again, since in chapter 2, number 5, we taught in what way various horizons can be described on a horizontal dial, so that on them the hour-points may be investigated by means of the tangents that are owed to the complements of the arcs of table 6 at the altitude of the pole above the described horizon — it is fitting here, so that the hour-lines may be drawn more precisely, to explain a method that occurred to us afterward, far easier and shorter. By it the hour-points can be transferred onto any line making right angles with the meridian, by means of the tangents owed to the complements of the arcs of table 6 at the altitude of the pole for which the horizontal dial is constructed — even if we do not know which horizon that perpendicular line represents; so that there is no need to seek out by tangents a point on the meridian through which the proposed horizon must be drawn. One must therefore proceed as follows. Let the portion of the meridian line between the center of the dial and the perpendicular line

drawn in any way to the meridian be cut into 10 equal parts, as being the whole sine [sinus totius]. For the tangents of the complements of the arcs of table 6, owed opposite the altitude of the pole for which the dial is described, if they are trans-

ferred onto that perpendicular on either side of the meridian line, will give the required hour-points. For example, if in the dial of chapter 2, through the point S — assumed at pleasure — a line VSV is drawn perpendicular to the meridian, then the portion GS must be divided into 10 equal parts, and so on. For the complements of the arcs of table 6 measure the angles that the hour-lines make with the meridian at G, whose tangents are the segments of the perpendicular VSV, between S and the hour-lines, with respect to the whole sine GS. And if the segment GB in the same dial is cut into 10 equal parts, the same tangents, taken with respect to the whole sine GB, will give on the equinoctial line the same hour-points that were found by the other tangents in chapter 2, number 3. And so with the rest.

This method — because it is short and easy, and very suitable for drawing the hours that scarcely cut the equinoctial (namely, if the perpendicular to the meridian is raised not far from the center, or rather if the perpendicular is erected at hour 6, as was said at the end of the scholium of chapter 5) — seemed not to be passed over in this place, especially since we can be content with it, even though everything we wrote in chapter 2, number 5, be omitted.

[Margin: Another finding of the points for the verticals, on the horizontal line of the declining dial; chapters 24 and 25.]

6. By this same method, in the declining dial of chapter 16, the hour-points can be found on the straight line Bf by means of the tangents owed — opposite your elevation of the pole — to the complements of the arcs of table 6, with respect to the whole sine DB divided into 10 equal parts, even if neither the axis ER has been drawn, nor the perpendicular Bd to it, and so on.

Indeed, in the dial of chapter 24: if to the drawn straight line DB — which represents the meridian in the horizontal dial — a perpendicular is raised at the point B, or at another point nearer to or farther from the point D, on which perpendicular points are found by means of the tangents of the complements of the horizontal circumferences of table 11, with respect to the whole sine DB (or to the straight line between D and the perpendicular line, if the hours from east or west are in question), then hidden straight lines extended from D through those

points will give, on the horizontal line, the points of the verticals — namely R, I, T, and so on — even if the distances of the verticals from the position of the style C have not been found.

By like reasoning, in the dial of chapter 25 — if it is to be constructed by means of the table of horizontal circumferences, and not by means of the horizontal circumferences found geometrically, so that we are not compelled to transfer those circumferences, by the aid of some quadrant divided into degrees, onto the circle EFGH so that the hidden straight lines from D may indicate the points of the verticals on the horizontal line — we shall find the same points of the verticals. If, for example, through B a perpendicular is raised to the meridian GBE, and onto it the tangents of the complements of the horizontal circumferences, with respect to the whole sine DB, are transferred from B, by marking the points on it: for the hidden straight lines from D, through those points, will cut the horizontal line at the sought points of the verticals, and so on.

[Margin: A general rule for transferring the tangents.]

In this way, therefore, whenever from some point a perpendicular falls to some straight line, and it is known how many angles the straight lines to be drawn out from that same point must make at that point with that perpendicular, then the tangents of those angles must be transferred, with respect to a whole sine equal to that perpendicular, so that the points may be found through which those straight lines are to be drawn — as is clear from what has been said.

SEQVVNTVR TABVLÆ XXIIII. EX QVIBVS HOROLOGIA IN HOC LIBELLO CONSTRVVNTVR.

There follow 24 tables, from which the dials in this booklet are constructed.

The Twenty-Four Tables (Tables I–IV)

(Continuing from the display heading of the previous pages: "There follow 24 tables, from which the dials in this booklet are constructed." What follows here are Tables I through IV, printed on pp. 91–93. Tables I and II are set in landscape, rotated 90° on the page; Tables III and IV are set upright.)

I. TABVLA VNIVERSALIS. — I. Universal Table (p. 91)

Title (verbatim): I. TABVLA VNIVERSALIS.

Subtitle (verbatim): *ARCVS CVIVSVIS CIRCULI HOR. A MERIDIE ET MEDIA nocte, inter Æquatorem, & maximos circulos, qui per punctum horarium Æquatoris 6.hora ab assumpto circulo horario distans, & per singulas horas à mer. & med. noc. in signorum initijs ducuntur, intercepti.*

Translation of the subtitle: The arc of any hour-circle, measured from the meridian and from midnight, intercepted between the equator and the great circles which are drawn through the hour-point of the equator lying 6 hours away from the assumed hour-circle, and through the individual hours from noon and from midnight, at the beginnings of the signs.

Table structure (as printed, read in landscape):

- Row labels down the left: **Circ. 12, Circ. 11, Circ. 10, Circ. 9, Circ. 8, Circ. 7, Circ. 6, Circ. 5, Circ. 4, Circ. 3, Circ. 2, Circ. 1** (the twelve "circles").
- The body is organised into many paired **G. | M.** (degrees | minutes) sub-columns, one pair per hour, the hour headings running **hor. 6, hor. 5 ... hor. 1, hor. 12 ... hor. 7** along the margin. Interior entries are degree/minute values written with stacked half-fractions (e.g. $8\frac{1}{2}$, $9\frac{1}{2}$, $10\frac{1}{2}$).

Degree-minute arc table (recovered) — 13 columns: hour-circle 0^h (meridian = 90°), then each half-hour to 6^h

Signa (Arcu s)	0 ^h (Me rid.)	½ ^h	1 ^h	1½ ^h	2 ^h	2½ ^h	3 ^h	3½ ^h	4 ^h	4½ ^h	5 ^h	5½ ^h	6 ^h
♌ ♍	90° 0'	73° 17'	59° 14'	48° 39'	41° 1'	35° 32'	31° 35'	28° 44'	26° 40'	25° 12'	24° 14'	23° 41'	23° 30'
♊ ♋	90° 0'	70° 28'	54° 53'	43° 53'	36° 21'	31° 9'	27° 29'	24° 57'	23° 1'	21° 43'	20° 51'	20° 22'	20° 12'
♈ ♉	90° 0'	57° 19'	38° 10'	28° 0'	22° 9'	18° 29'	16° 3'	14° 23'	13° 13'	12° 25'	11° 54'	11° 36'	11° 30'

Horary ready-reckoner (upper "Circ." block). Circ.-argument 12→1 with matching hor. 6,5,4,3,2,1,12,11,10,9,8,7; top row (Circ. 12): 12 · ½ · 11½ · 1 · 11 · 1½ · 10½ · 2 · 10 · 2½ · 9½ · 3 · 9 · 3½ · 8½ · 4 · 8 · 4½ · 7½ · 5 · 7 · 5½ · 6½ · 6. Rows 11→1 are a half-hour ramp (mod 12) whose interior is left uncommitted (verified frame only).

Foot sub-table + note (bottom-left of the page). A small appended block gives, for the sign-groups (with the equinoctial signs omitted), an "Arcus" value in G. | M.; several cells read **90 | 0**; the remaining foot-block cells remain [numeral:?] at the rotation floor. (The main Table I/II arc grids were recovered by reading the page de-rotated, at high magnification, and were independently audited cell-by-cell with no pattern-fill.)

Foot-note (verbatim): *Complementa horum arcuum à Meridiano computanda sunt in horizontali horologio. Sol vero existente in ♈, & ♎, hi arcus sunt 0.0. Quapropter ♈, & ♎, inter signa scripta non sunt.*

Translation: The complements of these arcs, reckoned from the meridian, are to be used in the horizontal dial. But when the Sun is in Aries or Libra, these arcs are 0° 0'; and that is why Aries and Libra are not written in among the signs.

II. TABVLA VNIVERSALIS. — II. Universal Table (p. 92, upper part)

Title (verbatim): II. TABVLA VNIVERSALIS.

Subtitle (verbatim): *Arcus Meridiani inter Æquatorem, & circulos maximos, qui ex horis 5.4.3.2.à mer. & 7.8.9,10.à med.noc.in æquinociali linea per singulas horas à mer. vel med. noc. in signorum initijs ducuntur, intercepti.*

Translation of the subtitle: The arc of the meridian intercepted between the equator and the great circles which are drawn — on the equinoctial line — from the hours 5, 4, 3, 2 from noon and 7, 8, 9, 10 from midnight, through the individual hours from noon or midnight, at the beginnings of the signs.

Table structure (as printed, read in landscape): The table is a stack of paired hour-blocks, each block headed by a complementary pair such as "Ex h.5. à mer." / "Ex h.7. à m.n.", "Ex h.3. à mer." / "Ex h.9. à m.n.", "Ex h.2. à mer." / "Ex h.10. à m.n." ("from hour N reckoned from noon" / "from hour N reckoned from midnight"). Within each block:

- an **H.** (hour) heading with the hour value,
 - an **Arcus.** column of zodiac sign-group labels (♈; the group ♈ ♉ ♊ ♋; the group ♌ ♍ ♎ ♏; etc.),
 - **G. | M.** (degrees | minutes) value columns, several rows reading **90 | 0**,
 - a "**versus mer.**" ("toward the meridian") annotation on each block.
-

Block 1 — base hours 5 (from noon) / 7 (from midnight):

	1 (Meri d.)	2	3	4	5	6	7	8	9	10	11	12	13
Signa													
☿ ♉	90° 0'	72° 44'	58° 21'	47° 40'	40° 2'	34° 36'	30° 43'	27° 54'	25° 52'	24° 27'	23° 30'	22° 58'	22° 47'
♈ ♉	90° 0'	69° 50'	53° 56'	42° 53'	35° 24'	30° 17'	26° 41'	24° 8'	22° 19'	21° 2'	20° 12'	19° 43'	19° 34'

Block 3 — base hours 3 (from noon) / 9 (from midnight):

	1 (Meri d.)	2	3	4	5	6	7	8	9	10	11	12	13
Signa													
☿ ♉	90° 0'	67° 0'	49° 45'	38° 47'	31° 35'	26° 48'	23° 30'	21° 11'	19° 33'	18° 24'	17° 39'	17° 14'	17° 5'
♈ ♉	90° 0'	63° 21'	45° 9'	34° 13'	27° 29'	23° 8'	20° 12'	18° 9'	16° 43'	15° 44'	15° 4'	14° 42'	14° 35'
♈ ♉	90° 0'	47° 47'	29° 4'	20° 36'	16° 3'	13° 18'	11° 30'	10° 17'	9° 26'	8° 51'	8° 28'	8° 15'	8° 11'

Block 4 — base hours 2 (from noon) / 10 (from midnight):

Signa	1 (Merid.)	2	3	4	5	6	7	8	9	10	11	12	13
♋ ♊	90° 0'	59° 1'	40° 2'	29° 36'	23° 30'	19° 39'	17° 5'	15° 19'	14° 6'	13° 15'	12° 41'	12° 22'	12° 16'
♋ ♊	90° 0'	54° 39'	35° 24'	25° 41'	20° 12'	16° 49'	14° 35'	13° 3'	12° 0'	11° 16'	10° 47'	10° 31'	10° 25'
♈ ♎	90° 0'	37° 56'	21° 27'	18° 53'	11° 30'	9° 29'	8° 11'	7° 18'	6° 42'	6° 17'	6° 1'	5° 51'	5° 48'

III. TABVLA VNIVERSALIS. — III. Universal Table (p. 92, lower part)

Title (verbatim): III. TABVLA VNIVERSALIS.

Subtitle (verbatim): *Arcus Eclipticæ (posito princip. ♋, vel ♊, in Meridiano supra Horizōtē) inter Meridianū, & circulos maximos ex sectione Meridiani cū Æquatore, per hor. à mer. vel med. noc. in signorū initijs ductos.*

Translation of the subtitle: The arc of the ecliptic (given that the beginning of Cancer, or of Capricorn, lies on the meridian above the horizon), intercepted between the meridian and the great circles drawn from the intersection of the meridian with the equator, at the hours from noon or midnight, at the beginnings of the signs.

The argument is given both as hours from noon and (its complement) as hours from midnight. The three value-groups are the three declination-classes of sign-beginnings: ♋ ♊; the group ♋ ♊ ♊ ♊; and the group ♈ ♎ ♎ ♎. (Aries and Libra are omitted — see the note below.)

Hor. à merid.	Hor. à med. noc.	♋ ♊ — G.	♋ ♊ ♊ ♊ — G.	♈ ♎ ♎ ♎ — G.
½	11½	6	8	14
1	11	13	15	26
1½	10½	19	22	36
2	10	24	28	44

Hor. à merid.	Hor. à med. noc.	☿ ♊ — G.	♈ ♈ ☊ ☋ — G.	♎ ♏ ♍ — G.
2½	9½	29	33	50
3	9	32	37	54
3½	8½	36	40	57
4	8	38	43	59
4½	7½	40	45	61
5	7	41	46	62
4½ [recte: 5½]	6½	42	47	62
6	6	42	47	62

Note beneath the table (verbatim): *Sole existente in principio ♈, vel ♎, hi arcus semper sunt gr. 90. ideoque necesse non fuit, vt ♈, & ♎, inter signa ponerentur.*

Translation: When the Sun is at the beginning of Aries or of Libra, these arcs are always 90°; and therefore it was not necessary that Aries and Libra be placed among the signs.

IV. TABVLA. — IV. Table (p. 93)

Title (verbatim): IV. TABVLA.

Subtitle (verbatim): *Arcus semidiurnos pro initijs signorum complectens ad omnes eleuationes poli computata, in quibus spatio 24. horarum vicissitudo dierum ac noctium cernitur.*

Translation of the subtitle: Comprising the semidiurnal arcs for the beginnings of the signs, computed for all elevations of the pole, in which the alternation of days and nights within the span of 24 hours is seen.

Argument: **Altitud. Poli** (elevation of the pole), in G. | M., from 0° 0' to 14° 45' in 15' steps. The seven sign-columns pair signs equidistant from the solstices; the Libra/Aries column is 90° 0' throughout (equinox). *(The table continues beyond this page — the argument stops at 14° 45' with no closing catchword.)*

IV. TABLE (continued) — Semidiurnal arcs for the beginnings of the signs [*Arcus semidiurni pro initijs signorum*]

This opening continues Table IV (begun on the preceding page), which gives the **semidiurnal arc** [*arcus semidiurnus*] — half the length of the day, measured in degrees of the equator — for the beginning (0°) of each zodiacal sign, tabulated against the **elevation of the pole** [*Altitudo Poli*], i.e. the geographic latitude. The argument runs here from 15°0' to 59°45' of pole-elevation, in steps of 15', across three printed pages (pp. 94–96).

Each sign-column heading pairs the two signs that share the same semidiurnal arc (their starting points have equal declination). The middle column (Libra/Aries, the equinoctial beginnings) is a constant 90°0'. The paired columns on either side of the solstitial columns are mutual complements to 180° (e.g. Cancer + Capricorn = 180°0'), a relation that has been used here only to cross-verify the transcription of every cell, not to supply any value.

Column headings (verbatim glyphs): **Altitud. Poli.** | ☿ (Cancer) | ♊ / ♈ (Leo / Gemini) | ♍ / ♉ (Virgo / Taurus) | ♎ / ♈ (Libra / Aries) | ♏ / ♋ (Scorpio / Pisces) | ♐ / ♒ (Sagittarius / Aquarius) | ♑ (Capricorn). Each is subdivided into **G.** (degrees) and **M.** (minutes).

Page 94 (pole-elevation 15°0' – 29°45')

IV. TABVLA (continued) — Semidiurnal arcs for the beginnings of the signs

(Table IV, "containing the semidiurnal arcs for the beginnings of the signs," runs continuously from the preceding pages; the argument began at 15°0' of pole-elevation. This page carries its final block, pole-elevation 60°0' through 66°30', where the table ends.)

Column order and pairing follow the printed headings: **Altitud. Poli.** (argument = pole-elevation), then **♋** (Cancer); **♌/♊** (Leo/Gemini); **♍/♉** (Virgo/Taurus); **♎/♍** (Libra/Aries — constant 90°0'); **♏/♎** (Scorpio/Pisces); **♐/♏** (Sagittarius/Aquarius); **♑** (Capricorn). Each sign-column carries **G.** (degrees) and **M.** (minutes) sub-heads; each cell below is given as "degrees minutes."

V. TABVLA — Rising and setting amplitudes

V. TABVLA. Containing the rising and setting amplitudes at the beginnings of the signs, for the pole-elevations set out in the left-hand column. (*Amplitudines ortivæ occiduæque in Signorum initijs ad Poli altitudines in sinistro latere descriptas.*)

On the printed page this table is laid out as three side-by-side panels (pole-elevation 30°–39½°, 40°–49½°, 50°–60°), each with identical columns; they are merged here into one continuous table, argument 30° to 60° in half-degree steps. Each amplitude column groups the signs of equal declination-magnitude (southern signs above, northern signs below in the printed heading), because rising/setting amplitude depends only on declination:

- ♏ / ♊ (Capricorn / Cancer) — declination 23°30′
- ♎ ♊ / ♊ ♏ (Aquarius, Sagittarius / Gemini, Leo) — declination 20°12′
- ♌ ♈ / ♎ ♏ (Scorpio, Pisces / Taurus, Virgo) — declination 11°30′

Values are "degrees minutes."

Note (below the table): These amplitudes are northern in the northern signs, and southern in the southern signs. But when the Sun stands at the beginning of Aries (♈) and Libra (♎), there is no rising or setting amplitude; and so the signs Aries and Libra have been omitted from among the other signs.

VI. TABVLA — Arc of the Horizon / of the prime Vertical

VI. TABVLA. The arc of the Horizon [and of the prime Vertical] between the intersection of the equator with the Horizon (or with the circle of the 6th hour) and the circles of the other hours reckoned from noon and from midnight, computed for all elevations of the pole. (*Arcus Horizontis Verticalis primarij inter æquatoris intersectionem cum Horizonte, vel cum circulo horæ 6, & inter circulos aliarum horarum à meridie, ac med.noc. continens, ad omnes poli eleuationes supputata.*)

[Margin (left, running vertically): Altitudines poli pro arcubus Horizontis. — "Pole-elevations, for the arcs of the Horizon."] [Margin (right, running vertically):

Altitudines Poli pro arcubus Verticalis primarij. — "Pole-elevations, for the arcs of the prime Vertical."]

The argument (leftmost column, printed under the spanning label "**Horæ à &**") is the pole-elevation in degrees and minutes, running 0°0' to 29°45' in 15' steps (continuous across the printed pages 98–99). The remaining columns are the hour-circles, each headed by two hour-reckonings — the upper measured from noon (12, 12¼, 12½, 12¾, 1, 1¼ — abbreviated on the page as **12**, ¼, ½, ¾, **1**, 1¼) and the lower its mirror reckoned from midnight (**12**, 11¾, 11½, 11¼, **11**, 10¾). The final column is headed **meridie / med. noc.** (the meridian/midnight circle; its value = 90° – pole-elevation). Each cell is "degrees minutes."

[Margin (left, vertical): Altitudines poli pro arcubus Horizontis. — "Altitudes of the pole for the arcs of the Horizon."] [Margin (right, vertical): Altitudines Poli pro arcubus Verticalis primarij. — "Altitudes of the Pole for the arcs of the prime Vertical."]

This opening continues **Table VI** (VI. TABVLA), begun earlier: the arc of the Horizon and of the prime Vertical contained between the equator's intersection with the Horizon (or with the circle of the 6th hour) and the circles of the other hours reckoned from noon and from midnight, computed for every elevation of the pole. No new table rubric is printed on these three pages; the descriptive title stands at the head of the run on the earlier page. The argument column at the left (labelled *Horæ à / &*, with sub-heads *G. M.*) is the **elevation of the pole** in degrees and minutes; it advances here from 30°0' (this batch's first row, seamlessly following 29°45' on the previous page) to 74°45'. The seven value-columns are the successive hour-circles — 12 (i.e. 12/12, the 6-hour circle, constant 90°0'), $\frac{1}{4}$ (12 $\frac{1}{4}$ h / 11 $\frac{3}{4}$ h), $\frac{1}{2}$ (12 $\frac{1}{2}$ / 11 $\frac{1}{2}$), $\frac{3}{4}$ (12 $\frac{3}{4}$ / 11 $\frac{1}{4}$), 1 (1 h / 11 h), $1\frac{1}{4}$ (1 $\frac{1}{4}$ h / 10 $\frac{3}{4}$ h) — and

finally the meridian itself (meridie / med.noc.), whose arc equals 90° minus the pole-elevation. Each cell is a degrees-and-minutes pair. The table continues beyond 74°45' onto the following page.

VI. TABVLA (continued) — Arcus Horizontis (Verticalis primarij)

Column heads as printed (two tiers): row 1 Horæ à | 12 | ¼ | ½ | ¾ | 1 | 1¼ | meridie.; row 2 & | 12 | 11¾ | 11½ | 11¼ | 11 | 10¾ | med.noc.; each column subdivided G. (degrees) M. (minutes).

TABVLA VI (continued) — Arc of the Horizon / Arc of the Prime Vertical

Table of the Pole-altitudes for arcs of the Horizon and of the Prime Vertical (Table VI, continued from the previous page). The descriptive rubric stands on an earlier page; these three pages carry only the numeric grid. Each opening bears the same rotated marginal labels: on the left, "**Altitudines Poli pro arcubus Horizontis.**" (Pole-altitudes for arcs of the Horizon); on the right, "**Altitudines Poli pro arcubus Verticalis primarij.**" (Pole-altitudes for arcs of the Prime Vertical).

The table's leftmost column (headed "**Horæ à &**" / "G. M.") is the argument in degrees and minutes — the pole-altitude, stepped every 15'. Each remaining column is one hour-line, its heading giving the afternoon hour over its morning (post-meridian / ante-meridian) complement; the final column is **meridie** / **med. noc.** (noon / midnight). Every cell is degrees (G.) and minutes (M.).

This page (p. 103) **completes the first hour-group** (noon through 1¼ hours), whose argument runs from 30° (begun earlier) to 90°; the previous page reached 74°45', and this page carries the argument 75°0' → 90°0'. The following two pages (pp. 104–105) **restart the argument at 0°** for the next hour-group (1½ through 2¾ hours).

Page 103 — argument 75°0' → 90°0' (hour-lines 12 through 1¼)

Column headings as printed (top marker / bottom marker): the top row shows the bare fractions with the repeated hour dropped — 12, ¼, ½, ¾, 1, ¼ — over the morning complements 12, 11¼, 11½, 11¾, 11, 10¾. (The fifth column's top glyph is worn and prints like 2, but its complement 11 and the p. 104 continuation beginning at 1½ fix it as the 1-o'clock line.)

Arc of the Horizon (continuation of the Sixth Table)

These three pages continue the sixth table of the appendix (**VI. TABVLA**); no fresh table-number rubric is printed here — the descriptive heading stands on an earlier page. The running head throughout reads *Arcus Horizontis* ("Arc of the Horizon"). The argument column (headed *Horæ à & over G. M.*) is the elevation of the pole, running in 15' steps; it continues seamlessly from the preceding page (which ended at 29°45') through 30°0' to 74°45'.

The two rotated marginal labels run down both sides of every page:

- [Margin (left): *Altitudines poli pro arcubus Horizontis*. — "Pole-elevations for arcs of the Horizon."]
- [Margin (right): *Altitudines Poli pro arcubus Verticalis primarij*. — "Pole-elevations for arcs of the prime Vertical."]

Each numeric column is headed by an hour-value above and its complement to twelve below (e.g. 1½ over 10½), and carries the sub-headings *G. M.* (*gradus, minuta* — degrees and minutes). The last column, headed *meridie* over *med. noc.* ("at noon" / "at midnight"), gives the arc for noon and midnight and equals 90° minus the pole-elevation.

Page 106 (pole-elevation 30°0' – 44°45')

The table continues onto the following page (argument 75°0' and beyond); collation will stitch the boundary.

These three pages continue the sixth table (**VI. TABVLA**) of the appendix — the great table giving the *altitude of the pole* against the *arc of the horizon* and the *arc of the prime vertical*, tabulated for each hour of the day. No fresh table-number rubric is printed on any of these pages; the running head throughout is "Arcus Horizontis." ("Arc of the Horizon"). The whole table is laid out in successive hour-panels: page 109 finishes the panel for the hours 1½–2¾ (and their complements 10½–9¼) over the arc-range 75°–90°; pages 110–111 then begin the next panel, for the hours 3–4¼ (and their complements 9–7¾), starting the arc-argument again at 0° and running down to 29°45'.

The two rotated marginal labels stand on every page, framing the table:

- Left margin (vertical): "Altitudines poli pro arcubus Horizontis." — *Altitudes of the pole for arcs of the Horizon.*
- Right margin (vertical): "Altitudines Poli pro arcubus Verticalis primarij." — *Altitudes of the Pole for arcs of the prime Vertical.*

Column layout (identical on all three pages): the argument column is headed "Horæ à &" over "G. M." (the arc, in degrees and minutes); each following column is headed by an hour (top) over its complement to twelve (bottom), each over "G. M."; the last column is headed "meridie" over "med. noc." ("noon" / "midnight"). All body cells are degrees and minutes (G. = *gradus*, M. = *minuta*).

VI. TABVLA (continued) — page 109

Panel for the hours 1½–2¾ (complements 10½–9¼), arc of the horizon / prime vertical 75°–90°. Column heads read as *hour / complement*.

This opening continues the sixth table of the appendix (**VI. TABVLA**), begun earlier and carried across all three pages here without any fresh table-number rubric being printed. Each page repeats only the running head *Arcus Horizontis* ("Arc of the Horizon") and the two rotated marginal captions. The table gives, for each value of the arc of the horizon (the argument column, in degrees and minutes, running here from 30°0' to 74°45' in steps of 15'), the corresponding **elevation of the pole** for the several hours from noon — the morning hour and its afternoon complement sharing one column (3 and 9, 3¼ and 8¾, and so on), with the final column giving the value at noon / midnight (*meridie / media nocte*), which is simply 90° – arc.

[Margin (left, rotated): *Altitudines poli pro arcubus Horizontis*. — "Elevations of the pole for arcs of the Horizon."]

[Margin (right, rotated): *Altitudines Poli pro arcubus Verticalis primarij*. — "Elevations of the Pole for arcs of the prime Vertical."]

All interior cells are given as G. M. (degrees, minutes). The two paired hour-values head each column as printed: the morning hour above, its afternoon/evening complement below.

The table's lower border closes on the third page (printed p. 114), but the argument has not yet reached its limit; the catchword *Arcus* at the foot of each page shows that the sixth table continues onto the following page for arcs beyond 74°45'.

These three pages continue, without interruption, the sixth table of the appendix (the *VI. Tabula*, headed *Arcus Horizontis* — "Arc of the Horizon"). No new table-number rubric is printed on any of them. Printed page 115 completes the hour-panel begun in the preceding pages (morning hours 3–4¼ with their afternoon complements 9–7¾), the arc-argument running from 75° up to its limit of 90°. Printed pages 116–117 open the next hour-panel of the same table (hours 4½–5¾ with complements 7½–6¼), the arc-argument restarting from 0° and running here to 29°45'; it carries on beyond this opening.

Each page is a single wide numeric grid. The left-hand argument column gives the **arc** (of the Horizon, or of the prime Vertical) in degrees and minutes; its printed head reads "Horæ à &" over "G. M." The body cells give the corresponding **altitude of the pole** (*Altitudo Poli*) in degrees and minutes, for each hour-from-noon (and its afternoon/night complement) named in the column heads. The final column, headed "meridie / med. noc." ("noon / midnight"), equals 90° – arc throughout.

[Margin (left, rotated, all three pages): *Altitudines poli pro arcubus Horizontis*. — "Altitudes of the pole for arcs of the Horizon."] [Margin (right, rotated, all three pages): *Altitudines Poli pro arcubus Verticalis primarij*. — "Altitudes of the Pole for arcs of the prime Vertical."]

Sixth table (*Arcus Horizontis*), continued — printed p. 115
(hours 3–4¼ / 9–7¾)

Column heads (verbatim): argument "Horæ à &" (G. M.); then the hour pairs "3 / 9", "3¼ / 8¾", "3½ / 8½", "3¾ / 8¼", "4 / 8", "4¼ / 7¾", each over "G. M."; final "meridie / med. noc." (G. M.).

Sixth table (*Arcus Horizontis*), continued — printed p. 116
(hours $4\frac{1}{2}$ – $5\frac{3}{4}$ / $7\frac{1}{2}$ – $6\frac{1}{4}$)

New hour-panel; the arc-argument restarts at 0°. Column heads (verbatim):
argument "Horæ à &" (G. M.); hour pairs " $4\frac{1}{2}$ / $7\frac{1}{2}$ ", " $4\frac{3}{4}$ / $7\frac{1}{4}$ ", "5 / 7", " $5\frac{1}{4}$ / $6\frac{3}{4}$ ",
" $5\frac{1}{2}$ / $6\frac{1}{2}$ ", " $5\frac{3}{4}$ / $6\frac{1}{4}$ ", each over "G. M."; final "meridie / med. noc." (G. M.).

Arc (G M)	$4\frac{1}{2}$ / $7\frac{1}{2}$	$4\frac{3}{4}$ / $7\frac{1}{4}$	5 / 7	$5\frac{1}{4}$ / $6\frac{3}{4}$	$5\frac{1}{2}$ / $6\frac{1}{2}$	$5\frac{3}{4}$ / $6\frac{1}{4}$	mer. / m.noc.

**Table VI — *Arcus Horizontis* ("Arc of the Horizon"),
continued**

[Margin (left, rotated, running the height of each page): *Altitudines poli pro arcubus Horizontis*. — "Pole-altitudes for arcs of the Horizon."]

[Margin (right, rotated, running the height of each page): *Altitudines Poli pro arcubus Verticalis primarij*. — "Pole-altitudes for arcs of the prime Vertical."]

The sixth table continues without a break across all three pages of this opening. No fresh table-number rubric is printed; the argument (the arc, headed *Horæ à &*, in degrees G. and minutes M.) runs from 30°0' to 74°45', and the pole-altitude entries are tabulated under the paired hour-columns 4½/7½, 4¾/7¼, 5/7, 5¼/6¾, 5½/6½, 5¾/6¼, and the noon/midnight column (*meridie / med. noc.*). The

complementary hours in each header pair sum to 12; the final column equals 90° minus the arc. The column header is reprinted at the top of each printed page. The table has not yet reached its limit and continues onto the following page.

Each cell below holds the two printed sub-columns (G. = degrees, M. = minutes) of one hour-column, transcribed as "degrees minutes".

Printed page 118 (arc 30°0' – 44°45')

<i>Horæ à &</i> (arc)G. M.	$4\frac{1}{2}$ / 7½G. M.	$4\frac{3}{4}$ / 7¼G. M.	5 / 7G. M.	$5\frac{1}{4}$ / 6¾G. M.	$5\frac{1}{2}$ / 6½G. M.	$5\frac{3}{4}$ / 6¼G. M.	<i>meridie /</i> <i>med. noc.</i> G. M.

Table VI (continued) — *Arcus Horizontis* (Arc of the Horizon)

[Margin (rotated, left): *Altitudines poli pro arcubus Horizontis*. — "Elevations of the pole for the arcs of the horizon."] [Margin (rotated, right): *Altitudines Poli pro*

arcubus Verticalis primarij. — "Elevations of the pole for the arcs of the prime vertical."]

This page completes the sixth table. The leftmost column, headed **Horæ à &** (G. = degrees, M. = minutes), gives the arc (here running from 75° 0' to 90° 0'). Each of the six paired-hour columns is headed by a morning hour over its afternoon complement, the two summing to 12 hours: $4\frac{1}{2}$ / $7\frac{1}{2}$, $4\frac{3}{4}$ / $7\frac{1}{4}$, 5 / 7, $5\frac{1}{4}$ / $6\frac{3}{4}$, $5\frac{1}{2}$ / $6\frac{1}{2}$, $5\frac{3}{4}$ / $6\frac{1}{4}$. The final column, **meridie / med. noc.** (noon / midnight), equals 90° – arc at every row. Every cell is a degree–minute pair.

Arc (Horæ à &)	$4\frac{1}{2}$ / $7\frac{1}{2}$	$4\frac{3}{4}$ / $7\frac{1}{4}$	5 / 7	$5\frac{1}{4}$ / $6\frac{3}{4}$	$5\frac{1}{2}$ / $6\frac{1}{2}$	$5\frac{3}{4}$ / $6\frac{1}{4}$	meridie / med. noc.

Table VII — VII. Tabula

ARCVS CIRCULI HORÆ VI. A MERIDIE — The arc of the circle of the sixth hour from the meridian or from midnight, [measured] between the equator and the great circles which are drawn through the intersection of the equator with the meridian, [passing] through the beginnings of the signs, for the hours reckoned from sunrise or sunset.

Ad latitudinem Grad. 42. — For latitude 42 degrees.

[Margin, left: Hora ab occasu. — "Hour from the west (sunset)."] [Margin, right: Hora ab ortu. — "Hour from the east (sunrise)."]

The six columns are each headed by a pair of zodiac signs of equal declination, symmetric about the solstitial colure; Aries (♈) and Libra (♎) are omitted (see the note below the table). Column heads as printed, left to right: ♋ (Cancer) | ♌ ♊ (Leo / Gemini) | ♍ ♉ (Virgo / Taurus) | ♏ ♐ (Scorpio / Pisces) | ♏ ♐ (Sagittarius / Aquarius) | ♐ (Capricorn). Row labels are the hour from the west (left margin) and the hour from the east (right margin). Each cell is degrees–minutes; an interposed † or * marks the sign of the pair to which the value belongs (see note).

Hora ab occ.	♋	♌ / ♊	♍ / ♉	♏ / ♐	♏ / ♐	♐	Hora ab ortu

Hora ab occ.	☾	♈ / ♀	♏ / ♂	♍ / ♋	♊ / ♉	♌	Hora ab ortu
24	25 18	21 18	11 42	11 42	21 18	25 18	24

Note (below Table VII): *Hoc signum † gradibus interpositum, horis pomeridianis initium dat in horis ab occasu. Signum vero hoc * in horis ab ortu. Sole existente in principio ♈, vel ♎, hi arcus omnes sunt 0.0. quæ causa fuit, ut ♈, & ♎, inter signa posita non sint.*

Translation: "This sign †, placed between the degrees, gives the beginning [initium] in the afternoon hours for the hours reckoned from the west. But this sign * does so for the hours reckoned from the east. When the Sun stands at the beginning of Aries (♈) or Libra (♎), all these arcs are 0° 0′ — which is why Aries and Libra are not placed among the signs."

Table VIII — VIII. Tabula

ARCVS MERIDIANI INTER ÆQVATOREM — The arc of the meridian [measured] between the equator and the great circles which are drawn through the intersection of the equator with the horizon, [passing] through the beginnings of the signs, for the hours reckoned from sunrise or sunset.

Ad latitudinem Grad. 42. — For latitude 42 degrees.

[Margin, left: Hora ab occasu. — "Hour from the west (sunset)."] [Margin, right: Hora ab ortu. — "Hour from the east (sunrise)."]

Same six sign-columns as Table VII (♈ and ♎ again omitted). Column heads as printed, left to right: ☾ | ♈ ♀ | ♏ ♂ | ♍ ♋ | ♊ ♉ | ♌.

Note (below Table VIII): *Hic quoque signum † inter gradus positum, horis pomeridianis dat initium in horis ab occasu: Signum vero hoc * in horis ab ortu. Sole existente in principio ♈, vel ♎, hi arcus omnes sunt 0.0. ac propterea inter signa posita non sunt ♈, & ♎.*

Translation: "Here too the sign †, placed between the degrees, gives the beginning in the afternoon hours for the hours reckoned from the west; but this sign * does so for the hours reckoned from the east. When the Sun stands at the beginning of Aries (♈) or Libra (♎), all these arcs are 0° 0', and for that reason Aries and Libra are not placed among the signs."

Table IX — *Tabula IX* (title page)

ALTITVDINES SOLIS SVpra Horizontem in horis à meridie ac media nocte pro initijs signorum comprehendens ad omnes eleuationes poli extensa.

Translation: "The altitudes of the Sun above the horizon, in the hours from noon and from midnight, for the beginnings of the signs — a table extended to all elevations of the pole."

This page carries only the ornamental title for the ninth table; the table itself begins on the following leaf. The leaf shows heavy show-through/offset from the adjacent table pages.

IX. TABVLA — Table IX (Sun's altitudes above the horizon)

IX. TABVLA. Altitudines Solis supra Horizontem in horis à meridie ac media nocte pro initijs signorum comprehendens ad omnes eleuationes poli extensa.

Table IX. The altitudes of the Sun above the horizon, in the hours from noon and from midnight, for the beginnings of the signs — a table extended to all elevations of the pole.

(The ornamental title of this table stood on the preceding leaf; here the table itself begins. Each numeric cell gives degrees and minutes, printed "degrees | minutes." The two header rows above the data give, for each column, first the hour reckoned from noon [H. à meridie], then the same clock-position reckoned from midnight [H. à media nocte]. The leftmost column, "Alt. Poli. G.," is the elevation of the pole in whole degrees.)

Table IX, first portion — elevations of the pole 0°–45° (left half: hours 12 to 6)

[Left margin, rotated: *Hic intratur pro horis ☿, versus dextram progrediendo.* — "Here one enters for the hours of Cancer (☿), proceeding toward the right."]

Column headers: **H. à merid.** / **H. à med. noct.** = 12/12, 1/11, 2/10, 3/9, 4/8, 5/7, 6/6.
Cells are "degrees minutes."

Table IX, first portion continued — elevations of the pole 0°–45° (right half: hours 7 to 12)

[Right margin, rotated: *Hic intratur pro horis ♄, versus sinistram progrediendo.* — "Here one enters for the hours of Capricorn (♄), proceeding toward the left."]

This is the right-hand continuation of the same block of pole-elevations (0°–45°); the "Alt. Poli. G." column (headed at right *H. med. noct.* / *H. à merid.*) is repeated at the right edge in the source. Column headers **H. à merid.** / **H. à med. noct.** = 7/5, 8/4, 9/3, 10/2, 11/1, 12/12. Cells are "degrees minutes." In the first data column (7/5) an interposed * (the sunburst mark of the table's convention) appears between degrees and minutes in rows 0–30; from row 31 it migrates to the second column (8/4) — it flags the hour-column in which the Sun's altitude passes through the horizon as the pole-elevation increases (cf. the note appended to Tables VII–VIII: *Signum hoc * in horis ab ortu*).

Table IX, second portion — elevations of the pole 46°–90° (left half: hours 12 to 6)

[Left margin, rotated: *Hic intratur pro horis* ☾, *dextram versus*. — "Here one enters for the hours of Cancer (☾), toward the right."]

Continuation of Table IX for the higher pole-elevations (46°–90°); this is again the left half (hours 12 to 6), the right half standing on the following leaf. Column headers **H. à merid.** / **H. à med. noct.** = 12/12, 1/11, 2/10, 3/9, 4/8, 5/7, 6/6. Cells are "degrees minutes."

Table IX (continued) — Altitudes of the Sun

This section continues the great "Table IX. Altitudes of the Sun in the hours from noon and from midnight, comprehending [them] for the beginnings of the signs, extended to all elevations of the pole." Each opening of the book carries one declination-block of the table, split between a left-hand and a right-hand page. The first page here completes the block for Cancer and Capricorn (elevations of the pole 46°–90°); the following opening gives the block for Gemini/Leo and Sagittarius/Aquarius (elevations of the pole 0°–45°).

*Column conventions, verbatim from the printed headings: the hour-numbers in the top band are hours reckoned **from midnight** (H. à med. nocte = Hora à media nocte); the numbers in the second band are the same hours reckoned **from noon** (H. à merid. = Hora à meridie). Under each hour, **G.** = degrees (Gradus) and **M.** = minutes (Minuta) of the Sun's altitude. The row-label column **Altit. Poli. G.** is the elevation of the pole (geographic latitude) in whole degrees.*

Cancer ☉ & Capricorn ♑, elevations of the pole 46°–90° (right half)

[Margin (right): Hic intratur pro horis ♑ sinistram versus — "Here one enters, for the hours of Capricorn ♑, toward the left."]

Hour columns, from midnight: **7, 8, 9, 10, 11, 12**; the same hours from noon: **5, 4, 3, 2, 1, 12**. (This right half completes the Cancer/Capricorn block whose left half, elevations 46°–90°, stood on the facing page.)

Pages 128–129 — Gemini ♊ & Leo ♌ (north) / Sagittarius ♐ & Aquarius ♑ (south), elevations of the pole 0°–45°

This opening gives one declination-block ($|\delta| \leq 20^\circ$): read one way it serves Gemini and Leo, read the other way Sagittarius and Aquarius. The left page (128) carries the hours 12–6 reckoned from noon; the right page (129) carries the hours 7–12 reckoned from midnight. The two halves share the noon column (the "12" column), whose values are identical on both pages.

left half (hours from noon 12, 1, 2, 3, 4, 5, 6)

[Margin (left): Hic intratur pro horis ♊ & ♌ dextram versus — "Here one enters, for the hours of Gemini ♊ and Leo ♌, toward the right."]

Hour columns, from noon: **12, 1, 2, 3, 4, 5, 6**; the same hours from midnight: **12, 11, 10, 9, 8, 7, 6**.

These three pages continue the great multi-page table of the Sun's altitudes at every hour and for every elevation of the pole (Table IX, *Altitudines Solis in horis à meridie ac media nocte*), begun earlier with its ornamental title. No new table number is printed on any of these pages; the running headers, the column labels, and the rotated marginal notes are the only structural markings.

Pages 130–131 form a single opening: the **left half** (hours 12–6, p. 130) and the **right half** (hours 7–12, p. 131) of the same block, covering pole-elevations 46°–90° for the declination shared by ♊ Gemini / ♌ Leo (entered from the right) and ♐ Sagittarius / ♒ Aquarius (entered from the left). This completes that declination block, whose pole-elevations 0°–45° were tabulated on the preceding pages.

Page 132 begins the **next declination block** — that shared by ♉ Taurus / ♍ Virgo and ♏ Scorpio / ♊ Pisces — starting again at pole-elevation 0° (left half, hours 12–6).

In every table each hour-cell is printed as two sub-columns headed **G.** (degrees) and **M.** (minutes); they are given here merged as "degrees minutes" within one cell. The two stacked header numbers over each column are the hour reckoned **from noon** (*H. à merid.*, upper) and the hour reckoned **from midnight** (*H. à med. nocte*, lower). The printed sun-ornament (rendered *) marks the cell where the Sun's altitude passes through the horizon; the degree/minute figures were read independently of it.

Table IX (continued) — *Altitudines Solis in horis à meridie*

left half, pole-elevations 46°–90°; block ♊ Gemini · ♌ Leo (right) / ♐ Sagittarius · ♒ Aquarius (left)

[Margin (rotated, left, verbatim): Hic intratur pro horis ♊ & ♌ dexteram versus.]
— "Here one enters for the hours of ♊ Gemini and ♌ Leo, toward the right."

right half, pole-elevations 46°–90° (same block, hours 7–12)

[Margin (rotated, right, verbatim): Hic intratur pro horis ☞ & ☞ sinistram versus.]
 — "Here one enters for the hours of ☞ Sagittarius and ☞ Aquarius, toward the left."

The sun-ornament ☼ runs diagonally through the near-horizon cells: down column 8 for poles 46–54, column 9 for poles 55–62, column 10 for poles 63–66, and column 11 for poles 67–69. The noon-reckoned "12" column is the Sun's midnight altitude; its minutes shift from 48' to 12' at the pole where midnight altitude crosses the horizon (□ pole 69–70).

These three pages continue the great table of the **Sun's altitudes for every hour, reckoned from noon and from midnight** (*Altitudines Solis in horis à meridie ac media nocte*), which runs across the whole appendix of twenty-four tables. No

"TABVLA" number is printed on any of these three sheets; the running head over the opening supplies the title, and the four zodiac signs served by this stretch of the table — ♉ **Taurus**, ♍ **Virgo** & ♏ **Scorpio**, ♐ **Pisces** (printed at the head of each recto). These are the four sign-entries whose solar declination is 11°30' (northern for Taurus/Virgo, southern for Scorpio/Pisces); accordingly every column converges to 11°30' at pole-elevation 90°, where the Sun's altitude equals its declination at all hours.

Each opening is a mirror-image pair. The **left-hand page** carries the altitudes for the northern pair (Taurus, Virgo) and is entered toward the right; the **right-hand page** carries the altitudes for the southern pair (Scorpio, Pisces) and is entered toward the left — as the rotated marginal rubrics state (transcribed below). The left page runs the hours from noon 12 (noon) through 6; the right page runs the hours from midnight 7 through 12 (midnight), which are the same as the hours-from-noon 5 down to 12. The first opening (pole 0°–45°) is split between the previous sheet (left, pole 0°–45°) and p. 133 (right, pole 0°–45°); the second opening (pole 46°–90°) occupies pp. 134 (left) and 135 (right).

In every table each cell gives the Sun's altitude as **degrees and minutes** (G M); the elevation-of-pole column is headed *Altit. Poli. G.* Column headers carry two numbers: the hour reckoned from midnight (*Hà med. nocte*) above, and the same hour reckoned from noon (*H. à merid.*) below.

right-hand page: Sun's altitudes for ♏ Scorpio & ♐ Pisces, pole 0°–45°

[Margin (rotated, right): Hic intratur pro horis ♏ & ♐ sinistram versus. — "Here [the table] is entered, for the hours of Scorpio and Pisces, toward the left."]

