Translator Version 2

Upright reason dictates that the recipients of the good, of whatever type and level of beneficence it may be, must show gratitude and blessing to the beneficent person in every way possible, commensurate with the value of the beneficence. And one who has benefited all the people of the world — for example, one who invented a new instrument for the good of the world, or a good book — it is fitting for every discerning person, out of the obligation of love of fellow beings, to at least purchase it, so that the man will profit and his heart will be encouraged thereby to invent yet more good instruments in the world. And similarly, all other wise-hearted people will likewise strive and exert themselves to invent good things and instruments needed for the repair of the world and its perfection.

And therefore, whoever says: "What do I need this new instrument for?" — he does not act well towards the world. For if not for the man who invented it, where would you be? And what would your city do? And more than this, if the man did not exert himself, what would the world do?

— R. Pinchas Eliyahu Hurwitz, *Sefer HaBris HaShalem* (1797)

A note on the work

Tomus IV is Clavius's *Gnomonices* — the most exhaustive Renaissance treatise on gnomonics, the science of sundials and shadow-casting. Across eight books it develops the geometry of the gnomon's shadow and shows how to lay out sundials (horologia) of every kind — horizontal, vertical, inclined, on any plane and for any latitude — with the underlying spherical-astronomical theory of hour-lines, and a description of an instrument for drawing them mechanically. It is dense with construction diagrams and with tables of shadow lengths and hour-line positions.

A note on the translation process

This translation was produced with the [translation-pipeline](#). See the linked repository for details on the process.

This text is the product of a highly refined automated translation process. It has undergone only cursory human review and should not be treated as an authoritative or scholarly rendering. It is offered solely as a reference and reading aid — a way to make an otherwise inaccessible work approachable — and any passage of real consequence should be checked against the original source.

Opera Mathematica, Tomus IV (Gnomonices Libri Octo) — Front Matter

[Front cover / binding]

No text.

[Front flyleaf / pastedown]

Blank flyleaf with modern handwritten annotations in pencil:

- Upper left, a shelfmark: "[?] Math. [?] 10 – 4" (partly cropped at the left edge; the leading character(s) run off the page).
- Below it, centred, the author's name written by hand: "Clavius".
- Upper right, a faint pencil sketch (indistinct), and scattered ink/foxing spots across the leaf.

[Margin: the pencilled "10 – 4" and "Math." appear to be an old library class-mark; the "4" corresponds to this being Tomus IV.]

[Front flyleaf verso — offset of title page + library label]

This leaf is blank parchment/paper that has picked up a faint mirror-image **offset (set-off)** of the printed title page from the facing leaf. The title page itself is not in this batch (it falls on the next leaf); what shows here is only the transferred ink, very faint and reversed, and cannot be read cell-for-word. The large display capitals and a few text blocks are partly discernible but are transcribed only where legible; the remainder is [?].

Faintly discernible offset of the title-page display lines (reversed, low contrast — best readings, uncertain):

- CHRISTOPHORI [?] [Christophori — "of Christoph"]
- CLAVII [?] [Clavii — "Clavius"]
- OPERVM MATHEMATICORVM [?] [Operum Mathematicorum — "of the Mathematical Works"]
- TOMVS QVARTVS [Tomus Quartus — "Volume Four"]
- Continens [?] [Continens — "Containing"]
- Several lines of smaller text below, illegible in offset: [?]

- A mid-page line in capitals: OMNIA IN HAC [?] EDITIONE [?] [Omnia in hac ... editione ... — "All (things) in this ... edition ..."] [?]
- Lower on the leaf, the faint offset of the printer's device/vignette and imprint lines: [?]

[Illegible: full offset text of the title page — reversed set-off transfer, not the printed page itself; the actual title page is on the following leaf and will be transcribed there.]

Library markings physically on this leaf:

- A pasted barcode label reading 36613880400015 (printed twice), with a red over stamped S, and beneath: "Bayer. Staatsbibliothek" [Bavarian State Library — the holding institution].

Opera Mathematica, Tomus IV (Gnomonices Libri Octo) — Christoph Clavius

[Front flyleaf recto]

Blank leaf. At the top left, a modern pencil shelfmark in a later hand:

[Margin: "2 Math. u. 10-4" — later library shelfmark, in pencil.]

The rest of the leaf is blank; a faint reversed offset of the title-page text and a faint pencil sketch (an oval/instrument outline) show through from the facing leaf. No printed text.

Title page

CHRISTOPH CLAVIUS OF BAMBERG [Christophori Clavii Bambergensis], OF THE SOCIETY OF JESUS —

MATHEMATICAL WORKS, VOLUME FOUR [Operum Mathematicorum Tomus Quartus]

Containing:

- The eight books of **Gnomonics** [Gnomonices libros octo].
- The **construction and use of the instrument** most conveniently suited to laying out sundials [Fabricam et usum instrumenti ad horologiorum descriptionem peropportuni].

- **A new account of sundials** [Horologiorum novam descriptionem].
- **A very brief compendium for laying out horizontal and declining sundials** [Compendium brevissimum describendorum horologiorum horizontalium ac declinantium].
- **Notes on the new account of sundials** [Notas in novam horologiorum descriptionem].

The whole, in this edition, greatly enlarged and enriched both with other matters and — above all — with astronomical tables most useful for the construction of sundials.

Printer's device. The Jesuit emblem: a radiant oval cartouche framed by scrollwork and winged putti (three cherubs above blowing trumpets, two below). At the center, within an inner oval, the monogram **IHS** surmounted by a cross, with three nails beneath. Around the sunburst ring, the legible fragments of the motto, reading around the oval, are: **LAVDA-** (lower left) ... **NOMEN** (top) ... **DOMINI** (right) ... **-BILE** (left) — i.e. *Laudabile nomen Domini* ["Praiseworthy is the name of the Lord," cf. Psalm 112(113):3]. Some ring letters are obscured by the overlying manuscript inscriptions and are read only in part [?].

- Motto ring (top): NOMEN
- Motto ring (right): DOMINI
- Motto ring (lower-left/left): LAVDA...BILE [Laudabile]
- Center: IHS monogram with cross above and three nails below

[Margin: Above and flanking the device, manuscript ownership inscriptions in an early hand — "Monast[er]ii Schyren[is]" (of the Monastery of Scheyern), repeated as two flanking flourished signatures, "Mon[aster]ii" (left) and "Schyren[is]" (right). Reading of the flourishes is uncertain [?].]

MAINZ [Moguntiae], at the expense of Antonius Hierat [Antonii Hierat], printed by Ioannes Volmari [Iohannes Volmar]. With the grace and privilege of His Sacred Imperial Majesty [Cum Gratia & Privilegio Sacrae Caesar. Maiest.].

In the year 1612 [Anno M.DC.XII].

[Title-leaf verso]

Blank. The reversed bleed-through of the title-page text shows from the recto. Near the center, an oval library stamp:

[Approval stamp: "BIBLIOTHECA REGIA MONACENSIS" — Royal Library, Munich (Bayerische Staatsbibliothek).]

No printed text on this side.

To the Most Reverend and Most Illustrious Prince

To the Most Reverend and Most Illustrious Prince and Lord, Lord Johann Gottfried [Ioannes Godefridus], Bishop of Bamberg [Episcopus Bambergensis] and Provost of the Cathedral Church of Würzburg [Cathedralis Ecclesiae Herbipolensis], etc., his most gracious Lord —

Christoph Clavius of Bamberg, of the Society of Jesus [Christophorus Clavius Bambergensis e Societate Iesu],

wishes EVERLASTING HAPPINESS.

If, to the joy I took from your most auspicious inauguration, most Reverend and most Illustrious Prince, God the Best and Greatest [Deus Optimus Maximus] had added this further favor — that I might present in person, with my own hand, those fruits of my studies which I had dedicated to your name and glory — I would judge that almost nothing was lacking to the happiness that falls to us mortals. For what could have befallen me in life more delightful than to behold with my own eyes the Church of Bamberg — from which I have now been absent for many years, not by my own will so much as by God's dispensation — in that very condition which I used to beg of God in daily prayers that it might one day attain? And what more to be wished than to commend my books in person to the one man to whom, almost alone, we owe our thanks for how great a good it is that is celebrated with such applause of the whole Christian world?