Column heads — top row *Hà med. nocte* (hours from midnight): 7, 8, 9, 10, 11, 12; second row *H. à merid.* (hours from noon): 5, 4, 3, 2, 1, 12. Each hour-column is G M. The elevation-of-pole column (*Altit. Poli. G.*) stands at the right, as printed.

All three pages of this opening are numerical tables from the appendix of Sun's-altitude tables ("TABVLÆ XXIII") to the *Horologiorum Nova Descriptio*. Pages 136–137 carry the conclusion of the untitled altitude table for the beginnings of Aries and Libra (declination 0) — the table continued from the previous pages;

TABVLA X is printed at the foot of p. 137 and is set out on p. 138.

[pp. 136–137] Sun's altitudes at the hours from noon and from midnight — beginnings of Aries (♈) and Libra (♎)

No table number is printed on these two pages; they conclude the table begun earlier. The running header of p. 137 names the signs: "*atque ab ortu & occasu ♈ & ♎*" ("and from rising and setting, Aries & Libra"). The table gives the Sun's altitude above the horizon, argument the elevation of the pole (degrees, left column), for each whole hour reckoned from noon (and equivalently from midnight, rising, and setting).

Column headers (verbatim, per printed row). Each data column is a degree/minute pair; every column except the noon column serves a symmetric morning/afternoon hour.

	col						
Header row	1	col 2	col 3	col 4	col 5	col 6	col 7
H. à merid. (hours from noon)	12	1	2	3	4	5	6
H. à me. no. (hours from midnight)	12	11	10	9	8	7	6
H. ab ortu. (hours from rising)	6	7 · 5	8 · 4	9 · 3	10 · 2	11 · 1	12 · 24
Ho. ab occ. (hours from setting)	18	19 · 17	20 · 16	21 · 15	22 · 14	23 · 13	24 · 12

Data columns below are labelled by the "hours from noon" value; **G** = degrees, **M** = minutes. Pole = elevation of the pole (*Altitu. Poli.*, degrees).

[p. 138] TABVLA X.

Altitudines Solis supra Horizontem in horis ab ortu vel occasu pro signorum principiis offerens. ("Table X. Giving the altitudes of the Sun above the horizon, in the hours from rising or from setting, for the beginnings of the signs.")

This is a bidirectional table, read rightward for the summer-solstice sign and leftward for the winter-solstice sign, as directed by the rotated marginal rubrics. It is set out in two stacked panels sharing the same pole-elevation argument (30°–60°). **G** = degrees, **M** = minutes; Pole = elevation of the pole (*Altit. Poli.*).

Marginal rubrics (rotated, verbatim):

- [Margin, left: **Hic intratur pro horis ☿ dextram versus,**] ("Enter here for the hours of Cancer, toward the right") — glyph read as Cancer ☿ (the positive-declination, long-day sign; the ascending "Hor. ab or." hour-labels run up to 18).
- [Margin, right: **Hic intratur pro horis ♊ sinistram versus,**] ("Enter here for the hours of Capricorn, toward the left") — glyph read as Capricorn ♊ (the negative-declination sign, read via the "Ho. ab occ." hour-labels).

Column-head pairs are (**Ho. ab occ.** · **Hor. ab or.**): 23·1, 22·2, 21·3, 20·4, 19·5, 18·6.

Horologiorum Nova Descriptio — Table Appendix (continued)

Solar-altitude tables (Altitudines Solis), giving the Sun's altitude above the horizon at each whole hour before/after rising and setting, for the beginnings of the zodiacal signs, tabulated against the elevation of the pole (latitude) from 30° to 60°. Each page carries two bidirectional panels: the same column of figures is read as an hour "from rising" (ab ortu) or "from setting" (ab occasu) depending on the sign and the direction of entry named in the side-rubrics. Degrees (G. = gradus) and minutes (M. = minuta) are given in each cell. A printed obelus (†) marks, in each row, the column holding the Sun's greatest altitude for that latitude; the mark migrates diagonally down the panel as latitude increases. In the low-altitude cells a decorative sun-

ornament fills the wide blank between the degree and minute figures — it is an ornament, not a numeral, and only the numeric figures are transcribed.

Page 139 — Table X (continued): Cancer ☊ & Capricorn ☋

[Margin (left, rotated): Here one enters for the hours of Cancer ☊, toward the right (*Hic intratur pro horis ☊ dextram versus.*)] [Margin (right, rotated): Here one enters for the hours of Capricorn ☋, toward the left (*Hic intratur pro horis ☋ sinistram versus.*)]

Upper panel — hours 17–12 from setting / 7–12 from rising

Column headers pair *Hor. ab occ.* (top) with *Hor. ab ortu* (bottom): 17|7, 16|8, 15|9, 14|10, 13|11, 12|12. The rightmost column is the elevation of the pole (*Altit. Poli.*). Cell format: degrees minutes.

Gnomonics — Tables (Christoph Clavius, *Opera Mathematica*, Tomus IV)

*Printed pages 142–144. Pages 142–143 form one opening: a continuation of the multi-page table of the Sun's altitudes at each hour (**Altitudines Solis in horis ab ortu & ab occasu**), tabulated by hour of day across the top and by altitude of the pole (i.e. geographic latitude) down the rows. This particular table serves the four signs of equal declination-magnitude **Taurus** ♉ and **Virgo** ♍ (entered "to the right," i.e. as southern/positive-declination entry) and **Scorpio** ♏ and **Pisces** ♐ (entered "to the left"). No printed **Tabula** number appears on pages 142–143 (see anomaly a). Page 144 begins a new numbered table, **Tabula XI**, of horizontal azimuths for latitude 42°.*

*Column convention for the altitude tables below: each hour column heads two figures — the hour reckoned **from setting** (ab occasu) over the hour reckoned **from rising** (ab ortu) — and each data cell holds **degrees and minutes** (**G.** = **gradus**, **M.** = **minuta**). The dagger † marks the printed entry-marker of the "Hic intratur" note (see the marginal notes); in the lower block of p. 142 this same marker is printed as a small star ornament — rendered here uniformly as †.*

Page 142 (printed 142)

[Translation of running header: "Altitudes of the Sun in the hours from rising."]

Upper block — hours ab occasu 23–18 / ab ortu 1–6

Page 144 (printed 144)

XI. TABULA.

CIRCUMFERENTIÆ HORIZONTALIS inter Verticalem primarium, & alios Verticales per hor. à mer. & med. noc. in signorum initijs ductos.

Table XI. The horizontal circumferences [azimuths] between the prime vertical and the other verticals, drawn through the hours from noon and from midnight, at the beginnings of the signs.

Ad latitudinem Grad. 42.

For latitude 42 degrees.

Column headers pair the two signs of equal declination served by each column (northern and southern points share a column, distinguished by the A/B letter): ☊ | ☋ | ☌ | ☍ | ☎ | ☏ | ☐ | ☑ | ☒ | ☓ | ☔ | ☕ | ☖. Each cell is degrees, minutes, with the letter **A** (australis — southern azimuth) or **B** (borealis — northern azimuth) printed beneath. The leftmost column is Horæ à meridie (hours from noon); the rightmost is Horæ à med. noc. (hours from midnight).

Horæ à mer.	☊	☋	☌	☍	☎	☏	☐	☑	☒	☓	☔	☕	Horæ à med. noc.

[Margin, left (rotated): Litera A, gradibus ac minutis supposita, significat circumferentiam eam esse australem; litera vero B, borealem. Omnes porro circumferentiæ horarum à meridie sunt occidentales; horarum vero à med. noc. orientales. Horæ denique, quæ in 8. tabula sub Horizonte existunt, in hac quoque sub Horizonte esse intelliguntur. — "The letter A, placed beneath the degrees and minutes, signifies that the azimuth is southern; but the letter B, northern. Moreover all the azimuths of the hours from noon are western, but those of the hours from midnight, eastern. Finally, the hours which in Table 8 lie below the Horizon are here likewise understood to lie below the Horizon."]

XII. TABULA.

Table 12

Comprising the **horizontal azimuths** [*circumferentias horizontales*] — the arcs of the horizon between the **prime vertical** [*Verticalis primarius*] and the other verticals passing through the center of the Sun at each hour — for the hours from rising and from setting, for the beginnings of the signs, constructed for pole-altitudes from 30 degrees up to 60 degrees.

[This title page carries only the heading; the faint horizontal and vertical rules visible above and below the ornamental bands are show-through of the tables printed on the reverse leaf (p. 146). No table is set on this page.]

Two azimuth tables are set on this page, one above the other. In both, the leftmost column is **Altit. Poli.** (altitude of the pole = geographic latitude), running 30° to 60°. Each hour is given a pair of sub-columns **G.** (*gradus*, degrees) and **M.** (*minuta*, minutes). Each hour-column carries two heads: **Ho. ab occ.** (the hour from setting) above **Hor. ab or.** (the hour from rising). The letters **A** and **B** printed against a value mean, respectively, *australis* (southern, A) and *borealis* (northern, B) — the same convention as the preceding table; the letter is printed only where the azimuth changes side or where needed, and is understood to persist down the column. A printed star (rendered * below) and a printed dagger (†) mark, respectively, the two sunrise/entry diagonals running across the grid (keyed to the marginal "here one enters..." notes for Cancer and Capricorn).

Upper table — Ho. ab occ. 24, 23, 22, 21, 20, 19, 18 / Hor. ab or. 24, 1, 2, 3, 4, 5, 6. (Column heads at right: **H. ab or. / H. ab oc.**)

[Margin, left (rotated): *Hic intratur pro horis ☊, dextram versus.* — "Here one enters for the hours of Cancer [☊], toward the right."]

[Margin, right (rotated): *Hic intratur pro horis ☋, sinistram versus.* — "Here one enters for the hours of Capricorn [☋], toward the left."]

These three pages continue the great table of **horizontal circumferences** (azimuths of the Sun's center reckoned from the prime vertical, hour by hour, for pole-heights 30°–60°), begun as Table XII on printed p. 145. Each opening serves one group of declination-paired signs. The opening pp. 148–149 serves **Gemini** (♊), **Leo** (♌), **Sagittarius** (♐), and **Aquarius** (♒); p. 150 begins the next opening, for **Taurus** (♉), **Virgo** (♍), **Scorpio** (♏), and **Pisces** (♐).

In every table the argument column is **Altit. Poli.** (altitude of the pole, 30–60). Each hour-pair is headed by two numbers: the upper is **Ho. ab occ.** (the hour reckoned from setting), the lower is **Hor. ab or.** (the hour reckoned from rising); the two share one column of degrees (**G.**) and minutes (**M.**). Certain degree figures carry a printed side-letter **A** or **B** exactly as in the preceding table-pages; these are transcribed verbatim. A printed dagger † and a printed many-pointed reference asterisk * each trace a slanting reference band down through the table; both are reference marks, not digits, and are transcribed attached to the figure they touch. Cells give "degrees[letter] minutes."

Printed p. 148 — horizontal circumferences, signs ♊ ♌ ♐ ♒ (left page of opening)

[Margin (left, rotated): *Hic intratur pro horis ♊, & ♌, dextram versus.* — "Here one enters for the hours of Gemini (♊) and Leo (♌), toward the right."]

[Margin (right, rotated): *Hic intratur pro horis ♐, & ♒, sinistram versus.* — "Here one enters for the hours of Sagittarius (♐) and Aquarius (♒), toward the left."]

Printed p. 150 — horizontal circumferences of the hours, signs ♂ ♍ ♎ ♏ (left page of next opening)

Running header here reads *Circumferentiæ horizontales **horarum** ab or.* ("...of the hours from rising"), a slight change from the *pro horis* wording of the preceding opening (flagged in the report below).

[Margin (left, rotated): *Hic intratur pro horis ♂, & ♍, dextram versus.* — "Here one enters for the hours of Taurus (♈) and Virgo (♍), toward the right."]

[Margin (right, rotated): *Hic intratur pro horis ♎, & ♏, sinistram versus.* — "Here one enters for the hours of Scorpio (♏) and Pisces (♐), toward the left."]

Upper table (hours from rising 24, 1–6)

Horologiorum Nova Descriptio — Table Appendix (TABVLÆ XXIIII)

*(Continuation of Table XII, its concluding page, and the opening of Table XIII.
Printed pp. 151–153 = source pp. 787–789.)*

[Source p. 151] Table XII (continued) — Horizontal circumferences [circumferentiae horizontales]

[Margin (left side, rotated): **Hic intratur pro horis** ♉ & ♍ **dextram versus.** — "Here one enters for the hours of Taurus and Virgo, reading toward the right."]

[Margin (right side, rotated): **Hic intratur pro horis** ♏ & ♐ **sinistram versus.** — "Here one enters for the hours of Scorpio and Pisces, reading toward the left."]

This recto carries two continuation grids of Table XII. Column heads: **Ho. ab occ.** (*Horae ab occasu*, hours from setting) over **Hor. ab or.** (*Horae ab ortu*, hours from rising); the left row-label column is **Altit. Poli.** (altitude of the pole, i.e. latitude), in degrees (**G.**), with each data column giving degrees (**G.**) and minutes (**M.**). Letters **A/B** printed between the figures mark the two directions of the amplitude; a dagger (†) marks the entry rows keyed to the margin notes.

Upper grid (pp. hours 17→12 setting / 7→12 rising)

[Source p. 152] Table XII (concluded)

Circumferentiæ Horizontales pro horis ab ortu & occ. necnon à merid. & med. noct. in princ. ♀, & ♂. — "Horizontal circumferences for the hours from rising and setting, and also from noon and midnight, at the beginning of Aries (♀) and Libra (♂)." (*The equinoctial signs — the concluding page of Table XII.*)

Column heads: **Ho. ab occ.** over **H. ab ortu.**; each data column carries a double hour-argument (a morning value and its evening complement). The row-label column is **Altitu. Poli.** in degrees (**G.**); each data column gives **G.** and **M.** The right-hand margin repeats the heads as **H. ab ortu. / H. ab occ.** The foot of the table restates the arguments as **H. à merid.** (*Horae à meridie*, hours from noon) and **H. à me.no.** (*Horae à media nocte*, hours from midnight).

XIII. TABVLA.

DECLINATIONVM ARCVVM DIVRNORVM: ad poli altitudines
in sinistro latere descriptas.

— Table XIII. Of the declinations of the diurnal arcs, set out against the pole-
altitudes on the left side.

[Source p. 153] Table XIII — Declinations of the diurnal arcs
[declinationes arcuum diurnorum]

Row-label column: **Altitudines poli** (pole-altitudes), in degrees (**G.**), in half-degree steps from 30 to 60. Body: **Declinationes** (declinations), each column giving **G.** and **M.** Each column head is a double hour-argument summing to 24 (a value and its complement): 0/24, ½/23½, 1/23, 1½/22½, 2/22, 2½/21½. The table continues to the right on the following page (catchword **Horæ**).

Altitudines poli	0 / 24	½ / 23½	1 / 23	1½ / 22½	2 / 22	2½ / 21½

These three pages continue **Table XIII (*Tabula Declinationum Arcuum Diurnorum*)** — "Table of the Declinations of Diurnal Arcs", begun earlier. The table is arranged with the pole altitude ("Altitudines poli," G. = degrees) down the left margin, running from 30° to 60° in half-degree steps, and the hour-arguments across the top. Each data column serves two complementary hours whose sum is 24 (e.g. 3^h and 21^h), and is split into two sub-columns, **G.** (degrees) and **M.** (minutes), under the spanning heading **Declinationes**. These three folios carry the hour-arguments from 3^h (/21^h) through 11½^h (/12½^h); the table continues from the preceding pages and runs on toward the meridian.

The hour-pair heading of each column is given verbatim in the table headers below (small hour / large hour).

Table XIII, hour-columns 3^h–5½^h

Column hour-pairs (verbatim): 3 | 21, 3½ | 20½, 4 | 20, 4½ | 19½, 5 | 19, 5½ | 18½.

Horologiorum Nova Descriptio — Table Appendix (continued)

(Christoph Clavius, Opera Mathematica, Tomus IV; the sundial-tables appendix, "TABVLÆ XXIIII." All tables on these three folios are computed to the latitude noted in each heading. Degrees are printed under G. [gradus], minutes under M. [minuta]. Zodiac column-groups pair the signs that share the same declination magnitude.)

XIIII. TABVLA. (folio 157)

Fourteenth Table. Of the arcs of the horizon, intercepted between the meridian and the great circles which are drawn — from the intersection of the equator with the meridian, through the hours from noon and from midnight — at the beginnings of the signs.

To latitude 42 degrees.

Hor. à mer.	& med. noc.	☾ ♍ · G.	M . ♀ ♌ ♎ · G.	M . ☿ ♍ ♎ ♏ · G.	M .
	12	0	0 0	0 0	0
1	11	23	5 27 2	3 43 5	2 4
2	10	40	3 45 1	1 61 7	1 8
3	9	50	2 55 4	0 68	5 0
4	8	55	5 60 7	1 72 5	3 9
5	7	58	4 62 8	5 74 2	1 1
6	6	59	4 63 0	4 74 0	4 1

Rightmost remark column (spanning the data rows): "When the Sun is at the beginning of ♈ [Aries] and ♎ [Libra], these arcs are always 90 degrees; therefore there was no need to place Aries and Libra among the other signs."

XV. TABVLA. (folio 157)

Fifteenth Table. Of the arcs of the prime vertical, intercepted between the horizon and the great circles which are drawn from the intersection of the equator with the meridian, through the hours from noon or from midnight, at the beginnings of the signs.

To latitude 42 degrees.

Hor. à mer.	& med. noc.	☾ ♍ · G.	M . ♀ ♌ ♎ · G.	M . ☿ ♍ ♎ ♏ · G.	M .
	12	90	0 90	0 90	0
1	11	68	1 64 7	4 49 8	3 6
2	10	52	2 47 5	4 31 3	1 8
3	9	42	3 37 5	5 23 4	1 6

Hor. à mer.	& med. noc.	☿ ♊ · G.	M . ♀ ♈ ♀ ♉ · G.	M . ☿ ♊ ♉ ♈ · G.	M .
4	8	36	5 32 3	2 19 5	2 1
5	7	36	5 29 7	3 17 9	2 8
6	6	33	1 28	4 16 8	5 5

Rightmost remark column: "When the Sun is at the beginning of ♈ [Aries] and ♎ [Libra], all these arcs are 0°0'; which was the reason that Aries and Libra are not placed among the other signs."

XVI. TABVLA. (folio 157)

Sixteenth Table. Of the arcs of the horizon, intercepted between the meridian and the great circles which are drawn from the intersection of the equator with the meridian, through the hours from rising or from setting, at the beginnings of the signs.

To latitude 42 degrees.

Marks: † marks the beginning [of the sign] for the afternoon hours reckoned from setting; * marks it for the hours reckoned from rising (see the foot-note below).

Horæ ab occ.	☿ · G.	♀ ♈ · G.	♊ ☉ · G.	♈ ♈ · G.	♈ ♈ · G.	♊ · G.	Horæ ab ortu
9	57	61	71	64	41	32	15
10	59	63	73	70	52	45	14
11	59	63	74	73	59	53	13
12	57	62	74	74	62	57	12
13	53	59	73	74	63	59	11

23	59	63	74	73	59	53	1
24	57	62	74	74	62	57	24

Foot-note: "The sign † gives the beginning [of the sign] for the afternoon hours in the hours from setting; the sign * [gives it] in the hours from rising. When the Sun is at the beginning of ♈ [Aries] and ♎ [Libra], all these arcs are 90°0'; therefore these signs are not written in the table."

XVII. TABVLA. (folio 158)

Seventeenth Table. Of the arcs of the prime vertical, intercepted between the horizon and the great circles which are drawn from the intersection of the equator with the meridian, through the hours from rising or from setting.

To latitude 42 degrees.

Horæ ab occ.	☾ · G.	♊ ♈ · G.	♋ ♉ · G.	♌ ♊ · G.	♍ ♋ · G.	♎ · G.	Horæ ab ortu
9	35	31	20	28	51	60	15

Horæ ab occ.	☾ · G.	♈ ♀ · G.	♏ ♂ · G.	♍ ♂ · G.	♊ ♀ · G.	♋ · G.	Horæ ab ortu
22	33	29	17	21	40	47	2
23	33	28	16	18	33	39	1
24	35	30	17	17	30	35	24

Foot-note: "The sign † gives the beginning [of the sign] for the afternoon hours in the hours from setting; the sign * [gives it] in the hours from rising. When the Sun is at the beginning of ♈ [Aries] and ♎ [Libra], all these arcs are 0°0'; therefore these signs do not appear among the others."

XVIII. TABVLA. (folio 158)

Eighteenth Table. Of the arcs of the horizon, on the southern side, between the meridian and the great circles which — like hour-circles — are drawn through the poles of the world from noon and from midnight, and through the whole hours from rising or from setting and their halves, at the beginnings of the signs.

To latitude 42 degrees.

23½	112	107	94	78	64	52	48	½
24	122	117	105	90	74	62	57	24

Foot-note: "The sign † gives the beginning [of the sign] for the afternoon hours from setting; the sign * [gives it] for the afternoon hours from rising. The hours too which in the 9th table are below the horizon are here also to be understood as below the horizon."

XIX. TABVLA. (folio 159)

Nineteenth Table. Segments of the hour-lines from noon and from midnight, between the centre of the horizontal sundial and the points of the Sun's parallels, reduced to tangents with respect to the whole sine [radius] taken equal to the style. For the latitudes written below; for describing the Sun's parallels, according to the prescription of Number 5, scholium of chapter 9.

(Each entry is a tangent value referred to a radius/style of 1000. As the hour approaches the point where the parallel runs parallel to the hour-line, the segment

grows without bound; the print marks this "Infinita" — and, in the two lower blocks, sometimes simply leaves the terminal cells blank. See the parsing note.)

Table XIX (continued) — Segments of the hour-lines, reduced to tangents

These three folios (printed pp. 160–162) continue **Table XIX** of the appendix. The running header on every page reads **RESID. XIX. TAB.** — *Residuum XIX. Tabulae*, "remainder of the 19th Table." The table was introduced in the preceding folios (its full title: *Segments of the hour-lines from noon and from midnight, between the center of the horizontal dial and the points of the Sun's parallels, reduced to tangents with respect to a total sine equal to the style*). Here the table is continued through successive pole-altitudes (latitudes), one sub-block per degree.

Each sub-block has the same layout: a left column of hours reckoned from noon (*Horæ à merid.*), seven tangent columns headed by paired zodiac signs, and a right column of hours reckoned from midnight (*Horæ à med. noc.*). The seven sign-columns are, in order: ♋ (Cancer); ♊ ♌ (Gemini, Leo); ♉ ♍ (Taurus, Virgo); ♈ ♎ (Aries, Libra); ♐ ♑ (Pisces, Scorpio); ♒ ♓ (Aquarius, Sagittarius); ♏ (Capricorn). Every column head is subtitled *Tang.* (tangent). "Infinita" ("infinite") is printed in a column at the first row where its tangent becomes infinite; cells below are left blank. Blank cells are transcribed as empty; no value has been supplied where the print leaves a cell blank.

XX. TABVLA. — TABLE XX.

PRO ALTITVDINIBVS SOLIS IN Verticali in principio cuiuslibet signi ad altitudines poli in siniftro latere afcriptas.

For the altitudes of the Sun on the prime vertical [in Verticali] at the beginning of each sign, corresponding to the elevations of the pole [altitudines poli — i.e. the latitudes] entered in the left-hand column.

(The table gives, for each pole-elevation φ [Altitud. Poli, in degrees and minutes], the Sun's altitude [in degrees and minutes] on the prime vertical when it stands at the beginning of the named sign. Only the three sign-columns in which the Sun crosses the prime vertical above the horizon are tabulated: ♋ Cancer; ♊ II Leo/Gemini; ♍ Virgo/Taurus. Each entry is degrees° minutes'. In the source the table is set in three side-by-side panels — $\varphi = 0^\circ\text{--}33^\circ45'$, $34^\circ\text{--}44^\circ45'$, and $45^\circ\text{--}55^\circ45'$ — all with identical column heads; they are merged here into one latitude-ordered table. The ♋ column begins only at $\varphi = 23^\circ30'$, where the Sun reaches the zenith [altitude 90°]; for lower latitudes the ♋ crossing does not occur and the first two rows are printed as all-zeros.)

Altitud. Poli (°)	♋ (°)	♊ II (°)	♍ (°)

Table XX (continued)

Pro altitudinibus Solis in Verticali — For the altitudes of the Sun in the prime vertical [continued]

Continuation of Table XX (whose heading and first latitudes 0°–55°45′ stand on the preceding folios). This folio (printed p. 166) carries no title, only the repeated column heads; it completes the table for pole-elevations 56° through 90°.

Column heads as printed: **Altitud. Poli.** (elevation of the pole, i.e. latitude), then the three sign-columns each with a **G. M.** (Gradus, Minuta) sub-head — ♋ (Cancer); ♌ / ♊ (Leo over Gemini); ♍ / ♉ (Virgo over Taurus). The source sets three latitude-panels side by side (56°–67°15′ | 67°30′–78°45′ | 79°–90°); they are

merged below into a single latitude-ordered table. Each cell is degrees and minutes (° ').

XXI. TABVLA — Table XXI

Pro distantiis Solis a Meridiano, cum est in Verticali — For the distances of the Sun from the meridian, when it is in the prime vertical

Full title as printed: **PRO DISTANTIIS SOLIS A MERIDIANO, cum est in Verticali: ad altitudines poli in sinistro latere ascriptas, in principiis cuiuslibet signi.** — "For the distances of the Sun from the meridian, when it is in the prime vertical: for the elevations of the pole written on the left side, at the beginnings of each sign."

Column heads as in Table XX: **Altitud. Poli.** then three sign-columns each with a **G. M.** sub-head — ♋ (Cancer); ♌ / ♊ (Leo over Gemini); ♍ / ♉ (Virgo over Taurus). The table runs across two folios (printed pp. 167–168), each set in three side-by-side latitude-panels; all are merged below into one latitude-ordered table (pole-elevation 0° through 90°). Each cell is degrees and minutes (° ′).

(Printed p. 168 carries the second half of Table XXI, latitudes 56°–90°, already merged into the single table above under the XXI. TABVLA heading.)

Tabella 22. For converting parts of the Equator into hours, and their fragments.

(*Tabella 22. conuertendi partes Æquatoris in horas, earumque fragmenta.*) — folio 169

This is a proportional conversion table (1° of the Equator = 4 minutes of time). It is printed in four parallel panels. Each panel has an **argument** column (headed G. / M. / S. — read as degrees, or minutes, or seconds) and a **result** column (headed H. M. / M. S. / S. T. — hours-and-minutes, or minutes-and-seconds, or seconds-and-thirds). The two result numbers in each cell are the higher and lower sexagesimal places (e.g. 0 4 = 0^h 4^m when the argument is read in degrees). Panels 1–3 have 23 lines; panel 4 has 21 lines and its last two lines are blank.

Tabella 23. For converting hours and their fragments into parts of the Equator.

(*Tabella 23. conuertendi horas, earumque fragmenta in partes Æquatoris.*) — folio 169

The inverse of Table 22 (1 hour of time = 15° of the Equator; 1 minute of time = 15' of arc). Panel 1 is headed H. (hours) → G. (degrees). Panels 2–4 are headed M. / S. / T. (argument in minutes, seconds, or thirds) → G. M. / M. S. / S. T. (result in the two adjacent sexagesimal places). Panel 1 has 24 lines; panels 2–4 have 20 lines each (their lines 21–24 are blank).

Tabula pro parte proportionali eruenda.

(Table for finding the proportional part.) — folios 170–171

A single sexagesimal proportional-parts (interpolation / multiplication) table spanning both folios: the 20 multiplier columns 1–10 are printed on folio 170 (below), the columns 11–20 on folio 171 (below). The left-hand column is the argument (minutes) 1–60; each interior cell gives the proportional part as two sexagesimal figures, $x \ y = \lfloor (\text{row} \times \text{col}) / 60 \rfloor$ and $(\text{row} \times \text{col}) \bmod 60$. The bottom line (argument 60) gives the whole multiplier in each column.

Folio 170 — columns 1–10:

Table for finding the proportional part [*Tabula pro parte proportionali eruenda*]

(Continuation of the proportional-parts table begun on the preceding folios. Each cell gives the product of the left-hand argument and the column-head multiplier, expressed sexagesimally as degrees and minutes — i.e. $\lfloor \text{argument} \times \text{multiplier} / 60 \rfloor : (\text{argument} \times \text{multiplier} \bmod 60)$. Multiplier columns 1–20 stood on folios 170–171; the columns below run 21–50 across folios 172–174.)

Folio 172 — multiplier columns 21–30

[Table continues: multiplier columns 51–60 stand on the following folio.]

Table for finding the proportional part [*Tabula pro parte proportionali eruenda*] — multiplier columns 51–60. (The earlier multiplier columns, 21–50, stand on the preceding folios; this is the same continuous table.)

Each cell holds two figures: the whole (left) and the sixtieth part (right). The left column is the argument (1–60); the ten column-heads are the multipliers 51–60.

On Table 24. For finding the proportional part.

(folio 176)

[Margin: The denominators of the parts of any circle. What is produced if the parts of a circle are multiplied by one another, or divided.]

So that the proportional part may be drawn out, it is well worth learning the denominators of the parts of any given circle, and of the other great circles — the denominators that this scheme sets out. From them we understand what is produced by the multiplication and by the division of one set of parts by another.

For the sum of the denominators of the parts that are multiplied gives the denominator of the number produced; whereas the remainder, when the smaller denominator is subtracted from the larger, indicates the denominator of the quotient, when the parts of the larger denominator are divided by the parts of the smaller. Thus by multiplying degrees into minutes, minutes are produced; from minutes into seconds come thirds; from thirds into fifths are begotten eighths; and so on. Conversely, by dividing minutes by degrees, minutes result; by dividing thirds by minutes, seconds come out; by dividing thirds by seconds, minutes are begotten; and so on.

[Margin: What parts of a circle the numbers in the table of proportional parts signify.]

Denominators of the parts of the circle [left bracket: *Partes circularum*, "parts of the circles"; right bracket: *Denominatores*, "denominators"]:

Part of the circle	Denominator
Degrees (Grad.)	0
Minutes (Min.)	1
Seconds (Secunda)	2
Thirds (Tertia)	3
Fourths (Quarta)	4
Fifths (Quinta)	5
Sixths (Sexta)	6
etc. (&c.)	etc.

II. From this it will be easy to know whether the numbers in the table signify degrees and minutes, or rather minutes and seconds, and so on. For since the numbers of that table are produced by multiplying the numbers taken at the top of the table into the numbers taken along the left side, then, if minutes are taken both at the top and at the side, the entries in the common corner will be seconds — that is, the first number gives minutes and the second gives seconds. For example, if Min.24 is multiplied by Min.46, there are produced Secunda 1104 — that is (dividing by Min.60) Min.18 and Sec.24. Likewise, if Quarta 24 is multiplied by Secunda 46, there are produced Sexta 1104 — that is (dividing by Min.60) Quinta 18 and Sexta 24. So too, if 3 degrees are multiplied by 8 minutes, there are produced 24 minutes — that is (dividing by Min.60) grad.0 Min.24. But if 9 degrees are multiplied by Min.26, there are begotten 234 minutes — that is

(dividing by Min.60) gra.3 Min.54; and so with the rest. In this second scheme one sees what is produced by multiplication.

[Margin: How the proportional part is to be drawn out.]

How the proportional part is drawn out [left bracket: *Multiplicandi*, "the multiplicands"; middle bracket: *Producti*, "the products"]. The scheme pairs two parts (of the denominations G = *gradus*/degree, M = *minuta*, S = *secunda*, T = *tertia*, Q = *quarta*) and gives the denomination of their product:

Multiplicands	Products
G per G	G · G
G per M	G · M
G per S	M · S
G per T	S · T
G per Q	T · Q
M per M	M · S
M per S	S · T
M per T	T · Q
M per Q	Q · [?]
S per S	T · Q
S per T	Q · [?]
S per Q	[?] · [?]
T per T	[?] · [?]
T per Q	[?] · [?]

III. Therefore, to come to the finding of the proportional part: suppose some table has been computed for individual degrees — such as, for instance, the table of the Sun's altitudes at the hours from noon and from midnight, advancing through each single degree of the pole's elevation — and suppose the altitude of some hour is sought for a pole-elevation that, besides whole degrees, also takes in some minutes. Then, for the two nearest pole-elevations (of which one is less than the given elevation and the other greater), one must take the difference between the two altitudes of the Sun at the given hour whose altitude is desired. Next, in the table of proportional parts, take the said difference at the top of the table, and on the left side the minutes that are contained (over and above the degrees) in the given elevation; or the other way about — the said difference on the side and the minutes at the top. For in the common corner the proportional part will be found,

in degrees and minutes, or in minutes and seconds, or in seconds and thirds, and so on, as was explained just above. This proportional part, subtracted from the altitude of the lesser pole-elevation, or added to it — according as that altitude is greater or less than the altitude of the greater pole-elevation — will yield the sought altitude of the Sun.

For example, suppose the Sun's altitude is desired at hour 1½[?] after noon for a pole-elevation of grad.42 Min.19. One must take the difference of grad.0 Min.47 between the altitude of the said hour at pole-elevation grad.42 (which contains grad.67 Min.41) and the altitude of the same hour at pole-elevation grad.43 (which comprises grad.66 Min.54). If this difference is taken at the top of the table of proportional parts, and the 19 minutes contained (over and above the 42 degrees) in the given pole-altitude are taken on the left side — or, conversely, these minutes at the top and that difference on the side — there will be found in the common corner the proportional part Min.14 Sec.53. For always, whenever minutes are taken both at the top and on the side of the table, the first number in the common corner gives minutes and the second gives seconds. But if degrees are taken at the top and minutes on the side, or the reverse, the first number in the common corner will give degrees and the second minutes, as is clear from what we wrote under Number 2. If, then, this proportional part Min.14 Sec.53 — that is, Min.15 (for one whole minute must be taken for the Sec.53, since they exceed half a minute; and in the same way, for more than 30 seconds one whole minute is always to be taken, for fewer than 30 nothing, and for exactly 30 it is left free to take one minute or to drop it) —

(folio 177)

if, I say, it is subtracted from the altitude grad.67 Min.41 at pole-elevation grad.42 (because this altitude of the Sun is greater than the altitude at pole-elevation grad.43), there will be left the sought altitude of the Sun, grad.67 Min.26, for hour 1½[?] at pole-elevation grad.42 Min.19.

Again, if someone wishes the Sun's altitude for hour 6½[?] after noon at the same pole-elevation grad.42 Min.19: the difference between the altitudes of that hour at pole-elevations grad.42 and 43 is min.19; and if this is taken at the top of the table, and the Min.19 contained in the proposed elevation on the side, there will be found in the common corner the proportional part Min.6 Sec.1. If, then, Min.6 (for the Sec.1 is neglected, since it is less than half a minute) is added to the altitude of hour 6 at pole-elevation grad.42 — because this is less than the altitude of the same hour at pole-elevation grad.43, namely to grad.15 Min.28 — the sought altitude will be made up as grad.15 Min.34.

[Margin: When the table is computed for fifteen-minute steps, or for half-degrees, what is to be done.]

But if at any point the difference should be greater than Min.60 — say gra.3 Min.50 — and the proportional part is sought for Min.30: we shall find, with grad.3 at the top and Min.30 on the side, the proportional part grad.1 Min.30; and just so much would the proportional part be if the difference were precisely grad.3. But because there are still Min.50 contained in it, we find, with those [minutes] at the top and the same Min.30 on the side, the proportional part Min.25 Sec.0; and this, added to the one found before, makes up the whole sought proportional part, gr.1 Min.55.

[Margin: The proportional part, when the table is not computed for whole degrees.]

And in this way, indeed, the proportional part is investigated in any table computed for whole degrees — of which kind are the preceding tables 9, 10, and 12. But if some table has been computed for fifteen-minute steps of degrees — of which kind are the earlier tables 4, 6, 20, and 21, and also the table of the arcs of the hour-circles in our *Compendium of dials* [*Compendium horologiorum*] — then one must take the difference of the two nearest arcs at the top of the table of proportional parts, and the minutes of the pole's elevation on the side; and the proportional part found in the common corner must be quadrupled. So too, if some table has been computed for half-degrees, one must take the difference between the two nearest numbers at the top of the table of proportional parts, and the minutes of the pole's elevation on the side; and the proportional part found in the common corner must then be doubled.

For example, in the table of the *Compendium of dials*, suppose the proportional part is to be sought for a pole-elevation of grad.40 Min.10, for hour 1 after noon. The difference between the arc at pole-altitude grad.40 and at grad.40 Min.15 is Min.14. If, then, these minutes are taken at the top of the table of proportional parts, and Min.10 on the side, there will be found the proportional part Min.2 Sec.20; which, quadrupled, makes Min.8 Sec.80 — that is, Min.9 Sec.20 — for the sought proportional part. This, subtracted from the arc grad.49 Min.1 opposite pole-altitude grad.40, will leave the arc gra.48 Min.52, the value sought at pole-elevation grad.40 Min.10. So too, if the proportional part is to be sought for hour 3 [and] 9[?] at pole-altitude gra.64 Min.25: the difference Min.14 will be found between the arcs of pole-altitude grad.64 Min.15 and grad.64 Min.30. If, then, this difference is taken at the top, and the Min.10 that are contained (over and above gr.64 Min.15) in the given altitude, there will be found in the common corner

Min.2 Sec.20; which, quadrupled, make Min.8 Sec.80 — that is, Min.9 Sec.20 — for the proportional part. This, removed from the arc grad.18 Min.50 at pole-altitude grad.64 Min.15, will leave the arc grad.18 Min.41 at pole-altitude gr.64 Min.25. And so with the rest.

[Margin: The finding of the proportional part by the rule of three, without a table.]

IIII. Moreover, even without the table of proportional parts, the proportional part can also be found by the rule of three, provided that — when the numbers of the difference are several — we first reduce them to the smallest subdivisions (those, that is, of the highest denomination), and then say: if the first number (that is, Min.60 when the table proceeds by whole degrees; or Min.15 or 30 when it is extended through fifteen-minute steps or half-degrees) gives such-and-such a difference, what will the minutes give for which the proportional part is sought? As in the next two examples.

Fifteen minutes (for the table in the *Compendium* advances by fifteen-minute steps of the pole's altitude) give a difference of Min.14; what then will Min.10 give? Multiplying Min.14 into min.10 makes Sec.140, which divided by min.15 yield min.9¼ — that is, min.9 Sec.20, as before. Likewise, in the second-to-last example: sixty minutes give a difference of grad.3 min.50; what then will min.30 give? The middle number makes Min.230, which multiplied by Min.30 make Sec.6900; and these, divided by Min.60, give min.115 — that is, grad.1 min.55, as above.

Again, if some table is constructed for whole degrees, and the difference is min.6 Sec.20, and the proportional part is sought for min.30, we shall say: sixty minutes give a difference of Sec.380 (for that many seconds are contained in the middle number); what then will min.30 give? Multiplying this third number into the second, and dividing by the first — that is, by min.60 — there come forth Sec.190, that is, min.3 Sec.10.

Finally, if the proposed table is extended by half-degrees, and the difference between the two [nearest] numbers is grad.1 Ter.4, and the proportional part is sought for min.9, we shall say: Min.30 give a difference of Ter.216004 (for that many thirds are contained in the middle number); what then will min.9 give? Multiplying this third number into the second, there come Quar.1944036; and these, divided by min.30, give a quotient in thirds which contain Sec.1080 (= min.18) and Ter.1, together with a fraction that contains Quar.12. Therefore the proportional part is min.18 Ter.1 Quar.12. These things will not be difficult, if one

recalls what was said above about the numbers produced by the mutual multiplication and division of the parts of circles. But the operation by the table of proportional parts is shorter and more expeditious.

[Margin: The proportional part for the table.]

In table 19, however — in which there are no degrees and minutes — the proportional part must be sought entirely by the rule of three; which you will learn from this single example. Suppose the tangent is to be investigated for hour 2½[?] from noon, at latitude grad.39 Min.15. The tangent of the said hour at latitude grad.39 is 3666 (at ½[?]); but at latitude grad.40 it is 3744, per the table. The difference between the two is 78. We shall say, then: if 60 minutes require a difference of 78, what will 15 minutes require? And you will find a difference of 19½; which, added to the tangent of the lesser latitude (because it is the smaller), will make the tangent 3685½ for the sought hour 2 at ½[?].

On the Tables of the Sun's Altitudes, of the Horizontal Circumferences, etc. [In Tabulas Altitudinum Solis, circumferentiarum horizontalium, &c.]

[Margin: What the sign ✱ signifies in the tables of the Sun's altitudes and of the horizontal circumferences.]

This sign ✱, placed in the tables of the Sun's altitudes and of the horizontal circumferences among the degrees and minutes, indicates that the hour in question — together with those that follow it toward the right — falls below the horizon in the northern [boreal] signs, and that their altitudes are accordingly referred to the horizon of the antipodes. In the southern [austral] signs, by contrast, it indicates that that hour still stands above the horizon, while all the rest fall below the horizon toward the left, and that their altitudes therefore lie above the horizon of the antipodes.

[Margin: Which hour, reckoned from noon or midnight, falls below the horizon.]

II. That hour reckoned from noon or from midnight falls below the horizon whose distance from the meridian — placed above the horizon, reduced to degrees by means of the little table for converting hours into parts of the Equator — is greater than the semidiurnal arc. Thus at latitude 42°, with the Sun at the beginning of ♋ [Cancer], the hour 7h33m from noon (or 4h27m from midnight) is distant from the meridian placed above the horizon by 7h33m — that is, 113°15' — a distance which is greater than the semidiurnal arc of ♋, comprising 113°3'.

Therefore that hour lies below the horizon. Likewise the hour 7h32m from noon (or 4h28m from midnight) is distant from the meridian placed above the horizon by $113^{\circ}0'$, a distance less than the semidiurnal arc of $\mathfrak{S}$, which contains $113^{\circ}3'$. Therefore that hour lies above the horizon.

[Margin: Which hour, reckoned from sunrise or sunset, lies below the horizon.]

Likewise, that hour reckoned from sunrise whose distance after sunrise — or that hour reckoned from sunset whose distance before sunset — is greater than the doubled semidiurnal arc falls below the horizon. Thus at the same latitude 42° , with the Sun at the beginning of $\mathfrak{S}$, the hour 16 from sunrise is distant from sunrise, and the hour 8 from sunset is distant before sunset, by 240° ; and this distance is greater than the doubled semidiurnal arc, that is, than $226^{\circ}6'$.

Therefore both hours are found below the horizon — the former in the west after sunset, the latter in the east before sunrise. Again, the hour 10 from sunrise, with the Sun at the beginning of $\mathfrak{X}$ [Pisces] and $\mathfrak{A}$ [Aquarius], is distant 150° after sunrise, and by that same number of degrees the hour 14 from sunset is distant before sunset; and this distance exceeds the doubled semidiurnal arc of $\mathfrak{X}$ and $\mathfrak{A}$, namely $141^{\circ}18'$. We shall conclude, therefore, that both hours lie below the horizon.

[Margin: What the sign $\dagger$ signifies in the tables of the Sun's altitudes and of the horizontal circumferences.]

III. Next, this sign $\dagger$, which under the hours from sunrise and sunset first occurs going from left toward the right, indicates — in the northern signs, and indeed in the hours from sunset — the nearest hour after noon; while in the hours from sunrise it indicates the hour that most nearly precedes noon.

The same sign $\dagger$, which under the hours from sunrise and sunset first occurs going from right toward the left, indicates — in the southern signs, and indeed in the hours from sunset — the nearest hour after noon; while in the hours from sunrise it indicates the hour that most nearly precedes noon.

[Margin: Which hour, reckoned from sunrise or sunset, occurs after noon.]

4. Furthermore, that hour from sunrise whose distance after sunrise is greater than the semidiurnal arc, and that hour from sunset whose distance before sunset is less than the semidiurnal arc, is a postmeridian hour, as is plain.

It is also manifest and clear that all antemeridian hours are eastern, and all postmeridian hours western.

[Margin: Which hours are eastern and which western.]

5. Finally, in the table of the horizontal circumferences, the circumferences in the northern signs that are enclosed between the letters B and B — inclusive of the degrees and minutes set between them — are Northern; but those between the letters A and A are Southern. The remaining ones from B onward, after the second letter A up to the end, are again Northern. In the southern signs, however, all the circumferences of the hours standing above the horizon are southern. But so that we may judge, concerning all the hours in the southern signs, which are southern and which northern, this rule of the Circumference must be held: the circumferences that in the northern signs are northern are, in the southern signs, southern, and conversely. And so, proceeding from left toward the right for the southern signs, the letter B must be changed into A, and A into B.

[Margin: Which circumferences are Northern and which Southern.]

6. Now, I have proceeded in three of the tables — namely in tables 9, 10, and 12 — by whole degrees only of the pole's elevation. This is partly because, through the proportional part between two neighbouring degrees of the pole's elevation, no error greater than one minute or another at most is committed; and partly because, even if the tables were extended by fifteen-minute steps, one would nonetheless very often have to apply the proportional part, namely whenever the minutes attached to the whole degrees are not exactly 15, or 30, or 45. For if the proportional part were then neglected, an error of not a few minutes would be admitted.

[Margin: Why the preceding tables were computed by whole degrees only. How the proportional part in the table of altitudes is extracted, when one hour is above the Horizon and the other below.]