But since I am hindered by the distance between us, and since an old age that grows heavier by the day keeps me confined to my bed, I have delegated my role to the Reverend Father Johann Reinhard Ziegler [Ioannes Reinhardus Zieglerus]. He, out of his remarkable love for the mathematical disciplines, has devoted a great deal of effort and labor to the editing of my Commentaries, and so may present these same works to your Highness in my name. From you I beg, again and again, that with the same love and goodwill with which you received the other volumes, you will be willing to accept this one too — which treats of

shadow-marking sundials [horologia sciotherica] — just as if it were being handed to you by my own hand: this I earnestly ask and beseech.

In this book I discuss at length the rising and setting of the Sun: at what moment of time, returning from the lower world, it reaches our horizon; with what swiftness of motion it then strives upward and climbs all the way to mid-heaven, where in full day it shines most beautifully and by its heat restores the strength of dying Nature. The recollection of this subject is all the more pleasant to me because it seems to bear a certain striking resemblance to Christian Princes.

For consider the face that all things tend to wear in the early morning, once the Sun has shone forth: the ill-omened birds are driven off into their hiding places, and the better birds begin to sing together; the grasses and flowers regain their beauty; and to the race of men and of cattle their native vigor returns into their limbs. Nearly the same is the transformation that provinces and cities tend to undergo when a man of that stamp is brought to the helm of empire — one whose proofs of virtue are so illustrious that no one can doubt he will require of others the same rule of life that he himself has kept. Then you may see the spirits of good men suddenly lifted up, taking hope and counsel toward the best of things, laying aside sloth and fear, and openly applying that line of the Poet:

Nothing need be despaired of with Teucer as leader and under Teucer's auspices.

By contrast, you may see the wicked, whom license had made bolder, lose heart, condemn their own base ventures, and look about for a way to flee. And you yourself, most Reverend and most Illustrious Prince, Germany lately beheld rising most happily like the Sun; and at that time it did not escape you what the disposition was of those who think rightly about the safety of their homeland and the standing of the Christian Commonwealth. This remains: that we obtain from God that, when you have happily risen to the highest summit of Virtue and Glory, He may grant you to remain at that same eminence for a very long time, and — so far as it can be — to set as late as possible. Rome [Romae], in the Year of the Lord 1612, on the Kalends of January.

GNOMONICS, IN EIGHT BOOKS

GNOMONICS, IN EIGHT BOOKS [GNOMONICES LIBRI OCTO], in which not only sundials [horologia solaria] but also other things that can be learned from the shadow of the gnomon are set out and demonstrated geometrically.

BY THE AUTHOR

CHRISTOPH CLAVIUS OF BAMBERG, OF THE SOCIETY OF JESUS [Christophorus Clavius Bambergensis, Societatis Iesu].

PREFACE TO THE GNOMONICS

By Christoph Clavius of Bamberg, of the Society of Jesus [Christophorus Clavius Bambergensis, e Societate Iesu].

Among all the arts and disciplines that God, the author of all things, has shared with the human race as tokens, so to speak, of his infinite wisdom, power, and majesty, by no means the least to be reckoned are those that the ancient philosophers called the Mathematical disciplines. For these are so thoroughly established that they admit nothing merely probable, but prove everything by clear and necessary arguments. And — as Ptolemy [Ptolemaeus], among others, acknowledged and professed — they draw men themselves toward searching out and cherishing the goodness of God; and by calling the minds of us all away from the craving for fleeting and perishable things, they urge us to fix our love upon the eternal and unchanging Good alone.

If this holds true of all the mathematical disciplines alike, how much more will it belong especially to Astronomy, which studies those heavenly spheres that the hand of God has fashioned with wonderful craftsmanship — spheres whose motion is so constant, and whose uniformity so great (even if there seems to be some disparity among them), that anyone who thinks carefully about them cannot help being carried away, once he has grasped their nature and motion, to admire and look up in wonder at the supreme Mover of them all.

Indeed, Astronomy cannot be praised as its dignity deserves. For it sets before us the magnitude of the heavenly spheres to behold; the utterly constant, yet varying, motion of the Sun; the fixed course of the Moon and of the remaining stars, their mutual conjunctions and their meeting with the Sun; the rising and setting of the stars, their arrangements, advances, and stations, their number, their extent, and their distance from the earth. I pass over what is by far the greatest thing of all: that there is a single science, Astronomy, which foretells the eclipses of the Sun and Moon, even though no fixed interval separates one eclipse from another, as experience itself shows. And the astronomers, striving to hand down to humankind — at least in part, and not only through the various records of written works — this admirable doctrine of the heavens, of the celestial bodies, and of their motions, went further: with an almost divine abundance of ingenuity

they invented many instruments in which, as in a mirror, one might survey the multitude and variety of the heavenly motions. Yet of all these instruments they devised none simpler, and none more readily made, than that timepiece which the Greeks call σκιοθηρικόν [Greek: skiothērikon, "shadow-catcher" — a sundial] and the Latins a *solarium* (sundial), on which the hours are read by the Sun. Its nature is such that, set in the sunlight, by the shadow of a single ray — that is, of a stylus [stylus] — it presents to view all the motion and position of the heavens, however varied, and above all that of the Sun. For on it, provided only that it is lit by the Sun, one can see what hour it is at any time of the year; which of the twelve parts of the sign-bearing circle — which the Greeks call ζωδιακός [Greek: zōdiakos, "zodiac"] — the Sun itself occupies; which house of heaven, and which Vertical [circle], and which

parallel of the Horizon it holds; what sign is beginning to rise above the Horizon, or to set; to what hour, in the other regions of the earth, any given hour corresponds; and the meridian of what place the Sun occupies at any hour.

Now the science that is concerned with the construction of this one instrument is called — from the gnomon (ἀπὸ τοῦ γνώμονος [Greek: apo tou gnōmonos, "from the gnomon"]) — γνωμονική [Greek: gnōmonikē, "gnomonics"]. Although many writers, both ancient and more recent, have written a great deal about it, none of them — in my judgment at least, and I say this to disparage no one — seems to have pursued it fully in every respect. For either they hand down the bare practice, the method by which sundials can be made, without applying any demonstration to their rules, as nearly all the more recent writers do; and from this they fall into errors that are quite intolerable, as is clear from Oronce Finé's [Orontius Finaeus] commentary on sundials. Or else, if some have tried to test those rules by the weight of demonstrations, they do it so briefly, and indeed so obscurely, that scarcely any usefulness can be gained from their labors.

Since, then, some men of great intellect complained to me of this and asked me to devote some effort and diligence to the science of gnomonics — so elegant, so pleasant, and moreover useful for so many purposes — I put a great deal of study and time into writing these books. In them my aim is to demonstrate, with the greatest possible clarity, not only the method by which hour-lines of every kind may be drawn on any plane surface, but also many other matters that bear on the motion of the Sun and of the heavens.

I have enclosed the whole work in eight books. In the **first**, various problems and theorems are demonstrated that bear on the analemma [analemma], on the conic sections, on the hour-circles, on the common intersections of the hour-lines, on

the declinations and inclinations of planes, and on other things of this kind. In the **second**, the method of laying out horizontal, vertical, meridian, polar, and equinoctial sundials. In the **third**, how sundials may be drawn that either decline from the prime vertical [Verticale primarium] or from the horizon, or are inclined to the horizon, or at once both decline from the vertical and are inclined to the horizon. The **fourth** deals with sundials on the right sphere [sphaera recta] and on the most oblique sphere — the one that has the pole at the zenith. It also explains by what technique the stylus is set in its proper place; what the method is of recognizing for what elevation of the pole, or what declination, or what inclination any given sundial appears to have been constructed; and by what procedure any sundial may be enlarged or reduced to suit any size of stylus. The **fifth** teaches by what means and method certain tables are to be constructed, by which sundials may afterward be drawn with little trouble. The **sixth** expounds Ptolemy's *Analemma* [Ptolemaeus, *Analemma*], and likewise Federico Commandino's [Federicus Commandinus] work on the drawing of sundials; from it, it becomes clear that the use of the analemma extends, unless I am mistaken, far more widely than Ptolemy handed down in his writings. I also add an easier method for declining and inclined sundials than the one Commandino showed — [teaching], moreover, what must be observed so that, from a horizontal sundial, another may be laid out on a wall (one whose declination is nonetheless known), for any size of stylus. In the **seventh**, the principal methods of drawing the hour-lines — which were discussed in the second and third books — are briefly repeated; yet no demonstrations are added here, so that those who are not very practiced in geometrical demonstrations may be able to construct any sundial without difficulty — with no demonstration interposed, and no delay. The **eighth** and last book, finally, deals with certain universal sundials, which are suited to every elevation of the pole, and also with some others that can be carried about and are of use for one elevation of the pole only — whichever shall seem to us the more serviceable. And so, unless my mind quite deceives me, I seem to have embraced in these eight books, arranged in this way, everything that properly belongs to gnomonics.