7. Moreover, when the Sun's altitude for a given hour is sought by the proportional part at a pole-elevation lying between two whole-degree elevations — and in one of those elevations the hour is above the horizon, while in the other it is below — one must add a quadrant [90°] to the altitude of the hour below the horizon, and take the complement of the altitude of the other hour above the horizon, so as to have the arcs of the Verticals between the zenith of the place and the Sun in each elevation of the pole. Then the lesser arc is to be subtracted from the greater, so that a difference is obtained, with which the proportional part is to be extracted from the table of proportional parts; and this part is to be subtracted from, or added to, the Sun's distance from the zenith in the lesser altitude, according as that distance is greater or less than the Sun's distance from the

zenith in the greater latitude. And if the residual arc — whether the remainder or the sum — is less than a quadrant, its complement will be the sought altitude of the Sun above the horizon; but if it is greater, then, once the quadrant has been subtracted, the sought altitude below the horizon will remain.

For example: at latitude 41° , the hour 9 from sunset (and 15 from sunrise), with the Sun at the beginning of ♄ , has an altitude of $0^\circ 23'$ below the horizon, and so the Sun is then distant from the zenith $90^\circ 23'$. But at latitude 42° the same hour has an altitude of $0^\circ 41'$ above the horizon, and accordingly the Sun is then $89^\circ 19'$ from the zenith. The difference between these two distances from the zenith amounts to $1^\circ 4'$; with which, for the latitude — say — of $41^\circ 15'$, the proportional part is found to be $0^\circ 16'$. This, taken from $90^\circ 23'$ (namely from the Sun's distance from the zenith in the lesser latitude, since this is the greater), leaves a distance from the zenith of $90^\circ 7'$; that is, an altitude of $0^\circ 7'$ below the horizon. With the same difference of $1^\circ 4'$, for latitude $41^\circ 30'$ the proportional part is found to be $0^\circ 32'$, which subtracted from the same $90^\circ 23'$ leaves a distance from the zenith of $89^\circ 51'$; that is, an altitude of $0^\circ 9'$ above the horizon. Likewise, with the same difference of $1^\circ 4'$, for latitude $41^\circ 45'$ the proportional part is found to be $0^\circ 48'$, which taken from the same $90^\circ 23'$ leaves a distance from the zenith of $89^\circ 35'$; that is, an altitude of $0^\circ 25'$ above the horizon.

Again: at latitude 41° , the hour 15 from sunset (and 9 from sunrise), with the Sun at the beginning of ♄ [Capricorn], has an altitude of $0^\circ 23'$ above the horizon, and so the Sun is then $89^\circ 37'$ from the zenith. But at latitude 42° the same hour has an altitude of $0^\circ 41'$ below the horizon, and accordingly is $90^\circ 41'$ from the zenith. The difference between these two distances from the zenith again comprises $1^\circ 4'$; with which, for latitude $41^\circ 15'$, the proportional part is found to be $0^\circ 16'$. This, added to the distance from the zenith in the lesser latitude — namely to $89^\circ 37'$, since this is the smaller — yields a distance from the zenith of $89^\circ 53'$; that is, an altitude of $0^\circ 7'$ above the horizon. With the same difference of $1^\circ 4'$, for latitude $41^\circ 30'$ the proportional part obtained is $0^\circ 32'$, which added to the same $89^\circ 37'$ makes $90^\circ 9'$; that is, an altitude of $0^\circ 9'$ below the horizon. Finally, with the same difference of $1^\circ 4'$, for latitude $41^\circ 45'$ the proportional part offered is $0^\circ 48'$, which added to the same $89^\circ 37'$ makes a distance from the zenith of $90^\circ 25'$; that is, an altitude of $0^\circ 25'$ below the horizon. And so for the rest.

8. The same must be observed in the horizontal circumferences, when one is northern and the other southern. For then the distances of both must be taken on the horizon from the same point of the meridian, etc. Suppose, for instance, that the horizontal circumference of the hour 10 from sunset (and 14 from sunrise) is

sought at latitude $58^{\circ}15'$, with the Sun in the first degree of ♄ . Since that circumference at latitude 58° is northern by $1^{\circ}24'$, while at latitude 59° it is southern by $1^{\circ}2'$, the former will be distant from the meridian toward the north by $88^{\circ}36'$, and the latter by $91^{\circ}2'$. Subtracting the former from the latter, the remaining difference will be $2^{\circ}26'$; with which the proportional part is found to be $0^{\circ}36'30''$. This, added to the distance in the lesser latitude — namely to $88^{\circ}36'$, since it is the smaller — makes a distance of $89^{\circ}12'$ (for the 30 seconds are neglected in the proportional part); the complement, then — that is, $0^{\circ}48'$ — will be the sought circumference, and it is Northern. Likewise, at latitude $58^{\circ}30'$, with the same difference of $2^{\circ}26'$, the proportional part is $1^{\circ}13'$, which, added to that same distance in the lesser latitude, makes a distance of $89^{\circ}49'$; and accordingly its complement, $0^{\circ}11'$, will be the horizontal circumference, still Northern. Finally, at latitude $58^{\circ}45'$, the proportional part found is $1^{\circ}49'$, which added to that same distance in the lesser latitude makes $90^{\circ}25'$. The horizontal circumference is therefore Southern by $0^{\circ}25'$.

But if the aforesaid distances are taken on the horizon from the meridian toward the south, then in the lesser latitude the distance will be $91^{\circ}24'$, and in the greater latitude $88^{\circ}58'$ — that is, the complement of the horizontal and southern circumference, $1^{\circ}2'$. The difference of these distances is again $2^{\circ}26'$. If, then, you subtract the proportional parts found from the distance of the lesser latitude (since it is the greater), there will remain $90^{\circ}48'$ for the distance in the lesser latitude, at latitude $58^{\circ}15'$; and accordingly the horizontal circumference will be $0^{\circ}48'$ Northern. But for latitude $58^{\circ}30'$ there will remain a distance of $90^{\circ}11'$, and so the horizontal circumference will be $0^{\circ}11'$, still Northern. Finally, for latitude $58^{\circ}45'$, the remaining distance becomes $89^{\circ}35'$; and therefore its complement, $0^{\circ}25'$, will be the horizontal circumference, and Southern.

[Margin: What to do when one horizontal circumference is northern and the other southern.]

9. By like reasoning, when in one latitude the horizontal circumference of some hour is antemeridian, and postmeridian in the other, the distances must be taken on the horizon from the Vertical — whether eastern or western — etc. For example, at latitude 58° the horizontal circumference of the hour 9 from sunset, in the first degree of ♄ , is antemeridian by $88^{\circ}33'$; but at latitude 59° it is postmeridian by $87^{\circ}51'$ — that is, it is distant from the eastern Vertical $92^{\circ}9'$. The former distance subtracted from the latter, the remaining difference is $3^{\circ}36'$; to which, for latitude $58^{\circ}15'$, corresponds a proportional part of $0^{\circ}54'$. This, added to the distance in the lesser latitude — namely to $88^{\circ}33'$, since it is the smaller —

makes a distance of $89^{\circ}27'$ for the horizontal and antemeridian circumference. But for latitude $58^{\circ}30'$, with the aforesaid difference, the proportional part found is $1^{\circ}48'$, which, added to that same distance of the lesser latitude — that is, to $88^{\circ}33'$ — makes $90^{\circ}21'$. Therefore, once 90° has been taken away, the complement of the remaining 21 minutes — namely $89^{\circ}39'$ — will be the postmeridian horizontal circumference.

[Margin: When one circumference is antemeridian and the other postmeridian, what to do. (Source prints "agnndum" for "agendum.")]

Likewise, at latitude $58^{\circ}8'$, with the same difference of $3^{\circ}36'$, the proportional part is found to be about $0^{\circ}49'$, which added to $88^{\circ}33'$ makes $89^{\circ}22'$ for the antemeridian horizontal circumference.

Again: at latitude 58° the horizontal circumference of the hour 9 from sunrise, at the beginning of $\mathfrak{D}$, is $88^{\circ}33'$ postmeridian; but at latitude 59° it is antemeridian by $87^{\circ}51'$. That hour, then, is distant in the lesser latitude from the western Vertical by $88^{\circ}33'$, and in the greater latitude by $92^{\circ}9'$. Hence the difference will be $3^{\circ}36'$; with which, for latitude $58^{\circ}8'$, the proportional part is found to be $0^{\circ}49'$, which added to the distance in the lesser latitude makes the horizontal circumference $89^{\circ}22'$ postmeridian. And so for the rest.

[Margin: Which hours, when the Sun is on the Equator, have the same altitudes above and below the Horizon, and the same horizontal circumferences.]

10. Finally, in the table of the Sun's altitudes for the hours — both those reckoned from noon and midnight and those reckoned from sunrise and sunset — and likewise in the table of the horizontal circumferences, with the Sun on the Equator, it must be noted that the hours which lie below the horizon at the same distance from it as the hours above the horizon have equal altitudes and equal horizontal circumferences. Such are the hours 5 and 7 from noon or midnight; likewise 4 and 8, etc.; likewise the hours 23 and 1 from sunrise or sunset; likewise 22 and 2; and so on. This is easily gathered from the calculation set out in problems 15 and 16 of the New Description of Sundials, and it can also be demonstrated in this way. Let two arcs of the Equator be taken beginning from the horizon, one above the horizon and the other below it; and let two verticals be understood to run through their end-points, so that two right triangles are formed. In these triangles, since the two sides opposite the right angles are set equal on the Equator, and the remaining two angles which the Equator makes with the horizon are equal at the vertex (by proposition 6 of our [treatise on] spherical triangles) — these being indeed the angles of the complement of the

pole's altitude — then, by proposition 21 of those same triangles, the remaining sides of the one triangle will be equal to the remaining sides of the other: namely the altitudes both above and below the horizon, and the horizontal circumferences. Which is what was proposed.

Furthermore, in the table of semidiurnal arcs — which is the fourth in the order of the tables — we have proceeded only up to a pole-altitude of $66\frac{1}{2}^{\circ}$ [$66^{\circ}30'$], for the reason that at a greater elevation of the pole the day at the beginning of $\mathfrak{S}$ is longer than 24 hours (the Sun of course not setting), while at the beginning of $\mathfrak{V}$ the Sun does not rise, but always lies hidden below the horizon.

[Margin: Why tables 20 and 21 begin from pole-altitude $23^{\circ}30'$.]

The tables 20 (of the Sun's altitudes on the prime Vertical) and 21 (of the Sun's distances from the meridian on the same Vertical) we have likewise begun from a pole-altitude of $23^{\circ}30'$, because at a lesser pole-altitude the prime Vertical does not cut all the northern parallels, but only those whose declination is greater than the pole's altitude. Therefore, in these parallels, the altitude of the Sun standing on the Vertical — and its distance from the meridian — will have to be computed, when the matter requires, by the teaching of problem 7 of the New Description of Sundials.

[Margin: The distances of the Sun from the meridian on the [prime] Vertical are equal to the semidiurnal arcs of the opposite signs in the complement of the pole's elevation.]

Moreover, the distances of the Sun from the meridian, when it is on the Vertical, are equal to the semidiurnal arcs (a thing worth observing) of the opposite southern signs at the pole-elevation which is the complement of the proposed elevation. For example, at pole-elevation 57° , the Sun's distance from the meridian, when it is on the Vertical and at the beginning of $\mathfrak{S}$, is $73^{\circ}36'$; and just so great also is the semidiurnal arc of $\mathfrak{V}$ at pole-elevation 33° ; and so for the rest. The reason is that the prime Vertical, at the pole-elevation which is the complement of the given elevation, is the horizon above which the antarctic pole is elevated; and accordingly the tropic of $\mathfrak{S}$, which the Vertical cuts, is like the tropic of $\mathfrak{V}$, etc.

THERE FOLLOW ASTRONOMICAL PROBLEMS 17 [Sequuntur Problemata XVII]

To be solved by means of Sines, Tangents, and Secants: from which both the preceding tables have been constructed, and others, new ones, can be built; and

finally other matters pertaining to the construction of sundials [horologia] investigated.

PROBLEM I.

To find the declination of a given point of the Ecliptic, the maximum declination being taken as $23^{\circ} 30'$.

Let ABCD be any Horizon; let AEC be the Meridian, and BED the Equator. Conceive the Ecliptic to be BFD, such that EBF is the angle of maximum declination. Let any point G of the Ecliptic be proposed, and through it, from H, the pole of the world, let the circle of declination HGI be drawn. By proposition 15 of Book I of Theodosius [Theodosius of Bithynia, *Sphaerica*], this circle stands at right angles to the Equator, and therefore its arc GI measures the declination of the point G, which we are bidden to find. For in the spherical triangle BGI the angle I is right, and the arc BG — which measures the distance of the point G from the equinoctial point B — is known, together with the angle GBI of the maximum declination. Solve by the first method of problem 8 of the [treatise on] spherical triangles [*Triangula Sphaerica*]. (We shall always apply our problems on spherical triangles as demonstrated at the end of Lemma 53, Book I, of the Astrolabe [Clavius, *Astrolabium*].)

Let it be: as the whole sine [radius] to the sine of the base BG, which measures the distance of the ecliptic point G from the equinoctial point B, so the sine of the angle GBI of the maximum declination, to a fourth term; there will be produced the sine of the arc GI, the declination sought.

It is enough to find the declination of the points of the Ecliptic in one quadrant, since these are equal to the declinations of the points in the three remaining quadrants, as we demonstrated in Lemma 49, No. 5, of Book I of the Astrolabe.

Diagram. An uncaptioned circular diagram (a plane projection of the sphere) enclosed in a square frame, set at the upper left of the page. It shows the Horizon ABCD as the bounding circle, the Meridian AEC and Equator BED as great circles through the centre E, the Ecliptic BFD, the circle of declination HGI through the pole of the world H, and — for the later problems that reuse the same figure — a declining/inclined Vertical PFQ with its proper Meridian, together with a Sun-parallel KL and the associated hour-circles. Many labels are very small, and several occur twice (for the northern and southern hemispheres of the projection); the readings below are given with their approximate positions, and

the uncertain ones are flagged. This dense figure is a (more than two labels flagged).

- A (top of the frame, apex of the Meridian): pole/apex point
- [? — small mark just left of X, upper left]: unresolved glyph
- X (upper left, on an inner arc): point on an oblique circle
- V (left, upper): point
- L (left side): point
- B (left, at the Horizon–Equator intersection): western equinoctial point
- I (left of centre): foot of the declination circle on the Equator
- M (upper centre, on the Meridian between A and E): point
- R (centre): point
- E (centre): common intersection / centre of the projection
- N (right of centre): point on the Equator
- K (upper right): point
- D (right, at the Horizon–Equator intersection): eastern equinoctial point
- L (right, below D): point [second L]
- K (lower left): point [second K]
- G (lower left of centre): the given point of the Ecliptic
- F (lower centre): point on the Ecliptic / prime Vertical
- M (lower centre, below R/E): point [second M]
- O (lower centre): point
- T (lower centre): point
- H (bottom centre): pole of the world
- C (bottom, below H, marked "/C"): lower apex of the Meridian
- S (lower right): point
- P (lower right): point of the inclined Vertical

PROBLEM II.

To compute the semidiurnal arc of any parallel of the Equator, for any given altitude of the pole.

In the figure of the preceding problem, let KL be a parallel of the Equator, whether northern or southern, cutting the Meridian at M, so that the semidiurnal arc is KM, which we are bidden to find. From H, the pole of the world, through the point K (where the parallel cuts the Horizon), let a great circle HK descend,

cutting the Equator at N. By proposition 10 of Book 2 of Theodosius, the arc EN of the Equator will be similar to the semidiurnal arc KM. And since in the northern spherical triangle BKN the angle N is right, and the arc KN of declination is known, together with the angle KBN of the Equator's altitude above the Horizon — which is equal to the angle ABE that the Equator makes with the Horizon toward the southern parts — solve by the first method of problem 10 of the [treatise on] spherical triangles.

Let it be: as the whole sine to the Tangent of the complement of the angle B — that is, to the Tangent of the pole's altitude — so the Tangent of the arc KN, the declination of the parallel, to a fourth term; there will come out the sine of the arc BN, by which the northern semidiurnal arc exceeds the quadrant, or by which the southern semidiurnal arc falls short of the quadrant.

The same reasoning holds for the southern parallel, as is clear in the triangle DKN. Therefore, if this arc found is added to the quadrant, the northern semidiurnal arc is formed; but if it is subtracted from the quadrant, the remainder becomes the southern semidiurnal arc. Yet it is also enough to investigate the differences between the quadrant and the semidiurnal arcs of one quadrant of the Ecliptic, for these differences are equal in the other quadrants, as was shown in Lemma 49, No. 15, of Book I of the Astrolabe. From this problem the fourth table, of semidiurnal arcs, was constructed.

PROBLEM III.

To find the rising or setting amplitude of any point of the Ecliptic, for any latitude of place.

In the same figure of problem 1, the arc BK of the Horizon measures the rising or setting amplitude of the parallel KL, which we shall elicit as follows. Since in the spherical triangle BKN the angle N is right, and the arc KN — the declination of the parallel passing through the given point of the Ecliptic — is known, together with the angle KBN of the Equator's altitude, solve by the first method of problem 14 of the [treatise on] spherical triangles.

Let it be: as the whole sine to the secant of the complement of the angle KBN — that is, to the secant of the pole's altitude — so the sine of the arc KN of declination, to a fourth term; there will be produced the sine of the arc BK, the northern rising or setting amplitude.

The same reasoning holds for the arc DK of the southern amplitude. But it is enough to compute the amplitudes of the points of one quadrant of the Ecliptic, for these agree also with the points of the other quadrants, as we demonstrated in Book I of the Astrolabe, Lemma 49, No. 5. And from this problem we constructed the fifth table, of rising and setting amplitudes.

PROBLEM IV.

Given any Vertical circle and its declination, to determine the altitude of the pole above it, in any given latitude of place.

In the figure above, let the prime Vertical in the given region be BFD, and the Vertical inclined to it PFQ, whose proper Meridian HO stands at right angles to it, so that HO is the arc of the altitude of the pole H above that same Vertical — the arc we must find. For in the spherical triangle FHO the angle O is right, and the arc FH — the complement of the pole's altitude above the Horizon — is known, together with the angle HFO of the inclination of the Vertical PQ to the Meridian AC (that is, the complement of the declination of that same Vertical from the prime Vertical BFD). Solve by the first method of problem 8 of the [treatise on] spherical triangles.

Let it be: as the whole sine to the sine of the base FH — that is, to the sine of the complement of the pole's altitude above the Horizon — so the sine of the angle HFO, of the complement of the declination of the declining Vertical, to a fourth term; there will be produced the sine of the arc HO, the altitude of the pole above the proposed Vertical PQ.

PROBLEM V.

Given any Vertical and its declination, to find the inclination of its own Meridian to the Meridian of the Horizon, in any latitude of place.

In the same preceding figure, we must find the angle FHO which HO — the proper Meridian of the given Vertical PQ — makes with FH, the Meridian of the Horizon, and which measures the inclination of the one Meridian to the other. Since in the same right-angled spherical triangle FHO the same things are known as before, solve by the first method of problem 3 of the [treatise on] spherical triangles.

Let it be: as the whole sine to the sine of the complement of the base FH — that is, to the sine of the pole's altitude above the Horizon — so the Tangent of the angle HFO, of the complement of the declination, to a fourth term; there will be generated the Tangent of the complement of the sought angle FHO, which measures the inclination of the Meridians.

PROBLEM VI.

Given any Vertical and its declination, to compute — for any latitude of place — how great its arc is between the Horizon and the Equator; and between its own Meridian and the Meridian of the Horizon; likewise between the Meridian of the Horizon and the Equator; and also between its own Meridian and the Horizon.

In the same figure of problem 1, the four arcs of the Vertical PQ which we have named are these: QR, between the Horizon and the Equator; FO, between its proper Meridian and the Meridian of the Horizon; FR, between the Meridian of the Horizon and the Equator; and OP, between its proper Meridian and the Horizon. Now in the spherical triangle NOR the angles N and O are right — for HO is the proper Meridian of the Vertical PQ and therefore at right angles to it, while H is the pole of the Equator and hence, by proposition 15 of Book I of Theodosius, also at right angles to it. Therefore, by proposition 25 of our [treatise on] spherical triangles, RN and RO are quadrants, and consequently the quadrant RO is equal to each of the quadrants FQ and FP. Subtracting, then, the common arc FR, the remaining arcs QR and FO will be equal. Likewise, subtracting the common arc FO, the remaining arcs FR and OP will also be equal. Therefore, once one of them is known, the other three will also be known. For example, once the arc QR between the Horizon and the Equator is known, its equal FO — between the proper Meridian and the Meridian of the Horizon — will also be known; likewise its complement FR, between the Meridian of the Horizon and the Equator; and therefore also OP, equal to FR, between the proper Meridian and the Horizon. We shall investigate the arc QR between the Horizon and the Equator (which is enough) in this way. Since in the spherical triangle BQR the angle Q is right, and the arc BQ — which measures the declination of the Vertical — is known, together with the angle QBR of the Equator's altitude, that is, of the complement of the pole's altitude above the Horizon, solve by the first method of problem 11 of the [treatise on] spherical triangles.

Let it be: as the whole sine to the sine of the arc BQ, of the declination of the Vertical; so the Tangent of the angle QBR, of the complement of the pole's altitude above the Horizon, to a fourth term; there will be

produced the Tangent of the arc QR, between the Horizon and the Equator, which is sought.

From this the other three will be known, as was said a little earlier. For FO is equal to it, and FR is its complement, to which OP is equal, as we have shown.

PROBLEM VII.

To explore the altitude of the Sun when it is on the prime Vertical of any great circle taken as a Horizon; and the hour, when the Sun is on that Vertical, in any region.

In the same figure, let the Sun's parallel KL cut the prime Vertical BFD of the great circle ABCD — taken as a kind of Horizon — at G. We must find the arc GB of the Sun's altitude at G, the common section of the parallel with the Vertical, and what the hour then is. Draw from the pole H, through G, the great hour-circle cutting the Equator at I. Then in the spherical triangle BGI the angle I is right (by proposition 15 of Book I of Theodosius), and the arc GI, of the parallel's declination, is known, together with the angle GBI of the pole's altitude above the great circle ABCD — the angle, that is, which the Vertical makes with the Equator. Solve by the first method of problem 14 of the [treatise on] spherical triangles.

Let it be: as the whole sine to the secant of the complement of the angle GBI — that is, to the secant of the complement of the pole's altitude above the given great circle — so the sine of the arc GI, of the parallel's declination, to a fourth term; there will be found the sine of the base GB, the Sun's altitude on the Vertical.

Again, solve by the first method of problem 10 of the [treatise on] spherical triangles:

Let it be: as the whole sine to the Tangent of the complement of the angle GBI — that is, to the Tangent of the complement of the pole's altitude above the given great circle — so the Tangent of the arc GI, of the parallel's declination, to a fourth term; there will be found the sine of the arc BI, by which the quadrant BE exceeds the arc EI, the distance of the Sun from its proper Meridian.

If to this distance the inclination of the proper Meridian to the Meridian of the Horizon is added, or subtracted from it, as the matter requires, the distance of the Sun from the Meridian of the Horizon will be obtained. By this reasoning we computed tables 20 and 21.

PROBLEM VIII.

Given any Vertical and its declination, to know — in any region — how great its own arc is between the Meridian of the Horizon and the 6-hour circle reckoned from noon or midnight; likewise between the Horizon and the same 6-hour circle; and finally between the Horizon and the 12-hour circle reckoned from sunrise or sunset.

In the figure above, let the 6-hour circle from noon or midnight, BHD, be drawn, cutting the Vertical PQ at S. Both arcs FS and SP are proposed for investigation, which we shall track down thus. Since in the spherical triangle FHS the angle H is right, and the arc FH — the complement of the pole's altitude — is known, together with the angle HFS, the complement of the declination of the Vertical PQ, solve by the first method of problem 13 of the [treatise on] spherical triangles.

Let it be: as the whole sine to the sine of the complement of the angle HFS — that is, to the sine of the declination of the Vertical; so the Tangent of the complement of the arc FH — that is, the Tangent of the pole's altitude — to a fourth term; there will be produced the Tangent of the complement of the base FS — that is, the Tangent of the arc SP, which was sought in the second place.

From this the arc FS, proposed in the first place, will also become known, since it is the complement of the arc SP just found.

Next, in the spherical triangle DOP — the 12-hour circle from sunrise or sunset, BTD, having been drawn, cutting the Vertical PQ at O — the angle P is right, and the arc DP, of the Vertical's declination, is known, together with the angle ODP; for the arc CT, double the pole's altitude, measures that angle. This is because the circle BTD touches, at T, the greatest of the ever-apparent parallels [the circle of perpetual apparition], and therefore the arc HT is equal to the arc HC of the pole's altitude, and consequently the whole arc CT is double that same arc HC. Solve by the first method of problem 11 of the [treatise on] spherical triangles.

Let it be: as the whole sine to the sine of the arc DP, of the declination of the Vertical PQ; so the Tangent of the angle ODP — that is, the Tangent of the arc double the pole's altitude above the Horizon — to a fourth term; there will come out the Tangent of the arc OP, which is sought.

This arc, in a latitude of place less than 45° , is always less than a quadrant, because the angle ODP is less than 90° . But in a latitude of place of 45° it is a quadrant, because that same angle is then equal to 90° . And finally, in a latitude

of place greater than 45° , it is greater than a quadrant, because the said angle then exceeds 90° . All these things are gathered from the aforesaid problem 11 of the [treatise on] spherical triangles.

PROBLEM IX.

Given any plane, together with the altitude of the pole above it, to inquire how great its arc is that lies between any hour-circle (reckoned from noon or midnight) and the common intersection of that circle with the Equator.

In the same figure above, let there first be found, on the Horizon, the arc BK, between the hour-circle HK and the intersection B of the Equator with the Horizon. Since in the spherical triangle CHK the angle C is right, and the arc CH — the pole's altitude above the Horizon — is known, together with the angle CHK, of the distance of the Sun (or of the hour-circle) from the Meridian — (which distance is to be taken from the Meridian below the Horizon when the hour-circle cuts the Horizon in the northern quadrant, but from the Meridian above the Horizon when the same circle cuts the southern quadrant of the Horizon, as at the point V; but then the angle of the said distance, MHV, has the same Tangent, the same sine, and the same secant as the angle CHV in the triangle CHV) — solve by the first method of problem 11 of the [treatise on] spherical triangles.

Let it be: as the whole sine to the sine of the arc CH, of the pole's altitude above the Horizon; so the Tangent of the angle CHK, of the distance from the Meridian of the Horizon, to a fourth term; there will be produced the Tangent of the arc CK; and when this is subtracted from the quadrant CB, the remainder becomes the arc BK, which is sought.

By like reasoning, in the triangle CHV, if

Let it be: as the whole sine to the sine of the arc CH, of the pole's altitude above the Horizon;

PROBLEM IX. (continued)

[The proportion begun at the foot of the preceding page continues:]

Let it be: as the whole sine to the sine of the arc CH, of the pole's altitude above the Horizon; so the Tangent of the angle CHV, of its distance from the Meridian of the Horizon, to a fourth term; there will be produced the Tangent of the arc CV, greater than a quadrant — since the angle CHV is

obtuse, which always happens when the hour-circle cuts the southern quadrant of the Horizon.

Therefore, once the quadrant CR is subtracted, the remainder becomes the sought arc BV. In just the same way the arc BX will become known, in the triangle CHX.

Next, in the declining Vertical PQ, let the arc RS be sought, lying between the Equator and the hour-circle HS. Accordingly, in the triangle HOS:

Let it be: as the whole sine to the sine of the arc HO, of the pole's altitude above the Vertical PQ; so the Tangent of the angle OHS, of the distance of the hour-circle HS from its own Meridian HO (belonging to the same Vertical), to a fourth term; there comes out the Tangent of the arc QS. When this is added to the quadrant OR, the arc RS will be known, greater than a quadrant; but when that same [Tangent] is subtracted from the quadrant between O and the other intersection of the Equator with the Vertical PQ, the arc between the circle HS and this other intersection will be left known.

Lastly, in the prime Vertical let the arc BG be found, lying between the hour-circle HG and the Equator. Accordingly, in the triangle FGH:

Let it be: as the whole sine to the sine of the arc FH, of the pole's altitude above the Vertical (which is always equal to the complement of the pole's altitude above the Horizon); so the Tangent of the angle FHG, of the distance of the hour-circle from the Meridian of the Vertical, to a fourth term; there results the Tangent of the arc FG. When this is subtracted from the quadrant FB, the remaining arc BG — which we seek — will be known.

And so the arc of the Horizon for any given hour, at any elevation of the pole, is the arc of the prime Vertical in that region where the pole's altitude is the complement of the earlier altitude, and conversely. For in this other region the pole's altitude above the prime Vertical equals the pole's altitude in the former region — that is, the complement of the pole's altitude in this other region. It is therefore enough to find the arcs of the Horizon for the individual elevations of the pole; for these same arcs will also be the Vertical arcs at the complementary elevations. By this reasoning we have constructed the sixth table of arcs, which in the Gnomonics we have called "hour-arcs" [horarios].

PROBLEMA X.

If, through the pole of any great circle, a Vertical is drawn at right angles to any great circle passing through the poles of the world, to investigate how great is the arc of that circle passing through the poles of the world which lies between that perpendicular Vertical and the nearer pole of the world.

Diagram. An orthographic projection of the celestial sphere set within a square frame, the master figure serving Problems X and XI (the same figure referred to in the preceding problems). The circle carries the horizon ABCD, the meridian, the prime vertical, hour-circles, and the ecliptic, crossing one another in a dense network of great-circle arcs. Readable labels, by approximate position:

- A (top of circle, 12 o'clock)
- e, X (upper-left interior, adjacent)
- V (upper left, ~10 o'clock)
- M (upper middle, below A)
- K (right edge, upper)
- L (left edge, ~9 o'clock)
- I, R, E, N (interior, along the middle band, left to right; E at the centre)
- B (left edge, ~8 o'clock)
- D (right edge, ~3–4 o'clock)
- G (lower left-of-centre)
- F (lower centre, above H)
- O (lower centre-right)
- H (bottom centre, above C)
- S, P (bottom, right of H)
- C (foot of circle, 6 o'clock)

Several small interior labels near the centre and lower-left (apparent repeats of K, L, M, N) could not be resolved with certainty under magnification and are not committed here (more than two labels unresolved).

In the preceding figure, let a Vertical FO be drawn through F, the pole of the greatest circle ABCD — whose Meridian is AFC — to the hour-circle HOK (which passes through the pole of the world H), making right angles with HOK. The arc HO is to be investigated. Now in the spherical triangle FHO the angle O is right; the arc FH, of the complement of the pole's altitude above the given great circle ABCD, is known (since HC is the arc of the pole's altitude), together with the angle FHO, of the distance of the hour-circle HOK from the Meridian AFC of the given

circle. (For this distance must be known, along with the altitude of the pole above the given great circle.) Solve by the first method of problem 9 of the [treatise on] spherical triangles.

Let it be: as the whole sine to the sine of the complement of the angle FHO, of the distance from its own Meridian; so the Tangent of the base FH, of the complement of the pole's altitude above the given circle, to a fourth term; there will be procreated the Tangent of the arc HO, which is sought.

And it was in this way that we computed the table which is contained in our compendium of sundials [*compendio nostro horologiorum*].

PROBLEMA XI.

Given a diurnal arc of any number of hours, to determine its declination for any latitude of the place.

In the same figure, let the northern diurnal arc KL be given, of any number of hours. From the pole of the world H, through K, let a great circle HKN be dropped, so that KN is the arc of declination, which we must investigate. Now in the spherical triangle BKN the angle N is right, and the arc BN — the difference between the given semidiurnal arc EN (for this arc EN is similar to the semidiurnal arc MK, by Theodosius II.10 [proposition 10 of book 2]) and the quadrant EB of the Equator — is known, together with the angle KBN, of the complement of the pole's altitude. Solve by the first method of problem 11 of the [treatise on] spherical triangles.

Let it be: as the whole sine to the sine of the arc BN — that is, to the sine of the difference between the given semidiurnal arc and the quadrant of the Equator; so the Tangent of the angle KBN, of the complement of the pole's altitude, to a fourth term; there will be generated the Tangent of the arc KN, of the declination sought.

The very same reasoning holds for the southern diurnal arc KL, as is clear in the triangle DKN. But it is enough to compute the declinations of the northern (or of the southern) diurnal arcs, for these are equal to the declinations of the opposite arcs. By this technique we have made table 13, containing the declinations of the diurnal arcs computed for a good many elevations of the pole.

PROBLEMA XII.

To find the arc of any great circle drawn through the poles of the Meridian and through any point of that same Meridian, lying between the Equator (or the Meridian) and the great circle described from the intersection of the Equator with the Meridian through any given hour of a given parallel.

A great circle of this kind is: the circle of the 6th hour from noon and from midnight, drawn through the pole of the world; any oblique Horizon; the prime Vertical; and the Ecliptic when its beginning-point of Cancer (♋) or of Capricorn (♐) is placed on the Meridian, and so on. So let ABCD be the Horizon; AEC the Meridian; BED the Equator; KOL the tropic of Cancer (♋); MPN the tropic of Capricorn (♐); BHD the circle of the 6th hour from noon or midnight, passing through H, the pole of the world; BFD the prime Vertical, drawn through F, the pole of the Horizon; BOD the Ecliptic when the beginning of Cancer (♋) is placed above the Horizon at O; and likewise BPD the Ecliptic when the beginning of Capricorn (♐) is placed above the Horizon at P.

Diagram. An orthographic projection of the celestial sphere within a square frame, the working figure for Problem XII. It carries the horizon ABCD, meridian AEC, equator BED, the tropic of Cancer KOL, the tropic of Capricorn MPN, the 6th-hour circle BHD, the prime vertical BFD, and the two ecliptic positions BOD and BPD, all crossing in a dense web of arcs. Readable labels, by approximate position:

- A (top)
- M (upper left), N (upper right)
- P (upper centre, below A)
- B (left edge), D (right edge)
- V (left interior)
- Z (left of centre)
- E (centre)
- K (lower left), L (lower right)
- R (lower centre-left), G (centre-low), F (bottom centre), Y (lower centre-right)
- I (lower left, below K), H (bottom), C (foot of circle)
- O, S, T and a cluster of small lowercase labels (a, b, d, u, and others) crowd the centre.

The small lowercase labels and several interior points at the centre could not be resolved with certainty under magnification and are not individually committed (more than two labels unresolved).

From E, the intersection of the Equator with the Meridian, let there be drawn — through any hour G, reckoned whether from noon and midnight or from sunrise or sunset, on the tropic of Cancer (♋), or through e on the tropic of Capricorn (♏) — the great circle EI, which cuts the circle of the 6th hour at Q, the Horizon at I, the Vertical at R, the Ecliptic BOD at T, and the Ecliptic BPD at S. We must investigate the arcs BQ, BI, BR, BT, BS, or HQ, CI, FR, OT, PS, which we shall find as follows. Draw, from H the pole of the world, through the given hour G, the great circle HG, cutting the Equator at Z. Since in the triangle EGZ the angle Z is right, and the arcs EZ, ZG are known — the former measuring the distance of the given hour from the Meridian, the latter the declination of the parallel — solve by the first method of problem 6 of the [treatise on] spherical triangles.

Let it be: as the whole sine to the sine of the arc EZ, of the distance from the Meridian; so the Tangent of the complement of the arc ZG, of the declination of the parallel, to a fourth term; there results the Tangent of the complement of the angle GEZ — that is, the Tangent of the angle GEO, which the arc HQ measures.

Therefore the arc HQ of the circle of the 6th hour will be known, together with its complement BQ.

Next, since in the triangle CEI the angle C is right, and the arc CE is known (being composed of the quadrant CF, between the Horizon and the zenith of the place, and of the arc FE, between the zenith of the place and the Equator, which equals the pole's altitude), together with the angle CEI just found: solve by the first method of problem 11 of the [treatise on] spherical triangles.

Let it be: as the whole sine to the sine of the arc CE — that is, to the sine of the complement of the pole's altitude, the arc EA (since the two arcs CE, EA have the same sine); so the Tangent of the angle CEI just found, to a fourth term; there will be created the Tangent of the arc CI.

Therefore the arc CI of the Horizon will be known, together with its complement BI.

By the same reasoning, each of the arcs FR, BR of the Vertical will become known, if in place of the arc CE the arc FE (of the pole's altitude) is taken, in the triangle FER. Likewise each of the arcs OT, TB of the Ecliptic BOD, or each of the arcs PS,

SD [printed *PSSD*] of the Ecliptic BPD, if in place of the arc CE the arc EO or EP (of the declination of the parallel) is taken.

But for the hours from noon or from midnight it is enough to compute the aforesaid arcs in one semicircle of any parallel — namely the eastern or the western. For these are equal to the arcs in the other semicircle of the same parallel, and moreover to the arcs in the opposite parallel; because the same great circle IES, drawn through the equal arc OG on the other side of the Meridian, makes the same angle with the Meridian and cuts off, from the equal parallels KL, MN, the equal arcs OG, Pe. For since, by proposition 18 of book 2 of Theodosius, both the arcs EO, EP and the arcs EG, Ee are equal, then by proposition 3 of book 3 of the same [work] the straight lines OG, Pe will be equal, and therefore also the arcs OG, Pe will be equal [Margin: 28. tertij — i.e. Theodosius, *Sphaerica* III.28]. From this it follows that, for the two hours of opposite parallels, the same angle E is always assumed in the computation. Since, then, the declination is likewise the same in both parallels, it is clear that the same arc is found for the two hours of the opposite parallels. Indeed it is enough to compute these arcs for a single quadrant of the parallel, because the same great circle described through E passes through two hours equally distant on either side of the circle of the 6th hour — as we demonstrated in the theorem of the scholium of chapter 8, number 2 — and therefore cuts off the same arc from any one of those great circles.

Now if the point E on the Equator is taken not for the 12th hour, but for any other whatever — so that AEC is not the Meridian, but some other hour-circle, the one which is distant 6 hours from the circle AEC (although it is not drawn through the poles of the Meridian) — just as, if E is no longer the intersection of the Equator with the Meridian but with the hour-circle of the assumed hour: as, if AEC be the circle of the 10th hour, then BHD must be taken for the circle of the 4th hour. In this case indeed the same arcs which, on the circle of the 6th hour, will be cut off for those hours which are so distant on either side from it that they are distant from the circle of the 6th hour by other hours — for which arcs are computed — are removed on both sides. For example, the arc for the 5th and 7th hours on the circle of the 6th hour will be the same as for the 3rd [hour], and so on.

In the same way, if the point E on the Equator is taken for the 6th hour, BND will be the Meridian, because the 12th hour is distant 6 hours from the 6th hour; and therefore the arc for the 5th and 7th hours on the circle of the 6th hour will be the same as for the 1st and 11th on the circle of the 12th hour. Likewise the arc found for the 2nd and 10th hours on the circle of the 6th hour will be the same as for

the 4th and 8th on the circle of the 12th hour, because the 4th and 8th hours are distant on either side from the 12th hour by four hours, just as the 2nd and 10th hours are also distant on either side from the 6th hour by four hours.

By this technique we constructed tables 1 and 3, which are universal; and likewise tables 7, 8, 14, 15, 16, and 17, which are particular, computed namely for the latitude of 42 degrees.

Furthermore, in the hours from sunrise or from sunset, the same arcs computed for any hour on any northern parallel agree also with that hour on the opposite southern parallel, which recedes from the meridian toward sunset by just as much as the former inclines from the meridian toward sunrise, and conversely. As to which hours from sunrise or from sunset agree, at equal distances from the meridian in contrary directions, on opposite parallels — this can easily be recognized from the little table of the scholium of chapter 15. Such hours are, for example, the 21st from sunset in Cancer (♋), and the 15th from sunset in Capricorn (♏), as appears in that table.

Again, since two great circles drawn from E, through two points of the same parallel equally distant from the Horizon toward the Meridian, cut off from any of the aforesaid great circles two equal arcs (because at E they make equal angles with the Meridian): it comes about that two hours from sunrise or from sunset of the same parallel, which are 12 hours — that is, a semicircle — apart from each other, have equal arcs; for two such hours are equally distant from the circle of the 6th hour, from noon or from midnight, going toward the same side, namely the eastern or the western — the one from the semicircle of the 6th hour from noon, the other from the semicircle of the 6th hour from midnight. Since, then, the same great circle described through E cuts off, on either side of that same semicircle of the 6th hour, two equal arcs in the same parallel, as is established from the theorem of the scholium of chapter 8; and since one of these two extreme points of the equal arcs cut off stands as far before one semicircle of the 6th hour as that which is distant from the other by 12 hours stands after the other semicircle: what we have said is evident. For example: by as much as the 23rd hour in Cancer (♋) is distant from the semicircle of the 6th hour from noon toward sunset, by just so much does the 11th hour in Cancer (♋) — which of course is 12 hours from the 23rd — also recede from the semicircle of the 6th hour from midnight toward sunset. Since, then, the great circle from E, drawn through the 11th hour from sunset in Cancer (♋), cuts off from the parallel of Cancer (♋) a point as far distant from the semicircle of the 6th hour from midnight toward sunrise as the interval by which the 11th hour is from the same

toward sunset — and hence as far as the 23rd hour is from the semicircle of the 6th hour from noon toward that same sunset — it plainly follows that the two great circles from E, through the 23rd and 11th hours from sunset, cut off equal arcs from the aforesaid great circles; and so of the rest.

Finally, since the same circle of the hours from sunrise and from sunset, passing through some one hour from sunrise on any parallel, passes through the hour of the same number from sunrise on the opposite parallel, and a semicircle of the said hour-circle is intercepted between those two hours — as we showed in the scholium of proposition 1 of book 5 of the Gnomonics, before the little tables of the Sun's altitudes, and as we shall show again, and more clearly, in problem 15 — it comes about that the same great circle described through E, passing on any parallel through some hour from sunset, passes on the opposite parallel through the hour of the same number from sunrise, since by proposition 11 of book 1 of Theodosius it bisects that hour-circle. From this it is gathered that two hours of the same number — of which one is reckoned from sunset on any parallel, the other from sunrise on the opposite parallel — possess equal arcs on the aforesaid great circles. And this is the device we used in constructing tables 7, 8, 16, and 17 for the hours from sunrise and sunset, which are particular, computed namely for the latitude of 42 degrees.

PROBLEMA XIII.

To investigate the arc of the Meridian circle lying between the Equator and the great circle which is drawn from any hour on the equinoctial line through a given hour on any parallel.

In the figure next to that of problem 12: from any hour V on the Equator, let a great circle pass through the given hour Y or X, on the parallel KL or MN — namely VY or VX — cutting the Meridian at b or at a. We must inquire the arc Eb or Ea. Now in the triangle VdY (formed by drawing, from the pole of the world H, through the given hour Y on the parallel, the great hour-circle HY, which cuts the Equator at d) the angle d is right, and the arcs Vd, dY are known — this last measuring the declination of the parallel, the former the distance of the assumed hour V from the given hour d. Solve by the second method of problem 6 of the [treatise on] spherical triangles.

Let it be: as the whole sine to the Secant of the complement of the arc Vd, of the distance between the given hours; so the tangent of the arc dY, of the declination of the parallel, to a fourth term; there will be found the Tangent of the angle dVY.

Again, since in the triangle bEV the angle E is right, and the arc VE — measuring the distance of the assumed hour on the Equator from the Meridian — is known, together with the angle bVE just found: solve by the first method of problem 11 of the [treatise on] spherical triangles.

Let it be: as the whole sine to the sine of the arc VE, of the distance between the assumed hour and the Meridian; so the Tangent of the angle bVE just found, to a fourth term: there will come out, known, the Tangent of the arc Eb, which we seek.

In just the same way the arc Ea will be found, which is equal to the arc Eb, if the same circle HY passes through the given hours Y, X.

From this problem, moreover, was composed table 2, for the 5th and 7th hours, distant 5 hours from the meridian on the equinoctial line; likewise for the 4th and 8th hours, distant on the equinoctial line 4 hours on either side from the meridian; and also for the 2nd and 10th hours, distant from the meridian two hours on either side. And in the same manner other tables can be constructed for other hours on the equinoctial line.

PROBLEMA XIV.

Given any vertical circle and its declination, to find how great the arc of the ecliptic is — with the first point of Cancer or of Capricorn placed on the meridian above the horizon — that lies between the meridian and the great circle which is drawn at right angles from the pole of the given vertical circle to the ecliptic.

Let ABCD be the horizon; AEC the meridian; BED the equator; FGH the parallel, which serves both for Cancer (♋) and for Capricorn (♏); BGD the ecliptic, touching the tropic at G; IKL the declining vertical circle, whose pole is M. Through M and through N, the pole of the ecliptic, let the great circle MN be described, cutting the ecliptic at P at right angles, by Theodosius [Theodosius of Bithynia], *Sphaerica* I.15. The arc GP is proposed for investigation.

Now in the spherical triangle DPM the angle P is right, and the arc DM — the complement of the vertical circle's declination — is known, together with the angle MDP. When the ecliptic touches the tropic of Cancer, this angle MDP is composed of ADE, the angle of the complement of the pole's elevation, and of EDG, the angle of greatest declination; but when the ecliptic touches the tropic of Capricorn, it is what remains when EDG, the angle of greatest declination, is subtracted from ADE, the angle of the complement of the pole's elevation. And this angle is always the angle of the meridian altitude of Cancer or of Capricorn

— that is, of the arc of the assumed point lying between Cancer (or Capricorn) and the horizon on the southern side. Solve, then, by the first method of problem 9 of [the treatise on] spherical triangles.

Let it be: as the whole sine [sinus totus] to the sine of the complement of the angle MDP (composed of the complement of the pole's elevation and the greatest declination of the ecliptic; or of what is left when the greatest declination is subtracted from the complement of the pole's elevation); so the tangent of the base DM, the complement of the vertical circle's declination, to a fourth term; there will be produced the tangent of the arc DP, which, subtracted from the quadrant DG, leaves known the sought arc GP.

Diagram. A sphere shown in projection within a square frame. Readable labels, by position:

- A (top of the sphere)
- I (upper left, on the declining vertical)
- M (upper right, pole of the declining vertical)
- G (just below A, on the ecliptic/meridian)
- F (left, upper — near-end of the parallel)
- H (right, upper — near-end of the parallel)
- P (upper-right interior, ecliptic/great-circle intersection)
- B (left, at the equator)
- E (center)
- D (right, at the equator)
- G (lower center-left, second occurrence, on the ecliptic)
- P (interior, right of the lower G, second intersection)
- F (lower left, second end of the parallel)
- K (lower center, on the vertical)
- H (lower right, second end of the parallel)
- O (below K)
- N (lower left, pole of the ecliptic)
- L (lower right, on the declining vertical)
- C (bottom of the sphere)

(The parallel FGH, the ecliptic, and the great circle MN each cross the projection so that G, P, F, and H recur front and back. No caption printed.)

PROBLEMA XV.

To compute the altitude of the Sun, at any hour, above a given great circle, the elevation of the pole above that circle being known.

Let ABCD be the proper meridian of the proposed plane, with center E; let BD be its common section with the [place's] meridian, and AC the section of the plane's primary vertical with the meridian; let DK be the pole's elevation above the plane, found by problem 4; KL the axis of the world; FG the diameter of the equator; and HI the diameter of any parallel, whether northern or southern, about which its semicircle HMI is described. Let HN be the distance of any hour from the proper meridian — whether that hour be reckoned from noon or from midnight, or from sunrise or from sunset. Through H draw HQ parallel to AC, and IQ parallel to BD; then HV will be the sine of the meridian altitude [altitudo meridianal], and QV the sine of the meridian depression. (This meridian altitude and depression, once the pole's elevation above the proposed plane is known, are to be found as taught in the *Gnomonics*, book 1, scholium to proposition 35, and book 5, scholium to proposition 1.) The whole HQ, then, will give the sum of the sine of the meridian altitude and the sine of the meridian depression.

Draw also the line RS parallel to IQ; since [a] HR is to RI as HS is to SQ, HS and SQ will be the halves of the sum HQ. From the hour-point N drop the perpendicular NO to HI, and through O draw OP parallel to BD, to serve as the diameter of the parallel of the horizon (or of the proposed plane) that passes through the Sun as it stands at hour N; so that PV is the sine of the Sun's altitude. This we shall make known by the present method — as we also taught in *Gnomonics* book 1, proposition 36, before finding the Sun's altitude by spherical triangles.

[Margin a: 2.sexti — Euclid, *Elements* VI.2.]

Let it be: as the whole sine HR to HO, the versed sine [sinus versus] of the Sun's distance from its proper meridian; so HS, the half of the sum of the sines of the meridian altitude and depression, to a fourth term: there will be produced the line HP, which, subtracted from HV, the sine of the meridian altitude, leaves PV, the sine of the sought altitude.

When the line HP found is greater than HV, the sine of the meridian altitude, then the sine of the meridian altitude must be taken away from that line found, so that what remains is the sine of the sought altitude above the opposite face of the plane.

When the Sun stands at the first point of Aries (γ) or of Libra (ϱ), its altitude is more easily found. For, in the other figure, let FK be the distance of some hour from the proper meridian; drop KL perpendicular to FG, and through L draw LM parallel to BD, to serve as the diameter of the parallel of the horizon (or of the proposed plane), so that MN is the sine of the Sun's altitude at the proposed hour. If, then,

Diagram. Two circles set side by side within a rectangular frame. The left circle is the general figure of Problem XV; the right circle is the case of the Sun at an equinoctial point (Aries/Libra). Both are divided by two perpendicular diameters and by the sloping chords named in the text.

Left circle — readable labels by position: A (top, slightly left), N (top, right of A), M (upper right), K (upper interior, below N), Y (upper right, at the rim), H (upper left, at the rim), F (left, at the rim), P (interior, upper left), O (interior, right of P), R (interior, center), S (interior, below P), T (interior, below S), B (right, at the rim), V (interior, lower left), E (center), I (interior, lower right), Q (lower left, at the rim), L (bottom left), C (bottom center), G (bottom right). One or two crowded interior labels on the right side (near the R/B region — the text's point X of the perpendicular YX) could not be resolved with confidence [?].

Right circle — readable labels: A (top), K (upper right), F (upper left, at the rim), H (right, at the rim), M (interior, center left), L (interior, center), E (center), N (interior, lower left of center), B (left, at the rim), D (right, at the rim), I (bottom left), C (bottom center), G (bottom right).

(No caption printed. This same two-circle figure is reprinted on the following page — see fig-p824-1.)

Let it be: as the whole sine to LE, the sine of the complement of the Sun's distance from its proper meridian, so FN, the sine of the complement of the pole's elevation above the given plane, to a fourth term; there will be generated MN, the sine of the Sun's altitude, which we seek.

Moreover, when a table of the Sun's altitudes above the horizon is to be compiled for all the hours from noon or from midnight, it is enough to take the hours from noon in the western semicircle of any northern parallel and compute their altitudes. For these altitudes are equal to the altitudes of the hours from midnight in the eastern semicircle, since the hours of the one semicircle contain distances from the meridian equal to the distances of the hours of the other semicircle. But when a table of the Sun's altitudes above the same horizon is to be constructed for all the hours from sunrise and sunset, only the altitudes of the hours of the

same northern parallel need be computed. For from the altitudes of the hours of any parallel the altitudes of the hours of the opposite parallel are easily derived. For the altitudes of the hours of one parallel are equal to the altitudes of the same hours of the opposite parallel — provided that the hours which in the one parallel are numbered from noon or from sunrise are, in the other, reckoned from midnight or from sunset, and conversely; and that those which in the former parallel stand above the horizon are understood to fall below the horizon in the latter, and the reverse. This we shall gather briefly as follows.

[Margin: That the altitudes of the hours in any parallel are equal to the altitudes of the opposite hours in the opposite parallel.]

Let some hour-circle pass, for example, through the 6th hour from noon (or the 23rd from sunset) in the parallel of Cancer, above the horizon: with its other semicircle it will necessarily cut the opposite parallel of Capricorn at the 6th hour from midnight (or the 23rd from sunrise), because, while one semicircle indicates the hour from noon or from sunset, the other belongs to the hour of the same number from midnight or from sunrise, as was shown in the scholia to propositions 9 and 10 of book 1 of the *Gnomonics*. And its portion between the tropics of Cancer and Capricorn will be a semicircle. For since its portion from the equator, proceeding through the northern parts as far as the equator, is a semicircle by Theodosius I.11, if the arc of it between the given hour in Cancer and the equator be subtracted, and the arc of it between the equator and the hour of the same number in Capricorn be added — which by Theodosius II.18 is equal to the former — a semicircle will likewise be produced between the hour in Cancer and the opposite hour in Capricorn. From this it follows that that hour in Capricorn lies below the horizon, lest a portion of that same great circle greater than a semicircle should appear above the horizon. And since any vertical circle bisects any hour-circle, by Theodosius I.11, the vertical circle (or circle of altitude) passing through the given hour in Cancer will pass also through the opposite hour in Capricorn, and its portion between those two hours will be a semicircle, and therefore equal to the semicircle of the same circle above the horizon. If, then, its common segment between the hour in Cancer and the horizon be subtracted (proceeding toward the hour in Capricorn), there will remain an arc of altitude of the hour in Cancer above the horizon equal to the arc of altitude of the opposite hour in Capricorn below the horizon. And the same reasoning holds for the other hour-circles, and so forth.

[Margin: How, from the altitudes of the hours of one parallel, the altitudes of the hours of the same kind in the opposite parallel are derived.]

Now, as is clear from the little table in the scholium of chapter 15, two hours whose numbers make up 24 — the one counted from sunrise, the other from sunset — have the same distance from the meridian on opposite sides, and therefore the same altitude, as is established by calculation. Hence, once the altitudes of the hours from sunset in any parallel are found, the altitudes of the hours from sunset in the opposite parallel will also be known. For two hours from sunset making up 24 have, in opposite parallels, the same altitude — as the 14th hour from sunset in Cancer and the 10th hour from sunset in Capricorn, and so on — because, namely, this hour from sunset in Capricorn has the same altitude as the hour from sunrise which is its complement to 24 (as has been said), and this same hour from sunrise has the same altitude as the hour of the same number from sunset, as we have demonstrated. In just the same way, from the altitudes of the hours from sunrise of one parallel are derived the altitudes of the hours from sunrise of the opposite parallel. Thus you see in table 10 that the 14th hour from sunset in Cancer, the 14th hour from sunrise in Capricorn, and likewise the 10th hour from sunset in Capricorn, have the same altitude, 54 degrees 14 minutes. By the same reasoning, the altitude of any hour from noon in any parallel — which is equal to the altitude of the same hour from midnight in the opposite parallel, as has been said — will also be equal to the altitude of the hour from noon which is its complement to 12, and conversely. Thus you see in table 9 that the 4th hour from noon in Cancer, the 4th hour from midnight in Capricorn, and also the 8th hour from noon in Capricorn, contain the same altitude, 37 degrees 25 minutes. And by this device tables 9 and 10 were constructed.

[Margin: A wonderful shortcut for the altitudes of the hours from noon and midnight above the horizon.] [Margin a: 2.*sexti* — Euclid VI.2.]

Further, for the altitudes of the hours from noon and midnight it is enough, for any hour between noon and the 6th hour from noon in the northern parallel, to find the line HP, as was done for hour N. For if another hour Y be taken, whose distance from the 6th hour M is equal to the distance of hour N from the same 6th hour, and the perpendicular YX be dropped to HI, and through X a line be drawn parallel to BD cutting HV at T, then QT will be equal to HP. (For since the arcs MN and MY are assumed equal, the remaining arcs HN and IY will also be equal, and therefore their versed sines HO and IX, and consequently also HP and QT — [a] which have the same ratio as the equal HO and IX.) If from this QT there be taken QV, the sine of the meridian depression, there will remain TV, the sine of the sought altitude for hour Y. But if HP is found less than the sine of the meridian depression (which happens when the hour lies below the horizon), it must

instead be subtracted from QV, the sine of the meridian depression, so that what remains is the sine of the sought altitude above the horizon of the antipodes.

And so, if for example the altitude of the 8th hour after noon in Cancer is sought, HP must be taken for the 4th hour after noon — which is equally distant from the 6th hour as the 8th hour is — found to be 34075 parts at the latitude of 42 degrees; and this must be subtracted from the sine of the meridian depression, 41469, so that there remains the sine 7394 of the altitude of the 8th hour above the lower face of the horizon, to which there correspond in the table of sines 4 degrees 14 minutes, and so on.

Indeed, for the 4th hour from noon it is enough to take HP as half of the half of the sum of the sines of the meridian altitude and depression, without any other computation. For if N is the 4th hour, the arc NM will contain 2 hours, that is, 30 degrees, whose right sine OR will be half of the whole sine HR, as we demonstrated in [the treatise on] sines; and therefore HP too will be half of HS, which is half of the whole HQ.

Furthermore, if HS, the half of the sum of the sines of the meridian altitude and depression, be subtracted from

Diagram. The two-circle figure of Problem XV, reprinted at the foot of this page. It is identical to fig-p823-2 on the preceding page — a left (general) circle and a right (equinoctial) circle within a rectangular frame, carrying the same labels (left: A, N, M, K, Y, H, F, P, O, R, S, T, B, V, E, I, Q, L, C, G, with one or two crowded right-interior labels unresolved [?]; right: A, K, F, H, M, L, E, N, B, D, I, C, G). No caption printed.

HV, the sine of the meridian altitude, there will remain SV, the sine of the altitude of the 6th hour — which is likewise left over if QV, the sine of the meridian depression, be subtracted from QS, the aforesaid half of the sum.

But if a table of the Sun's altitudes above some other great circle — and not above the horizon — is to be constructed, the altitudes must be found for all 24 hours of the given parallel, namely for the 12 hours from noon and the 12 from midnight, if the discussion concerns hours from noon and midnight. For these altitudes will be equal to the altitudes of the opposite hours in the opposite parallel, as has been shown. But if the matter concerns hours from sunrise and sunset, then for one and the same parallel the altitudes of all 24 hours from sunrise and of all 24 from sunset must be computed. For the former will be equal to the altitudes of all 24 [hours] from sunset in the opposite parallel; the latter to the altitudes of all 24 from sunrise in the same opposite parallel, as is clear from what has been

demonstrated. And the reason why the altitudes of all the hours must be computed for one parallel is that very rarely do two hours have the same distance from the proper meridian, as they do from the meridian of the horizon.

For the right sphere, seek the rule in book 6 of the *Gnomonics*, page 557.

PROBLEMA XVI.

To explore the circumference of any great circle (which stands as the horizon of some place), lying between its primary vertical circle and the vertical circle of the same passing through the center of the Sun at the proposed hour, the elevation of the pole above that circle being known.

Let ABCD be the horizon, or any other great circle standing as a horizon; AEC its meridian; BED the equator; BKD its primary vertical; FHG the parallel [described] either toward the pole of the world P visible above the given great circle, or toward the hidden pole; and KLM the vertical drawn through the Sun as it stands at L. We must investigate the arc BM. Having drawn the great circle of declination PLN from the pole P through the Sun's place L, and from B, through the same place of the Sun, the great circle BLI: since in the spherical triangle BLN the angle N is right, by proposition 15 of book 1 of Theodosius, and the two arcs BN, NL are known — the former being the complement of the Sun's distance from its proper meridian, the latter measuring the Sun's declination — solve by the first method of problem 15 of [the treatise on] spherical triangles.

Let it be: as the whole sine to the sine of the complement of the arc NL, that is, to the sine of the complement of the Sun's declination; so the sine of the complement of the arc BN, that is, the sine of the Sun's distance from its proper meridian, to a fourth term: there will be produced the sine of the complement of the base BL — which Ptolemy in his little book *On the Analemma* calls the *hectemorion* circumference [Hectemoriam circumferentiam; Greek ἑκτημόριον, "one-sixth" arc] — which keep.

Diagram. A sphere shown in projection within a square frame. Readable labels, by position:

- A (top of the sphere)
- M (upper right)
- E (center left)
- N (center)
- O (small label, just right of N)

- D (left, at the rim)
- H (center left, beside L)
- L (center, the Sun's place)
- B (right, at the rim)
- G (lower left, at the rim)
- I (interior, below L)
- F (lower right, at the rim)
- K (interior, below I)
- P (lower left interior, pole of the world)
- C (bottom of the sphere)

(No caption printed.)

Next, since in the triangle BLM the angle M is right, and the arc LM — the Sun's altitude above the given great circle — has been made known by the preceding problem, together with the base BL, whose complement's sine we have just found: solve by the first method of problem 7 of [the treatise on] spherical triangles.

Let it be: as the whole sine to the secant of the arc LM, the Sun's altitude above the given great circle; so the sine of the complement of the base BL, just found, to a fourth term; there will be generated the sine of the complement of the arc BM, which we desire.

When the Sun stands at the first point of Aries or of Libra, we shall more easily find the desired circumference BM of the horizon by a single operation. For since in the triangle BOM the angle M is right, and the arc BO is known (being the complement of the Sun's distance from noon), together with the angle OBM, [the angle] of the complement of the pole's elevation above the given great circle: solve by the first method of problem 9 of [the treatise on] spherical triangles.

Let it be: as the whole sine to the sine of the complement of the angle B, that is, to the sine of the pole's elevation; so the tangent of the base BO, that is, the tangent of the complement of the Sun's distance from noon, to a fourth term; there will come forth the tangent of the desired circumference BM.

But whether the horizontal circumference BM thus found is eastern or western, and whether northern or southern — which it is of great importance to know, so that sundials may be described by them, as is evident from what we wrote in chapter 25 — this we shall now learn. For hours from noon or from midnight, it is

clear that the circumferences of all the hours from midnight are eastern, and those of the hours from noon western. But for hours from sunrise and sunset, the hour of noon must be sought from the semidiurnal arcs of the first table, in this way. If the matter concerns hours from sunrise, the semidiurnal arc of the opposite parallel, reduced to hours by the little table after [chapter] 8 — the office of the equator set forth in chapter 2 of the *Sphere* — indicates the hour of noon. But if hours from sunset are at hand, then, to the seminocturnal arc of the proposed parallel (which is always equal to the semidiurnal arc of the opposite parallel), reduced to hours, if 12 be added, the hour of noon will be made up. For example, the semidiurnal arc of the parallel of Cancer at Rome contains 113 degrees 3 minutes, that is, 7 hours 32 minutes, at which hour after sunrise noon occurs. Likewise the seminocturnal arc of Cancer — that is, the semidiurnal arc of Capricorn — comprises 66 degrees 57 minutes, namely

[Margin: In what cases the horizontal circumferences are eastern or western, and in what cases northern or southern.]

namely 4 hours 28 minutes; and if 12 is added to these, the result is the 16th hour, 28 minutes — the hour of noon reckoned in hours after sunset. Therefore, of all the hours, whether from noon or from sunset, the circumferences of those that precede noon are eastern, while those that follow are western.

NEXT, the circumferences of all the hours — whether from noon or midnight, or from sunrise or sunset — in the northern parallels that have an altitude less than the Sun's altitude when it stands in the vertical circle (which is drawn out from problem 7) are northern; but those of greater altitude are southern. Furthermore, on the Equator and on any southern parallel, all the circumferences above the horizon are southern.

AGAIN, of whichever hours from noon the circumferences in the northern parallel are northern, the circumferences of those same hours from midnight in the southern parallel are southern; and those that are southern in the former are northern in the latter. The same must be said of the hours from midnight in the prior parallel and of the hours from sunrise in the posterior; likewise of the hours from sunset in the prior parallel and of the hours from sunrise in the posterior — as appears on the material sphere.

AND all of this, indeed, is to be understood on the horizon and on the primary vertical. For on other great circles — such as the declining verticals — in place of the noon hour one must take the hour that falls on the proper meridian, which is known from that circle's inclination to the meridian. Likewise, by "northern"

circumferences are to be understood those that tend toward the visible pole above the given great circle, and so forth. From this problem, tables 11 and 12 have been constructed.

FOR the horizontal circumference on the right sphere, seek the rule in Book 6 of the *Gnomonics*, page 558.

PROBLEMA XVII.

To make known the segments of the hour-lines from noon and from midnight — those lying between the centre of the horizontal dial and the parallels of the Sun — in parts of the Tangents, with respect to a whole sine of 1000 equal to the stylus.

Diagram. A rectangular construction figure for the horizontal dial. Within a ruled rectangular frame, a main diagonal rises from the lower-left toward the upper region; a second, cross-hatched (toothed) oblique line represents the stylus CD, and a scale of parts is ticked off along the lower-left diagonal at 10, 20, 30. The apex of the hour-line construction is at the top centre. Readable labels, with approximate positions:

- A (top centre): centre of the dial / apex of the hour-lines
- M (top, immediately right of A): endpoint on the top edge
- F (upper right): endpoint of the perpendicular CF
- G (upper left, on the rising diagonal): endpoint of the perpendicular CPG
- K (top-left corner of the frame): point on the 6-o'clock hour-line AK
- D (right side, on the descending line): foot of the axis / stylus endpoint
- O (centre, below A/M): intersection point on the hour-line
- R (centre-left, below G): point on the rising diagonal
- I (left, below R): point on hour-line AE (a parallel-point)
- C (centre, below O): the place of the stylus (locus C)
- T (centre, right of C): point on the construction
- H (centre, below C): parallel-point on the meridian
- E (lower left): endpoint of the hour-line / equinoctial line
- B (centre-lower): point on the meridian AB
- N (lower centre): parallel-point
- V (bottom centre): endpoint
- L (lower left): parallel-point (of Capricorn)
- Scale marks 10, 20, 30 along the lower-left diagonal (division of the stylus into parts)

The accompanying text also names the Sun's parallel-points on this figure as Cancer [♋], H, I, K (for the summer parallel) and Capricorn [♐], N, L (for the winter parallel).

Let the centre of the dial be A, and the meridian line AB; the stylus CD, and its place C; the axis of the world AD; the equinoctial line BE; the 6-o'clock hour-line AK, and any other hour-line AE. Let the point of the parallel of Cancer [♋] be, on the meridian, H; on the hour-line AE, the point I; and on the 6-o'clock line, the point K. It is required to reduce the segments AH, AI, AK to parts of the Tangents with respect to the whole sine CD, of 1000 parts, and so on.

At AE erect the perpendicular CPG; and, having drawn CF perpendicular to CG (with CF equal to the stylus CD), take PG equal to the joined straight line PF. Then PG will be the whole sine of the Tangents PA, PI, PE. And since, by problem 10, the arc of the Tangent AP is known, the Tangent AP itself will be known with respect to the whole sine PG. Now, when the arc of the Tangent AP is subtracted from the complement of the declination of Cancer [♋], the remainder will be the arc of the Tangent PI, with respect to the same whole sine PG. And if the Tangents PA and PI are added together, AI will be made known in parts of the whole sine GP, or PF — and thus it will likewise be known in parts of the whole sine CD.

The angle CAP is known, from the arc of the horizon between the meridian and the hour-circle AE — that is, from the complement of the arc of the horizon in table 6. And since, in the right triangle ACP, when AC is set as the whole sine, the sine of the angle CAP is CP (as is clear from the doctrine of sines), CP will be known in parts of the whole sine AC. But CD — that is, CF — is also known (for, AC being set as the whole sine, the Tangent of the angle CAD is CD): the Tangent of the pole's altitude is known in the same parts. Therefore, if it be made — (we take, in the calculation, the Sines, Tangents, and Secants in parts of the whole sine 100000, so that the result may come out more exactly):

As FC, the Tangent of the pole's altitude, to itself, taken as the whole sine;
so CP, the sine of the angle CAP (which is the complement of the arc of the horizon in table 6), to a fourth term: CP will become known, in parts of the same whole sine CF, equal to the stylus CD — namely, taken as the Tangent of the angle CFP; and so the angle CFP will be known.

If, then, it be made again:

As FP, taken as the whole sine, to AI, known in parts of the whole sine FP,
or PG; so FP, taken as the Secant of the found angle CFP, with respect to

the whole sine FC, or CD, to a fourth term: the same AI will come forth, known in parts of the same whole sine CF, equal to the stylus.

By way of example: Let us suppose AE to be the hour-line of 3 from noon, or of 9 from midnight, at a pole-altitude of 42 degrees. The angle CAP will be 33 degrees 47 minutes — namely, the complement of the arc of the horizon for hours 3 and 9, in table 6, in the row of pole-altitude 42 degrees. And the sine of that same angle CAP, with respect to the whole sine AC, will be 55605. But CF — that is, CD, the Tangent of the angle CAD (of the pole-altitude, 42 degrees), with respect to the whole sine AC — will be 90040. Let it therefore be made: as CF, 90040, to itself, taken as the whole sine 100000; so CP, 55605, to a fourth term; and CP will be generated as about 61756, the Tangent of the angle CFP. In the table of Tangents, therefore, the angle CFP will be found as 31 degrees 42 minutes.

Again, let it be made: as FP, the whole sine, to AI, 132508 — (for the arc between A and the vertical perpendicular CP, found by problem 10, is 38 degrees 9 minutes; and when this is taken away from the complement of the declination of Cancer [☊], 66 degrees 30 minutes, there remain 28 degrees 21 minutes for the arc between P and I. The Tangent AP, therefore, with respect to the whole sine FP, is 78551; and PI is 53957; and their sum, AI, is 132508) — so FP, 117535, the Secant of the found angle CFP, 31 degrees 42 minutes, with respect to the whole sine CF, or CD, to a fourth term; and the same AI will be found as 155743, with respect to the whole sine CD, 100000.

QVOD

And if that same arc AP, 38 degrees 9 minutes, be subtracted from the complement of the declination of Aries [♈] — that is, from 90 degrees — the remaining arc PE will be 51 degrees 51 minutes (I mean the arcs to which the segments AP, PE, and so on correspond); its Tangent, 127306, together with the Tangent AP, 78551, makes up the whole AE, 205857. If, then, it be made: as FP, the whole sine, to AE, 205857; so FP, 117535, the Secant of the found angle CFP, 31 degrees 42 minutes, with respect to the whole sine CD, to a fourth term; AE will be found as 241954, with respect to the whole sine CD, 100000.

LIKEWISE, if that same arc AP, 38 degrees 9 minutes, be taken from 113 degrees 30 minutes — namely, from the arc composed of the quadrant AE and the declination of Capricorn [♐], 23 degrees 30 minutes — there will remain the arc between P and L, the point of Capricorn [♐], on the hour-line AE, of 75 degrees 21 minutes; whose Tangent, 382537, together with the Tangent AP, 78551, makes 461088 for the straight line AL, between A and L, the point of Capricorn [♐]. If,

then, it be made: as FP, the whole sine, to 461088, the straight line AL between A and L, the point of Capricorn [φ], with respect to the whole sine FP; so FP, 117535, the Secant of the found angle CFP, 31 degrees 42 minutes, to a fourth term; there will be produced the straight line AL, between A and L, the point of Capricorn [φ], of 541940 (about), with respect to the whole sine CD.

NOW, if from the found straight line AL, 541940, you subtract the AE found above, 241954, the remainder will be the straight line EL, between E and L, the point of Capricorn [φ], of 299986, with respect to the same whole sine CD.

SIMILARLY, if from the found AE, 241954, you take away the found AI, 155743, there will remain EI, 86211 — which is what we noted at the end of the scholium of chapter 9.

ON the meridian AB, the arc AC just named is the complement of the pole's altitude — namely, the Tangent of the angle ADC, with respect to the whole sine CD. But CH is the Tangent of the arc that remains after the subtraction of the arc AC (the complement of the pole's altitude) from AH (the complement of the declination of Cancer [ϑ]), or after the subtraction of the complement of the declination of Cancer [ϑ] from the complement of the pole's altitude, if the latter be the lesser, and so on. Hence the sum of the two Tangents AC, CH will give AH itself, known in parts of the whole sine CD. So too, if from the arc AN — composed of the quadrant AB and the declination of Capricorn [φ], BN — the complement of the pole's altitude, CB, be subtracted (or rather, if to the pole's altitude CB the southern declination BN be added), there will remain, or be composed, the arc CN, whose Tangent, together with the Tangent AC (of the complement of the pole's altitude), will make up the whole AN, known and sought in parts of the whole sine CD.

FURTHERMORE, when the complement of the pole's altitude is greater than the complement of the declination, this must be subtracted from that, and the Tangent of the remaining arc must be taken away from the Tangent of the complement of the pole's altitude, so that the straight line we seek may remain. But in chapter 8, number 7, we prescribed another method for finding the Tangents to be transferred from C, the place of the stylus, so that the points of the parallels may be found on the meridian.

ON the 6-o'clock hour-line AK, the aforesaid arc is nothing. Therefore, if it be made:

As DA, the whole sine, to AK, the Tangent of the complement of the parallel's declination; so DA, the Secant of the angle ADC (of the

complement of the pole's altitude), with respect to the whole sine CD, to a fourth term: AK will be generated, in parts of the same whole sine CD.

ON any hour AM whatever, before the 6th hour of the morning or after the 6th hour of the evening, that arc is AP — the same that was found for the corresponding hour opposite AE below the 6th hour, but not toward the parallel. It must therefore be added to the complement of the declination, and from the Tangent of the composed arc the Tangent of the aforesaid arc must be subtracted, so that there remains the portion of the proposed hour from A up to the parallel. Then this same portion is to be investigated in parts of the whole sine CD, just as was done for the corresponding hour opposite AE below the 6th hour, by means of the angle CFP and the whole sine FP, and so on, which do not change.

HENCE table 19 has been constructed for very many pole-altitudes.

IN the figure, too, any number of parts equal to the stylus CD have been taken on the straight line, and the first of them divided into 10 equal parts, so that, if a dial be completed for latitude 42 degrees, the points of the parallels may be found on the hour-lines from table 19, computed for the same latitude. For thus you see that the points Cancer [♋], H, I, K, and Capricorn [♐], N, L have been found.

[Margin: Another, easier solution of the problem.]

BUT we shall dispatch this same problem 17 more expeditiously in the following way. From table 1, under the line whose heading is "Circ. hor. 12," take the arc of any sign corresponding to any hour of its line, and subtract it from the pole-altitude, if it can be subtracted; and add the Tangent of the remaining arc to the Tangent of the complement of the pole's altitude. [Margin: When the arc of table 1 is less than the pole's altitude.] Then take the Secant of the angle that the given hour makes at the centre with the meridian — which angle is given to us by the complement of the arc of table 6, the one that agrees with that same hour, on the side toward the pole's altitude above the horizon, on the left. For, if it be made:

As the whole sine, to the number composed of the Tangent of the complement of the pole's altitude and the Tangent of the arc that remains after subtracting the arc of table 1 from the pole-altitude; so the Secant of the angle that the line of the given hour makes with the meridian, to a fourth term: there will be produced the sought Tangent — that is, the segment of the hour-line between the centre of the dial and the point of the proposed parallel, in parts of the whole sine equal to the stylus.

FOR, if the arc of the given hour in table 1, corresponding in the adjoining figure to the straight line PT, be subtracted from the pole-altitude, which corresponds to the straight line BC, there will remain the arc corresponding to the Tangent CT, with respect to the whole sine CD. And if the Tangent CT of the said remaining arc be added to the Tangent AC (of the complement of the pole's altitude), the whole AT will become known, in parts of the whole sine CD. And since the line TI, drawn parallel to the equinoctial, cuts the hour AE at I, the point of the parallel whose arc BT, corresponding to the given hour in table 1, was taken (as we wrote in chapter 8, number 7); and since the straight line AI is the Secant of the angle TAI, with respect to the whole sine AT — it is clear that, if it be made: as the whole sine AT, to AT itself, known in parts of the whole sine CD (which AT is composed of the two Tangents AC, CT); so AI, the Secant of the angle TAI, with respect to the whole sine CD, to AI, in parts of the same whole sine CD — because the whole sine AT stands to the Secant AI as AT, known in parts of the whole sine CD, stands to AI, in the same parts, and so on.

[Margin: When some arc of table 1 is greater than the pole's altitude.]

BUT if some arc of table 1 be greater than the pole-altitude, the pole-altitude must be subtracted from it, and the Tangent CO of the remaining degrees must be taken away from AC, the Tangent of the complement of the pole's altitude, so that AO may remain known in parts of the whole sine CD. For, if it be made again:

As the whole sine

As the whole sine AO, to AO itself, which is left after the subtraction of CO, the Tangent [taken] from AC, the Tangent of the complement of the pole's altitude — which Tangent CO is owed to the arc that remains after subtracting the pole-altitude from the arc of table 1; so AP, the Secant of the horary angle OAP, to a fourth term: AP will be generated, in parts of the whole sine CD.

[Margin: When the arc of table 1 is equal to the pole's altitude.]

If perchance some arc found in table 1 be equal to the pole-altitude, let it be made:

As the whole sine AC, to AC itself, the Tangent of the complement of the pole's altitude; so the Secant of the horary angle, to a fourth term: and the sought Tangent will be produced.

[Margin: What to do for the 6-o'clock hour.]

FOR the 6-o'clock hour, let it be made:

As the whole sine AD, to AK, the Tangent of the complement of the parallel's declination, with respect to the whole sine AD; so AD itself, taken as the Secant of the angle ADC (of the complement of the pole's altitude), with respect to the whole sine CD, to a fourth term: and AK will be produced, in parts of the same whole sine CD.

It is better, for the 6-o'clock hour, to take the Tangent of the complement of the declination, with respect to the whole sine AD.

[Margin: When the hour is at a greater distance from noon than 6 hours.]

WHEN the given hour is before the 6th hour of the morning, or after the evening one, it will indeed make with the meridian the same angle that the opposite hour of the same name makes. But then, to the complement of the arc of table 1, the complement of the pole's altitude must be added; and from the Tangent of the composed arc, the Tangent AC (of the complement of the pole's altitude) must be taken away. For, if it be made:

As the whole sine, to the number that remains after the subtraction of the Tangent of the complement of the pole's altitude from the Tangent of the arc composed of the complement of the pole's altitude and the complement of the arc of table 1; so the Secant of the horary angle, to a fourth term: the segment of the hour-line between the centre A and the point of the parallel will be found, in parts of the whole sine CD.

[Margin: What to do for the southern parallels.]

FURTHERMORE, for the southern parallels, the arc of table 1 must always be added to the pole-altitude, so that the Tangent CV of the composed arc may become known, in parts of the whole sine CD. For when this is added to AC, the Tangent of the complement of the pole's altitude, the whole AV will be known, in parts of the same whole sine CD. Wherefore, if it be made:

As the whole sine AV, to AV itself, which is composed of AC (the Tangent of the complement of the pole's altitude) and the Tangent CV (of the arc composed of the pole-altitude and the arc of table 1); so AL, the Secant of the horary angle VAL, to a fourth term: AL will come forth, known in parts of the whole sine CD.

[Margin: What to do when the Sun is on the Equator.]

FINALLY, when the Sun is on the Equator, BC (the Tangent of the pole's altitude) must be added to AC (the Tangent of the complement of the pole's altitude), so that the whole AB may become known, in parts of the whole sine CD. For, if it be made:

As the whole sine AB, to AB itself, composed of the Tangent of the pole's altitude and the Tangent of the complement of that same altitude; so AE, the Secant of the horary angle EAB, to a fourth term: AE will be generated, known in parts of the whole sine CD.

What must be done on the meridian line has been explained in the prior solution of the problem.

BY this art, therefore, we have computed table 19 for very many elevations of the pole, so that the points of the Sun's parallels may be readily found on the horizontal dial.

[Margin: How table 19 is adapted to the vertical and declining dial.]

MOREOVER, this same table 19 has a use in the dial that is parallel to the primary vertical, provided the said found Tangents are taken as the complement of the pole's altitude above the horizon. Thus, for latitude 42 degrees, one must take, for the vertical dial, the Tangents computed for latitude 48 degrees — because the altitude of the pole above the primary vertical, in latitude 42 degrees, is that great.

INDEED, if, on a declining dial, there be drawn from both sides of the stylus-line, from the centre, lines distant from the stylus-line by 15, 30, 45, 60, 75 degrees, and so on, in the manner of the hour-lines on a horizontal dial (as we set out in chapter 18, number 4), and if the altitude of the pole above the declining plane be found by problem 4, then the Tangents computed for that altitude in table 19, transferred from the centre, will indicate the points of the parallels, just as on the horizontal dial. But when the altitude of the pole found above the declining plane is not found in table 19 — that is, when, beyond the degrees, it also contains some minutes — the proportional part must be taken, between the next lower and the next higher pole-altitude, in the Tangents of table 19; which is not difficult. For example, since in latitude 49 degrees the Tangent of the 3rd and 9th hour for Cancer [♋] is about $14 \frac{8}{10}$, while in latitude 50 degrees the Tangent of the same hours is $14 \frac{5}{10}$, in latitude 49 degrees 30 minutes the Tangent of the same hours will be $14 \frac{6}{10}$, a little more, for the 3rd and 9th hour. [Margin: When the pole's altitude contains minutes beyond whole degrees, what to do.] Or, more surely, the proportional part corresponding to the minutes attached to the pole-altitude is to

be sought, in the manner of the astronomers, so that the points of the parallels may be caught more accurately. I know the matter would be more exact if, for the found altitude of the pole, the Tangents were computed as we have taught here; but no great error will arise from the proportional part. And the same is to be observed on the horizontal dial, when the altitude of the pole contains whole degrees and about 30 minutes.

[Margin: The hour-segments between the centre and the perpendicular lines drawn from the place of the stylus — where they are to be found already computed.]

ABOVE, in problem 10, we likewise computed, for several elevations of the pole, the segments of the hour-lines between the centre of the horizontal dial and the perpendicular drawn from the place of the stylus to those hour-lines: so that, if it seem good, the points of the Sun's parallels may be investigated through them, as we taught in the scholium of chapter 9, number 5. But since the whole sine varies at each hour, one must employ the equilateral triangle of chapter 24, so that those various whole sines may more easily be cut into 10 equal parts, as we explained in chapter 24, number 7.

THESE same segments also have their place in the primary vertical dial, and in any declining dial whatever: just as we said a little earlier about the Tangents.

POSTRE-

PROBLEMA XVII (conclusion)

Finally — so that I may leave out nothing that can assist the construction of a horizontal dial — I shall gladly, for the benefit of students (and especially of Isidorus Rubertus [Isidoro Ruberti], Doctor of both Laws and Auditor to the most illustrious Cardinal Salviati, and of Theodosius Rubeus [Teodosio Rubei], Doctor of Sacred Theology and of both Laws, who earnestly pressed me to do it), briefly teach the method by which, from the horizon-arcs of tables 14 and 16, the points of the parallels can be found on a horizontal dial, even when the horizontal line cannot be drawn upon it. This we accomplished long ago for the declining dial, in the scholium to chapter 19, number 4. The procedure is as follows. On the dial of chapter 2, from point B — where the meridian line intersects the equinoctial — describe a circle at the radius of some quadrant divided into 90 degrees. For if the horizon-arcs of table 14 are transferred onto this circle from the meridian line (for the hours reckoned from noon and from midnight [à mer. & med. noc.]), and likewise the arcs of table 16 (for the hours reckoned from the east or the west [ab

or. vel occ.)), then the straight lines drawn from B through the ends of those arcs will cut the hour-lines — both those from noon and midnight and those from the east or west — at the points of the parallels. For example: since in table 16 the arc for the 21st hour from the west, in Cancer [♋], contains 57 degrees 45 minutes, then if on the circle described from B an arc of 57 degrees 45 minutes is taken, beginning from the meridian line, the straight line from B running through the end of that arc will cut the 21st hour at the point of Cancer [♋], and so on.

[Margin: The method by which, from the horizon-arcs of tables 14 and 16, the points of the parallels are found on a horizontal dial.]

DEMONSTRATION. The proof of this matter is exactly the same as that of the hour-lines drawn from centre G — through the horizon-arcs of table 6, in the circle described from G — in chapter 5. For the great circles that cut off the arcs of tables 14 and 16 all pass through points D and B (the gnomon C D being set upright to the dial), just as the hour-circles are drawn through points D and G, and so on.

But if one prefers to carry out the same thing by Tangents, without describing a circle from B, then the Tangents of the arcs of tables 14 and 16 must be transferred onto the line of the 6th hour K G L from point G, and onto the line R a from point R, in the opposite direction — the Tangents, I say, reckoned with respect to the whole sine B G divided into 10 equal parts, just as the Tangents belonging to the complements of the arcs of table 6, transferred onto the equinoctial line with respect to the same whole sine G B, mark out the points of the hours, as is clear from what we wrote in the scholium to chapter 25, number 5.

Nor indeed shall I pass over this point either: that the points of the parallels can be found still more precisely from table 2 (whose use I set forth in chapter 8, number 10, and chapter 18, number 6), should the hour-point assumed on the equinoctial happen to lie too close to the meridian line. The method is this. On the equinoctial, beyond the meridian line, take a portion equal to the distance between the assumed hour-point and the meridian line — or two such portions, or more — and through its end draw a line parallel to the meridian. Then, on the horizontal dial, from the point assumed on the equinoctial through the place of the stylus C — but on the declining dial through point B, where the meridian intersects the horizontal — draw a straight line cutting the aforesaid parallel at a point, which is to be marked. For if from this point, whether upward or downward, one transfers onto that parallel double, triple, and so on, the intervals of the Tangents which are to be carried from the place of the stylus C on the

horizontal dial (or from B on the declining dial) into the meridian — according to the prescription of chapter 8, number 10, and chapter 18, number 6 — that is, in proportion as the distance between the point assumed on the equinoctial and the aforesaid parallel is double, or triple, and so on, of the distance between the same assumed point and the meridian line — then straight lines must be drawn from that assumed point through the points on the meridian and on that parallel, so that for each straight line three points are obtained. This practice will be demonstrated from proposition 4 of book 6. For example: suppose the operation is to be carried out from the 2nd hour on the equinoctial. Since the arc of Cancer [♋] for the 5th and 11th hours, in table 2, contains 17 degrees 5 minutes, when this is subtracted from the altitude of the pole on the horizontal dial there remain 24 degrees 55 minutes. The Tangent of these, $4\frac{6}{10}$, transferred from C downward onto that parallel, gives the point through which the straight line from the 2nd hour on the equinoctial cuts the 11th and 5th hours at the points of Cancer [♋], as was said in chapter 8, number 10. But because the 2nd hour lies close to the meridian, take the distance between that hour and the meridian twice over beyond the meridian, and through its end draw a line parallel to the meridian, to be cut by the straight line drawn from the 2nd hour through C. For if from the point of intersection one transfers downward the aforesaid Tangent $4\frac{6}{10}$ tripled, another point will be found on that parallel, and so on. On the declining dial, this same arc of 17 degrees 5 minutes must be subtracted from the complement of the pole's altitude, and so on, as was said in chapter 18, number 6.

[Margin: How the use of table 2 may be made more precise for finding the points of the parallels.]

TABLE OF TANGENTS, THE WHOLE SINE BEING SET AT 1000

(TABVLA TANGENTIVM POSITO SINV TOTO 1000.)

Table of Tangents — Degrees of the quadrant 0–9

Column headers 0–9 are **degrees** (Gradus Quadrantis); the far-left column is minutes of the degrees of the quadrant (Minuta Graduum Quadrantis, read downward 0→60); the far-right column is minutes of the degrees of the complements (Minuta Graduum Complementorum, read upward). The degree labels along the foot (Gradus Complementorum) are 89 88 87 86 85 84 83 82 81 80.

Table of Tangents (whole sine 1000) — continued

Appended table of tangents to Clavius's Horologiorum Nova Descriptio (the third work in the volume), whole sine (sinus totus) = 1000. Degrees of the quadrant run across the top; minutes of a degree (0–60) down the left margin (Minuta Graduum Quadrantis); the complementary degrees run across the foot (Gradus Complementorum) and complementary minutes down the right margin (Minuta Graduum Complementorum), so a single grid serves a degree read from the top and its complement read from the bottom. This portion covers degrees 20–49, continuing the table begun earlier (degrees 0–19).

degrees 20–29

Top degree-headers (verbatim): **20 21 22 23 24 25 26 27 28 29** Foot
complementary-degree headers (verbatim): **69 68 67 66 65 64 63 62 61 60**

Foot: **Gradus Complementorum.** — complementary degrees **69 68 67 66 65 64 63 62 61 60.**

degrees 30–39

Top degree-headers (verbatim): **30 31 32 33 34 35 36 37 28 39** — the ninth header is printed **28** where the sequence requires **38** [recte: 38]; the column's values (781...810) are those of tangent 38°, so the header digit is a compositor error. Foot complementary-degree headers (verbatim): **59 58 57 56 55 54 53 52 51 50**

Foot: **Gradus Complementorum.** — complementary degrees **49 48 47 46 45 44 43 42 41 40.**

The table of tangents ends here at degree 49 (its complement, 40, is reached at the foot). No further table (e.g. secants), colophon, or FINIS appears within these three pages; the tangent table continues on the following opening for the remaining degrees.

Table of Tangents [Tabula Tangentium] — Degrees of the Quadrant [Gradus Quadrantis]

Continuation of the appended Table of Tangents (whole sine = 1000). These three pages cover degrees 50–79. The layout of each page is unchanged: the left-hand column gives the minutes of a degree of the quadrant [Minuta Graduum Quadrantis], read downward from 0 at the top; the head-row gives the whole degree; the right-hand column gives the minutes of the complementary degree [Minuta Graduum Complementorum], read upward; and the foot-row gives the complementary degree [Gradus Complementorum]. Each degree column runs from its own minute 0 (top) to minute 60 (bottom), where minute 60 of one degree equals minute 0 of the next.

Every cell below is transcribed individually from the scan at high magnification. Values that break the smooth progression of their column are transcribed as printed, with the corrected reading given in [recte: ...].

Degrees 50–59

Head-row degrees: 50 51 52 53 54 55 56 57 58 59.

Foot-row (complementary degrees): 19 18 17 16 15 14 13 12 11 10. — [Foot: Gradus Complementorum.]

TABLE OF TANGENTS (concluded) — *Degrees of the Quadrant*

[Margin (left, vertical): Minuta Graduum Quadrantis. — "Minutes of the degrees of the quadrant."] [Margin (right, vertical): Minuta Graduum Complementorum. — "Minutes of the degrees of the complements."]

The final opening of the Table of Tangents (whole sine = 1000). The top column-heads give the whole degrees 80–89; the left-hand column gives the minutes (0–60) of those degrees; the right-hand column gives the minutes (60–0) of the complementary degrees; and the foot gives the complementary whole degrees (9–0), so that the same grid serves as a table of cotangents read upward. The tangent reaches its final value at 90° (**Infinita** — "infinite").

[Margin (foot): Gradus Complementorum. — "Degrees of the complements."]

SOME PRACTICAL EXERCISES

Excerpted from the *New Description of Sundials* [*Horologiorum Nova Descriptio*], so that sundials may be laid out quickly — though, to be understood more plainly, most of them require much of what is set out in that book.

A few further things are also added here that are wanting in that same book.

The hours from noon and from midnight, on a plane parallel to the horizon [horae a meridie et a media nocte in plano quod horizonti aequidistat]

Praxis I [First Exercise]

Before anything else, four rules — that is, straightedges with certain marked divisions — must be prepared out of some fairly stiff card. The first is to be constructed as follows. Taking the gnomon [stylus] of the intended dial at will,

mark off along the sides of the rule as many equal parts as you please, and join them by straight lines parallel to one another and perpendicular to the sides. Then, once the first part AB has been divided into 10 equal parts and the surplus cut away, the first rule is ready. The second — which will be used in common for finding the points on very many lines — is constructed by letting a single side carry any number of equal parts you like (provided, however, that each of them exceeds the gnomon by a good margin), the first of these, AB, being likewise distributed into 10 equal parts. As for the third rule, for finding the points on the equinoctial line, and the fourth, for the points on the 6-o'clock line, we shall deal with them a little later, once we have first drawn these two lines on the dial.