As for the scholia I have attached to most of the propositions, this was done with the following purpose: either to explain, in those scholia, whatever helps toward a clearer understanding of the proposition's demonstration; or to investigate by other routes the same things that were demonstrated in the propositions; or, finally, to put forward something new, not out of keeping with the plan of the work. For had I thrown everything into the propositions, I would have wearied the reader by the very length.

In the demonstrations we shall cite our authorities from Euclid [Euclides] and from our scholia upon him, according to our own edition; from Apollonius of Perga [Apollonius Pergaeus] on the elements of conics, according to Federico Commandino's edition; and from Theodosius [Theodosius] on the spherical elements, likewise according to our own edition. I shall also bring in the books on triangles of Johann of Königsberg [Regiomontanus], or those of Jabir of Seville [Geber Hispalensis], the Arab, on spherical triangles, or my own [treatise on] spherical triangles — which, together with Theodosius, and with a treatise and table of sines gathered into a single volume indispensable to the whole of Astronomy, will shortly appear. And so anyone who has not diligently applied himself to these matters has no reason to be confident that he can understand our demonstrations in this Gnomonics — although I teach the drawing of everything in such a way that anyone, even one wholly unskilled in all demonstrations, can grasp for himself what he must observe in carrying it out.

I should also like the reader to be warned of this: that all the sundials in this Gnomonics have been worked out for the latitude of the kindly City of Rome [Roma], even though the rules themselves are common to any elevation of the pole, or latitude of a place. In the scholia of the second and third books, too, and throughout the seventh, I teach how sundials may be drawn from any given size of stylus — whose position on the plane of the sundial is also assigned — a thing that no one before me (so far as I know) has ever accomplished, since almost everyone draws the sundial before determining the size of the stylus. One man, to be sure — Federico Commandino — does the same; but he does it by way of the analemma, and not by the method that most of those who lay out sundials commonly follow. Nor indeed shall I omit to mention that I have attempted, by an unusual method as well — a certain new approach by way of the cylinder — to draw the hour-lines on any plane whatever; and this method (I would venture to say) is the only one among them all by which all the hours, and the parts of the hours, can be conveniently drawn, as will be seen in the second and third books.

Therefore, if in this work I shall have brought some light to those who study so noble and delightful a science, I wish the credit for it to be referred to God, the author of all good things. But if I have satisfied the great minds of others less fully than I ought, or would have wished, I judge this must be ascribed both to the slenderness of my own talent and to the difficulty of the subject — seeing that in most matters I had no guide whom I could follow in any way, and nearly all the demonstrations were only recently thought out by me, as anyone will readily judge who cares to compare this Gnomonics of ours with the sundial-writings of others. Yet I believe I have opened up the road in this matter so well that it will be

easy for anyone — even one of only moderate understanding in geometrical demonstrations — to go forward of his own accord, and to put the finishing touch upon this science and, as it were, to set the crowning peak upon the work I have begun.

GNOMONICS, BOOK ONE

By the author, Christoph Clavius [Christophorus Clavius] of Bamberg, of the Society of Jesus

Since all those things that can be known through the shadow of the gnomon when the Sun shines, we have undertaken to describe in this our *Gnomonics* by careful reasonings — that is, by the firmest geometrical demonstrations and, as far as it can be done (with the good help of God, the Best and Greatest), by the clearest ones — and since very few before us have done this (for we see that all the rest, with one or two exceptions, have handed down a bare description of these matters, applying no demonstration at all), we judge it will not be out of place to spend this whole first book on various problems and theorems, together with matters to be explained both geometrically and astronomically. These, I say, we judge will be greatly profitable — indeed altogether necessary — so that afterwards the individual points bearing on the description of sundials can be demonstrated more briefly and more clearly.