[Margin: Construction of the first rule.] [Margin: Construction of the second rule.]

2. So, on some plane, having drawn the straight line AB as the meridian line — running roughly through the middle of the plane — let the position of the gnomon be chosen at point C, and through it draw CD perpendicular to the meridian, making the line CD equal to the gnomon AB assumed on the first rule. Then, since at the latitude of the place, 42° , the tangent of the complement of the pole's elevation contains $11 \frac{1}{10}$ [?] parts, we shall apply the first rule to the meridian line, placing the point marked with the number 10 at C, with point B inclining toward G. For if with some very sharp stylus a point G is marked on the meridian terminating the tangent of $11 \frac{1}{10}$ [?], the point found will be G, the center of the dial; and through it the perpendicular KL drawn to the meridian will give the 6-o'clock line. If you prefer, you may also use a compass instead of the rule.

[Margin: Description of the dial.] [Margin: How the tangents of the complements of arcs are found in the table — the tangents of complements are found by taking the degrees of the arcs whose complements are in question at the foot of the Table of Tangents, and the minutes, if any, on the right-hand side.] [Margin: The center of the dial.]

Diagram. Four paper rules (straightedges), drawn one above the other, each a long strip with a graduated scale and an endpoint lettered B at the left. From top to bottom:

- Rule 1 — captioned "**Pro linea merid.**" ("For the meridian line"), with a small superscript **a** (marginal cross-reference letter). It carries a graduated scale in two parallel rows reading **10 · 20 · 30 · 40 · 50 · 60** (left to right); endpoints lettered **B** (far left) and **A**.

- Rule 2 — captioned "**Communis**" ("The common [rule]"); endpoint **B** at the left.
- Rule 3 — captioned "**Pro linea aequinoctiali**" ("For the equinoctial line"), graduated **10 · 20 · 30 · 40**; endpoint **B** at the left.
- Rule 4 — captioned "**Pro linea horae 6.**" ("For the 6-o'clock line"), graduated **10 · 20 · 30**; endpoint **B** at the left.

For if, once the first rule has been divided, you take the tangent of $11 \frac{1}{10}$ [?] with the compass and carry it up from C, you will find the same center of the dial. I want this understood of the other tangents to be transferred as well: namely, that they may be transferred either by a rule or straightedge, or by a compass. Again, since the tangent of the pole's elevation, 42° , comprises 9 parts, we shall place point A of the rule at C, with its point B inclining downward — that is, to the side opposite point G. For if, as before, we mark on the meridian the point B terminating the tangent of 9, then from B the straight line HI must be drawn perpendicular to the meridian, to serve as the equinoctial line.

[Margin: How the tangent of an arc is found in the table — the tangents of degrees are found by taking the degrees at the top of the Table of Tangents and the minutes on the left-hand side.] [Margin: The equinoctial line.]

3. Now the third rule (or straightedge) is constructed by taking any number of segments equal to the interval DB, the first of which, AB, is divided into 10 small equal parts. In the same way you will construct the fourth rule, if for the interval DB you take the interval DG, and so on. And these four rules, or straightedges, are enough for...

[Margin: Construction of the third and fourth rules.]

constructing every horizontal dial, as will become clear. The second straightedge, too, will find use in other dials and figures. That the first rule has a different form from the rest was done so that by means of it we may find the points of the Sun's parallels on the hour-lines, as we shall teach in its proper place.

4. By the third rule (or straightedge), constructed for the equinoctial line, there will be found on the equinoctial line the points of the hours, of their halves, and of their quarters — provided that the tangents taken from the little table of the scholium of chapter 1 are transferred onto it from B in both directions, as was set forth in No. 3 of chapter 2. Therefore, if through the center G and through these points straight lines are sent out along the equinoctial line, the dial of the hours from noon and from midnight will be described (whose arrangement is shown here). With the lines turned

toward us for the dial (so that the equinoctial line comes nearer to us than the 6-o'clock line), those placed to the left belong to the hours after noon, while those set to the right belong to the hours after midnight, as the numbers I, II, III, VII, VIII, and so on, written on the hour-lines, indicate. Only the whole hours have been drawn, to avoid confusion; nevertheless the points of the half-hours are marked on the equinoctial, so that by their help the hours from sunrise or sunset may be described. And if you should want the half-hours also from sunrise or sunset, the points of the quarter-hours will have to be found; and if anyone should want the quarters of these, the points of the half-quarters — that is, of the eighth-parts — must also be investigated, as will be told in Exercise 2.

[Margin: How the hour-points on the equinoctial are found.] [Margin: The dial of the hours from noon and from midnight. Why the points of the half-hours, quarters, and eighth-parts must be found on the equinoctial.]

Diagram. A horizontal-sundial construction (dial of the hours from noon and from midnight, for latitude 42°), within a rectangular frame. All the hour-lines radiate from a single dial center **G**, set near the middle of the figure. A horizontal **dotted line** runs across the figure as the equinoctial line; the **meridian** is the vertical line, and the **6-o'clock line (KL)** is perpendicular to it through **G**.

Around the border the hour-lines are numbered in Roman numerals. Legibly read: along the top **V, VI, VII, VIII**; down the right side the sequence **IX, X, XI, XII, I, II, III** (the numerals here are set rotated and only partly legible — several [?]); along the bottom **IIII**; up the left side **VII, VI, V**.

Interior construction labels read from the scan (positions approximate):

- **G** — dial center (convergence of all hour-lines).
- On the meridian: **L** (upper), **T** (below **G**).
- On/near the equinoctial line: **D, I, B, E, C, A, O** (running toward the center), with a further point read as **P** or **R** [?] below the center.
- Left-hand quarter-circle arc with points **N, F, M**; frame letters **S** (upper left) and **K** (left edge).
- **H** (lower center, on the equinoctial construction).
- At the foot, the second ("common") rule laid out as a graduated strip in two rows reading **60 · 50 · 40 · 30 · 20 · 10**, with endpoints lettered **A** and **B**.

The text draws the arc **HEI** from **G** and the equal arc **MFN** on the opposite side; the 3-o'clock line runs through **N, G, H**, and the 9-o'clock line through **M, G, I**.

Several small, rotated perimeter numerals and interior letters are only partly legible

5. But in order that the hour-lines may be drawn more accurately, other points must be found through which they ought to pass; for in this way one can scarcely go wrong in drawing them. And if some hour-line does not pass through all its own points, one must examine carefully at which point the error lies, and the error must be corrected. We shall find more of these points on the lines parallel to the meridian line and to the 6-o'clock line, by means of the second (common) straightedge, in this way. First of all, the 3- and 9-o'clock lines are to be drawn as exactly as can be done, by this method. From the equinoctial, cut off BH and BI equal to the interval BD; for through H and I the 3- and 9-o'clock lines are to be drawn from the center G, as was demonstrated in chapter 3, No. 1. And so that we may find the third point for each of the two, we shall describe from G the arc HEI, and with the same interval, on the opposite side, the arc MFN. For if arcs FM, FN are cut off equal to the arcs EH, EI, then the 3-o'clock line must be drawn through N, G, H, and the 9-o'clock line through M, G, I.

[Margin: How the 3- and 9-o'clock lines are to be drawn exactly.]

6. Once the 3- and 9-o'clock lines have been drawn, we shall lay off along the straight line AB, by means of the second set-square [normal], four equal segments GA, GO, GK, GL; and through the points A and O we shall draw lines parallel to the 6-o'clock line, cutting the 3- and 9-o'clock lines at R, S, P, Q. We then join the straight lines PR and QS, which — as we proved in chapter 4, No. 6 — will be parallel and equal to the line AO, and will be bisected at T and V; and so their halves will be equal to AB on the second rule [regula]. Likewise, through K and L we shall draw KX and LY parallel to the meridian line, and join the straight line XY, which by the same reasoning will be parallel and equal to KL, and will be bisected at Z. If the plane were large enough, we should have drawn on the opposite side another line parallel and equal to KL, joining by a straight line the points where XK and YL meet the 3- and 9-o'clock lines.

Now if, from the points Z, T, V, the tangents of the whole hours — that is, the tangents of 15° , 30° , 45° , and so on, with respect to the whole sine [sinus totius] AB — are transferred on both sides onto the straight lines XY, PR, QS by the second set-square, the hour-points will be found on those lines at distances of 15° , 30° , 45° , etc. from Z, T, V, just as was done on the equinoctial line: so that the points nearest to K and V correspond to the 5- and 7-o'clock lines, 15° distant from

the 6-o'clock line, and so on. The same is to be understood of the fractional parts of the hours, if the tangents of the half- and quarter-hours are taken from the table of the scholium of chapter 1 — all of which we proved in chapter 4. Moreover, by the same reasoning we shall find, on the equinoctial and on the lines XY, PR, QS, the point through which a straight line drawn from G represents the great circle passing through the poles of the world and through any degree of the equator whatever, as we wrote in chapter 4 just before No. 2, and in No. 10 of the same chapter. Here belong the cautions we said (chapter 2, No. 4) must be observed in testing the hour-points found by tangents.

[Margin: Finding the hour-points off the equinoctial line.]

[Margin: How to draw the straight line representing the great circle through the poles of the world and through any degree of the equator.]

7. Furthermore, on the straight lines XK, YL, PQ, RS — whose distances from the center G are equal to AB on the second set-square — we may also, if we wish, find these same hour-points from Table 6, in this way. The hour-points from 9 after midnight up to 3 after noon, and from 9 after noon up to 3 after midnight, will be found on the lines PQ, RS by the tangents of the complements of the arcs of Table 6. But the hour-points from 3 after noon up to 9, and from 3 after midnight up to 9, will be found on the lines XK, YL by the tangents of the very arcs themselves in the same Table 6, without complements — by tangents, I mean, taken with respect to the whole sine AB and transferred by the third set-square on both sides from O, A, K, L onto the lines PQ, RS, XK, YL. For example: the arc of the 3- and 9-o'clock line for latitude 42° in Table 6 contains $56^\circ 13'$; and the tangent of its complement is about $6 \frac{7}{12}$ [fraction ?] parts, which, taken from the second set-square and transferred from O and A on both sides onto PQ, RS, gives the points P, S of the 9-o'clock line and the points Q, R of the 3-o'clock line. But the tangent of the arc itself, $56^\circ 13'$, contains $14 \frac{2}{10}$ [fraction ?] parts, a little more; and this, transferred from K and L, will yield the points X, Y of the 3- and 9-o'clock lines. And so with the rest.

[Margin: A further finding of the hour-points off the equinoctial.]

The reason for this is that the angles which the hour-lines make at the center G with the 6-o'clock line correspond to the arcs of Table 6, while the angles that these same lines make with the meridian correspond to the complements of those same arcs of Table 6. And it is established that the portions of the straight lines XK, YL, PQ, RS between the points T, L, O, A and the hour-lines are the tangents of

those angles, or arcs, with respect to the whole sines GK, GL, GO, GA, which are equal to AB on the second set-square.

8. Lastly, the hour-points may also be found on the equinoctial line by this other method. Take the interval BD, with a straight line Ba laid off equal to it (whether upward or downward). If, from a, at the interval HI (between the 3- and 9-o'clock lines — for the points of these hours are found by transferring the interval BD from B on both sides, as we said), the equinoctial line is cut on both sides, the points of the 4- and 8-o'clock lines will be found; and from these, with the same interval, the points of the 5- and 11-o'clock lines, and likewise of the 7- and 1-o'clock lines. And if the spaces between the 8-o'clock line and the point B, and between the 4-o'clock line and the same point B, are each divided into three equal parts, the parts nearest B will give the points of the 10- and 2-o'clock lines. And thus the points of all the whole hours will now be found. But if, from the points of the odd hours, the equinoctial is cut on either side by these intervals up to a, the points of the half-hours will be found; and if from these, again by intervals up to a, the equinoctial is cut on either side, the points of the quarter-hours will be found.

[Margin: Another finding of the hour-points.]

In just the same way we shall find the hour-points on the lines XY, PR, QS, if we take Zd, Tb, Vc equal to the interval XZ, or PT, or VQ. For if, at the interval XY (or PR, or QS), the lines XY, PR, QS are cut on both sides from d, b, c, there will be found on them points distant by four hours from Z, T, V — just as on the equinoctial from a at the interval HI, and so on. And if the segments between Z, T, V and those points found are divided into three equal parts, we shall have points distant by two hours from Z, T, V; and from these four hours found we shall find all the rest, as on the equinoctial line, and so forth — all of which we proved in chapters 3 and 4. And this method is very useful for testing the points found by tangents.

Now, since for drawing the quarter-hours from sunrise and sunset we need the eighth-parts of the hours from noon and midnight (as will be said in Praxis III), it must be shown how the eighth-parts may be found by tangents. One eighth-part of a single hour comprises $1^{\circ}52'30''$. Therefore, to the tangent that corresponds to the degrees and minutes, one must add half the difference between that tangent and the next following, if the degrees were taken at the top of the table and the minutes down the left side. For when the degrees are taken at the foot of the table and the minutes down the right side, that same half must be subtracted. For

example: hour 5 $\frac{1}{2}$ contains $76^{\circ}52'30''$; and it corresponds to $76^{\circ}52'$, tangent 4286. If, then, half the difference between this tangent and the next following — namely 3 — is added, we make the tangent 4289. And that same half, subtracted from 4292, gives the same tangent 4289, corresponding to $13^{\circ}7'30''$ taken at the foot of the table. And so with the rest.

[Margin: How the eighth-parts of the hours are found by tangents.]

THE ARCS OF THE SIGNS ON A HORIZONTAL DIAL, for the hours from noon and from midnight.

PRAXIS II.

[Margin: Finding the points for the arcs of the signs, from noon and from midnight.]

1. Once the hour-lines have been drawn faintly, as we taught in the preceding exercise, we shall find on them the points of the signs most readily from Table 19, by the method we set out at page 61, near the end, No. 5 — provided the pole's altitude

is found exactly in that table, or differs by only a few minutes. Otherwise they must be investigated by the points on the 6-o'clock line found from Table 1, as we taught in chapter 8, Nos. 1, 2, 3, 4, and 6; or by the points found on the meridian from Table 2, as was explained in No. 10 of the same chapter 8; or finally, as we taught in No. 7 of the same chapter, provided the tangents are transferred to the hour-lines by means of the first set-square, which we constructed in No. 1 of the preceding exercise, as was said in the addition before No. 9 of chapter 8. Once the tropics of Cancer [☊, Cancer — the summer tropic] and Capricorn [☋, Capricorn — the winter tropic] have been drawn, only the lines enclosed between them complete the dial; so all the rest must be cut away as superfluous. As an example of this last method, explained in No. 7 of chapter 8, I have placed a point on Capricorn, found on the 3-o'clock line from noon. For in Table 1, under hour 3, in the circle of hour 12, opposite Capricorn, is found an arc of $31^{\circ}35'$; and adding the pole's altitude of 42° (since it is a southern sign) the arc becomes $73^{\circ}35'$, to which is due a tangent of $33 \frac{7}{10}$ [fraction ?], a little more. So the first set-square, applied

Diagram. A full-page horizontal-sundial construction (the hours from noon and from midnight, for latitude 42°), within a rectangular frame — the same construction figure that appears on the preceding page, reprinted here. All the hour-lines radiate from a single dial center **G** near the middle of the figure. A horizontal dotted line runs across the figure as the equinoctial line; the meridian

is the vertical line, and the 6-o'clock line runs through G perpendicular to it. A quarter-circle arc on the left carries points **N, F, M**; a smaller arc **HEI** appears near the center-right. At the foot is the second (common) graduated rule laid out as a strip in two rows, reading **60 · 50 · 40 · 30 · 20 · 10** (endpoints lettered **A** and **B**).

Around the border the hour-lines are numbered in Roman numerals. Legibly read: along the top **V, VI, VII, VIII**; down the right side (rotated, only partly legible) **IX, [X ?], XI, XII, I, [II ?], III** [several [?]]; along the bottom **IIII**; up the left side **VII, VI, V**.

Interior construction labels read from the scan (positions approximate):

- **G** — dial center (convergence of all hour-lines).
- On/near the meridian: **L** (upper), **T** (below G), **K** (lower, on the foot dotted line).
- Upper-left frame corner: **S**.
- Left quarter-circle arc: **N, F, M**; left-frame letters **A** (upper) and **R** (lower).
- Right of center, toward the upper right: **D, I** (near the arc), **C** (script), **Y**.
- On/near the equinoctial line running toward the center: **B, E, Θ/O [?], A** (script), with **P** below.
- **H** — lower center, on the equinoctial construction.
- **Z** — center-right, near hour XII.
- **X** — lower right, near the foot-strip endpoints **A, B**.

Several small, rotated perimeter numerals and interior letters are only partly legible

to the line CD, so that the little edge of the set-square drawn through the numbers 30, 30 coincides with the line CD, while the point terminating at $3\frac{1}{10}$ [fraction ?] on the segment AB reaches the 3-o'clock line — the point found will be **e**, for the parallel of Capricorn. And the same reasoning holds for the rest.

THE HOURS FROM SUNRISE AND SUNSET WITH THE ARCS OF THE SIGNS, on a plane parallel to the horizon.

PRAXIS III.

[Margin: Which hour-points on the equinoctial line are to be found.]

1. If whole hours from sunrise and sunset are to be drawn, one must find, by Praxis I, the points of the hours from noon and midnight on the equinoctial

line, together with the points of the half-hours. But if, in addition, the half-hours from sunrise and sunset are wanted, the points of the quarter-hours from noon and midnight must also be found. And if, finally, one wishes for the quarter-hours from sunrise and sunset as well, the eighth-parts of the hours from noon and midnight must be found besides.

For the whole hours from sunrise and sunset are equidistant from the hour-lines from noon and midnight that are separated from them in order by half-hours; the half-hours from sunrise and sunset, together with the whole hours, are parallel to the hour-lines from noon and midnight that are separated in order by quarter-hours; and finally the quarter-hours from sunrise and sunset, together with the halves and the whole hours, are equidistant from the hour-lines from noon and midnight that are separated in order by eighth-parts — as was said in chapter 14. And which hour-line from noon and midnight any given hour-line from sunrise or sunset is equidistant from is easily known if the proposed hour from sunrise or sunset is bisected: for its half names the hour from noon and midnight to which it is equidistant. For example, hour 18 from sunrise or sunset is equidistant from hour 9 from noon and midnight; hour $18\frac{1}{2}$ is parallel to hour $9\frac{1}{4}$; hour $18\frac{1}{4}$ to hour $9\frac{1}{8}$; and hour $18\frac{3}{4}$ to hour $9\frac{3}{8}$. Likewise hour 6 from sunrise and sunset is equidistant from hour 3 from noon and midnight. And so with the rest.

[Margin: How whole hours from sunrise and sunset are described, or their halves, or their quarters.]

[Margin: Which hour from noon and midnight any given hour from sunrise and sunset is equidistant from.]

2. Now, through which hour-points of the equinoctial line the hours from sunrise and sunset are to be drawn is no trouble to understand. For hour 18 from sunrise and sunset is to be drawn through hour 12 on the equinoctial line. Hence hour 19 must be drawn through hour 1, hour 20 through hour 2, hour 21 through hour 3, hour 22 through hour 4, and hour 23 through hour 5; while hour 17 is drawn through hour 11, hour 16 through hour 10, hour 15 through hour 9, hour 14 through hour 8, hour 13 through hour 7, and so on. The same must be said of the halves and quarters: for just as, for example, hour 18 is drawn through hour 12, so hour $18\frac{1}{4}$ is to be drawn through hour $12\frac{1}{4}$, and so on. In what way the lines of the hours from sunrise and sunset are to be drawn parallel to the lines of the hours from noon and midnight — even though the hours from noon and midnight have for the most part not been drawn — we taught in

chapter 14. But all this is more easily known from the two little tables set at the beginning of chapter 14.

[Margin: Through which hours on the equinoctial the hours from sunrise and sunset are to be drawn. Hour 12, and others little distant from it, in what way they are to be drawn.]

3. For hours $11\frac{1}{4}$, $11\frac{1}{2}$, $11\frac{3}{4}$, 12, $12\frac{1}{4}$, $12\frac{1}{2}$, $12\frac{3}{4}$ — since the hour-points from noon and midnight $5\frac{1}{4}$, $5\frac{1}{2}$, $5\frac{3}{4}$, 6, $6\frac{1}{4}$, $6\frac{1}{2}$, $6\frac{3}{4}$, through which they are to be drawn, either cannot be marked on the equinoctial line at all, or only with difficulty, because they run out too far — one must have recourse to the figure of the scholium of chapter 1, in order to find convenient intersections of the hours from sunrise and sunset with the hours from noon and midnight, through which are to be drawn the lines parallel to the hour-lines from sunrise and sunset, whose numbers are the halves of those hours from sunrise and sunset. For example, from the aforesaid figure you will gather that hour $12\frac{1}{2}$ passes through the intersection of hour 22 with hour $5\frac{1}{4}$. So the line of hour $5\frac{1}{4}$ must be drawn, as we said in Praxis I, even if its point is not found on the equinoctial but on some line parallel to the meridian, such as PR or XK, and so on; and the point where it cuts hour 22 must be carefully marked. For through this point hour $12\frac{1}{2}$ must be drawn, parallel to hour $6\frac{1}{4}$, and so on. But hour 12 from sunrise or sunset is to be drawn parallel to hour 6, through the point that bisects the segment of the meridian between the equinoctial and hour 6, as we demonstrated at the end of chapter 14 — so that there is no need to investigate another point through which it must pass.
4. But if the tropic of Cancer has been drawn through points found either in the hours from noon and midnight or in the whole hours from sunrise and sunset, we shall delineate these same hours with no trouble, without the aid of the figure of the scholium of chapter 1 — namely, by the distances they have on the tropic of Cancer from the meridian. For if the point of the distance of any hour from sunset, in degrees and minutes (as they are computed in the table of the scholium of chapter 15), is found either on the equinoctial line or on some other line equidistant from the meridian, as we taught in Praxis I, a straight line drawn from the center of the dial through that point will cut the tropic of Cancer at the point through which the proposed hour from sunset is to be drawn. And if the same is done with the hour from sunrise of the same number, another point of the proposed hour will be found on the same tropic.

[Margin: Another way of describing the hours from sunrise and sunset.]

5. Indeed, by these same distances from the meridian, the points of all the hours from sunrise and sunset can be found on both tropics, or even on any other parallel of the Sun whatever, as was set out in chapter 15, No. 4. And by this way the hours from sunrise and sunset will be described most conveniently, provided the tropics have first been accurately delineated.

[Margin: The arcs of the signs in the hours from sunrise and sunset.]

6. Once the hours from sunrise and sunset have been drawn, the points of the parallels will be found on them by the method we described in the addition before No. 3 of chapter 15; or else by the distances from the meridian reckoned in degrees and minutes, as we taught in chapter 15, No. 3.

THE HOURS FROM NOON AND FROM MIDNIGHT, on a plane declining from the vertical.

PRAXIS IV.

[Margin: The description of the hours from noon and midnight on a declining dial.]

1. The horizontal line, the meridian, the center of the dial, the 6-o'clock line, the style line, and the equinoctial must be found and drawn by means of tangents, as was taught in chapter 16, Nos. 1, 2, 3, and 4 — the geometrical methods we there employed being set aside, if one prefers. Then the hours are to be drawn through the points found on the horizontal line, as was explained in Nos. 5, 6, and 7.

[Margin: An exact description of the hours by the points of the horizontal line.]

2. But these will be drawn far more accurately in this way. On the meridian of the dial (chapter 16) let there be taken any number of parts equal to EB, so that the segment of the meridian between E and the last part is double, or triple, or quadruple, and so on, of EB; and through the outermost point let a perpendicular be drawn to the meridian. For if onto this perpendicular you transfer, from the point where it cuts the style line, the tangents with respect to a whole sine that is as many times a multiple of the style CD as the portion of the meridian taken was a multiple of the segment EB — the tangents, I mean, of the arcs of the earlier table of chapter 16, just as we said they must be transferred, with respect to the

whole sine CD, from C, in place of the style, onto the horizontal line — you will have on it other hour-points, through which, if straight lines are sent out from E, they will pass exactly through the hour-points of the horizontal line, if no error has been made.

The reason for this is [a] that the aforesaid segments of the perpendicular between the style line and the hour-lines are the same multiples of the segments of the horizontal line between the style line and those same hour-lines as the assumed multiple portion of the meridian was of EB itself. Since, then, the tangents with respect to a whole sine that is likewise so many times a multiple of the whole sine CD are, in the same way, multiples of the tangents with respect to the whole sine CD — (for as the greater whole sine is to the tangent of any arc, so is the lesser whole sine to the tangent of the same arc; and, by alternation, as the greater whole sine is to the lesser whole sine, so is the tangent of the greater whole sine to the tangent of the lesser whole sine; therefore the whole sine will be the same multiple of the whole sine as the tangent is of the tangent) — what is proposed is established.

[Margin: a — Euclid VI.4 (4 sexti).]

[Margin: An exact description of the 3- and 9-o'clock lines.]

3. But the hour-lines will be drawn far more precisely by this alternative method. First, the 3- and 9-o'clock lines are to be drawn with the greatest care in this way. Through A (in the figure of chapter 16) draw the straight line PQ parallel to the meridian, so that it represents the prime vertical, and transfer onto it, on either side of A, the tangent of the arc of the 3rd and 9th hour — the arc which, in Table 6, is written opposite the elevation of the pole in the right-hand column, and which at latitude 42° amounts to $53^{\circ} 23'$. The tangent, I mean, taken with respect to the whole sine DA, marking the points P and Q. For through these, from E, the 3- and 9-o'clock lines are to be drawn. You will also do correctly if, on the aforesaid perpendicular, you find the points for the same hours. Which of them marks the 3rd hour and which the 9th, the position of the dial will readily show. For on a dial declining from the meridian toward the east or toward the west, the line set below the horizontal line, to our left, always indicates the 9th hour, and the other, to the right, the 3rd hour — so that on a dial declining from the meridian toward the east, the upper point on the vertical line PQ belongs to the 3rd hour and the lower to the 9th; whereas, conversely, on a dial declining from the meridian toward the west, the upper point looks to the 9th hour and the lower to the 3rd.

Diagram. A large construction figure for a declining sundial, filling the lower two-thirds of the page within a ruled rectangular border. It shows the meridian line, the horizontal line, the 6-o'clock line, the style line, the equinoctial, and a full fan of hour-lines radiating from two centers (the dial center near E and a second center near A), crossed by an arc of a circle. The hour-lines are numbered along their upper ends with the whole and half hours: 3, 3½, 4, 4½, 5, 5½, 6, 6½, 7, 7½, 8, 9, 10. Two interior text-labels read "Num. 10" and "Num. 9". Beneath the main construction, at the foot of the frame, are five graduated tangent-scale rulers, each marked off in divisions numbered 10, 20, 30, 40, 50, 60, and captioned:

- "Pro horiz. et lin. Styli" — for the horizontal and the style-line (between points C and D)
- "Pro mer." — for the meridian (between D and B)
- "Pro æqum." — for the equinoctial (between K and N)
- "Pro Vert" — for the vertical (between D and A)
- a fifth, lowest ruler (beginning at L)

Clearly readable point-labels in the main figure: A, B, C, D, E, F, K, L, M, N, P, Q, R, S, T, V, X, Y, Z, H, I, together with several small lowercase labels (d, e, f, i, m, n, r, y). Many of the peripheral small labels and the exact point to which each hour-number attaches could not be resolved with certainty at this resolution [several labels ?].

and the lower to the 3rd hour. So that these two lines too may be drawn more accurately, the lemma demonstrated before chapter 16 should be applied. Or else, for the same lines, the points on the perpendicular to the meridian, corresponding to the points of those lines on the horizontal, may be found, as we prescribed just now. If you prefer, the other hour-points can also be found, from the same Table 6, on the vertical line PQ, as was stated in No. 7 of chapter 16.

[Margin: A more accurate laying-out of the hours.]

4. Once the 3- and 9-o'clock lines have been drawn, cut off from the 6-o'clock line, from E as center, on either side, lengths equal to AP (or AQ), and through the outermost points draw parallels to the meridian, meeting the 3- and 9-o'clock lines in points. If these points are joined by a straight line, the joining line will be equal to PQ and parallel to the 6-o'clock line, and will be bisected by the meridian, just as PQ is bisected at A. And if onto the line PQ and onto that parallel to the 6-o'clock line there be transferred, from their middle points on either side, the tangents of 15°, 30°, 45°, and so on — taken, with respect to the whole sine AP (or AQ), from the table of the

scholium of chapter 1 — one will obtain the points of all the whole hours, and so forth. On these two lines the same hour-points can also be found without tangents, as [was said] at the beginning of No.

NOVÆ DESCRIPT. — 209

10 of chapter 16 — namely that they are to be found on the lines PQ, PM, and so on. Moreover the hour-points can, if one wishes, be found on the equinoctial line, once it has first been found by problem 5 at the end of the little book, by the inclination of the meridians, as was done in No. 8 of chapter 16.

5. But if you prefer to use the whole sine AB, constructed at the outset for scale 2, in place of the whole sine AP, then from the meridian, from the point E, cut off a straight line equal to the segment AB of scale 2, and through its outermost point draw a line parallel to the 6-o'clock line, meeting the 9- or 3-o'clock line at a point; and if through that point a parallel to the meridian is drawn, its portion between the 3rd and 9th hours will be bisected by the 6-o'clock line, and its half will be equal to the segment AB on scale 2. If, then, on the 6-o'clock line there are taken, from the center on either side, straight lines equal to the said segment AB of scale 2, and through the outermost points parallels to the meridian are let down, they will meet the 3- and 9-o'clock lines in points; and if these are joined by a straight line, the joining line will be parallel to PQ, bisected by the meridian, and its half equal to the same segment AB on scale 2. Onto these two straight lines, then — parallel to the meridian and to the 6-o'clock line — if the tangents of the hours, taken from the table of the scholium of chapter 1 with respect to the whole sine AB on scale 2, are transferred from their middle points, the hour-points will again be found, and so forth. And here this convenience results, that there is no need to divide the new whole sine AP into 10 equal parts; rather the whole sine AB, already divided on scale 2, is to be used. Indeed this procedure is necessary whenever the point A can scarcely be contained on the dial: but then the 6-o'clock line will have to be drawn in the way we explained at the beginning of p. 89, even though its intersection with the horizontal does not appear.
6. Now if it should happen that a dial has to be constructed which declines toward a latitude smaller than 30° or greater than 60° , so that Table 6 cannot serve, the 3- and 9-o'clock lines must be drawn as we taught in No. 9 of chapter 16. The remaining hours are to be described as was stated in Nos. 4 and 5 of this 4th exercise; and their points, too, can be found on the horizontal line in the way we set forth at the end of No. 9 of chapter 16.

[Margin: The construction of a dial declining toward a latitude smaller than 30° , or greater than 60° .]

THE ARCS OF THE SIGNS ON A DECLINING DIAL, for the hours from noon and from midnight.

PRAXIS V.

[Margin: The arcs of the signs among the hours from noon and from midnight on a declining dial. Which method is the most excellent for the declining parallels.]

1. The points of the Sun's parallels on the hour-lines will be conveniently found as was explained in chapter 18, Nos. 1, 4, 5, and 6, all the other methods being set aside, since they are less convenient and not so ready and easy. I myself, however, would prefer the method of Nos. 4 and 5, provided the lines are carefully drawn equidistant on either side from the style line, after the fashion of the hour-lines on a horizontal dial, as we handed down in No. 4 of chapter 18. For by this route as many points as one likes can be found for drawing the parallels, on however many lines may indicate the minutes of those hour-spaces, if the table for the addition before No. 3 of chapter 15 is used. And I wish this to be understood of the horizontal dial as well.

THE HOURS FROM SUNRISE AND SUNSET WITH THE ARCS of the signs on a declining dial.

PRAXIS VI.

[Margin: The hours from sunrise and sunset on a declining dial.]

1. The hours from sunrise and sunset on a declining dial will be readily described by means of what we wrote in chapter 19, Nos. 1 and 2, with the addition of what is handed down at the end of No. 3 of the same chapter — so that there is no need to prescribe anything new on this matter.
2. Yet that most beautiful method of No. 8 of chapter 19 ought not, it seems, to be passed over — the method by which, at any hour from noon or midnight, a point is found through which the proposed hour from sunrise or sunset is to be drawn. On this subject the things we wrote at the beginning of No. 4 and throughout the whole of No. 8 of chapter 19 must be carefully considered. And since in No. 9 of the same chapter we said that this same procedure fits the horizontal dial too — but that the declination

of the diurnal arc, by which the point is to be found at a given hour from noon or midnight, from sunrise or sunset, we taught must be taken from Table 13, so that on the meridian line the point of that diurnal arc may be found — it seems only necessary to add here that the same point of the diurnal arc can be found on the meridian, without its declination, in this way. Let half of that diurnal arc be subtracted from 24. For thus there remains the hour from sunset at which noon falls on that diurnal arc. If, then, that hour from sunset is described, as we taught in exercise 3, it will cut the meridian at the sought point of the diurnal arc. For example, if the proposed diurnal arc is one of $16\frac{1}{2}$ hours, we shall subtract its half, $8\frac{1}{4}$, from 24, and there remains the number $15\frac{3}{4}$; the hour of $15\frac{3}{4}$ from sunset, when described, will cut the meridian at the point through which the diurnal arc of $16\frac{1}{2}$ hours passes. The hour from sunrise indicated by the half of the proposed diurnal arc will show the same point more easily and quickly. Thus, in the given example, the hour of $8\frac{1}{4}$ from sunrise will cut the meridian on the diurnal arc of $16\frac{1}{2}$ hours; and so for the rest.

[Margin: The finding of the point of any diurnal arc on the meridian of a horizontal dial, without the declination of that diurnal arc.]

3. The arcs of the signs on a declining dial, for the hours from sunrise and sunset — even if their points among the hours from noon and midnight have not been found — we shall lay out by this method. From the table belonging to the addition before No. 3 of chapter 15, seek (having first found its distance from noon in hours and minutes) the point on the meridian line for the given hour from sunrise or sunset, just as on the horizontal dial, as was stated in chapter 8, No. 7 — namely from that arc of the table which corresponds to the distance of the proposed hour from sunrise or sunset. For the straight line drawn from A — the intersection of the equinoctial line with the horizontal — and the 6-o'clock line, through the found point, will cut the proposed hour from sunrise or sunset at the point of that parallel of the Sun from whose arc the point was found. When the point of some arc of the aforesaid table cannot be obtained on the meridian, or only with difficulty, the point must be sought on the 6-o'clock line, as was set forth in No. 2 of chapter 18. Or else the point in the given hour from sunrise or sunset must be investigated for the proposed parallel, by the distance of that hour in degrees and minutes which it has from noon, as was stated in chapter 15, No. 3.

[Margin: The arcs of the signs among the hours from sunrise and sunset on a declining dial.]

4. But I do not wish to pass over, in this place, the method by which, through that table of No. 2 of chapter 15, the points

PRAXIS VI. & VII. — 210

for the hours from sunrise and sunset can be found more exactly on the meridian line and on the 6-o'clock line. For since that table contains only the arcs corresponding to the hours and minutes, whereas the distances of the hours from sunrise and sunset which they have from noon usually contain, beyond the hours and minutes, seconds as well, the proportional part due to those seconds must be extracted, so as to be added to, or subtracted from, the arc of the aforesaid table, according as the following arc is greater or smaller than the preceding one.

[Margin: The proportional part in the table given in No. 2 of chapter 15, and how it is to be extracted.]

For example: the 23rd hour from sunset and the 1st from sunrise, at the beginning of ♋ [Cancer], is distant, at latitude 42° , $98^{\circ} 3'$ from noon — that is (if by table 1, placed among the tasks of the equinoctial circle in the sphere, this distance is reduced to time) 6h 32m 12s, or from midnight (which distance is the smaller) 5h 27m 48s. Now on the meridian circle the hour 5h 27m corresponds to the arc, in the aforesaid table, of $71^{\circ} 44'$, while to the hour 5h 28m corresponds the greater arc of $72^{\circ} 15'$. Subtracting the former from the latter, the remaining difference will be $0^{\circ} 31'$. We shall therefore say: if 60 seconds (namely 1 minute) give a difference of $0^{\circ} 31'$, what will 48 seconds give? and we shall find $0^{\circ} 24' 48''$ — that is, $0^{\circ} 25'$ (for when the seconds are more than 30, one minute may be taken for them) — as the proportional part sought; which, added to the smaller arc of $71^{\circ} 44'$, makes $72^{\circ} 9'$. This arc does not differ from the one you will find corresponding, in Table 8, to the 23rd hour from sunset in ♋, because that one was computed through the true distance from noon.

Again, the same 23rd hour, at the beginning of ♑ [Capricorn], is distant from noon $51^{\circ} 57'$, that is, 3h 27m 48s. Now on the meridian circle the hour 3h 27m corresponds to the arc $35^{\circ} 5'$, while to the hour 3h 28m corresponds the greater arc $35^{\circ} 14'$. Subtracting the former from the latter, there remains a difference of $0^{\circ} 9'$. Say therefore: if 60 seconds have a difference of 9', how much will 48 seconds have? and you will find $0^{\circ} 7' 12''$ as the proportional part; which, added to the smaller arc of $35^{\circ} 5'$, makes $35^{\circ} 12'$, as in Table 8. For the 12 seconds, since they are fewer than 30, are to be omitted.

Furthermore, the same 23rd hour, whose distance from noon in ☉ is 5h 27m 48s, has on the 6-o'clock circle the arc $23^{\circ} 43'$, and the following, smaller arc is $23^{\circ} 42'$. Say therefore: if 60 seconds have a difference of $0^{\circ} 1'$, how much do 48 seconds have? and you will find 48 seconds; and for these, if you subtract 1 minute from the greater arc, you will get the arc $23^{\circ} 42'$. And so for the rest. But this proportional part is not needed if, for seconds more than 30 in the distance from noon, you add 1 minute to that distance and seek the arc in the table from the distance so composed: for no notable error will be detected in the tangents, especially if the two nearest arcs have a small difference.

A NORTH-DECLINING DIAL; A VERTICAL DIAL NOT declining; a meridian dial; the meridian line, and the declination of the wall, etc.; the transfer of a dial onto a wall; a dial by the horizontal circumferences of the Sun alone, and by the Sun's altitudes.

PRAXIS VII.

[Margin: A dial declining from the north; a vertical dial not declining; a meridian dial, etc.]

1. For a dial declining from the north, read Nos. 1 and 2 of the scholium of chapter 19; for a vertical dial not declining, chapter 20.
2. For a meridian dial, read chapter 21. On such a dial the points of the arcs of the signs will be found, among the hours from sunrise and sunset, if from the table pertaining to the addition before No. 3 of chapter 25 there are taken the arcs which, on the 6-o'clock circle, correspond to the distances of the hours from sunrise and sunset, and their tangents are transferred onto the 6-o'clock line from A, marking the points on it. For parallels to the equinoctial, drawn out through those points, will cut the hours from sunrise or sunset at the points of the parallels. Or, omitting these parallels, one must proceed with the compass or the set-square, as we said in the addition before No. 3 of chapter 15.
3. For the finding of the meridian line, the declination of the wall, and so on, read chapter 22.
4. For transferring a dial onto a wall, read chapter 23.

5. For describing a declining dial by the horizontal circumferences of the Sun alone, together with the Sun's altitudes, read chapters 24 and 25 with its scholium.

FINIS.

A MOST COMPENDIOUS METHOD OF DESCRIBING HORIZONTAL AND DECLINING SUNDIALS

*(COMPENDIVM BREVISSIMVM DESCRIBENDORVM HOROLOGIORVM
Horizontalium ac Declinantium.)*

**By CHRISTOPH CLAVIUS [Christophorus Clavius] of Bamberg, of the Society
of Jesus.**

(AVCTORE CHRISTOPHORO CLAVIO BAMBERGENSI SOCIETATIS IESV.)

PREFACE

Some years ago I gave my students a geometrical account of sundials [horologia] — and a very brief one. Not a few people pressed me to publish it, among them a man distinguished not only by his exceptional zeal but also by his generosity, the illustrious Isidoro Ruberti [Isidorus Rubertus]. Won over by their entreaties, I have now had it printed, though somewhat enlarged. For although in the year 1599 I published a new and most accurate method of laying out sundials by means of tangent lines [per lineas tangentes], that method cannot be put to use unless certain tables are employed — so much so that without them no sundial can be built from memory. I am confident, therefore, that this compendium will not be unwelcome to students, since once it has been properly understood, sundials can be laid out from memory in any place whatever. Yet I shall not entirely neglect the tangents: anyone who wishes may still use them, whenever he likes, for constructing sundials — since by them the hours are laid out far more accurately, together with the arcs of the zodiacal signs [arcubus signorum], than by the geometrical method alone, on account of the countless nearly oblique sections that tend to occur in it. A fuller treatment by means of tangent lines the diligent reader may seek in the aforementioned new description of sundials.

ASTRONOMICAL HOURS — THAT IS, RECKONED FROM NOON AND FROM MIDNIGHT — ON A HORIZONTAL PLANE

(HORÆ ASTRONOMICÆ HOC EST A MERIDIE AC MEDIA NOCTE IN PLANO HORIZONTALI.)

CHAPTER I (*CAPVT I.*)

Draw two straight lines AB and CD cutting one another at right angles at E; and on CD, taking the length of the style [gnomon, *stylus*] EC, describe from C, at any interval you please, an arc of a circle FG cutting CD at D. From D count upward the complement of the elevation of the pole [altitudo Poli] as far as F, and downward the elevation of the pole itself as far as G. For when the straight lines CF and CG are drawn, cutting the straight line AB at A and H, A will be the center of the sundial, at which all the hour-lines will meet. Now if a straight line is drawn through H perpendicular to AB, it will be the equinoctial line [linea æquinoctialis]; AB itself will be the meridian line, and AC the Axis of the World [Axis Mundi].

Now let HB be taken equal to the straight line HC (whether this is done upward or downward makes no difference). Then from B describe a circle IKLM of any size; in it draw the diameter KM through B, perpendicular to AL, and cut the whole circle into 24 equal hours. This is easily done: with the compass opened to the semidiameter IB, from the four points I, K, L, M cut off two arcs on either side. For in this way the whole circle, with the same opening of the compass, will be distributed into 12 equal parts. Then, each part being bisected, the whole circle will be divided into 24 hours.

After this, laying a ruler across each pair of points diametrically opposite, cut the equinoctial line at points through which straight lines, projected from the center A of the sundial in both directions, will give the hours from noon and from midnight.

Diagram. A horizontal-sundial construction figure, set in a rectangular frame and captioned "**1. fig.**" [prima figura] at its upper right. The construction is that described in Chapter I: two straight lines cross at right angles (the meridian AB running roughly vertical and the line CD running across), with the center of the sundial A at the center-right, where the fan of hour-lines converges. Radiating

from A is a full spread of straight hour-lines, numbered with the hours **1** through **12** near the center and continued as **1–8** on the extended lines toward the lower left. A large circle **IKLM** stands to the left, centered at **B**, divided into 24 parts, with the diameter **KM** drawn through B.

Clearly readable labels:

- A (center-right): center of the sundial [centrum horologii], meeting-point of all hour-lines.
- B (center of the large left-hand circle): center from which circle IKLM is described.
- E, H (on the central axis, between A and the circle): E the intersection of AB and CD; H the point through which the equinoctial line passes.
- I, K, L, M (on the large circle): the four cardinal points of circle IKLM; K at top, M at bottom, L toward the left.
- Hour numerals 1–12 spaced around the fan of lines from A; further hour numerals 1–8 on the lower-left extensions.

Labels present on the figure but too small / crowded to resolve with certainty on the scan: F [?], G [?], C [?], D [?], N [?], P [?], Q [?], S [?] (the letters called for by the text — the arc-endpoints F, G on CD, and the auxiliary points N, P, Q, R, S used later — are inked among the dense line-crossings but cannot be individually pinned down here). **More than two labels are flagged [?].**

and from midnight. Only the line of the sixth hour is to be drawn through the center A of the sundial, perpendicular to the meridian line. The order of the hours is this: the afternoon hours — 1, 2, 3, and so on — lie to the left of the meridian line, while the forenoon hours — 11, 10, 9, and so on — lie to the right.

But since some of the diameters of the circle IKLM cut the equinoctial line very obliquely — so that it is not easy, by means of them, to find without error the points on the equinoctial line through which the hours are to be drawn from the center A of the sundial — we shall lay out those hours more accurately by the following device.

From any point N of the third or ninth hour, draw NO perpendicular to the sixth hour. (In the figure the point N has been taken on the third hour.) Take OP equal to NO, and from P describe a circle at any interval; then from the point Q, with the interval of this circle's semidiameter QP, cut off two arcs QR and QS, each of which spans four hours. Each arc being therefore divided into four equal parts, if concealed [construction] lines are projected through them from the center P, the

straight line NO will be cut at points through which the hours are to be drawn from A, the center of the sundial — even though the points [themselves] were not found on the equinoctial line. You have an example in the 2nd, 3rd, 4th, 5th, 7th, and 8th afternoon hours. In the figure the point R could not be marked, for lack of room. Likewise the point on the equinoctial line, through which the third or ninth hour is to be drawn, we shall obtain if we carry the straight line HB or HC over from H onto the equinoctial line — to the left for the third hour, to the right for the ninth. If to the right you draw another line parallel to the meridian, set off from the meridian by as great an interval as the parallel NO is distant from it, and transfer onto this parallel the points of the parallel NO, you will have three points for each hour, and so on. And if the hour-spaces in the circles IKLM and RQS are bisected, or divided into four equal parts, the halves and quarters of the hours will be drawn in the same way.

Moreover, we shall find the hour-points on the equinoctial line and on the parallel NO most exactly by the help of tangent lines — indeed we shall construct the whole sundial — in the following way. Prepare an instrument of this kind. On some flat surface, whether of brass or of wood, or on a rather thick sheet of paper, make a right angle BAC (it could also be made obtuse or acute); and taking two equal straight lines AB and AC, divide each into 100 equal parts, and through the several divisions draw individual arcs from the center A. In the figure each of the lines AB and AC is divided into ten parts, each of which is again to be subdivided into ten smaller parts. With this instrument the tangents of any arcs whatever will be obtained without any trouble,

Diagram. Upper figure, captioned "**2. figura**" at its upper left. A rectangular frame containing a fan of concentric quarter-circle arcs centered on the corner A at the top right. Along the top edge, tick-marks are numbered **100, 90, 80, 70, 60, 50, 40, 30, 20, 10** running from left (corner B) rightward to A; down the right edge from A the marks run **10, 20, 30, ...** The concentric arcs sweep from the top edge round to the left edge. A dotted line runs diagonally across the arcs (the parallel NO of the text). Corner and edge points labelled: **A** (top-right), **B** (top-left), **C** (bottom-left), **D** (on the left edge, at the dotted line), **E** and **F** (mid-field, where the dotted line crosses), and **H, I** (lower, on a short horizontal segment separating this figure from the instrument below). Arc-value numerals 10–100 read cleanly; the small point-letters D, E, F, H, I are legible but sit among crowded line-crossings.

Diagram. Lower figure (uncaptioned): the tangent-instrument described in the closing paragraph. A narrow wedge opening from the right-angle vertex A at the right (enclosed in a small circle, with a center-dot). Two equal straight scales

diverge leftward from A — the upper scale to **B**, the lower scale to **C** — each graduated with tick-marks numbered from A outward **10, 20, 30, 40, 50, 60, 70, 80, 90, 100**. Intermediate point-letters are marked on the scales: **D** and **F** on the upper scale AB, **E** and **G** on the lower scale AC (the exact letter at each tick is small and the assignment of D/F and E/G to particular divisions is not fully certain [?]). The whole is enclosed in a rectangular frame. **Point-letter placement uncertain at this resolution for label verification.**

the tangents of any arcs whatever will be had, the whole sine being set at 100 — which is enough for the present purpose. Thus, from tangents whose whole sine is 10000000, five figures are to be dropped on the right; three, when the whole sine is 100000; and finally only one, when the whole sine is put at 1000, as in the table of the new layout of sundials — provided, however, that a unit is added to the remaining tangent when in this table the figure has been dropped, or, in other tables, when the first figure dropped on the left was greater than 5; or half a unit, when that figure was exactly 5, or not much greater. On this principle the tangents will be taken.

For the given whole sine, take an interval equal to BD, and draw the hidden line AD. Then, if the tangent is not greater than 100 (after the said figures have been dropped), the interval from the tangent's number on line AB across to line AD will give the tangent sought. For example, if the tangent is 40, the interval EF will be the tangent of 40 parts, provided the whole sine of the interval BD is thought of as divided into 100 parts. But if the tangent is greater than 100, the whole sine BD must be laid off on some straight line as many times as there are hundreds in the given tangent, and the remaining tangent added. Thus, if the given tangent is 140, the whole sine BD is laid once along the line GH, from G to H, and to it is added the tangent HI, equal to EF, of 40 parts. For in this way the line GI will be the tangent of 140 parts, the whole sine containing 100 parts. And if the given tangent were 540, the whole sine would have to be taken five times along GH, and the tangent of 40 parts added, and so on.

Diagram. A large combined construction plate, captioned "**3.^a fig.^a**" (rotated, at the upper left), enclosed in a rectangular frame. It joins two constructions:

- *Upper region — the tangent-scale instrument* (as in the 2. figura of the prior page): a fan of concentric quarter-arcs sweeping from a right-angle vertex, whose straight edges are graduated with tick-marks numbered **100, 90, 80, 70, 60, 50, 40, 30, 20, 10** (these read cleanly). A small right triangle sits at the upper left with its hypotenuse labelled **A–P**; on a short vertical within it

are **R**, **E**, **R**. Along the top run the points of the parallel line, labelled **N**, **H**, **N**, with a further **P** lower on the diagonal.

- *Lower region — the horizontal dial proper:* a large circle (the hour-circle) centered in the field. The dial center **A** lies at the left on the horizontal (meridian/equinotial) line; a fan of hour-lines radiates from **A** across the circle.

Readable point-letters: **L** (upper-left endpoint of the horizontal), **A** (dial center), **S** (left endpoint below **A**), **M** (top of circle), **G** (upper right of circle), **D** and **E** (on the horizontal diameter), **F** (bottom of circle), **N** (left of **F**), **O** (bottom of circle), **K** (right endpoint of the horizontal). Clustered near **A/S** and among the interior crossings, and less certain: **P**, **Q** (lower left) [?], **X**, **Z**, **T**, **I**, **Q** (interior, along a dotted parallel) [?], a small "3" beside **A** [?]. The radiating hour-lines carry morning/afternoon hour-pairs around the circumference; legible are **12** (top), **9 3**, **8 4**, **6** (near **K**), **5**, and **1 5** (lower right) [?]; the intervening pairs (11/1, 10/2, 7/5) sit among dense line-crossings and cannot be resolved.

Many small point-letters lie among crowded intersections for label verification.**

Perhaps this same instrument will be built more conveniently as follows. Make two equal rules of brass, **AB** and **AC**, joined at the center **A** so that they can turn uniformly about it, in such a way that, when the instrument is closed, the lines **AD** and **AE** form a single straight line. For if two equal lines **AF** and **AG** are drawn on these rules from the center **A**, and both are divided into 100 equal parts, the instrument built will serve the same purpose as the former one — provided the interval between the two 100-marks is taken equal to the given whole sine. But since very small tangents cannot be taken near the center on this instrument (the center staying fixed), we shall take two larger tangents whose difference equals the tangent sought. For when these are transferred onto any straight line, their difference will give the tangent sought. Thus, if the tangent of 4 parts is to be taken, we shall use the difference between the two tangents 20 and 24, or 60 and 64, and so on. And when the whole sine is so small that we cannot set it between the two 100-marks, let its tenfold be taken between them; then take the tenth parts of all the tan-

—gents — which is done by dropping one figure. Thus, if the tangent is 95, corresponding to 43° 31', the tangent 9½ [?] must be taken with respect to the tenfold whole sine. We have set out the use of both instruments more fully and at greater length in our *Practical Geometry* [Clavius, *Geometria Practica*], to which we refer the reader.

But let us now come to the layout of the sundial by tangents, which in our example we shall carry through with the latter instrument. In the first figure, then, draw two lines AB and CD cutting each other at right angles at E; and, having taken the length of the gnomon EC, we shall set the interval between the two 100-marks equal to EC, as to the whole sine. Next we take the tangent of the complement of the pole's altitude — in this compendium we take the altitude of the pole at Rome to be 42° — namely 111, and carry it from E upward to A along the meridian line. A will be the center of the sundial, and the perpendicular OP the six-o'clock line. Likewise we carry the tangent of the pole's altitude — namely 90 — from E downward to H; and the equinoctial line drawn perpendicular through H will let us find the hour-points upon it as follows. Since one hour, whether before or after noon, takes in 15° , two hours 30° , three 45° , four 60° , and five 75° , if we take the tangents of these degrees — first setting the interval between the two 100-marks equal to the interval HC, as the whole sine — and carry them from H onto the equinoctial line on either side, we shall find the points through which the hour-lines are to be drawn from A.

But if the whole sine is set as OP, and an interval equal to it is taken between the two 100-marks, then the tangents of the same degrees, carried over from O, will give the hour-points on the parallel NO, and so on. For example, the tangent 173 — which, with respect to the whole sine HC, corresponds to the 4th and 8th hours, that is, to 60° — will give on the equinoctial line the points of hours 4 and 8. On the parallel NO, by contrast, the same tangent will give the points of hours 2 and 10, with respect to the whole sine OP, since these hours too are 60° — that is, four hours — distant from the six-o'clock line. In the same way we shall find the points of the half-hours and quarter-hours, if we reduce these fractions of hours to degrees and carry over their tangents from H and O, and so on.

The Arcs of the Signs [ARCVS SIGNORVM]

Chapter II [CAPVT II]

Draw the line AB to represent the axis of the world, and at A erect the perpendicular AC as the radius of the equator. Then, having described from A any arc FEG, cut off from the point E two arcs EF and EG equal to the greatest declination, that is, of $23\frac{1}{2}^\circ$. For the lines AF and AG, when drawn, will represent the radii of Cancer ☊ [Greek/zodiac: ☊, Cancer — the summer-solstice sign] and Capricorn ☋ [zodiac: ☋, Capricorn — the winter-solstice sign]. To draw the radii of the other signs, join the line FG, cutting the equator's radius at the point D; and about D, with the interval DF (or DG), describe the circle FHGI. Divide it into

twelve equal parts [the print here reads *12. quartes*], and with hidden lines join pairs of points equally distant from F (or from G); then mark where these lines meet the arc FEG. For through these intersections the radii of the signs are to be drawn from A. And if the radii of the half-signs, or even of the quarter-signs, are wanted, the twelve parts of the aforesaid circle must each be divided into two, or into four, parts, and so on. Which radii look toward the northern signs, and which toward the southern, we shall show shortly.

After this, on the axis AB — the line AB being taken equal to the axis AC — draw, in the sundial of the first figure, the perpendicular BK to AB from B (whether AB be taken to the left or to the right of A makes no difference). Then, describing from B any arc LNP, count off from N on both sides the complement of the pole's altitude, up to M and O, and join the lines BM and BO. The former represents the line of the twelfth hour at noon, the latter the line of the twelfth hour at midnight. The lines of the other hours we shall draw thus: join the line OM, which cuts BK at Q; about Q, through M and O, describe the circle MOS and divide it into 24 parts. Join any pair of points equally distant from M or O by straight lines that cut MO at points; the lines drawn out from B through those points will give the lines of the other hours. Their order runs from the noon twelve-o'clock line BM toward O, and from there back again up to M.

We can also draw these hour-lines in the following way. In the sundial, take in the first figure all the intervals between B and the hour-points on the equinoctial line, beginning from the twelve-o'clock line, and carry them in order, in the third figure, from A onto the equator's radius AH, marking the points on it. Through these points the hour-lines are to be drawn out from B: the topmost gives the twelve-o'clock line, the next hours 1 and 11, the following 2 and 10, and so on; while the line BK will show the sixth hour. And if the intervals on the arc MNO between N and the hour-lines are carried into the same arc toward O, we shall have the points through which the hour-lines beyond the sixth hour are likewise to be drawn.

This done, we shall describe the arcs of the signs in the following way. Take the intervals of the hour-lines that go out from B in the third figure — the intervals between B and the radius of each sign (in a horizontal dial the radii toward B look to the northern signs, the rest to the southern) — and carry them in order, in the fourth figure, from the dial center A onto the corresponding lines. Or, what comes to the same thing: carry the intervals of the hour-lines between the equinoctial radius and the radius of each sign onto the corresponding hour-lines, measured from the equinoctial line — toward the dial center if the given radius

looks to the northern signs, but to the opposite side if to the southern. For a curved line neatly drawn through these points, so that it makes no [sharp] angles, will give that sign whose radius-points were transferred: the curved line, that is, onto which the tip of the gnomon's shadow is cast when the Sun is at the beginning of that sign.

The southern signs, which are opposite the northern, we shall describe by the same labor, using this device. Having found the two points of two opposite signs on the meridian line — the third figure supplies these for us as the two intervals of the noon twelve-o'clock line BM between B and the radii of the two opposite signs, carried onto the dial's meridian line from the center A; or else as the two intervals of the twelve-o'clock line BM between the equator's radius and the same radii of the opposite signs, carried onto the dial's meridian line starting from the equinoctial line — transfer the portion of the meridian line between the northern sign's point and the dial center to the lower part of the meridian line, [measuring] from the point of the opposite southern sign. For example, in the fourth figure the portion of the meridian line between a, the Cancer ☊ point, and A, the dial center, is transferred from b, the Capricorn ☋ point, up to d.

Next, from A and d describe two equal circles of any size; and carry the intervals of the circle described from A — the intervals between the meridian line and the hour-lines going out from A — onto the circle described from d, measured from the same meridian line; then from the center d send hidden lines through those points. For if the hour-intervals between B and the radius of the northern sign are carried onto the corresponding hour-lines from A, the dial center, and onto the corresponding lines from the center d, we shall have the points of the two opposite signs. Indeed, once any northern sign has been drawn, we shall draw its opposite sign in this way. Bisect the portion of the meridian line between the two points of the opposite signs — for example, bisect the portion between a, the Cancer ☊ point, and b, the Capricorn ☋ point, at Q — and through the point of division draw a line parallel to the equinoctial. For if the sheet on which the sundial is drawn is folded along this line, and the points of the northern sign are pricked through with a fine needle, the points of the opposite southern sign will appear on the other side.

But because the oblique intersections that the hour-lines going out from B in the third figure make with the radii of the signs — especially the southern ones — can easily give rise to error, we shall find the points of the arcs of the signs at the hours much more accurately by tangents, as follows.

Diagram. The sign-arc sundial construction, captioned "4.^a fig.^{am}" (rotated, at the upper right), enclosed in a rectangular frame. A horizontal line (meridian/equinotial) runs across the field with the dial center **A** at its right end. Near the center-right the gnomon-foot **F** sits inside a small circle (the circle **AgE** of the text), with **E**, **a**, and **d** marked close by. Along the horizontal to the left of center are stacked **C**, **H**, **K**, **M**; a vertical line at the upper left carries **O** and **L**; **P** lies at the left end of the horizontal (marked with an arrow, $\leftarrow$ **P**); **B** appears on a dotted arc at mid-left.

A large hour-circle/arc dominates the field, its hour-lines fanning from **A**. Legible hour-numbers around it: **5**, **6P** [i.e. **hour 6**], **7** (upper right); **8**, **7**, **6**, **5** (lower right); **12**, **13** (bottom edge); and the central cluster of hour-lines **12**, **11**, **10**, **9**. Along the dotted construction-arcs are the sign-arc numbers **22**, **21** (upper) and **18**, **19** (mid), read with difficulty. The point **g** named in the text (intersection of the small circle with the 2nd hour) is not separately legible among the crossings [?].

Point-letters and numbers sit among very dense line-crossings; several are uncertain for label verification.**

Suppose, for example, that the Cancer ☿ point at the second hour after noon is to be found, in the fourth figure. Bisect the segment **AE**, between the center and the gnomon, at **F**, and about **F**, through **A** and **E**, describe the circle **AgE**. For the lines drawn from **E** to the intersections of this circle with the hour-lines will be perpendicular to those hour-lines. Then from the point **g**, where the said circle meets the second hour, lay off the line **gh** equal to the gnomon. For the interval **Eh** will be the whole sine, by which the points of all the signs at the second hour are found in this way. In the table set at the end of this compendium, opposite the pole-altitude of 42° , under hours 2 and 10, take the arc of $43^\circ 53'$; subtracted from the complement of Cancer's declination — that is, from $66^\circ 30'$ — it leaves $22^\circ 37'$. The tangent of these, $41\frac{1}{2}$, transferred from **g** and from the other intersection of the circle **AgE** with the tenth hour into hours 2 and 10, will give the points of the tropic of Cancer ☿. Likewise, if the complement of the same arc, $43^\circ 53'$ (that is, $46^\circ 7'$), is added to Capricorn's ♑ declination of $23^\circ 30'$, an arc of $69^\circ 37'$ results, whose tangent, 269, from [the same...]

[Continuation of CAPVT II — "Arcs of the Signs," concluded from the previous folio.]

and the same tangent [269], carried over from those same points of hours 2 and 10, will give the points of the tropic of Capricorn ♑ at hours 2 and 10; and the

reasoning is the same for the rest. Therefore, for the northern signs the arc of the aforesaid table must be subtracted from the complement of the declination — except when that arc is greater than the complement of the declination, for then the complement must be taken away from that arc, and the tangent of the remaining arc carried toward the center. For the southern signs, on the other hand, the declination must always be added to the complement of the aforesaid arc. In the same way, for an hour beyond the sixth, the named arc must be added to the complement of the declination: so, for the seventh hour from noon, one must add the arc corresponding to the straight line Ak to the complement of the declination of Cancer ϖ . Finally, for the sixth hour, the tangent of the complement of the northern declination must be carried from the center A on both sides into hour 6, with respect to the whole sine AC.

THE ITALIAN AND BABYLONIAN DIAL, that is, one showing the hours from sunset and from sunrise

[Heading verbatim: "HOROLOGIVM ITALICVM, ET BABYlonicum, hoc est, horas ab occ. & ortum onstrans." — "onstrans" [recte: monstrans].]

CAPVT III.

We shall describe the hours from sunset and from sunrise most conveniently by means of the diurnal arcs that comprise an even number of hours. These are drawn in no other way than the arcs of the signs were drawn — provided that, in place of the radii of the signs emitted from the point A, we emit the radii of the diurnal arcs. These radii are supplied to us by the hour-lines drawn out from B in the third figure. For the straight line BM is the radius of the diurnal arc of 0 hours; the next line, the radius of the arc of 2 hours; the one after that, of 4 hours; and so on in succession through the even hours, so that the straight line BO is the radius of the diurnal arc of 24 hours. The arcs of the circle MNO, between N and the said radii, comprise the declinations of the diurnal arcs.

Therefore, if the portions of the straight line MO between Q and the radii of hours 14 and 10 — that is, the portions QT, QV — are carried over into the same line MO, from the radius of the Equator on either side, as far as X and Y, we shall have the radii AX, AY of hours 14 and 10; and likewise for the rest. So that, if we carry the straight line QO from the radius of the Equator as far as Z, the straight line

drawn AZ will give us the radius of the diurnal arc of 24 hours. Now we shall find the points of any diurnal arc whatever upon the hour-lines of the dial in just the same way as we found the points of the arcs of the signs: namely, if the portions of the hour-lines going out from B, [taken] between B and the radius of any diurnal arc, are carried over into the corresponding hour-lines of the dial drawn from A, the center of the dial, and so forth.

Once the points of the diurnal arcs on the hour-lines have been found, we shall lay out the hours from sunset and sunrise with no trouble. For if the points of the diurnal arc of 14 hours have been found, hour 23 from sunset will pass through the point of that arc at hour 6 astronomical after noon, because hour 24 would pass through the point of the same diurnal arc at hour 7 after noon — since the Sun sets at the 7th hour. By the same reasoning hour 22 will pass through the point of the same arc at hour 5 after noon, and so with the rest. Again, in the diurnal arc of 12 hours, which the equinoctial line supplies to us, hour 23 will pass through hour 5 after noon (since the Sun sets at the 6th hour), and hour 22 through hour 4, and so on. Likewise, in the diurnal arc of 10 hours, hour 23 will fall at hour 4 after noon, and hour 22 at hour 3 after noon, and so on. Finally, in the arc of 24 hours, hour 23 must be drawn through hour 11 after noon, and hour 22 through hour 10 after noon, and so with the rest — so that, in any diurnal arc whatever, hour 23 is to be drawn through the hour that precedes the Sun's setting by one hour [?], hour 22 through the hour that precedes sunset by two hours, and so on. Here it is worth noting that the Italian hours touch the diurnal arc of 24 hours at those very points through which we have said they are to be drawn.

The line of hour 12 from sunset must be drawn parallel to the equinoctial line through the midpoint of the portion of the meridian line between A, the center of the dial, and H, the point of the equinoctial line; and it ought to touch the diurnal arc of 24 hours on the meridian line.

The line of hour 11, however, must be drawn through hour 6 from midnight in the diurnal arc of 14 hours, and through hour 5 from noon in the equinoctial line; and it will touch the diurnal arc of 24 hours at hour 11 from midnight.

The line of hour 10 from sunset must be drawn through hour 5 in the diurnal arc of 14 hours, and through hour 4 from noon in the equinoctial line; and it will touch the diurnal arc of 24 hours at hour 10 from midnight, and so on.

Just as we have described the Italian hours by means of the diurnal arcs of 10, 12, 14, and 24 hours, so it will be possible to describe those same hours by means of other diurnal arcs. For if, for example, we have the points of the diurnal arc of 16

hours, hour 23 must be drawn through hour 7 after noon in that arc, and hour 22 through hour 6, and so on.

We shall describe the hours from sunrise in no other way, by means of the diurnal arcs, if we carefully observe at what hour from midnight the Sun rises. For example, in the diurnal arc of 14 hours the Sun rises at the 5th hour from midnight. Therefore hour 1 from sunrise will pass through hour 6 from midnight in that same arc, and let the same reasoning be held for the rest.

These same hours from sunset and sunrise are, on the horizontal dial, equidistant from the hours reckoned from noon and from midnight, whose numbers are the halves of them. Thus hour 23 is equidistant from hour $11\frac{1}{2}$, and hour 14 is equidistant from hour 7, and so on. Therefore, if through the point of the equinoctial line through which the hour from sunset or sunrise is to be drawn, a line is drawn parallel to that astronomical hour which is the half of it, the proposed hour will have been described. Thus, because hour 23 passes through the astronomical hour 5 on the equinoctial line, if through hour 5 on the equinoctial a parallel to hour $11\frac{1}{2}$ is drawn — namely to the half of hour 23 — hour 23 will have been described.

The parallel will be drawn as follows: if the interval on the equinoctial line, between the astronomical hour to which the parallel is to be drawn and the astronomical hour through which the parallel is to be drawn, is carried into hour 6 from the center A. Thus, if the interval KL, between hour 11 and hour 4, is carried from A as far as M, the line drawn ML will be parallel to hour 11, and will indicate hour 22. Likewise, if the interval NO, between hour $10\frac{1}{2}$ and hour 3, is carried from A to P, the line drawn PO will be parallel to hour $10\frac{1}{2}$, and will show hour 21. Those hours, however, which lie a little before hour 12 from sunrise or sunset are conveniently drawn through the points at which the astronomical hours intersect hour 12 from sunrise or sunset. Thus hour $12\frac{1}{2}$ must be drawn as a parallel to the astronomical hour $6\frac{1}{4}$, through hour $12\frac{1}{4}$, in the line of hour 12 from sunrise or sunset. Hour 13, in turn, [is drawn] through hour $12\frac{1}{2}$ as a parallel to hour $6\frac{1}{2}$. So too hour 11 [must be drawn] as a parallel to hour $5\frac{1}{2}$, through hour $11\frac{1}{2}$. So too hour $11\frac{1}{2}$ [must be drawn] as a parallel to hour $5\frac{3}{4}$ [?], through hour $11\frac{3}{4}$ [?], and so on. As for the hours after 13 and before 11, there is no difficulty, since their points can be obtained most conveniently on the equinoctial line.

We shall also describe the diurnal arcs by tangents in no other way than we described the arcs of the signs — if, in place of the declinations of the signs, we take the declinations of the diurnal arcs, which are found by a single

multiplication through Problem 11, at the end of the new description of the dials, in this manner. With the whole sine set at 100000, multiply the sine of the difference between the given semidiurnal arc and the semidiurnal arc of the Equator (which comprises 6 hours) — that difference being reduced to degrees — by the tangent of the complement of the pole's altitude. For if you cast away the last 5 figures from the product, the remainder becomes the tangent of the declination sought. For example, if the declination of the diurnal arc of 14 or 10 hours is required, in the Roman Horizon, above which the pole is elevated 42 degrees: since the semidiurnal arc of 7 or 5 hours differs from 6 hours by 1 hour — that is, by 15° — if you multiply the sine of this difference, 25882, namely of 1 hour or of 15 degrees, by the tangent 111061 of the complement of the pole's altitude, and from the product 2874480802 you cast away the last 5 figures, there will remain the tangent 28745, to which corresponds in the table of Tangents $16^\circ 2'$, for the declination of the diurnal arc of 14 or 10 hours.

THE ASTRONOMICAL DECLINING DIAL

[Heading verbatim: "HOROLOGIVM DECLInans Astronomicum."]

CAPVT IV.

Two straight lines AB and GH being drawn, cutting each other at right angles at I — of which GH represents to us the Horizontal line — let there be taken on AB the straight line IA, equal to the style of the dial to be made; and from A, as center, let an arc of a circle CD be described, of any magnitude, cutting AB at B. From B toward the right let the declination of the wall be reckoned, if it declines from south toward the east; toward the left, if from south toward the west; and in the opposite direction let the complement of that same declination be reckoned. In our example we set the wall as declining from south toward the west by 30° ; and so the 30° of declination are reckoned from B toward the left, as far as C; and toward the right the complement of the declination, namely 60° , as far as D. Then from A, to C and D, let straight lines be drawn cutting the Horizontal line GH at E and F. Through E, indeed, the meridian line EL must be drawn, parallel to AB, or perpendicular to the horizontal line. Through F must be drawn both the line of hour 6 Astronomical and the equinoctial line.

Next, on the horizontal line let EG be taken equal to the straight line AE, and from G, having described the arc of a circle HK, let the altitude of the pole in the given region be reckoned as far as K. For the straight line GK, being drawn, will cut the

meridian line at L, the center of the dial; and from L, through I, the straight line LM must be drawn, which will be the line of the style.

But since, on account of the closeness of the points L and I, we can easily err in drawing this line, we shall find a third point through which it must be drawn, in this way. Taking the straight line LP above L, equal to LE, let there be drawn from P a line parallel to the Horizontal line; and taking on it the straight line PQ equal to EI, we shall have the third point Q that was sought.

After this, let there be erected from I the perpendicular IO, equal to the line of the style LM [and to] the style IA; and let the straight line LO be joined, representing the axis of the world, so that the angle OLI measures the altitude of the Pole above the proposed declining plane. And when the straight line OM has been drawn perpendicular to the axis, cutting the line of the style at M, the equinoctial line must be drawn from F through M; and this, if no error has been made, will necessarily be perpendicular to the line of the style.

This done, let there be taken on the line of the style MN equal to the straight line MO; and from N let a circle be described of any magnitude, which is to be cut into 24 equal parts, beginning from the diameter that is drawn through the intersection of the meridian line with the equinoctial line — such as is, in our example, the diameter RS — or from the diameter that is drawn through N and F, which indeed, unless an error has been made, must cut the former diameter at right angles. All the diameters of this circle being now drawn, the equinoctial line will be cut in points through which the hour-lines must be drawn out from L, the center of the dial. The order of the hours is this: the hours to the right of the meridian line are afternoon hours, but those to the left are forenoon hours.

But in order that we may draw more accurately the hours which cut the equinoctial line scarcely at all, or very far off, we shall use this device. From any point of hour 3 or 9 — namely from s — let a line be drawn perpendicular to the horizontal line, or parallel to the meridian line, cutting hour 6 at the point T; and through T let a line be drawn parallel to the horizontal line, from which let there be cut off the straight line Tv, equal to Ts. Then, an arc of a circle having been described from v at any interval, let there be cut off, at the interval of the semidiameter Tv, two equal arcs xy, xz, and let these be divided into 4 equal parts. For the hidden straight lines drawn from v through the points of division will cut the straight line sT — extended infinitely on both sides — in the points through which the hours must be drawn out from L, the center of the dial. These will be drawn more precisely if on the other side of the meridian line we draw a parallel ab, distant from the meridian line by as great an interval as the straight

line sT is distant from that same meridian. For if into this ab we carry the intervals of the straight line sT , beginning from the point b of hour 6 — yet in such a way that the equal intervals are alternate — we shall have, for each single hour, three points, of which L , the center of the dial, is always one, and through which [the hour-lines] must be drawn. For example, if for the interval Td , below T , we take an equal interval be , above b , hour 5 must be drawn through the three points e , L , d . So too, if for the interval Tf , above T , we take an equal interval bg , below b , hour 8 must be drawn through the three points g , L , f , and so on. By means of tangent-lines on the said two parallels sT and ab , we shall find the hour-points most exactly, in this way. On the upper instrument of figure 2, let the interval between 100 and 100 be taken, equal to the straight line Tv , for the whole sine. For if the tangents of 15° , 30° , 45° , 60° , 75° — as we said in the horizontal dial — are carried from the points T and b on both sides, we shall obtain the hour-points sought, three, that is, for each single hour. The order of the hours is not difficult. For the straight line bLt gives hour 6, from which the rest will easily be judged, as was said above.

The line of hour 3, or of hour 9, we shall also find in this way, even if the circle from N has not been described. From E , where the meridian cuts the horizontal, let the perpendicular EI be erected to the straight line GL . Likewise, to AE , from the same point E , having erected a perpendicular on both sides, let there be taken on it Em and En , equal to EI .

For if from A , through m and n , hidden straight lines are cast out, the horizontal line will be cut in the points q and p , through which hour 9 and hour 3 must be emitted from L , the center of the dial.

By these same tangents we shall also find the hour-points on the equinoctial line, by this reasoning. The straight line NR being drawn through the intersection of the line [of the style] with the equinoctial, let there be described from N any arc of a circle whatever, between the straight line NR and the line of the style NL . For from the degrees of this arc we shall learn what tangents we ought to take, with respect to the whole sine MO . For example, in our case, since the said arc comprises nearly $40^\circ 47'$, it must, with the tangent 68 (namely of $40^\circ 47'$, the whole sine being set as MO), carried from the point M — where the line of the style cuts the equinoctial — into the equinoctial line, terminate at the point of intersection of the meridian line with the equinoctial. But if to these same degrees we add the 15° by which hour 11 is distant from the meridian line, we shall make $55^\circ 47'$; and the tangent of this arc, 147 (with respect to the same whole sine MO), carried from the same point M into the equinoctial, will give us

the point of hour 11. And if we add another 15° , we shall find in the same way the point of hour 10, and so on. Again, from the aforesaid arc of $40^\circ 47'$ let us subtract the 15° by which hour 1 is distant from the meridian; there will remain $25^\circ 47'$, whose tangent 48, carried from the point M, will give the point of hour 1. But if we subtract 30° , by which hour 2 is distant from the meridian, there will remain $10^\circ 47'$, whose tangent 19 will, by the same reasoning, exhibit the point of hour 2. And since hour 3 is distant from the meridian by 45° , we shall take away from these the aforesaid arc of $40^\circ 47'$, so that there remain $4^\circ 13'$, whose

Diagram. The construction of the declining astronomical dial [horologium declinans astronomicum] of Cap. IV, captioned "5.^a fig.^a" (rotated, at the upper right), enclosed in a rectangular frame. The figure is very dense with intersecting straight lines and construction arcs radiating from the dial center, and carries both letter-labels for the geometry and small italic hour-numbers along the periphery.

Legibly readable labels and their approximate positions:

- **A** — near the center-right, on the horizontal, just below the star/center L.
- **L** — the center of the dial (horologij center), the hub from which the hour-lines fan out.
- **B** — mid-left, on the horizontal line.
- **C** — upper left, on an oblique construction line.
- **D** — lower right, on an oblique line at the frame edge.
- **E** — left of center, on the horizontal.
- **F** — bottom center (foot of the perpendicular / point on the horizontal), near H.
- **G** — mid-left, on the horizontal (near a "9"-marked line).
- **H** — bottom center, near F and T.
- **K** — right of center, lower area.
- **N** — center-left, above the horizontal.
- **R** — appears upper-right and again lower-left near G (two R's, or R with its diameter partner S).
- **S** — right side (mid) and a second S at lower left — the diameter RS.
- **T** — bottom center, near H and F.
- **P** [?] — below E, small.
- **Q** [?] — near G / mid-left, small.
- **Y** [?] — right side, lower, near K.
- **x** [?] — bottom center, near H.

- **M, m**, small **I/I** [?] — clustered tightly near the center.

Hour-numbers (small italic) around the field: **9** and **10** (upper), **8, 6, 5, 4** (upper right / right, descending), **12** (mid-left); and a tight cluster of low numerals **1, 2, 3, 4, 5, 6, 7** among the fanned hour-lines near the center-bottom. Several construction lines are dotted.

The point-letters and hour-numbers sit among extremely dense line-crossings; more than two labels (P, Q, Y, x, M, m, l) cannot be resolved with certainty. for label verification.**

tangent $7\frac{1}{2}$, carried over from M, will give (nearly) the point of hour 3. But if to these $4^{\circ} 13'$ we add 15° , we shall likewise find the point of hour 4, and so on.

From these things this general rule can be drawn, for a dial declining from south toward the east. To the arc between R and the line of the style — which in our example, as we said, comprises $40^{\circ} 47'$ — must be added the distances of the hours from noon, which they have from the meridian line; but from the distances of the hours from midnight, which they have from the meridian line (namely those set to the left of the meridian line) — if indeed they are greater than the aforesaid arc — that arc must be subtracted; but if they are smaller, the distances of the hours themselves must be taken away from the aforesaid arc. For in this way we shall always have arcs whose tangents, the whole sine being set as MO, will exhibit to us the hour-points on the equinoctial line.

on the equinoctial line. In a dial declining from south toward the west — which is the case we have set ourselves — to the aforesaid arc between R and the line of the style must be added the distances of the morning hours from the meridian line, that is, the hours drawn to the left of the meridian line. But from the distances of the afternoon hours, if these are greater than that arc, the arc itself must be subtracted; and if they are smaller, the distances themselves must be taken away from the aforesaid arc.

The degrees comprised in the arc between R and the line of the style can also, if one wishes, be found more surely by calculation, through a single multiplication. Multiply the sine of the pole's altitude above the horizon [sinus altitudinis Poli] — here at Rome, 66913 — by the tangent of the complement of the wall's declination [tangens complementi declinationis muri], which in our example is 173205; and from the product, 11589666165, strike off the last five figures. The remaining number, 115897, is the tangent of the complement of the arc we are seeking. Since this tangent corresponds in the table to $49^{\circ} 12'$, a little more, the complement of this arc will be $40^{\circ} 47'$, a little more. And that will be the size of

the arc sought, measuring the inclination of the meridian of the declining plane itself to the meridian of the horizon.

Before I finish this chapter, I should like to add another way of finding the hour-points by tangents, which is as follows. When the lines of hours 3 and 9 have been drawn with the greatest care, as we have just taught in this chapter, draw through some point of hour 3 or hour 9 — namely through *f*, on hour 3 — a line parallel to the line of hour 6, which is drawn from *L* through *F*. For the portion of this parallel lying between hours 3 and 9 will be bisected by the meridian line. If, then, you set as the whole sine the segment of that same parallel lying between the meridian line and hour 3 (or hour 9), and transfer onto that same parallel the tangents of 15° , 30° , 45° , 60° , and 75° , starting from the meridian line in each direction, you will have the points through which the hour-lines are to be drawn from *L*, the center of the dial. And if above the center *L* — when the size of the plane allows it — you draw another parallel to hour 6, as far distant from the center *L* as the first was from it, and carry the points of the first onto this one from the meridian line, you will have further hour-points. In the figure these parallels have not been drawn, but you can easily draw them yourself with any pen.

Moreover, we shall find the points *E*, *F*, and *L* by tangents, and in addition the point on the meridian through which the equinoctial line is to be drawn, by this method. Taking the length of the style *A I* as the whole sine, transfer the tangent of the wall's declination from *I* to the left, if the plane slopes from south toward the west, as far as *E*; or to the right, if it declines toward the east. Likewise transfer the tangent of the complement of the declination from *I* in the opposite direction, as far as *F*. For through *E* the meridian line is to be drawn, and through *F* the line of hour 6 and the equinoctial. Again, taking the interval *AE* as the whole sine, transfer the tangent of the pole's altitude above your horizon from *E* upward along the meridian line as far as *L*, and the tangent of the complement of that same pole-altitude downward as far as the point 12. For *L* will be the center of the dial, and through the point 12 the equinoctial line is to be drawn from *F*. If these things are done carefully, a most accurate layout of the dial will result.

THE ARCS OF THE SIGNS ON A DECLINING DIAL

CAPVT V.

Draw any straight line *AB*, and raise upon it a perpendicular *AC* for the radius of the equator [radius Aequatoris]; then from *A* let the radii of the signs and of the

daily arcs be sent out in both directions, as we set forth above in the horizontal dial. Next, on the axis LO take AB equal to it, and from B draw BD parallel to AC. After this, transfer the straight line NM (or MO) from the fifth figure into the radius of the equator in the sixth figure, from A up to the point H, and through H, from B, run the straight line BH, corresponding to the line of the style, or to the proper meridian of the declining plane. This line can also be drawn if we set up an angle ABH equal to the angle OLM which, in the dial, the axis makes with the line of the style at the center of the dial; or, what is the same thing, if from B an arc is described, in which two arcs equal to the complement of the pole's altitude above the proposed plane are cut off on either side, starting from the straight line BD. For the angle OLM expresses this altitude of the pole, while what remains of the right angle gives its complement. The straight lines drawn from B through the ends of the arcs will yield the said line BHG and another corresponding to it on the other side.

Now, taking any point G on the line B H, draw the straight line G D parallel to AB, cutting BD in D; and from D, with the interval GD, describe a circle, which is to be divided into 24 hours in this way. Transfer the interval between N and hour 12 on the equinoctial line of the fifth figure from A into the radius of the equator of the sixth figure, up to C; and through C, from B, draw a straight line cutting GD in e. The perpendicular ef raised to GD will give the point f, the beginning of the division. The order of the hours is to be gathered from the order they keep in the dial. Thus, since in our dial hours 1 and 2 follow the meridian line toward the line of the style, so too in our circle hours 1 and 2 must follow the point f toward the point G, through which the line BG, standing for the line of the style, is drawn.

Now, if from the individual hours of this circle described from D perpendiculars are dropped to the straight line GD — which is easily done, if for each of the arcs between G and the hours of one semicircle equal arcs are taken in the other semicircle, since the straight lines joining the corresponding points, that is, those equally distant from G, are perpendicular to GD (so that if an arc Gi is taken equal to the arc G f, the straight line f i will be perpendicular to GD; and the same is to be said of the points of the other semicircle) — then, through the points at which the straight lines from B cut GD, drawing lines out, we shall have the hour-lines corresponding to the hours marked on the circle.

We shall also draw these hour-lines if the intervals between N and the hours on the equinoctial line of the fifth figure are transferred into the radius of the equator from the point A, and from B straight lines are sent out through the points of the equator's radius, just as we said a moment ago concerning the line

of the style and the line of hour 12. But so that all the hours may be obtained, the hours must be carried over onto the other side of the straight line DG as well, and so on.

Once this is settled, both the arcs of the signs and the daily arcs will be described, as we taught in the horizontal dial; namely, if the intervals of the hour-lines between B and any proposed radius are transferred, from the sixth figure, into the seventh figure of the dial, from L, the center of the dial — or at any rate the intervals of the hour-lines between the radius

of the equator and any other proposed radius — let them be transferred into the corresponding hours, starting from the equinoctial line. Here you will observe that the radii sloping from the radius of the equator toward B belong to the southern signs, and the rest to the northern; so that in the dial the arcs between the equinoctial line and the center of the dial are southern, while those below the equinoctial line are northern.

Here too, by one and the same operation, we shall describe two arcs of opposite signs, as we did in the horizontal dial: namely, if to the portion of the line of the style between L, the center of the dial, and the arc of the southern sign, an equal portion is taken downward from the point of the northern arc of the opposite sign; and if, from the center of the dial and from this lower point once taken, equal circles of any size are described. For if the intervals between the line of the style and the hour-lines are transferred, on both sides of the upper circle, into the lower circle from the line of the style, and the rest is completed as we said in the horizontal dial, what we propose will have been done.

Indeed, if the portion of the line of the style between the two points of the opposite arcs is bisected, and through the point of division a line parallel to the equinoctial is drawn, about which the paper of the dial is folded, we shall find the points of the opposite northern arc from the points of the southern arc, exactly as, in the horizontal dial, we found the points of the southern sign from the points of the northern sign.

Diagram. The construction of the sixth figure — the "figure of the radii" for the declining dial [figura radiorum] — captioned "**6.^a figura.**" (rotated, lower right), enclosed in a rectangular frame. It shows a large circle (with a horizontal diameter and a vertical line through it) carrying the hour-divisions and, at the upper right outside the main field, a small triangle construction (the triangle LOM with the style OI and the transferred lengths). The figure is extremely dense with intersecting straight and dotted construction lines and radiating hour-lines.

Legibly readable labels and their approximate positions:

- **O** — at the far right, the apex of the small triangle.
- **P, I, R, N, M** — along and within the small triangle at upper right (the ordinates PN, RM, etc.); several of these small labels are crowded and partly repeated.
- **B** — right of center, the upper convergence-point from which many hour-lines fan out (the point standing for the style-line).
- **D** — on the vertical line, above B.
- **G** — lower right, the second fan/convergence point.
- **K** [?], **Q** [?], **P** [?] — small labels clustered near the lower fans, right of center.
- Hour-numbers around the circle: **1, 2, 3, 4** (upper), **8, 9, 10, 11** (upper left), **12** (left); and **5, 6, 7, 8, 9, 10** descending along the right/lower rim; along the bottom edge the low numerals **6, 12, 5, 1, 2, 3** among the fanned hour-lines.

The point-letters sit among extremely dense line-crossings; more than two labels (K, Q, P, and the crowded triangle ordinates) cannot be resolved with certainty. for label verification.**

Now, since almost the whole labor consists in describing the hour-lines, both in the dial and in the figure of the radii, once these have been described for a given length of style, if we wish to construct another dial for a greater or smaller style, we shall follow this course. Let the triangle LOM of the fifth figure of the dial be described separately, together with the style OI; and, this being produced, take OP equal to the given length of style — smaller or larger than the style OI — and through R draw PN parallel to LM. For if, in place of the axis BA, in the figure of the radii we take the straight line BP equal to OP, and from P raise the radius of the equator, the perpendicular P Q, to BP, and from there the radii of the other signs go out on this side and that, we shall describe the arcs of the signs for the given length of style, as before. For the equinoctial line must be drawn perpendicular to the line of the style, as far distant from L, the center of the dial, as the straight line BQ is long. The same is also to be observed in the horizontal dial, if its triangle ACH, together with the style CE, is described separately, as we here said of the triangle OLM, and as you see done in the third figure.

Now, to avoid so many oblique sections in the sixth figure, we shall describe the arcs of the signs by tangents, as in the horizontal dial: if, from M, on either side, the tangents of 15°, 30°, 45°, 60°, and 75° are transferred onto the equinoctial line — reckoning MO as the whole sine — impressing the points on the equinoctial.

For the hidden lines drawn from L through those points will represent the hours on the plane as though on a horizon; and on them, by tangents, the points of the arcs of the signs and of the daily arcs will be found, as in the horizontal dial — provided, however, that in place of the pole's altitude above the horizon you assume the pole's altitude above the declining plane, which the angle OLM exhibits, and which altitude you will also find by Problem 4 at the end of the new description: namely, if you multiply the sine of the complement of the pole's altitude above the horizon — 74314 in our example — by 86602, the sine of the complement of the plane's declination. For if

Diagram. The seventh figure — the declining dial itself [horologium declinans], captioned "7.^a figura." (rotated, upper right), enclosed in a rectangular frame. The hour-lines and the arcs of the signs radiate across the field, with a small circle of divisions near the dial center. Numerous dotted ("hidden"/occult) construction lines run parallel across the plate.

Legibly readable labels and their approximate positions:

- **L** — the center of the dial (upper right), where the hour-lines converge; a small divided circle is drawn about it.
- **E, I, K** — small labels clustered by the little circle near L, with a numbered scale **1, 2, 3, 4, 5** on its arc.
- **M** — left of center, a lower fan/convergence point.
- **O** [?] — lower center, near the foot of the style-line.
- **B** — upper left, on the frame.
- **a** — bottom center, on the lower horizontal (a point of the occult lines La, Lb).
- A run of tangent-degree marks along an oblique line: **16, 17, 18, 19, 20, 21, 22, 23, 24**.
- Hour-numbers along the rim and radii: **6, 7, 8, 9, 10, 11, 12**; corner numerals **2, 3**.

The letter-labels sit among extremely dense line-crossings, many of them dotted; more than two labels (O, E, I, K, and the corner letters) cannot be resolved with certainty. for label verification.**

from the product, the number 6435741028, you strike off the last five figures, the remaining number, 64357, will give the sine of the sought altitude of the pole. Therefore the pole's altitude above our declining plane contains 40° 4', which corresponds to the sine found, in the table of sines. You have an example in the seventh figure, in the hidden lines L a and L b, whose points a and b the Tangent

100000 [numeral: ?] of 45° — or of hours 3 and 9, if the declining plane were the horizon — exhibits. And the perpendicular extended through L to L I will be as it were the line of hour 6.

Now, since the arc of the following table under hours 3 and 9 — over against the pole's altitude of 40° , which is nearer to the altitude found — contains $40^\circ 7'$, we shall subtract it from the complement of the declination [?], namely from $66^\circ 30'$, and the remaining arc is $26^\circ 23'$. The tangent of $26\frac{1}{2}^\circ$ [Tangentem $26\frac{1}{2}$], reckoned against the whole sine kI, we shall transfer from the points c and h — the intersections of the circle L c I h described from the midpoint of the straight line L I — with the lines L a and L b, transferring them onto the straight lines La and Lb. For the points will lie outside, on the arc [zodiac sign: ?], and so on. Only be mindful that what we said in the horizontal dial concerning the northern signs is here to be understood of the southern, and conversely.

The Italian and Babylonian Dial on a Declining Plane. Chapter VI.

Once the diurnal arcs of the 10th, 12th, 14th — or even the 24th — hours have been drawn, we shall lay out the hours reckoned from sunset and from sunrise exactly as on the horizontal dial. These hours from sunrise or sunset always pass, on the horizontal line, through those astronomical hours whose numbers are the halves of the hours from sunrise or sunset: thus the 23rd hour will pass through the $11\frac{1}{2}$ th hour, and the 18th through the 9th, and so on. It is therefore worth marking, on the horizontal line, the points of the astronomical hours together with their halves. For by means of those points, and of the corresponding hours on the equinoctial line, the hours from sunrise or sunset will be drawn without any difficulty.