Now the matters that seem to us to require demonstration, before we describe any sundial, are chiefly these. [Margin: The argument of the first book.] By what method the analemma [analemma] — from which alone almost the whole rationale of describing sundials is drawn — is to be constructed; that the vertex of the gnomon in any sundial takes the place of the center of the whole world in sundials; what conic sections [sectiones conicae] (which some call arcs of the signs) are traced in any proposed plane by the tip of the gnomon's shadow — that is, whether they are circles, or parabolas, or opposite hyperbolas, or indeed ellipses; then by what art sections of this kind are to be laid out in the proposed plane (for the tip of the shadow always runs along some one of these sections, except at the time of the equinoxes, when the tip of the shadow describes a straight line, as we shall demonstrate); what position the hour-circle [circulus horarius] has in the heavens, so that we may afterwards correctly draw the hour-lines [lineae horariae], which are nothing else than the common sections of those circles and of the plane on which the sundial is depicted; which hour-lines from noon or midnight, and from sunrise or sunset, intersect one another at one and

the same point in any given plane (for this will be of great use in laying out the hours from sunrise or sunset); in which planes the hour-lines from noon or midnight meet at a single point, as at some center, and in which they are parallel to one another; by what means the declination of each proposed plane from the vertical circle, and its inclination both to the horizon and to the meridian, may be ascertained; how great the elevation of the pole is above any declining or inclining plane, and other matters of the kind that will be seen to bear on such declining and inclining planes and to serve the purpose; by what device the declination of a parallel — whose diurnal arc is known — may be investigated; and finally many other things, without which the demonstrations we shall employ in laying out sundials cannot in any way be carried out or understood.

To all these will be added three further problems, by which the semidiurnal arc, the magnitude of twilight, the altitude of the sun from the known hour of the day, and conversely the hour from the altitude of the sun at any time of the year and for any elevation of the pole or latitude of the place, may be found out. So much for the argument of this first book. Now, before we approach the matter itself, a few things seem to need saying first about timepieces [horologia] in general, and about their necessity and invention. Then, too, about sciotheric [shadow-] timepieces, which pertain more closely to our Gnomonics, and about their various kinds and inventors; and finally the variety of the hours must be briefly treated.

On timepieces in general, and their necessity and invention

[Margin: What a timepiece is. What an hour is. From what the hours are named.]

The very word "horologium" [horologium] shows that a timepiece is an instrument by which the hours are marked out or detected; for it signifies, as it were, "the reckoning of the hours" [horarum ratio], so that whatever in some way indicates the hours may be called a horologium. An hour is one of those equal spaces into which the day is customarily divided. For although among the ancients the four seasons of the year — spring, summer, autumn, and winter — were called "hours" [horae], from the Greek ἀπὸ τοῦ ὁρίζειν [Greek: apo tou horizein, "from bounding/defining" — the verb ὁρίζειν, "to bound"; glyphs faint], as Plato [Plato] holds in the *Cratylus*, because they bound and define those parts of the year, yet today we call those equal spaces of the day "hours" because, as Macrobius [Macrobius] holds (*Saturnalia* I), the sun produces them by its own course and motion — the sun which among the Egyptians was called Horus (for so they named Apollo [Apollo], who is the same as the sun).

Others, however, prefer that the hours be named from the Greek word ὥρα [Greek: horos, "boundary" or "limit"], which signifies a boundary or an end, because we mark off and terminate that continuous span of time by the hours as by boundaries. Finally, in tracing the derivation of the word "hours" one has even come down to filth. For there are those who would hold that these equal little parts of the day are called "hours" from the Greek word [Greek: [?]] — the word meaning "urine" (οὔρον/οὐρεῖν); printed glyphs too faint to resolve], which means urine. For they say that Hermes Trismegistus [Hermes Trismegistus] first observed the hours — that is, the equal spaces of the day — from the urine of a certain animal sacred among the Egyptians, which was dedicated to Serapis, that is, to the sun. For when he had noticed that this animal (a truly ridiculous thing, and more worthy of the Egyptians than of Trismegistus) passed urine twelve times by day and as many times by night — whether the night were long or short — always at equal intervals, he thought it agreeable to reason to divide day and night into just as many equal spaces, which were named "hours" from the urine of that animal. Hence perhaps it came about that almost the whole of antiquity divided every day and night into twelve hours. But on this matter we shall say more a little later.