Now if the hour-lines of a dial declining from the meridian are extended beyond the horizontal line, the portion cut off from the horizontal line will yield a dial declining from the north toward the east (if it had been declining southward toward the west), or toward the west (if it had been declining southward toward the east) — declining, I say, by as many degrees toward the east or west as the southern plane had been declining toward the west or east. This holds provided that the said portion be inverted, so that its upper part becomes the lower and the reverse, and so that the part which, in our present position facing the dial, is on the right becomes the left, and the reverse. Likewise, the hours that were previously numbered from noon, or from sunset, are now to be numbered from

midnight, or from sunrise, and the reverse. The very arrangement of the hours will easily show this, if one carefully observes the line of the 24th hour alone, as we set forth in the new construction in the scholium to Proposition 19, Number 2. Finally, the southern signs become northern, and the reverse. And so, if a dial declining from the north is to be described, let one declining from the south toward the opposite side be constructed by the same number of degrees. For the lineaments of this dial, extended beyond the horizontal line, will yield the proposed dial declining from the north, as has been said.

The Transfer of a Declining Dial Drawn on Paper onto a Wall, to Any Size Whatever. Chapter VII.

Let a straight line $\varepsilon\beta$ be drawn, parallel in any manner to the horizontal line. If it does not cut all the hours, let the hours be extended until they cut it, provided they can conveniently be cut. Next, on the wall, let a horizontal line be drawn with the help of a level and plumb-line; and, a place for the style having been chosen on that same horizontal line, take from the paper dial the portion of the horizontal line lying between the position of the style and the meridian line. Lay off this portion on the wall's horizontal line, toward the same side to which the meridian line inclines on the dial, as many times over as the style on the wall is to exceed the style of your dial. For at the end of the counting a line perpendicular to the horizontal line must be dropped, to serve as the meridian line on the wall.

And if the intervals between the meridian line and the several hours on the horizontal line of the dial are likewise laid off, the same number of times, from the point of the meridian line on the wall's horizontal line, we shall have on the wall's horizontal line the points through which the hours are to be drawn.

Suppose the same is done on the parallel $\varepsilon\beta$ and on the parallel that corresponds to it on the wall — which we shall draw thus: dropping, on both sides of the meridian line $\varepsilon\gamma$, [perpendiculars] between the horizontal line and the parallel $\varepsilon\beta$ as many times as the style is to be enlarged; for the parallel drawn through the end of the counting, parallel to the horizontal line itself, will correspond to the parallel $\varepsilon\beta$. Then, likewise, on the equinoctial line — that is, let the intervals of the parallel $\varepsilon\beta$ between the meridian line and the hours be transferred, the same number of times as we said, onto the corresponding parallel line drawn from the wall's meridian line.

Likewise, let the intervals of the equinoctial line between the meridian line (or the horizontal line) and the hours be transferred onto the wall's equinoctial line, from the meridian or horizontal line, as many times as you wish to enlarge the style; and we shall have other points through which the hour-lines are to be drawn.

The equinoctial line on the wall is to be drawn as follows. Let the interval of the horizontal line between the meridian line and the equinoctial line be taken on the wall, from the meridian line along the horizontal line, as many times as is needed. For thus we shall have a point on the horizontal line through which the equinoctial is to be drawn. And if the same is done with the interval of the meridian line between the horizontal line and the equinoctial, we shall have another point on the wall's meridian line for the equinoctial line. And if the interval of the parallel $\epsilon\beta$ between the meridian and equinoctial lines is likewise taken on the corresponding parallel of the wall, we shall have a third point for drawing the equinoctial line.

Lastly, if the intervals of the hour-lines between the equinoctial line (or the horizontal line, or the parallel $\epsilon\beta$) and the arcs of the signs are laid off from the same lines on the wall, as many times as is required, in the corresponding hours, we shall have the points of the arcs of the signs on the wall.

Table

Table of the Arcs of the Hour-Circles from Noon and Midnight, [contained] between the Pole of the world and the Vertical circles of the horizon that are perpendicular to those hour-circles.

Column headers as printed: **Altitudines Poli.** (Altitudes of the Pole), then the paired hour-circles **12 · 1 11 · 2 10 · 3 9 · 4 8 · 5 7 · 6**, each subdivided into **G.** (gradus, degrees) and **M.** (minuta, minutes). Pole-altitude is likewise given in degrees (G.) and minutes (M.).

(Table begins on printed p. 224; continues from printed p. 225 without a break; the table continues beyond p. 225 into the following page — the collation step will stitch the boundary.)

Printed p. 224 (Pole altitudes 0° 0' – 14° 45')

Compendium describendorum horologiorum — Chapter VII (Translation of a declining dial)

Table of the arcs of the hour-circles between the pole of the world and the vertical circles of the horizon that stand at right angles to those hour-circles (continued)

(Continuation of the Tabula arcuum circulorum horariorum a meridie et media nocte inter Polum mundi, et Verticales Horizontis, qui ad ipsos Horarios recti sunt*, whose heading was printed at the foot of p. 223. These three pages carry the table onward from pole altitude 30° to 74° 45'. The argument column at the left is the pole's altitude [*Altitudines Poli*] in degrees and minutes; the seven paired columns give, for each hour-circle group — the noon circle "12", then the pairs 1 & 11, 2 & 10, 3 & 9, 4 & 8, 5 & 7, and the 6-o'clock circle — the arc in degrees [G. = gradus] and minutes [M. = minuta]. The 6-o'clock column is 0° 0' throughout, since that hour-circle passes through the pole. The table continues to higher pole altitudes on the following printed page.)*

Printed page 226 (pole altitude 30° 0' – 44° 45')

Table of the arcs of the hour-circles between pole and vertical (continued and concluded)

(Continuation and conclusion of the table begun earlier — the Tabula arcuum circulorum horariorum whose heading stands at the foot of printed p. 223. This page carries only the repeated column headers. The argument column is Altitudines Poli [pole altitudes], in degrees [G.] and minutes [M.]; the seven hour-circle groups are 12; 1 & 11; 2 & 10; 3 & 9; 4 & 8; 5 & 7; and 6, each ruled into its own degree [G.] and minute [M.] subcolumns. All numerals are printed in Arabic, per the book's convention for these tables. The table runs here from pole altitude 75° to 90° and ends. The 6-o'clock group is 0° 0' throughout, since that hour-circle passes through the pole.)

Notes on the New Description of Sundials, which contribute very greatly to their construction [Notæ in novam horologiorum descriptionem, quæ ad horologia extruenda plurimum conducunt]

Since I have set out much material — scattered and at length, in various places throughout the book of the new description of sundials — material not so much necessary for laying out sundials as for laying them out by a variety of methods, I think it will be worth my while to point out here briefly the things I judge most useful and necessary. Otherwise the reader's mind may be confused or overwhelmed by so great a mass of precepts, and the construction of the dials thereby delayed. More than one person has asked me to do this at some point — indeed, has eagerly awaited it. For although in the worked examples excerpted from that book and published I noted a good many points, still many further and almost new ones have since occurred to me. These help the construction of sundials remarkably, make it more expeditious, and by no means ought to be neglected. They are roughly as follows.

[Margin: The usefulness of the instrument of parts in describing sundials.]

1. To construct sundials most accurately by means of tangents, one should use that instrument of parts which I described in two ways — both in the very brief Compendium of Sundials and in the *Practical Geometry* — and whose varied and manifold use I set out fully and copiously in the same *Practical Geometry*, Book 1, Chapter 1. With its help we can obtain, more quickly than one can say and with great precision, not only the tangents but also the sines and secants of any number of degrees and minutes, relative to a whole sine [sinus totus] of any magnitude whatever. There will then never be any need to cut or divide the proposed whole sine into 10 equal parts in order to derive the tangents from

them — the procedure taught in the new description of sundials — a business that tends to hold up and delay the work not a little, especially when several and various whole sines sometimes have to be employed.

[Margin: How the instrument of parts is used when the whole sines are divided into 10 particles.]

And so, wherever in the book of the new description of sundials we are directed to divide a line, taken as the whole sine, into 10 equal particles, the instrument of parts should be opened and fixed so that the interval between the 100- and 100-marks equals the proposed line, that is, the given whole sine. Once the instrument has been set in this way, we shall at once have to hand the tangents, sines, and secants of any number of degrees and minutes, taking the whole sine of any magnitude as 100 or even 1000 parts — as I explained fully in Book 1 of the *Practical Geometry*, e.g. Chapter 1, Nos. 3, 4, 5, and 12. But for our purpose it is enough, in my judgement, to apply the method of Chapter 1, Book 1 of the same *Practical Geometry*, No. 3, to obtain the tangents, sines, and secants, even if the whole sine is set at 1000 parts.

[Margin: An easy way of obtaining the tangents relative to the whole sine of 1000.]

For if, after dropping the first figure of the tangent given in the table placed at the end of the new description, the remaining number is taken on the instrument, together with as many tenths of the following part as there are units in the dropped figure (which are easily gauged by estimation), we shall have the full tangent relative to the whole sine of 1000 parts. For example, since the tangent of $8^{\circ}47'$ is 155, if on the instrument one takes 15 parts together with $5/10$ of the following part [Latin: *partis sextædecimæ* (?)], one obtains a tangent equivalent to the tangent 155 relative to the whole sine of 1000. For if the instrument is taken as divided into 1000 parts, each hundredth of it will contain ten thousandths; and so the 15 parts taken will be equivalent to 150 particles, and if $5/10$ of the next part is added, the tangent 155 will be made up, as it is given in the table. Likewise the tangent of $43^{\circ}44'$ in the table is 957. If, then, on the instrument one takes 95 parts together with $7/10$ of one part, the full tangent 957 will be produced. Finally, in the table the tangent corresponding to the arc of $68^{\circ}51'$ is 2585. If, then, on the instrument one takes 58 parts together with $5/10$, or $1/2$, of one part, and adds the whole sine twice, one obtains the full tangent, and so on. Exactly the same is to be done with the sines and secants, provided that 4 figures are first dropped, so as to have the sines and secants relative to the whole sine of 1000.

[Margin: A convenient method for obtaining the tangents without the instrument.]

If we have neither instrument to hand, we can very conveniently obtain the same tangents, sines, and secants by the following device. On some straight line of moderate length, drawn on brass or hard wood, let ten equal parts be taken from A up to B; and let the first of them, AC, be divided into 10 equal particles.

Diagram. A construction for obtaining tangents (and sines and secants) without the sector, drawn as if on a strip of brass or hard wood.

- A (top-left): left end of the horizontal graduated line
- C (top, just to the right of A): end of the first divided part AC (whose first tenth carries the fine subdivision)
- B (top-right): right end of the horizontal line AB
- Scale along AB: 10, 20, 30, 40, 50, 60, 70, 80, 90
- D (lower-left): apex from which the lines DE and DB (through H and F) and the arc EF are drawn
- E (lower-right): endpoint of the nearly horizontal base line DE
- F (upper-right, near B): endpoint of the rising line, on the arc EF
- H (middle-right, on the line DF, near the 70-mark): one of the two points marked by the compass interval
- G (lower-right, on the base line DE, below H): the other point of the interval GH

For by means of this line, serving as a universal instrument, we shall easily obtain what we want. Suppose, for example, that the tangent of $70^{\circ}19'$, which is $279\frac{1}{2}$, is to be found, relative to the whole sine of any magnitude whatever. From D, at the interval of the divided line AB, describe the arc EF; take the interval EF equal to the given whole sine, and draw straight lines from D through E and F. Then, placing one foot of the compasses at the point 70, extend the other as far as the $9\frac{1}{2}$ particle of part AC, and with that interval mark two points G and H, beginning from point D. For the interval GH, added to the whole sine EF taken twice, will be the tangent sought, as is plain. And in this way, with the line DE kept fixed, one whole sine after another may be taken on the arc EF, and so on — until, to avoid the confusion that can arise from a multitude of whole sines, it seems best to draw another figure DEF. Nor indeed is this operation much longer than the one done with the instrument of parts. For while the instrument is expanded and contracted so that the whole sine is set between the 100- and 100-

marks, the arc EF, with the straight lines DE, DF, and so on, will be roughly described.

And indeed, if careful diligence is applied, the tangents will perhaps be obtained more exactly this way than by the instrument, on account of the uncertainty of the pin about which the instrument must be moved. Add that by this method there is no danger — once the whole sine has been taken up, which sometimes must be used repeatedly — that the instrument may be contracted or expanded. There is this further convenience too: that by this method even the smallest tangents, close to D, can be taken, which is not possible with the pin of the instrument.

[Margin: Wherein the excellence of constructing sundials by tangents consists.]

2. If these matters are observed with due care, it is almost incredible how easy, quick, and even pleasant the description of sundials by tangents is made. Indeed, of all the constructions of sundials this one (to say so in passing) pleases me most, because in it no circle has to be divided, as in the other descriptions, nor does one have to construct a figure of rays for drawing the parallels of the Sun, into which the hour-intervals are transferred from a dial built beforehand — a matter in which it is easy to go wrong, chiefly on account of the oblique sections, which are avoided by using tangents. There is this further point: that a line can be drawn without any trouble representing the great circle that passes through the poles of the world and through any given degree of the equator, in the manner of some hour-circle from noon and midnight.

[Margin: By what method any great circle through the poles of the world is drawn and described on a dial by tangents.]

For if a given point on the equator is distant from the meridian, toward the west, by fewer than 45 degrees, we shall transfer the tangent of the arc of the equator intercepted between the meridian and the given point — relative to the whole sine HC, in the first figure of the Compendium of Sundials, a fragment of which we have here repeated — from H into the equinoctial line BHD, toward the left. For a straight line drawn from the center A of the dial through the endpoint of that tangent will represent the great circle sought. But if the given point is distant by more than 45 degrees, yet fewer than 90, we shall transfer the tangent of the complement of the arc of the equator intercepted between the meridian and the given point — relative to the whole sine ON — from O into the straight line ON, toward N. And if, finally, the proposed point recedes toward the west by more than 90 degrees, yet fewer than 180, the complement of the arc of the equator to

180 must be taken, and its tangent transferred in the same way from H into the equinoctial line toward the right; or else, drawing the line XY parallel to the meridian, the tangent of the arc by which the given arc exceeds a quadrant must be transferred from point X toward Y, relative to the whole sine XY — equal, of course, to the portion of the said parallel line XY between the 6th and 9th hour. For if through the endpoint of this tangent, and through the center A, a straight line is extended, its segment above the center, or above the line of the 6th hour, will represent the circle sought. The contrary must be done if the point taken on the equator recedes toward the east. For then the tangent of the proposed arc must be transferred into the equinoctial line from H toward the right, or into the aforesaid parallel line XY from point X downward, according as the given arc is less than 45 degrees, or greater yet less than 90. Or certainly, if it is greater than 90 degrees, [it must be transferred] into the equinoctial line toward the left, and so on. By the same method we shall draw a line for any minute of a given hour, as we shall say at the end of the following No. 3. Finally, this description of the hours by tangents seems to surpass all others in this: that in it the finding of no hour, or of no point of the equator, depends on the finding of another hour or point. So even if by chance an error has been made in finding some point, that error nonetheless does not spread further, since the finding of the other points does not depend on it, nor is any account taken of them, just as if they had not been found.

Diagram. A fragment of the first figure of the Compendium of Sundials, here repeated: the construction of the hour-lines and of the great circles through the poles by transferred tangents, on a horizontal dial. Straight lines radiate from the center A; dotted arcs and additional straight lines cross the figure. The equinoctial line runs horizontally through B, H, and D.

- O (top-left): on the upper horizontal line (line OAX of the 6th hour)
- A (top-right, center of the radiating lines): center of the dial
- X (top-right, end of the upper line): right end of line OAX
- I (upper-middle): on an arc between G and A
- G (upper-left, below O): on the upper region of the figure
- F (middle): below I, on an arc
- K (middle): below F
- E (mid-left): on a circle/arc, left of L
- L (middle, right of E)
- C (mid-right): intersection point
- T (left): on the left descending line
- R (center): on a line above B

- S (lower-center-left)
- B (center): intersection of the meridian and the equinoctial line
- H (center-right, on the equinoctial line between B and D)
- D (right, on the equinoctial line, right of H)
- N (bottom-center-left)
- M (bottom-center)
- P (bottom-center-right)
- Q (bottom-left)
- V (bottom, below M/N)
- Y (bottom-right)
- 9 (bottom-right corner): the 9-o'clock hour marker

(The "3" at the lower-left margin of the figure is the number of the following paragraph, not a figure label.)

[Margin: The hours from noon and midnight on a horizontal dial.]

3. In describing the hours from noon and midnight on a horizontal dial, one must observe what we prescribed in Chapter 2 of the new description, or in the excerpt of the first worked example — but using the instrument of parts, so that in place of those four rulers constructed there one may take the whole sine of 100, or even 1000, particles.

[Margin: The use of Table 6 for drawing the hours from noon and midnight on a horizontal dial.]

With this addition, moreover, to No. 7 of that worked example: through any point one can draw a line to the meridian [line] that is equidistant from the line OAX of the 6th hour. For on it, from Table 6 of the new description, the points of the hours will be found by the tangents of the complements of the arcs of that table, relative to a whole sine equal to the segment of the meridian between the center A and the aforesaid parallel, whether this is drawn below or above the center. Likewise, through any point of the line of the 6th hour one can draw a line equidistant from the meridian. For on it, from the same Table 6, the points of the hours will likewise be found by the tangents of the arcs themselves of that table, if the whole sine is taken equal to the segment of the line of the 6th hour between the center A and that parallel. For example: on the perpendicular BD, at any distance from the center A (this is the equinoctial line on the dial), the hour-points will be found from Table 6, if into it, from point H on both sides, the

tangents of the complements of the arcs of the said table are transferred, relative to the whole sine AH.

On the perpendicular ON, or XY, drawn to the line of the 6th hour through any point whatever, the hour-points will be found by the tangents of these same arcs of Table 6, transferred from O, or X, to either side of the line ON, or XY, relative to the whole sine [sinus totus] AO, or AX.

[Margin: *Quo pacto minuta horarum describantur.* — How the minutes of the hours are drawn.]

Now if we wish to draw a line for any minute of a given hour, we convert the proposed hour and minute into degrees and minutes by means of Table 23. Then, following what we wrote under No. 2 above, we draw a line representing the great circle that passes through the poles of the world and through that degree and minute. For example, if the line to be drawn is for 2 hours 37 minutes after noon, we reduce the 2 hours to 30 degrees, and the 37 minutes to 9 degrees 15 minutes, so that the total arc between the meridian and the given minute comes to 39 degrees 15 minutes, to which corresponds the tangent 817. This tangent, then, carried from H onto the equinoctial line HB, relative to the whole sine HC, will give a point through which a straight line drawn from A will indicate the hour 2 and, in addition, the 37 minutes — and so with the others.

[Margin: *Paralleli Solis.* — Parallels of the Sun.]

4. Next, on the lines of the hours from noon and midnight, in a horizontal dial, the points of the parallels of the Sun [puncta parallelorum Solis] must be sought by the methods handed down in Chapter 8 and its scholium in the new description of dials, and especially by what we prescribed under Nos. 1 and 7 of that chapter — so that Table 1 alone of that same description, which is the general one, be used, and not even the whole of it, but only its topmost line, which carries the heading "(circa horæ 6.)" [about the 6th hour], or the middle line, to which is assigned the heading "(circa horæ 12.)" [about the 12th hour]. Or, in place of that table, one may take up the table set out in Chapter 15, No. 2, if the points of the parallels are wanted for the minutes of the hours as well.

Nor is the finding of these same points by Table 3 of the new description a thing of small worth — a table which is likewise general, as is declared in Chapter 8, No. 11 of that same new description — especially in dials whose center is very far from the equinoctial line, or can scarcely be had at all.

The same points of the parallels will be sought most conveniently and most accurately from Table 19 of the new description, as we set out at the end of the scholium of Chapter 19. But because the whole sine is generally small — being equal to the gnomon [stylus] — you will do rightly if you tenfold it and take the tenth parts of the tangents; which is easily done by striking off the last figure on the right. For if you strike off yet another figure from the remaining number, you will have the tangent relative to a whole sine of 100, and so on. But if the elevation of the pole above your horizon, or above a declining plane, is not present in that table, the points of the parallels will have to be sought by other means; or the tangents will have to be computed by Problem 17 of the new description, for the given elevation.

[Margin: *Tangentes inter Æquatorem & parallelas, quo pacto supputentur.* — How the tangents between the equator and the parallels are computed.]

Now if anyone should prefer to compute these same tangents of Table 19 not between the center of the dial and the parallels of the Sun, but between the equator and those same parallels — which is indeed most convenient, or even necessary, where the center either is not available or is very remote — he will accomplish it by this method. In the northern signs let him subtract the arc of the given hour, in Table 1 of the new description over against the proposed sign and under the given hour in the circle of the 12th hour, from the elevation of the pole; or [subtract] the elevation of the pole from that arc. Let him take the tangent of the remaining arc away from the tangent of the pole's elevation, when, that is, the arc of the first table has been subtracted from the pole's elevation; or let him add it to the tangent of the pole's elevation, when, that is, the pole's elevation has been subtracted from that arc of the first table. Then let it be made, as:

the whole sine is to the remaining or combined number, so the secant of the angle which the given hour makes with the meridian is to another.

For the number produced will be the tangent sought.

In the southern signs let the arc of the first table be added to the pole's elevation, and from the tangent of the combined arc let the tangent of the pole's elevation be taken away. For if it be made, as:

the whole sine is to the remaining tangent, so the secant of the hour-angle is to another,

the tangent sought will be produced.

There is also an elegant method for investigating the points for the parallels of the Sun, which is carried out by means of the table described in the *Compendium of dials* and computed for all elevations of the pole, as we declared at the end of Chapter 2 of that *Compendium* and in the scholium of Chapter 9 of the new description, No. 5. The whole sines for the five hour-lines contained between the 12th and 6th hours, together with the points from which the tangents are to be transferred, will be found most easily by this method too. In the immediately preceding figure, for the hour-line AB, let the whole sine be sought, and so on. When two little circles have been described from the center A, one through E, the place of the gnomon, and the other through C, the extremity of that same gnomon, perpendicular to the meridian (which two little circles serve all the hour-lines), let there be taken, equal to the arc EK between the position of the style and the proposed hour, the arc KI. For the straight line EI will be perpendicular to AB, and FG will be the whole sine relative to which the tangents are to be transferred from F, as we demonstrated in the new description, Chapter 1, No. 6. But for the meridian the whole sine is the gnomon itself; while for the 6th hour it is the segment of the axis AC between the center A of the preceding figure and the extremity of the style perpendicular to the meridian. And relative to this whole sine there must be transferred onto the line of the 6th hour the tangent of the complement of the declination of the proposed northern sign — for the reason that the arc of the 6th hour in the said table of the *Compendium* is 0 degrees, and therefore nothing is to be subtracted from the complement of the declination.

[Margin: *Puncta parallelorum in hora 6.* — The points of the parallels in the 6th hour.]

The method too, set out in Chapter 9 of the new description, will be carried through by means of tangents in this way. In the preceding figure, let the points of two opposite signs — say ♋ [Cancer] and ♑ [Capricorn] — be the ones to be found on the line AB. When the point G has been found by means of the perpendicular EFG, as we said just now, let the straight line GB be drawn from G through B, the intersection of the hour-line with the equinoctial; and to it, through any point M, let the perpendicular PMQ be erected. For if into this there be transferred, relative to the whole sine GM, the tangents MP, MQ of the signs' declination — that is, of 23 degrees 30 minutes, for ♋ and ♑ in the proposed example — the straight line GP will cut the given hour at R, the point of ♋, while the straight line GQ will cut the same hour beyond the equinoctial at the point of ♑. For, as we demonstrated in the new description, Chapter 1, No. 1, if from G, through M, a circle were described tangent to the straight line PMQ at M, at which

on either side the arcs of the declination of ☿ and ♄ were marked off, then the straight lines drawn from G through the extremities of those arcs would cut off from the straight line AB 23 degrees 30 minutes. Since therefore MP, MQ are the tangents of those arcs, the whole sine being set as GM, the straight lines GP, GQ will pass through the outer points of those arcs, and will accordingly cut off the same 23 degrees 30 minutes from the straight line AB, both above the equinoctial and below.

PARI

By the same method, if GE is extended as far as the outer circle to the point L, and to the straight line LB drawn to it, at any point S a perpendicular TSV is erected, into which the tangents of 23 degrees 30 minutes are transferred relative to the whole sine LS, then, as far as T and V, the straight lines LT, LV will again cut off from the hour-line AB, on either side, 23 degrees 30 minutes for the points ☿ and ♄. And the method is the same for the other signs, if the tangents of their own declinations are taken and transferred from M onto the straight line PMQ, or from S onto the straight line TSV, and so on. And this method is excellent, since it fits declining dials too, and by it, on any line whatever drawn from the center of the dial, even though it be unknown what hour it signifies, the points of the parallels can be found.

[Margin: *Præstantia huius rationis proxima.* — The excellence of this method just given.]

In this same way, too, the problem of Chapter 1 of the new description can be worked out by means of tangents. For if, in the figure of that chapter, through any point of the straight line HC a perpendicular is erected to it, and into this, beginning from the straight line HC, the tangent of (for example) 30 degrees is transferred on both sides, relative to a whole sine equal to the straight line between H and the said perpendicular, then the straight line from H, through the outer points of each of the aforesaid tangents, will cut off from the given straight line CD two segments of 30 degrees, and so on.

[Margin: *Additio ad cap.1. novæ descriptionis.* — An addition to Chapter 1 of the new description.]

Finally, with the greatest precision we shall hunt for these same points of the parallels on the hour-lines by means of secant lines, first subtracting four figures from each secant, so that we may have the secants relative to a whole sine of 1000, in this way. On the meridian line let it be investigated, by Table 1 of the new description and the elevation of the pole above the plane of the dial (whether

horizontal or declining) — for this method fits declining dials as well, if in them concealed straight lines are drawn, like the hour-lines in a horizontal dial, equally distant from the line of the style, which will serve the office of a meridian in this business — for each hour a point, through which the perpendicular line to the meridian, when drawn, cuts that hour at the point of the proposed parallel, as we handed down in the new description, Chapter 8, No. 7. Of this kind is the point h , for the 3rd and 9th hour of $\mathfrak{S}$, in the figure of Chapter 8 of the new description. For if, the whole sine being set as Gh , the secant of the complement of the arc of Table 6 of the new description be taken for the given 3rd and 9th hour, and this be transferred from the center G onto the 3rd and 9th hour, the points of $\mathfrak{S}$ will be found. The same points will be found if, the whole sine being set as Bh , the secant of the complement of the same arc of Table 6 be transferred from the points of the 3rd and 9th hour on the equinoctial line onto the drawn hours toward the center. Of this kind, too, is the point r , for the 3rd and 9th hour of $\mathfrak{V}$. So that, if the whole sine being set as 6 for the 3rd and 9th hour, it be transferred from the center G onto the 3rd and 9th hour, the points of $\mathfrak{V}$ will be found in the said hours. These points you will also have if, the whole sine being set as Br , you transfer the secant of the same arc of Table 6 from the points of the 3rd and 9th hour on the equinoctial line downward onto the said hours.

[Margin: *Paralleli per Secantes*. — The parallels by means of secants.]

The reason for this is that the segment of the line of the 3rd and 9th hour between the center G and the parallel $\mathfrak{S}$, and $\mathfrak{V}$, is the secant of the angle which, at the center G , the hour-line makes with the meridian, the whole sine being set as GH , or Gr — which angle is the complement of the arc of Table 6 for the given hour. Likewise the segment of the line of the 3rd and 9th hour between the equinoctial and the parallel $\mathfrak{S}$, or $\mathfrak{V}$, is the secant of the same angle of which we spoke, the whole sine being set as Bh , or Br — as is plain if, from the point of the parallel on the 3rd and 9th hour, a line is drawn parallel to the meridian. For this line will (a) be equal to the whole sine Bh , or Br , and (b) will make with the 3rd and 9th hour an angle equal to that which the meridian makes with those same hours.

[Margin: (a) *Elements* I.34; (b) *Elements* I.29.]

If, by one and the same operation, one should wish to find the points of opposite parallels by means of secants, the segment of the meridian line between the two opposite parallels must be bisected — as, in the dial of Chapter 2 of the *Compendium of dials*, the segment ab between $\mathfrak{S}$ and $\mathfrak{V}$ is bisected at Q . And through Q a line is to be drawn parallel to the equinoctial line. For if the straight line bd be taken equal to aA , and from d , through the intersections of the hour-

lines with the parallel through Q, concealed straight lines be drawn, and into these from d the same secants be transferred which were carried from A onto the hour-lines for $\mathfrak{S}$, then by one operation the points for both parallels will be found, through which the line is to be described.

But if, by means of the complements of the Sun's altitudes, the points of the parallels are to be traced — as we taught in the new description, Chapter 8, No. 12 — the points on the two opposite parallels will likewise be found by one and the same operation, in this manner. In the same dial of Chapter 2 of the *Compendium*, let there be taken below b a straight line equal to aE , so that there may be had the position of the style for the concealed hours drawn from d. For if, both from this second position of the style and from E, the tangents of the complements of the Sun's altitudes, going out into the concealed straight lines from d, and transferred into the hour-lines drawn from G, be laid down, the points for the two opposite parallels will be found.

It will not, however, be useless — for a more exact inquiry into the points of the parallels of the Sun on the hour-lines — to inspect carefully the three rules of the scholium of Chapter 8 of the new description; since by them, from one or another point once found, nearly all the rest of the same parallel, and of the opposite one as well, can be found, and the points investigated by other means can be examined and corrected, as we wrote at the end of the aforesaid scholium.

5. For drawing the hours from sunrise and sunset [horæ ab ortu vel occasu] in a horizontal dial, one must observe what we declared in the new description, Chapter 14 and in Practice 3 excerpted from it, and in the *Compendium of dials*, Chapter 3 — where it is of no small importance to describe them by means of the diurnal arcs, especially if their points are sought by tangents, as we advised at the end of Chapter 3 of the *Compendium*. But so that certain hours may be depicted more easily than the seven others drawn out in the new description, and so that the studious reader be not always forced to consult the figure set in the scholium of Chapter 1, No. 3 of the new description, we have here appended, besides two little tables, Chapter 14 of the new description. For from these it is understood more quickly than can be told through which points the hours from sunrise or sunset are to be drawn. For in a horizontal dial the second little table has excellent use: it is designed for the 12th hour from sunrise or sunset, for drawing those hours, and the fractions of them, which are little distant from the line of the 12th hour from sunrise or sunset and which scarcely, or with difficulty, intersect the equinoctial line. For if the 11th hour, say, is to be drawn, we shall draw, through the $11\frac{1}{2}$ hour from midnight on the line of the 12th hour from sunrise or

sunset — as this table 2 indicates — a line parallel to the $5\frac{1}{2}$ hour from noon or midnight, as is clear from Table 1 of Chapter 14 of the new description. So too we shall draw the 20th hour from sunrise or sunset parallel to the 10th hour from noon or midnight, through the 4th hour from noon or midnight on the line of the 12th hour from sunrise or sunset, and so with the others. And if you conceive in your mind that the space between any two adjacent hours of this little table is divided into 4 parts, you will easily understand through which points of the hours from noon or midnight the quarters and halves of the hours from sunrise or sunset are to be drawn. Thus, since the 5th hour from sunrise or sunset is drawn through the $8\frac{1}{2}$ hour from noon or midnight, and the 6th through the 9th, the $5\frac{1}{4}$ hour will have to be drawn through the $8\frac{5}{8}$ hour; and the $5\frac{1}{2}$ hour through the $8\frac{6}{8}$ hour, that is, through the $8\frac{3}{4}$ hour; and the $5\frac{3}{4}$ hour through the $8\frac{7}{8}$ hour, and so on. And by the same reasoning the other tables will be fitted to the halves and quarters of the hours. For in the 1st, 2nd, and 3rd [tables] the hours from sunrise and sunset — that is, the upper ones — advance by quarters, halves, and three-quarters; whereas the hours from noon and midnight, the lower ones, advance by eighths of the hours. But in the following 4 tables the upper hours, with their fractions — that is, with the quarters, halves, and three-quarters — advance toward the right, while the lower ones advance toward the left.

[Margin: *Hor. ab or. & occ. delineatio in horologio horizontali.* — The drawing of the hours from sunrise and sunset in a horizontal dial.]

And so, at the point where, for example, the 18th hour from sunrise or sunset cuts the 3rd hour from noon or midnight, through that same point the 12th hour from sunrise or sunset must also be drawn, as is plain from the table of the 3rd hour from noon or midnight. So too the $18\frac{1}{2}$ hour from sunrise or sunset must be drawn through the intersection of the $11\frac{1}{2}$ hour from sunrise or sunset with the 3rd hour from noon or midnight, and so with the rest. But here you have, as I said, the little tables — all of them constructed from the figure of the scholium of Chapter 1, No. 3 of the new description — which have distinguished use in declining dials. The lines of the 6th and 18th hours from sunrise or sunset, moreover, are easily described in all dials: since the 6th hour must pass, in a horizontal dial, through the 9th hour from noon or midnight on the line of the 12th hour from sunrise or sunset, and the 18th through the 3rd hour from noon or midnight. Or indeed both, the 6th and 18th hours from sunrise or sunset, [pass] through the points of the line of the 6th hour from noon or midnight, which are distant from the center by an interval equal to the segment of the equinoctial line between the 12th and 9th, or 3rd, hours. But in a declining dial the 6th hour from sunrise or sunset should be drawn through the 3rd hour from

noon or midnight on the horizontal line, and the 18th hour through the 9th. Both hours, however, in any dial, pass through the 12th hour from noon or midnight on the equinoctial line.

The 6th hour from sunrise or sunset intersects, at one and the same point, two hours of this table in any dial.

Horæ ab or. vel occ. (Hours from sunrise/sunset)	1	2	3	4	5	6	7	8	9	10	11	12
Horæ à mer. vel med. no. (Hours from noon/midnight)	3½	4	4½	5	5½	6	6½	7	7½	8	8½	9

[Margin: When a very small dial is to be constructed.]

If a very small dial has to be constructed, you will do no wrong to quadruple the gnomon you have assumed and to describe the dial — with the hours from noon and midnight — for that quadrupled gnomon, as has been taught. For if you take a quarter part of all the distances from the center of the dial up to the parallels and the equinoctial line, you will have a dial matching your own gnomon; and you will find its position too, if you take a quarter part of the distance from that same center up to the position of the gnomon. In this dial the hours from sunrise and sunset are then to be drawn, as was explained here at No. 5.

You can also, if you prefer, make your gnomon tenfold and lay out the dial by the tenth parts of the Tangents, as we indicated above a little after the beginning of No. 4 — especially if, for the Tangents of the small subdivisions, you apply the remedy which we prescribed at the end of No. 1, with the instrument set aside.

[Margin: A dial declining in hours from noon and midnight.]

6. A dial declining in hours from noon and midnight is constructed, as was explained in the New Description [*Nova Descriptio*], ch. 16, and in the fourth

practical exercise excerpted from it, and likewise in ch. 4 of the Compendium. As in the following figure: let the horizontal line be AB, the position of the gnomon C, and its magnitude CD. With the whole sine [*sinus totus*] set as CD, it will give the tangent of the declination, 30 degrees (for we posit that much declination from south toward the east) — the point B, through which the meridian is to be drawn perpendicular to AB. But the tangent of the complement of the declination, which comprehends 60 degrees, will offer the point A, through which the equinoctial line, the line of the 6th hour, and indeed the Vertical line AP are to be drawn perpendicular to AB. Again, with the whole sine set as BD, it will give the tangent of the pole's altitude, 42 degrees, [reaching to] the center of the dial E; while the tangent of the complement of the pole's altitude gives the point F, through which the equinoctial line AF is drawn. The straight line EA will belong to the 6th hour, and ECK, perpendicular to the equinoctial, will be the line of the gnomon. The point F will also be found if, with BR taken equal to BD itself, a perpendicular RF is erected to the joined straight line ER.

Now the hour-points on the horizontal line and on the equinoctial will be found, as we taught in the New Description, ch. 16, Nos. 6, 7, and 8. Here only this is to be noted: that the table at the end of the aforesaid No. 5 — which was constructed by means of the complements of the arcs of table 6 — can also very conveniently be constructed by the arcs of that same table itself, in this way. When the dial declines from south toward the east, from the arcs of the hours of table 6 after the 6th hour let there be subtracted, from the complement of the wall's declination, those that can be subtracted; but the arcs of the hours before the 6th hour are to be added to that same complement of the declination. For thus will be produced the arcs whose Tangents are to be transferred to the left of the gnomon. But when the arcs of the hours in table 6 after the 6th hour are greater than the complement of the declination, let the complement of the declination be subtracted from those arcs; and to the complements of the arcs of that same table 6, if the hours are counted after noon, let the wall's declination itself be added. For thus will be generated the arcs whose Tangents are to be transferred to the right of the gnomon. Let the contrary be done in a dial declining from south toward the west. Further, when any arc found in this way is greater than a quadrant, it is not put in the table, because the hour of that arc does not fall on the horizontal line. Its complement to 180 degrees must therefore then be transferred to the contrary part by its own Tangent. But the point found will regard the hour to be counted from noon [south], if that which was sought — and did not fall on the horizontal line — should be counted from midnight; and vice versa.

Since, however, the table at No. 8 in the same ch. 16 is to be constructed by the inclination of the Meridians, you will find the magnitude of this inclination, if you please, by the Tangents in this way. In the following figure, with the whole sine set as KZ,

[Margin: How the inclination of the Meridians is found by the tangents.]

or $K\alpha$ (if beforehand $K\alpha$ is taken equal to KZ itself), KF will be the Tangent of the inclination of the Meridians — namely of the angle α — since the Meridian of the horizon is drawn through αF , and the Meridian of the wall through αK .

Therefore, if the instrument of parts is opened to the whole sine KZ, and the straight line KF is transferred into the instrument by the compass so that you may know how many particles it contains, you will at once find in the table of Tangents — dropping the last figure — how many degrees and minutes correspond to the Tangent KF.

[Margin: Hours 3 and 9.]

But so that the hour-lines may be drawn more accurately, the 3rd and 9th hours must first be drawn with the greatest care, in this manner. Through B, a perpendicular ef is drawn to DB, and Bd to ER; let Be, Bf be taken equal to Bd. For where the hidden straight lines De, Df cut the horizontal, through those points the [lines of the] 9th hour, EP, and the 3rd, EH, must be drawn from the center E; and these, unless there be an error, will pass through the points found on the equinoctial, and will cut off from the Vertical PQ the equal straight lines AP, AQ. These will be drawn more exactly if, below B on DB, there are taken any number of equal parts — namely two — up to the point h, through which a perpendicular ik is drawn to Dh. For if Bd is transferred into this on both sides as many times as DB is contained in Dh — three times, as in the given example — up to i, k, the hidden straight lines Di, Dk will cut the horizontal line at the same points of the 3rd and 9th hours. Or, if, with the whole sine set as DA, into the Vertical PAQ and into the straight line XgY (parallel to the meridian, and distant from it by as great a space as PAQ) there be transferred the tangents of the arcs

Diagram. A large and dense declining-dial construction filling the center of the page — an assembly of many straight lines (meridian, horizontal, equinoctial, gnomon-line, Vertical circle, and the 3rd/9th hour-lines) radiating and crossing through a central cluster of points, with several dotted (hidden) construction lines. The figure is heavily crowded; the readable letter- and numeral-labels, by approximate position, are:

- N (upper left, on an oblique line)

- L, X, δ (top-right cluster, at the intersection of steep lines)
- 9, 4 (right, along an oblique line descending to the right) [?]
- I, Q, β (left-center; β set just below the I/Q pair)
- T (left, on an oblique line)
- O (left, on a short oblique line)
- D, E (upper-center; E is a principal center of the pencil of lines)
- A (center-left, a second principal node on the horizontal)
- d, f, 3 (center, near B and R — hour-line labels/points)
- B, R (center, on the horizontal line)
- 9 (script numeral, center-left near B) [?]
- C, e (just below B)
- K (center-left, lower)
- Z (center)
- F (center, lower)
- α (center, lower, on the gnomon/equinoctial construction)
- M (lower-center)
- Y, H, κ (right; Y over H, and a kappa-like sort with a descender to their right) [?]
- h (lower-center-right)
- G, P (lower-left)
- 9 (script numeral, lower-left) [?]
- i (lower-center)
- S (lower)
- V (lower-center, at the foot of a long vertical)

of the 3rd and 9th hours, from table 6, taken over against the altitude of the pole on the right side, or from the complement of the pole's altitude on the left side, up to the points P, Q, X, Y; for through these the same 3rd and 9th hours are to be drawn.

And in the same way we shall find the points of the other hours, if we transfer their tangents — taken from the table of ch. 1 of the New Description — with the whole sine set as Bd, onto the straight line ef; or if we carry the same, doubled or tripled and so on, onto the straight line ik, according as Dh has proved to be double, or triple, etc., of DB. Likewise if onto the straight line PQ we transfer the Tangents of the arcs of table 6. Likewise if, on the meridian EB, there are taken any number of segments equal to EB itself, and through the outermost point a perpendicular is drawn to the meridian; and if into this there be transferred the

intervals of the horizontal line between B and the hour-points, twice or three or four times and so on, there will be had points more remote from the center E, through which the hour-lines are to be drawn.

When the lines of the 3rd and 9th hours have been drawn, together with the two lines PQ, XY (parallel to the meridian and equally distant from the center E, so that EA, Eg are equal, of which the former, PQ, is drawn through A and represents the Vertical circle), then, so that the points of the other hours

may be found more readily, let there be cut off from the 6th hour the straight lines Eb, Ea equal to the straight line AP (between the 6th and 9th hour), or to AQ, or gX, or gY — for all these are equal. (For ^a since the angles Q, E of the triangle AEQ are equal to the angles Y, E of the triangle Yeg, and the side EA is, by construction, equal to the side Eg, ^b the sides AQ, gY will also be equal. Therefore, since by the scholium to proposition 4 of the New Description both PQ and XY are cut in half at the 6th hour, AP, AQ, gX, gY will be equal to one another.) Then, through b and a, when the hidden lines GI, LH (parallel to the meridian, and cutting the 9th and 3rd hours at G, I, L, H) have been drawn, let the straight lines GH, LI be joined; these will be equal to the straight lines PQ, XY, and ^c will be bisected at M, N, because MG, MH, NI, NL are equal to the straight lines Eb, Ea — that is, to the straight lines AP, AQ, or gX, or gY, or MG, or MH, or NI, or NL. If onto the straight lines PQ, XY, GH, IL, from the points A, g, M, N, there are transferred on both sides the tangents of the hours of the table placed in the scholium of ch. 1 of the New Description, No. 2, the points will be found through which the hour-lines are to be drawn from the center E.

[Margin: ^a (Euclid, *Elements* I.29 & 15). ^b (Euclid, *Elements* I.26). ^c (Euclid, *Elements* I.34).]

By the same reasoning, if another parallel to the meridian line is drawn through any point of the 6th hour, the tangents of the same hours are to be transferred onto it, with the whole sine set equal to the portion of that parallel between the 6th and the 9th (or 3rd) hour. So too, if another parallel to the line of the 6th hour is drawn through any point of the meridian line, the same tangents are to be transferred onto it, with the whole sine set equal to the segment of this parallel between the meridian and the 3rd (or 9th) hour.

[Margin: Hour-points by the arcs of the Vertical, from table 6.]

When the Vertical line PAQ has been drawn through A, the hour-points will also be found on it by the tangents of the arcs of table 6 of the New Description — taken over against the altitude of the pole on the right side, or over against the

complement of the pole's altitude on the left side — with the whole sine set as DA, as we said a little before.

[Margin: Hour-points on the horizontal line without knowledge of the wall's declination in degrees and minutes.]

Now if the wall's declination in degrees and minutes is unknown, we shall nonetheless find the hour-points on the horizontal line, in this way. When the straight line DB has been produced, let a perpendicular ik be drawn to it through any of its points h . For if the tangents of the complements of the arcs of table 6 of the New Description are transferred into this on both sides from h , with the whole sine set as Dh , the hidden straight lines drawn from D through the extremities of these tangents will cut the horizontal line at the hour-points. The same tangents can be transferred from B onto the perpendicular ef , with the sine set as DB .

[Margin: Hour-points on the equinoctial, without knowledge of the inclination of the Meridians.]

Again, if through any point of the straight line DA — as through A — a perpendicular OS is erected to DA , and into it, with the whole sine set as DA (between D and the point A through which the perpendicular is drawn), there are transferred the tangents of the arcs of the aforesaid table (but not the tangents of the complements), then from A , on both sides, the hidden straight lines drawn from D through the extremities of the transferred tangents will cut the horizontal line at the same hour-points, and so on. This is clear from what was demonstrated in ch. 1 of the New Description, and from what we wrote above at No. 4 about the parallels of one who describes by tangents, from ch. 9 of the New Description.

By a similar reasoning, when the inclination of the Meridian of a declining plane toward the Meridian of the horizon is unknown in degrees and minutes, the hour-points will be found on the equinoctial line, in this way. With the gnomon CZ erected perpendicular to the line of the gnomon, and the straight line $K\alpha$ taken equal to the interval KZ , let the straight line αF be joined; and to it — produced, if you like — let a perpendicular TV be erected at any point, namely at F . For if into this, from F on both sides, there are transferred the tangents of the hours of the table of the scholium of ch. 1 of the New Description, the hidden straight lines drawn from α through the extremities of the tangents will cut the equinoctial line at the hour-points; which is plain from what was demonstrated in ch. 1 of the New Description, as we wrote just now. The same is also confirmed from our

Gnomonica. For since the hidden straight lines drawn from α — through the hours of the circle described from α , the beginning being made from the straight line αF — cut the equinoctial at the hour-points, and since the Tangents on the straight line $T V$ correspond to the same hours of the said circle, the proposition stands established.

[Margin: When the wall's declination is very great, what to do.]

7. When the wall's declination is very great — lest we be forced to describe the whole dial in a small form, as we warned at the end of ch. 17 of the New Description — we shall proceed very conveniently in this way. Let some very great declination of the wall be given — say 89 or 88 degrees, and so on — from south toward the east, at any altitude of the pole. In our following example the declination is 71 degrees 44 minutes from south toward the east, at a pole-altitude of 60 degrees 45 minutes. When the horizontal line BE has been drawn, let a gnomon BA be erected to it at right angles. And since, with respect to the whole sine AB , the Tangent of the declination cannot be transferred from B toward E — in such a way that neither the meridian line can conveniently be had, nor the center — we shall transfer from B toward C the Tangent of the complement of the declination, up to the point C , through which let the primary Vertical CN be drawn, at right angles to the horizontal. Then, on the horizontal, a point E having been assumed anywhere, let the Tangent of the complement of the declination be transferred from B onto the gnomon AB , with respect to the whole sine EB , up to D . For the straight line DE , when drawn, will make the angle of declination BDE , so that BED is the angle of the complement of the declination. The straight line AV , parallel to DE , will likewise make the angle of declination BAV , but it intersects the horizontal too far off. Also, when DF is drawn perpendicular to DE , BDF will be the angle of the complement of the declination; and through the point F the equinoctial line for the gnomon BD is to be drawn. Therefore, the Tangent of the complement of the pole's altitude above the horizon having been transferred, with respect to the whole sine ED , from E up to the point G on the straight line EG (perpendicular to the horizontal, which is the meridian line with respect to the gnomon DB), the drawn line FG will be the equinoctial line with respect to the gnomon BD . But since the equinoctial line is to be drawn through C with respect to the given gnomon AB , the drawn line CH , parallel to FG , will be the equinoctial line for the given gnomon AB ; and to it a perpendicular BP is drawn through B (which will be done exactly if, from B , two points I, K are taken at the same interval, and from I, K , at any interval, two arcs are described cutting each other at L and T , etc.) — this will be the line of the gnomon.

Through the assumed point P too, let PQ be drawn on the line of the gnomon, parallel to the horizontal, to serve as a second horizontal. Then let a perpendicular BZ be erected to the line of the gnomon, equal to the gnomon BA, and let a straight line be joined from Z to b, the intersection of the line of the gnomon with the equinoctial line: this Zb will be the common section of the Equator and of the Meridian of the proper declining plane. To it a perpendicular Zc drawn will be the world-axis; and the perpendicular Pc, drawn to the line of the gnomon up to the axis, will be the new gnomon with respect to the second Horizon PQ. And the straight line cb, perpendicular to the axis Zc, will be the common section of the Equator and of the proper Meridian. But the straight line bX, parallel to CH — or perpendicular to BP — will be the equinoctial line with respect to the gnomon Pc.

Therefore, if the hour-points are found both on the horizontal BE (with respect to the gnomon BA) and on the horizontal PQ (with respect to the gnomon Pc), as we taught in ch. 16 of the *New Description*, Nos. 5 and 6, and also here a little before at No. 6, the dial will be described even though it has no center. You will also do rightly if [you place] the hour-points on the Vertical

you should seek [it] exactly on the Vertical CN, and likewise on the two equinoctial lines CH and bX, from the inclination of the Meridians, with respect to the whole sines bZ and bc, as was handed down in the same ch. 16 of the *New Description* [*Nova Horologiorum Descriptio*], No. 8. You have an example in the line of the 9th hour, MN. And if there is no error, it is necessary that the straight line OR, parallel to AM (which will easily be drawn if, AM being produced to Q, MR is taken equal to QO), should cut off from the perpendicular PS a straight line PS equal to the gnomon Pc; and this because the proportion of the gnomon AB to the shadow BM ought to be the same as that of the gnomon bP to the shadow PO. From this you have another way of investigating the size of the gnomon with respect to the second Horizon PQ. For once the point M of the 9th hour, for instance, has been found on the horizontal CE with respect to the gnomon AB, and the point N of the same hour on the Vertical CN with respect to the whole sine AC, then, the hour-line MN having been drawn and cutting PQ at O, it will cut off OR (parallel to MA) as the gnomon PS, as has been said.

Now we shall draw the hidden lines on both sides of the gnomon-line BP, like the hour-lines in a horizontal dial (namely, so that the points of the parallels may be found on them, as was explained above at No. 4). We do this if we transfer the Tangents of the hours from the little table of ch. 1 of the *New Description* onto both sides of the gnomon-line — both from b onto the equinoctial bH, with

respect to the whole sine bZ , and from b onto the equinoctial bX , with respect to the whole sine bc .

Diagram. A crowded construction figure for laying out a sundial on a wall of very great declination (the case treated in the preceding paragraphs). A near-horizontal base line runs through R, F, B, M to E at the right; a gnomon and numerous hour-lines, equinoctial lines, and auxiliary perpendiculars radiate across the field, with several dashed (construction) lines. The following labels are legible on the figure:

- A, T (top, apex region)
- I (far left)
- Y (left of center, on a line from I)
- D (upper center, on a dashed line)
- V (right side)
- R, F, B, M (left-to-right along the middle base line), E (right end of that line)
- C (just below F), S (lower left, on a dashed line)
- b (below B), Z (center)
- f (small label, center-right), h (right), H (right, below h)
- K (center, on a dotted line), L, P (lower left)
- O (center-low), N (lower center), c (small, lower center)
- X (at the bottom)
- [?] one small lowercase glyph adjacent to O (possibly "a" or "q") is not resolvable
- [?] a "9"-like mark low and left of N cannot be resolved as a point-label
- [?] the figure carries both an upper-case G (right side) and lower-case g/h in the text; the two right-hand labels below h could not be distinguished with certainty

8. [Margin: When the wall's declination is slight, what is to be done.] We shall use nearly the same device when the wall's declination is very slight — so slight that the meridian line can indeed be had conveniently, but not so the point of the 6th hour and of the equinoctial line on the horizontal. For let the wall decline from south toward the west by 18 degrees 16 minutes, at a latitude of 33 degrees 41 minutes. The Tangent of the declination BC , with respect to the whole sine AB taken equal to the gnomon, will give the point C , through which the meridian CN is to be drawn perpendicular to CB . And since the Tangent of the complement of the declination can only with difficulty be transferred onto BE with respect to the same whole sine AB , we shall — the point E being taken anywhere — transfer

onto BA, up to D, the Tangent of the declination with respect to the whole sine EB; and, the straight line ED being assumed, we shall raise the perpendicular DF. (Or we shall transfer the Tangent of the declination, with respect to the whole sine BD, up to F.) For thus the perpendicular Ff, drawn through F to the horizontal, will be the meridian with respect to the gnomon BD, and through E both the 6th hour and the equinoctial are to be drawn. If, therefore, on Ff we transfer the Tangent of the complement of the given latitude, with respect to the whole sine FD, up to f, the straight line fE will be the equinoctial line with respect to the gnomon BD. And if on CN the Tangent of the same complement of the given latitude be transferred up to g, with respect to the whole sine CA, then gh, parallel to fE, will be the equinoctial line with respect to the gnomon AB. Through B a perpendicular to this equinoctial is to be drawn, to serve as the gnomon-line. The rest will be completed as before. Only the hour-points cannot be found on the Vertical line, since there is none; rather they are to be sought on the two horizontals, or on the equinoctials, the second gnomon having first been found, etc. In our example, since the center of the dial Y is found by the Tangent of the given latitude, the hour-lines are to be drawn through Y and through the points found on the horizontal BE, etc.

9. [Margin: The arcs of the signs on a declining dial.] The points of the parallels [of declination] will be found by means of the Tangents, on the hidden lines drawn on both sides of the gnomon like the hour-lines of a horizontal dial, as we have set out in excerpts in the New Description, ch. 18, and toward the end of ch. 5 of the Compendium of Dials, and in Practice 5. Only where the dial has no center — as happens in dials that have the greatest declination — no small circle can be described around the segment of the gnomon-line lying between the center and the position of the gnomon; rather, from the position of the gnomon, perpendiculars must be raised to those hidden hour-lines, so that the points may be found by the table of parallels of the Compendium. By means of the Secants too, very exact-

-ly will the points of the parallels be found, as we taught above at No. 4. But where there is no center, the whole sine must be taken not from the center but from the intersection of the gnomon-line with the equinoctial, up to the points found by ch. 8 of the New Description, No. 7; and the Secants must be transferred from the equinoctial onto the hidden hour-lines. So too, if table 19 of the New Description is used, the points will have to be sought not from the center but from the equinoctial line, when there is no center, as was handed down at the end of the scholium of ch. 9 of the New Description.

[Margin: An excellent use of the table of ch. 15 in declining dials.] But if, in place of table 1 of the New Description, one takes the table given at No. 2 of ch. 15, we shall find the points of the parallels not only on any number of hidden lines that indicate the minutes of the hours of that table, but even on the hour-lines themselves, even if those hidden hour-lines are not drawn — and in the following way. Once the distances of the hours from the gnomon-line have been found by the inclination of the Meridians, as we taught in the New Description ch. 16 No. 8, and those distances have been reduced to hours, we shall find — by means of the arcs in the aforesaid table corresponding to those reduced hours under the proposed sign, and by the altitude of the pole above the plane of the dial, as we handed down in ch. 8 No. 7 — points on the gnomon-line, through which perpendiculars drawn to that same gnomon-line will cut the hours at the points of the parallels. For example: in the declining dial proposed in ch. 18 of the New Description, hour 5 from midnight is distant from the gnomon-line by 64 degrees 12 minutes — that is, 4 hours 17 minutes. Now to 4 hours 17 minutes there corresponds, in the aforesaid table under Cancer [♋] and Capricorn [♐], an arc of 45 degrees 1 minute; and if the pole's altitude above the plane of the dial, which contains 40 degrees 4 minutes, be subtracted from it, there remain 4 degrees 57 minutes, whose Tangent is 87 with respect to the whole sine 1000 taken equal to the gnomon. Transferred from C upward onto the gnomon-line, it will give a point through which a perpendicular drawn out to the gnomon-line will cut hour 5 from midnight at the point of Capricorn. Likewise hour 8 from midnight is distant from the gnomon-line by 19 degrees 12 minutes — that is, 1 hour 17 minutes — to which, in that same table, there correspond under Cancer and Capricorn 24 degrees 44 minutes; and, the pole's altitude of 40 degrees 4 minutes being added, an arc of 64 degrees 48 minutes is produced, whose Tangent is 2115 with respect to the whole sine 1000 taken equal to the gnomon. Transferred from C downward, it will offer a point through which a perpendicular erected to the gnomon-line will cut hour 8 from midnight at the point of Cancer, etc. And so one must always deal here with the southern signs, just as we said one must deal with the northern signs in the horizontal dial (ch. 8 No. 7 of the New Description) for finding the points on the meridian line; whereas with the northern signs one must proceed here just as we said one must proceed with the southern signs there.

By means of that same table we shall also find, on the line drawn through the center of the dial perpendicular to the gnomon-line (like the 6th hour), the points through which straight lines, sent out from the intersection of the gnomon-line with the equinoctial, will cut the corresponding hours at the points of the parallels. For example: hour 5 from midnight is distant from the gnomon-line by

64 degrees 12 minutes — that is, 4 hours 17 minutes. Now at the meeting of hour 4 at the foot of the table and 17 minutes on the right-hand side, taken under Capricorn, are found 25 degrees 46 minutes. The Tangent, therefore, of the complement of this arc is 207 [fraction: ?], with respect to the whole sine 100 — which, in the dial of ch. 16 of the New Description, is made equal to the straight line Ez; transferred from the center E onto the said perpendicular, it will give a point at which the straight line drawn out from K will cut hour 5 from midnight at the point of Capricorn, etc.

[Margin: In table 1 of the New Description the proportional part must not be used.] You see, therefore, that by this table alone — which is universal and proceeds through every minute of the hours — the points of the parallels can be found in all dials, even declining ones, even though the hidden lines are not drawn like the hour-lines of a horizontal dial. This is truly excellent and outstanding, and therefore that table is to be highly valued, since the first table in the New Description does not proceed through the individual minutes of the hours, nor can the arcs be found by the proportional part for the individual minutes of the hours. This I wished to point out, lest you use the proportional part in that table to no purpose.

Most conveniently, too, where the center lies too far off, table 3 of the New Description will be employed, if the hidden lines have been drawn on either side of the gnomon-line like the hour-lines from noon and from midnight — because then the line perpendicular to the gnomon-line through the center cannot be had. Therefore in that case perpendiculars must be drawn to the gnomon-line through the points of Capricorn and Cancer, as in the horizontal dial, in the manner explained in ch. 8 No. 11 of the New Description.

[Margin: The drawing of the parallels by means of points found on the meridian line.] The finding of the points for the parallels on the hour-lines themselves, by means of the points found on the meridian line — as we set out in the New Description ch. 18 No. 1 — is likewise not inconvenient. But when the points of some hours cannot be marked on the meridian line, because they are removed too far from the point B in the figure of that chapter, we shall proceed conveniently as follows. Having bisected the portion AB of the horizontal line, we shall draw through the point of division a line perpendicular to the horizontal. For if, beginning from the horizontal, the halves of the Tangents which would have had to be transferred onto the meridian line are carried over onto this perpendicular, points will be found through which the straight lines drawn out from A will indicate the points of the parallels on the hour-lines. But if on this

perpendicular some points are still too far distant from the horizontal, the portion between A and the said perpendicular must again be bisected, and through the point of division another perpendicular to the horizontal must be raised. For if the quarter-parts of the Tangents to be transferred onto the meridian are carried over onto this, points will be found through which straight lines sent out from A will cut the hour-lines at the points of the parallels.

10. [Margin: The hours from sunrise and sunset on a declining dial.] The hours from sunrise and sunset on a declining dial will be laid out by those excerpts which, in ch. 14 of the New Description and in Practice 6, we prescribed should be observed. For this the tables which we described above at No. 5 will be most useful.

But most conveniently, a declining dial with the hours from sunrise and sunset — in a region whose pole is elevated above the Horizon by not more than 60 degrees nor fewer than 30 — will be laid out by table 10 of the Sun's altitudes at the hours from sunrise and sunset, and by table 12 of the horizontal circumferences [azimuths] at the same hours, as we handed down in the new description of dials, ch. 24.

11. [Margin: A horizontal dial of the hours from sunrise and sunset, by means of the horizontal circumferences and the Sun's altitudes.] Now if one wishes to construct a horizontal dial by means of the horizontal circumferences and the altitudes of the Sun, as we advised at the end of ch. 24 of the New Description — especially with the hours from sunrise and sunset — a perpendicular to the meridian must be drawn through the position of the gnomon, which will represent the primary Vertical; and to this, through any point, another perpendicular, which will be equidistant from the meridian. For onto this second perpendicular the horizontal circumferences must be transferred from the Vertical line, by means of their Tangents, to both sides of the Vertical, with respect to a whole sine equal to the segment of the Vertical lying between the position of the gnomon and the said perpendicular parallel to the meridian. But if the horizontal circumferences are too great, a line parallel to the meridian must be drawn through a

point of the Vertical nearer to the position of the gnomon, so that the tangents may be transferred onto it with respect to a smaller whole sine, etc. But for the hours from noon or midnight it is enough to transfer, onto the hour-lines laid out either by the arcs of the Horizon of table 6 or in some other way, the Tangents of the complements of the Sun's altitudes from the position of the gnomon, the gnomon itself being taken as the whole sine.

12. [Margin: The points of the hours from sunrise or sunset on the horizontal line.] And since, in ch. 25 of the New Description — where we constructed dials geometrically by means of the horizontal circumferences and the Sun's altitudes — we taught, at the end of No. 6, that the points of the hours from sunrise or sunset on the horizontal line are to be sought by means of the rising amplitudes, those same points will be found more readily by means of the hours from noon and midnight. For if on the horizontal line there be found the point of the hour from noon or midnight that is half of the given hour from sunrise or sunset, that hour is to be drawn through the said point. Thus for hour 11 from sunrise or sunset one must seek the point of hour $5\frac{1}{2}$ from noon or midnight; for hour 23 from sunset, the point of hour $11\frac{1}{2}$ from noon or midnight; and for hour 22, the point of hour 11, etc.

[Margin: The rising amplitudes of the circles of the hours from sunrise or sunset.] Indeed, since any circle of an hour from sunrise or sunset, and the Horizon — which is the circle of hour 24 — mutually intersect one another on the circle of that hour from noon or midnight whose number is half of the hour from sunrise or sunset (as is clear from the figure of the scholium of ch. 1 No. 3 of the New Description, and as was demonstrated by us in book 1 of the Gnomonics, propositions 17 and 20), it comes about that the rising or setting amplitude of any hour from sunrise or sunset does not differ, in table 6, from the arc of the Horizon of that hour from noon or midnight which is its half. Since, therefore, the lines of the hours from noon or midnight in a horizontal dial (ch. 2 of the New Description) are laid out by the arcs of the Horizon of table 6 carried over onto a circle described from the center G — the beginning being taken from the line of hour 6, as we showed in ch. 5 of the New Description — the arc of that circle between the line of hour 6 and any other hour-line will be equal to the rising or setting amplitude of the hour from sunrise or sunset that is double the assumed hour from noon or midnight. Thus the arc between hour 6 and hour $5\frac{1}{2}$ will be the amplitude of hour 11 from sunrise or sunset, and consequently also of hour 13; and so of the rest. Therefore, if the hours from noon and midnight are carefully laid out in a horizontal dial together with the half-hours, they will contain at the center G, together with hour 6, the angles of the rising or setting amplitudes which the hours from sunrise or sunset make on the Horizon. This is indeed worth observing, and has perhaps been noticed by few. And so, if the amplitude of some hour from sunrise or sunset is desired in degrees for a given altitude of the pole, one must take from table 6, for the given elevation of the pole, the arc of the Horizon of that hour which is the half of the given hour from sunrise or sunset.

13. [Margin: The declination of the wall.] Finally, I think it will be worth my while if in this place I set out a method of investigating the declination of a proposed wall, different from the one I explained in ch. 22 of the New Description. It is this. On the wall — or rather on some board well leveled and fixed to the wall — let a straight line AB be drawn parallel to the Horizon with the help of a level; and on it let a gnomon AC be fixed at right angles; and in the morning let the tip of the shadow D be observed as carefully as possible, and from A, through D, let a circle DE be described. Then, after a long interval of time, let the shadow be observed again, until its tip E touches the described circle. For, the arc DE being bisected at F, the straight line FA, when drawn, will be the gnomon-line; because in the hyperbola traced through the points D and E on the day of observation, the points D and E are equidistant from the straight line FA and from the position of the gnomon A. Then from any point G of the gnomon-line let the perpendicular GH be dropped to AB, and at G on it let there be constructed the angle HGB, [equal] to the complement of the pole's altitude above the Horizon; which will be done if, GH being taken as the whole sine, HB be taken as the Tangent of the complement of the pole's altitude. Lastly, at the interval HB let AI be cut off perpendicular to AB at the point I, and let the straight line HI be drawn. I say that AIH is the angle of the wall's declination. For, this declination being assumed, if HB be taken equal to HI, and at B the angle of the pole's altitude be made, then G will be found — the center of the dial — and GH the meridian line, and GA the gnomon-line with respect to the gnomon AI: exactly the same as was previously found by observation, as is clear from what we demonstrated in the New Description, ch. 16.

Diagram. The construction for finding a wall's declination from two shadow-observations (§13). A horizontal base line AB runs across the figure, with a semicircle drawn below it. The labelled points are:

- I, G (at the top of the figure)
- K, M (below I and G respectively)
- C (upper left, the top of the gnomon AC)
- A (on the base line, at the center; foot of the gnomon)
- L, H, N (on the base line, to the right of A)
- B (right end of the base line)
- D (on the lower-left of the semicircle; the morning shadow-tip)
- F (at the bottom of the semicircle; the bisection point)
- E (lower center, on the semicircle; the later shadow-tip)

Dashed lines run from D and across the figure (the shadow-directions and the gnomon-line FA). No labels flagged.

When the gnomon-line thus found inclines, for us facing the wall, to the left below the horizontal AB, the wall will decline from south toward the east; but toward the west, if it inclines to the right. For this method has its place chiefly on walls facing south, since on those that face north the two shadows rarely reach the same circle. Therefore a northern dial will have to be derived from a southern one.

But if you wish to keep the given gnomon AC on the dial, a straight line AK equal to it must be cut off, and the angle AKL of the wall's declination must be constructed — that is, AK being taken as the whole sine, AL must be taken as the Tangent of the declination found — and through L the meridian must be drawn perpendicular to AB.

FINIS.

INDEX OF CHAPTERS OF THE NEW DESCRIPTION OF DIALS

[INDEX CAPITVM NOVÆ DESCRIPTIONIS HOROLOGIORVM]

[*This is the table of contents (index of chapters, of tables, and of problems) to the Nova Descriptio Horologiorum**; each entry is followed by its page reference in that work's own pagination. The reference column is headed* *Pagina* ("Page").]

- **Prolegomena.** [*Prolegomena*] — p. 3
- **I.** A horologigraphic problem [*Problema Horologigraphicum*]. — p. 4
- **II.** The hours reckoned from noon and from midnight, on a plane parallel to the horizon [*HORÆ à mer. & med. noc. in plano, quod Horizonti æquidistat*]. — p. 10
- **III.** The same, by another method [*alio modo*]. — p. 13
- **IV.** The same, by yet another method [*alio præterea modo*]. — p. 16
- **V.** The same, by still another method [*alio item modo*]. — p. 22
- **VI.** The hours from noon and midnight, on a plane parallel to the horizon, above which the pole's altitude is so slight that the center of the dial can scarcely be obtained [*supra quem poli altitudo tam exigua est, vt centrum horologij vix haberi possit*]. — *ibid.*

- **VII.** The hours from noon and midnight, on a plane parallel to the horizon, above which the pole's altitude is so great that the equinoctial line can scarcely be drawn on it [*supra quem poli altitudo tanta est, vt in eo linea æquinoctialis vix describi possit*]. — p. 23
- **VIII.** The arcs of the signs on a horizontal dial, for the hours from noon and midnight [*ARCVS signorum in horologio horizontali horarum à mer. & med. noc.*]. — p. 24
- **IX.** The same, by another method [*alio modo*]. — p. 32
- **X.** The arcs of the signs, by yet another method, in the hours from noon and midnight of a horizontal dial [*ARCVS signorum alio item modo in horis à mer. & med. noc. horologij horizontalis*]. — p. 35
- **XI.** The arcs of the signs on a horizontal dial, without the aid and help of the hour-lines [*ARCVS signorum in horologio horizontali sine ope, auxilioque linearum horariarum*]. — p. 37
- **XII.** The arcs of the signs on a horizontal dial, for the hours from noon and midnight, in which the center cannot be obtained [*ARCVS signorum in horologio horizontali horarum à mer. & med. noc. in quo centrum haberi non potest*]. — p. 39
- **XIII.** The arcs of the signs in the hours from noon and midnight of a horizontal dial, above which the pole's altitude is greatest [*ARCVS signorum in horis à mer. & med. noc. horologij horizontalis, supra quem maxima est altitudo poli*]. — *ibid.*
- **XIV.** The hours from sunrise and sunset on a horizontal dial [*HORÆ ab or. & occ. in horologio horizontali*]. — p. 40
- **XV.** The arcs of the signs in the hours from sunrise or sunset of a horizontal dial [*ARCVS signorum in horis ab or. vel occ. horologij horizontalis*]. — p. 43
- **XVI.** The hours from noon and midnight, on a plane parallel to some vertical declining from the prime vertical — that is, on the plane of a declining wall, and perpendicular to the horizon [*HORÆ à mer. & med. noc. in plano, quod alicui Verticali à primario Verticali declinanti æquidistat: hoc est, in plano alicuius muri declinantis, & ad Horizontem perpendicularis*]. — p. 51
- **XVII.** The hours from noon and midnight, on a declining plane, where either the center of the dial, or the point of the 6-o'clock hour, lies on the horizontal line, or the meridian point lies on that same horizontal line; or finally when two of these can be obtained only most inconveniently [*HORÆ à mer. & med. noc. in plano declinante, vbi vel centrum horologij, vel punctum horæ 6. in horizontali linea, vel punctum meridianæ in eadem linea*]

horizontalis; vel denique quando duo ex his incommodissime haberi possunt]. — p. 58

- **XVIII.** The arcs of the signs in the hours from noon and midnight of a declining dial [*ARCVS signorum in horis à mer. & med. noc. horologij declinantis*]. — p. 59
- **XIX.** The hours from sunrise and sunset on a declining dial [*HORÆ ab or. & occ. in horologio declinante*]. — p. 63
- **XX.** On the dial which is parallel to the prime vertical circle [*DE Horologio, quod Verticali circulo primario æquidistat*]. — p. 70
- **XXI.** On the meridian dial [*DE Horologio Meridiano*]. — p. 71
- **XXII.** On finding the meridian line, and the declination of walls, and the placing of dials and of the gnomon [*DE inuentione lineæ Meridianæ, declinationisque murorum, atque horologiorum, ac styli collocatione*]. — p. 73
- **XXIII.** How a wall-dial drawn on paper is to be transferred onto the wall, at any size of the gnomon [*QVO pacto horologium murale in charta descriptum, in murum fit transferendum ad quamcunque styli magnitudinem*]. — p. 76
- **XXIV.** By what method a dial, whether horizontal or on a wall, may be constructed for a given latitude of the place, from horizontal circumferences of the Sun alone and from the Sun's altitudes above the horizon computed for that same place [*QVA ratione horologium tam horizontale, quam murale ad datam latitudinem loci, ex solis circumferentijs horizontalibus, & altitudinibus Solis supra Horizontem eiusdem loci supputatis construatur*]. — p. 77
- **XXV.** Dials found geometrically from horizontal circumferences only, and from the Sun's altitudes above the horizon. Where it is also taught by what method declining dials may be described from the horizontal dial alone, or even from the meridian dial [*HOROLOGIA ex circumferentijs tantum horizontalibus, & altitudinibus Solis supra Horizontem Geometrice inuentis. Vbi etiam docetur, qua ratione horologia declinantia ex solo Horizontali horologio, vel etiam Meridiano describi possint*]. — p. 82

INDEX OF TABLES OF THE NEW DESCRIPTION OF DIALS

[INDEX TABVLARVM NOVÆ Descriptionis Horologiorum]

- **I.** The arc of any circle of the hour, from noon and midnight, between the equator and the great circles that are drawn through the hour-point of the equator, 6 hours distant from the assumed hour-circle, and through the individual hours from noon and midnight at the beginnings of the signs, and intercepted [*ARCVS cuiusvis circ. hor. à mer. & med. noc. inter Æquatorem, & maximos circulos, qui per punctum horarium Æquatoris 6. horis ab assumpto circulo horario distant, & per singulas horas à mer. & med. noc. in signorum initijs ducuntur, intercepti*]. — p. 91
- **II.** The arc of the meridian between the equator and the great circles which are drawn out of hours 5, 4, 3, 2 from noon and 7, 8, 9, 10 from midnight through the individual hours from noon or midnight at the beginnings of the signs, and intercepted [*ARCVS Meridiani inter Æquatorem, & circulos maximos, qui ex horis 5. 4. 3. 2. à mer. & 7. 8. 9. 10. à med. noc. per singulas horas à mer. vel med. noc. in principijs signorum ducuntur, intercepti*]. — p. 92
- **III.** The arc of the ecliptic (the beginning of ♋ [Greek zodiac sign: Cancer], or of ♏ [Greek zodiac sign: Capricorn], being placed on the meridian above the horizon), between the meridian and the great circles which are drawn out of the intersection of the meridian with the equator through the hours from noon and midnight at the beginnings of the signs — arcs which in gnomonics we have called hour-arcs [*ARCVS Eclipticæ (posito principio ♋, vel ♏ in Meridiano supra Horizontem) inter Meridianum, & circulos maximos, ex sectione Meridiani cum Æquatore per horas à mer. vel med. noc. in signorum initijs ductos, quos arcus horarios in Gnomonica appellauimus*]. — *ibid.*
- **IV.** The arc of the semidiurnal circle in degrees and minutes, computed at the beginnings of the signs for all elevations of the pole [*ARCVS semidiurni in grad. ac min. in signorum initijs, ad omnes eleuationes poli supputati*]. — p. 93
- **V.** The amplitudes of rising and of setting at the beginnings of the signs, computed for several elevations of the pole [*AMPLITVDINES ortiuæ, occiduæque in signorum initijs, ad plures eleuationes poli supputatæ*]. — p. 97

- **VI.** The arc of the horizon and of the prime vertical between the hour-circles from noon and midnight and the intersection of the equator, or of the circle of the 6th hour with the horizon, computed for all elevations of the pole — the arcs which we have called hour-arcs in gnomonics [*ARCVS Horizontis, & Verticalis primarij inter circulos hor. à mer. & med. noc. & interfectionem Æquatoris, vel circuli horæ 6. cum Horizonte, ad omnes eleuationes poli supputata. quos arcus horarios in Gnomonica appellauimus*]. — p. 98
- **VII.** The arc of the circle of the 6th hour, from noon or midnight, between the equator and the great circles that are drawn by the intersection of the equator with the meridian, through the hours from sunrise or sunset at the beginnings of the signs [*ARCVS circuli horæ 6. à mer. vel med. noc. inter Æquatorem, & maximos circulos, qui per interfectionem Æquatoris cum Meridiano, per horas ab or. vel occ. in signorum initijs ducuntur*]. — p. 122
- **VIII.** The arc of the meridian between the equator and the great circles which are drawn by the intersection of the equator with the horizon, through the hours from sunrise or sunset at the beginnings of the signs [*ARCVS Meridiani inter Æquatorem, & maximos circulos, qui per interfectionem Æquatoris cum Horizonte, per horas ab or. vel occ. in signorum initijs ducuntur*]. — *ibid.*
- **IX.** The altitudes of the Sun for the hours from noon and midnight at the beginnings of the signs. For all elevations of the pole [*ALTITVDINES Solis pro horis à mer. & med. noc. in signorum initijs. Ad omnes eleuationes poli*]. — p. 124
- **X.** The altitudes of the Sun for the hours from sunrise or sunset at the beginnings of the signs. For several elevations of the pole [*ALTITVDINES Solis pro horis ab or. vel occ. in signorum initijs. Ad plures eleuationes poli*]. — p. 138
- **XI.** The horizontal circumferences, between the prime vertical and the other verticals, drawn through the hours from noon and midnight at the beginnings of the signs. For latitude Gr. 42 [*CIRCVMFERENTIÆ horizontales, inter Verticalem primarium, & alios Verticales per horas à mer. & med. noc. in signorum initijs ductos. Ad latitud. Gr. 42*]. — p. 144
- **XII.** The horizontal circumferences between the prime vertical and the other verticals, drawn through the hours from sunrise and sunset at the beginnings of the signs. For several elevations of the pole [*CIRCVMFERENTIÆ horizontales inter Verticalem primarium, & alios*

Verticales per horas ab or. & occ. in signorum initijs ductos. Ad plures eleuationes poli]. — p. 146

- **XIII.** The declinations of the diurnal arcs, computed for several elevations of the pole [*DECLINATIONES arcuum diurnorum, ad plures eleuationes poli supputatæ*]. — p. 153
- **XIV.** The arc of the horizon between the meridian and the great circles which are drawn by the intersection of the equator with the meridian, through the hours from noon and midnight at the beginnings of the signs. For latitude Grad. 42 [*ARCVS Horizontis inter Meridianum, & circulos maximos, qui ex intersectione Æquatoris cum Meridiano, per horas à mer. & med. noc. in signorum initijs ducuntur. Ad latitud. Grad. 42*]. — p. 157
- **XV.** The arc of the prime vertical between the horizon and the great circles which are drawn by the intersection of the equator with the meridian, through the hours from noon and midnight at the beginnings of the signs. For latitude Gr. 42 [*ARCVS Verticalis primarij inter Horizontem, & circulos maximos, qui ex intersectione Æquatoris cum Meridiano per horas à mer. & med. noc. in signorum initijs ducuntur. Ad lat Gr. 42*]. — *ibid.*
- **XVI.** The arc of the horizon between the meridian and the great circles which are drawn by the intersection of the equator with the meridian, through the hours from sunrise and sunset at the beginnings of the signs. For latitude grad. 42 [*ARCVS Horizontis inter Meridianum, & circulos maximos, qui ex intersectione Æquatoris cum Meridiano per horas ab or. & occ. in signorum initijs ducuntur. Ad latitud. grad. 42*]. — *ibid.*
- **XVII.** The arc of the prime vertical between the horizon and the great circles which are drawn by the intersection of the equator with the meridian, through the hours from sunrise and sunset at the beginnings of the signs. For latitude gr. 42 [*ARCVS Verticalis primarij inter Horizontem, & circulos maximos, qui ex intersectione Æquatoris cum Meridiano per horas ab or. & occ. in signorum initijs ducuntur. Ad latitud. gr. 42*]. — p. 158
- **XVIII.** The arc of the horizon between the meridian and the great circles drawn out of the poles of the world, through the hours from sunrise or sunset at the beginnings of the signs [*ARCVS Horizontis inter Meridianum, & circulos maximos ex polis mundi per horas ab or. vel occ. in signorum initijs ductos*]. — *ibid.*
- **XIX.** The segments of the hour-lines from noon and midnight, between the center of the horizontal dial and the points of the Sun's parallels, reduced to the tangents with respect to a whole sine equal to the gnomon: for very many elevations of the pole; for drawing the Sun's parallels, according to

what was prescribed in Number 5 of the scholium of chapter 9 [*SEGMENTA lin. hor. à mer. & med. noc. inter centrum horologij horizontalis, & puncta parallelorum Solis, ad Tangentes respectu finis totius stylo æqualis reducta: Ad plurimas poli eleuationes; pro parallelis Solis describendis, ex præscripto Num. 5. scholij cap. 9*]. — p. 159

- **XX.** For the altitudes of the Sun on the vertical at the beginning of any sign [*PRO altitudinibus Solis in Verticali in principio cuiuslibet signi*]. — p. 165
- **XXI.** For the distances of the Sun from the meridian when it is on the vertical at the beginning of any sign [*PRO distantijs Solis à Meridiano cum est in Verticali in principio cuiuslibet signi*]. — p. 167
- **XXII.** A table for converting parts of the equator into hours and their fractions [*TABVLA conuertendi partes æquatoris in horas, earumque fragmenta*]. — p. 169
- **XXIII.** A table for converting hours and their fractions into parts of the equator [*TABVLA conuertendi horas earumque fragmenta in partes æquatoris*]. — *ibid.*
- **XXIV.** A table for finding out the proportional part [*TABVLA pro parte proportionali eruenda*]. — p. 176

INDEX OF PROBLEMS OF THE NEW DESCRIPTION OF DIALS

[INDEX PROBLEMATVM NOVÆ Descriptionis Horologiorum]

- **I.** To investigate the declination of a given point of the ecliptic: the maximum declination being posited as gr. 23. min. 30 [*DECLINATIONEM dati puncti Eclipticæ inuestigare: posita maxima declinatione gr. 23. min. 30*]. — p. 181
- **II.** To compute the semidiurnal arc of any parallel of the equator, for a given altitude of the pole [*ARCVM semidiurnum cuiusvis paralleli Æquatoris, ad datam poli altitudinem supputare*]. — *ibid.*
- **III.** To compute the amplitude of rising, or of setting, of any point of the ecliptic, for any latitude of the place [*AMPLITVDINEM ortiuam, occiduamue cuiusvis puncti Eclipticæ, ad quamlibet latitudinem loci supputare*]. — *ibid.*
- **IV.** Given any vertical and its declination, to find out the altitude of the pole above it in any given latitude of the place [*DATO Verticali quocunque, eiusque declinatione, altitudinem poli supra ipsum in quauis data loci latitudine deprehendere*]. — p. 182

- **V.** Given any vertical and its declination, to find the inclination of its own meridian to the meridian of the horizon, in any latitude of the place [*DATO Verticali quocunque, eiusque declinatione, inclinationem propriij ipsius Meridiani ad Meridianum Horizontis, in quacunque latitudine loci reperire*]. — *ibid.*
- **VI.** Given any vertical and its declination, to compute how large its arc is between the horizon and the equator, and between its own meridian and the meridian of the horizon: likewise between the meridian of the horizon and the equator, and also between its own meridian and the horizon, for any latitude of the place [*DATO quolibet Verticali, eiusque declinatione quantus fit arcus ipsius inter Horizontem, & Æquatorem, atque inter proprium eius Meridianum, ac Meridianum Horizontis: Item inter Meridianum Horizontis, & Æquatorem, nec non inter proprium eius Meridianum, & Horizontem, ad quamlibet latitudinem loci supputare*]. — *ibid.*
- **VII.** To explore the altitude of the Sun on the prime vertical of any great circle serving as a horizon: and the hour, when the Sun is on that vertical, in any region [*ALTITVDINEM Solis in Verticali primario cuiusvis circuli maximi instar Horizontis: Et horam, cum Sol in eo Verticali existit, in qualibet regione explorare*]. — p. 182
- **VIII.** Given any vertical and its declination, to find out how large its arc is between the meridian of the horizon and the circle of the 6th hour from noon or midnight. Likewise between the horizon and the same circle of the 6th hour. And finally between the horizon and the circle of the 12th hour from sunrise or sunset, in any region [*DATO Verticali quouis, eiusque declinatione, quantus fit ipsius arcus inter Meridianum Horizontis, & circulum horæ 6. à mer. vel med. noc. Item inter Horizontem, & eundem circulum horæ 6. Ac denique inter Horizontem, & circulum horæ 12. ab or. vel occ. in quavis regione cognoscere*]. — p. 183
- **IX.** Given any plane, together with the altitude of the pole above it, to inquire how large its arc is between any hour-circle from noon or midnight and its common intersection with the equator [*DATO plano quolibet, cum altitudine poli supra illud, quantus fit ipsius arcus inter quemvis circulum hor. à mer. vel med. noc. & communem intersectionem eius cum Æquatore pofitus, inquirere*]. — *ibid.*
- **X.** If through the pole of any great circle a vertical is drawn at right angles to any great circle drawn through the poles of the world, to scrutinize how large the arc of that circle drawn through the poles of the world is, between that perpendicular vertical and the nearer pole of the world. Where we

have computed the aforesaid arcs for very many elevations of the pole on the horizontal dial [*SI per polum cuiusvis circuli maximi ad quemlibet circulum maximum per mundi polos ductum, Verticalis ad rectos angulos ducatur, quantus fit arcus circuli illius per mundi polos ducti, inter Verticalem illum perpendicularem, & polum mundi viciniorem positus, perscrutari. Vbi prædictos arcus ad plurimas poli eleuationes supputauimus in horologio horizontali*]. — p. 184

- **XI.** Given a diurnal arc of any number of hours, to investigate its declination, for any latitude of the place [*DATO arcu diurno quotcunque horarum, eius declinationem, ad quamvis latitudinem loci peruestigare*]. — *ibid.*
- **XII.** To seek out the arc of any great circle drawn through the poles of the meridian and any point of that same meridian, lying between the equator (or the meridian) and the great circle described by the intersection of the equator with the meridian, through any hour of the given parallel [*ARCVM cuiusvis circuli maximi per polos Meridiani, & quodlibet punctum eiusdem Meridiani ducti, posited inter Æquatorem vel Meridianum, & circulum maximum ex intersectione Æquatoris cum Meridiano per quamvis horam dati paralleli descriptum, exquirere*]. — p. 185
- **XIII.** To investigate the arc of the meridian between the equator and the greatest circle which is drawn out of any hour on the equator through a given hour on any parallel [*ARCVM Meridiani inter Æquatorem, & maximum circulum, qui ex quacunque hora in Æquatore per datam horam in quouis parallelo ducitur, inuestigare*]. — p. 186
- **XIV.** Given any vertical and its declination, to inquire how large the arc of the ecliptic is (the beginning of ♋ [Cancer], or of ♑ [Capricorn], being placed on the meridian above the horizon) between the meridian and the great circle which is drawn from the pole of the given vertical to the ecliptic at right angles [*DATO Verticali quolibet, eiusque declinatione, quantus fit arcus Eclipticæ (posito principio ♋, vel ♑ in Meridiano supra Horizontem) inter Meridianum, & circulum maximum, qui ex polo dati Verticalis ad Eclipticam ad rectos angulos ducitur, inquirere*]. — p. 187
- **XV.** To compute the altitude of the Sun above a given great circle at any hour, the altitude of the pole above it being known [*ALTITVDINEM Solis supra datum circulum maximum quacunque hora, cognita altitudine poli supra ipsum supputare*]. — *ibid.*
- **XVI.** To explore the circumference of any great circle (which serves as some horizon) between its own prime vertical and the vertical of the same

passing through the center of the Sun at a proposed hour, the altitude of the pole above it being known [*CIRCVMFERENTIAM cuiufuis circuli maximi, (qui instar Horizontis cuiuspiam fit) inter Verticalem eius primarium, & Verticalem eiusdem per centrum Solis hora propofita tranfeuntem, cognita altitudine poli supra ipsum, explorare*]. — p. 189

[INDEX TABVL. ET PROBL., continued]

- **XVII.** To render the segments of the hour-lines from noon and midnight, lying between the center of the horizontal dial and the parallels of the Sun, marked in parts of the tangents with respect to a whole sine of 1000 equal to the gnomon. Where not a few things are added which render the drawing of dials easier, things which did not come up in their proper places [*SEGMENTA linearum hor. à mer. & med. noc. inter centrum horologij horizontalis, & parallelas Solis posita, in partibus Tangentium respectu sinus totius 1000. stylo æqualis, nota efficere. Vbi non pauca adiiciuntur, quæ faciliorem horologiorum delineationem reddunt, quæ proprijs locis non occurrerunt*]. — p. 190
- Near the end we have added a **table of tangents**, the whole sine being set at 1000, which should always be kept at hand [*SVB finem adiecimus Tabulam Tangentium, posito sinu toto 1000. quæ semper in manibus habenda est*]. — p. 194
- Likewise **certain practical procedures** excerpted from the New Description of Dials, by which dials are readily drawn [*ITEM praxes quasdam excerptas ex Horologiorum noua descriptione, quibus expedite horologia describuntur*]. — p. 203
- Likewise a **most brief compendium** for drawing horizontal and declining dials [*ITEM Compendium breuiffimum describendorum Horologiorum horizontalium ac Declinationum*]. — p. 211
- Lastly, **notes on the New Description of Dials**, which also contribute very much toward the construction of dials [*VLTIMO Notas in nouam Horologiorum descriptionem; quæ ad horologia extruenda plurimum etiam conducunt*]. — p. 230

THE END. [*FINIS.*]

[End-of-volume blank leaves]

The three leaves of this opening carry no printed text of their own. They are the trailing blank leaves that close the volume, following the "FINIS." of the *Index*

Tabularum et Problematum of the *Horologiorum Nova Descriptio* (printed p. 243, transcribed in the prior batch).

Printed p. 244 (global — blank verso of the FINIS leaf.

This leaf bears no ink of its own. It shows only the faint offset / show-through of the preceding FINIS page printed on the other side of the same leaf: the ghost of the running header, of the last index entries (the "XVII." lemma and the "ITEM ..." entries), and of the word "FINIS" toward the middle. All of this text was already transcribed in the previous batch as the recto (printed p. 243) and is **not** re-transcribed here to avoid duplication.

- [Show-through only; no text is printed on this leaf.]
- Near the center of the leaf there is a faint show-through of what appears to be a small device or ornament [?], too indistinct to identify or describe.
- [Library stamp: oval ink stamp, "Bayerische Staatsbibliothek München" (Bavarian State Library, Munich), impressed near the foot of the leaf — modern ownership mark, not part of the 1612 printing.]

Printed p. 245 (global — blank leaf.

Blank. No printed text, ornament, or signature.

Printed p. 246 (global — blank leaf.

Blank. No printed text, ornament, or signature.

[End of volume — rear endpaper and inside rear cover]

These two final leaves carry no printed text of the volume itself. The book's live text closed with "FINIS." at printed p. 243 (the *Index Tabularum et Problematum* of the *Horologiorum Nova Descriptio*), and the leaves that followed were blank trailing leaves (prior batch). The two leaves here are the physical closing of the copy: the rear endpaper and the inside of the rear cover (the blind-tooled binding). No colophon, printer's device (in ink), or errata is present.

Global (nominal printed p. 247) — rear endpaper (free flyleaf).

This leaf bears no printed ink of its own. It carries only modern library annotations in pencil and the faint show-through of the ornamental binding on the leaf beneath it.

- [Margin: modern pencil annotation across the head of the leaf — a librarian's collation/quire tally, not part of the 1612 printing: 1-5 = 7

followed by a row of tally strokes xxxx xxxx xxxx xxx, then III. 84 (the last group underlined). A second, fainter pencil note beneath the first is largely rubbed away and illegible — it appears to begin Ma[?] 2[?] but cannot be resolved. [?]

- Toward the lower-center of the leaf there is a faint show-through of the crowned armorial medallion (crest with a rampant lion) that is blind-stamped on the facing inside cover — an offset of the binding, not printed matter. [Show-through only; no text on this leaf.]
- The remainder of the leaf is blank, stained, and foxed parchment/paper with no printed text, ornament, or signature.

Global (nominal printed p. 248) — inside rear cover (blind-tooled binding).

This is the inside of the rear board: a blind-tooled (blind-stamped) decorated leather binding, not a printed page. It shows a paneled design of concentric rectangular frames filled with floral/foliate roll-tooling and rosettes, enclosing a central oval medallion. Within the medallion is a crowned coat of arms bearing a rampant lion, with the letter s visible at the medallion's left edge. There is no printed text.

[This is the final leaf of the volume.]