[Margin: The necessity of timepieces.] As for the necessity of timepieces, there is no reason for me to spend many words. For I think it escapes no one how wretched and unhappy the human race would be if it had no way of distinguishing the hours. For we see that most people (as each of us also finds in himself) who do not know what hour it is are affected — like those who do not know in what region they are — by a kind of numbness of mind, and, in my judgment, not without reason. For by the distinction of the hours individuals measure out their several labors and their leisure, and set themselves fixed times for all their occupations. Indeed, since the life of men is for the most part taken up with dealings and meetings, we truly could not do without the use of timepieces, since by their benefit we appoint for ourselves certain hours and certain spans of time in which we can conveniently come together to carry out our affairs, without any loss to our household or other concerns.

Nearly all well-ordered states bear witness to this very thing: in their cities and towns they everywhere build, at public and private expense, various kinds of timepieces — sundials and others — and maintain keepers and overseers of them at yearly salaries; which they would do on no sound reasoning, unless they judged the use of these to be of the highest necessity to their communities. Almost all farmers and men living apart bear witness to the same thing too: since they have no timepieces, and yet cannot do without them without great

inconvenience, they strive to relieve this inconvenience by whatever means they can. Hence we see them for the most part measuring the shadow of their own bodies, or marking one sign after another by the sun's rays, or finally noting in the sky itself certain intervals of the sun's motion by day and of the other stars by night — so that by these observations at least, even if not wholly accurate ones, they may in some way perceive and measure off the distinctions and spans of the hours.

[Margin: The various kinds of timepieces.] Since, then, the knowledge of the hours is so useful, and indeed so necessary to all commonwealths, our forebears with the greatest zeal always devised varied and ingenious instruments (which we call *horologia*) by which we might tell apart the intervals of the hours. All of these can be brought back to two kinds. Some, by the shadow of the sun alone by day, or by the shadow of the moon by night, or by the observation of the other stars, indicate the hours — of which we shall write more below. Others show the hours by some mechanical instrument and by various motions, and these are manifold. For since the former sundials would show no hours at all in cloudy weather, it was necessary to find another way of marking the hours. Hence it came about that some made use of water-timepieces [*hydraulica horologia*], in which the hours are sought out by the aid of the motion of water — a matter in which Ctesibius of Alexandria [Ctesibius] was wonderfully praised. For he, as Vitruvius [Vitruvius] reports in book 9, by marvelous ingenuity constructed (to use the words of Vitruvius) a hollow made of perfect gold, or bored out of a gem, since such materials are neither worn away by the striking of the water nor take in dirt so as to be clogged. For the water flowing uniformly through that hollow raised up an inverted float [*scapus inversus*], on which a ruler was set; and the revolving drums fitted with equal teeth are made complete — the teeth of which, driving one another, produce measured turnings and motions, and the rest of this kind — from which the parts of the day, that is, the hours, could be known and distinguished.

Pliny [Pliny], at the end of book 7, writes that Scipio Nasica [Scipio Nasica] first divided the hours of night and of day alike by water, in the year of the City 595. But some set out certain bronze vessels filled with water and finely perforated; for according to how much of the water fell into another vessel, when they examined the inscribed marks, they understood how much time had elapsed. Such timepieces they called *clepsydrae* [*clepsydrae*], from the likeness of the perforated vessel, because they in a way "steal" the water and pour it out drop by drop, sending it from vessel to vessel through a narrow hole. Hence we often read that orators were granted three or four *clepsydrae* — that is, hours — for

speaking in olden times. Others assert that those vessels were of finely perforated glass, in which the hours were marked out by equal measures, and at the bottom of which that little hole let the water out drop by drop, so that by the diminishing of the water the elapsed hours were detected.

To these, in this age of ours, have succeeded certain timepieces made of glass, which have enclosed within them very fine sand or dust that slips down bit by bit through a very small hole from the upper part into the lower, and show the elapsed hours in this way. But beyond doubt all the timepieces so far enumerated are surpassed in many respects by that timepiece which, almost in our own age, has been invented by marvelous artifice and ingenuity — assembled from certain toothed wheels, balanced by weights, [set] to mark the hours and the parts of the hours, and to demonstrate the celestial motions, and other very convenient things of this kind. But we shall write nothing in this work about these mechanical timepieces, since they are foreign to our design. Therefore let us return to the former timepieces, which we have said indicate the hours by the shadow of the sun or by the rays of the other stars.

On sciotheric timepieces and their various kinds

All the timepieces which we said just before show the hours by the shadow of the sun alone are usually called "solar" [solaria] by writers, or "sciotheric" [sciotherica], from the shadow of the sun; for σκιόθηρον [Greek: skiothēron, "a place suitable for catching the shadow"] means a spot fit for catching the shadow. Hence σκιόθηρα [Greek: skiothēra, "shadow-catchers" — mathematical instruments for taking the shadow] are the mathematical instruments by which shadows are usually caught, so that a sciotheric timepiece is an instrument in which, by the shadow of the sun or of the rays of the other stars — which are like a shadow — a fixed hour of the day and its quantity, the rising and setting of the sun, the signs of the zodiac in which the sun is, and very many other things bearing on celestial matters are shown by artifice. [Margin: What a sciotheric timepiece is. The various kinds of sciotheric timepieces.] Now a sciotheric timepiece can be divided in many ways. For first, some are called "hanging" [pensilia], because they hang freely from the hand and, when directed toward the sun or any other stars, let us know the hours: such are all those we use, whether with pinnacidia [pinnacidia] — that is, certain little tablets perforated with square holes, such as are usually fixed in the dioptra of an astrolabe — or with some very small hole, or finally with a thread and plumb-line, on which a certain movable little knot is sometimes placed for distinguishing the hours; of which kind are astrolabes, cylinders, quadrants, astronomical rings, hour-rings

[horaria], and others of this sort, which we shall treat in the eighth book. But others are "fixed" [stabilia], and require a certain settled position in some plane, so that it is not necessary for them to hang — those, namely, which show the hours by the shadow of a gnomon or stylus. And these are distributed into two kinds. For some are laid out on a plane surface, which is equidistant from some celestial great circle; others on a surface that is not plane — as on a concave or convex hemisphere, or on a cylinder, convex or concave, or on any other non-plane surface — and these are depicted as we shall write in the eighth book. For now let us review the kinds of those that are described on plane surfaces, with which we shall chiefly be concerned in this work.

[Margin: Solar timepieces are divided by reason of the great circles from which they are equidistant, and from which they take their name.]

Of solar timepieces, then, that are described on some plane surface, there are very many kinds, according to the multitude of the celestial great circles from which the plane surfaces of the timepieces are equidistant, and from which the timepieces themselves have taken their names, as we shall teach in proposition 2 of this book. But since chiefly nine great circles can be considered in the heavens, differing in position and situation, it comes about that there are just as many kinds of timepieces that are described on some plane surface. The great circles are these: the Horizon; the Vertical circle properly so called, passing through the vertex of the head; the common sections of the Equator and of the Horizon; the Meridian; the circle of the sixth hour from noon or midnight, [passing] through the poles of the world and through those same common sections of the Equator and Horizon; the Equator; any Vertical circle deflecting from the properly-so-called Vertical and perpendicular to the Horizon; a great circle declining from the Horizon and passing through the common sections of the Meridian and of the Horizon, and perpendicular to the Vertical properly so called; a great circle inclined to the Horizon, described through the common sections of the Equator, of the Vertical properly so called, and of the Horizon, and perpendicular to the Meridian; and finally a great circle inclined to the Horizon, to the Meridian, and to the Vertical properly so called. Now since each of these circles except the Horizon has two faces, which can be lit by the sun during the day — as the Vertical properly so called, and likewise the one that declines from it, has one face verging toward the south and another looking toward the north; the Meridian one that looks toward the rising and another that looks toward the setting; and all the remaining circles inclined to the Horizon have an upper face, which looks toward the Zenith or vertex of the head, and a lower one, which

looks toward the Nadir — it comes about that in all there are seventeen kinds of timepieces of this sort, which may be named as follows:

[Margin: How many kinds there are of solar timepieces that are described on a plane surface.]

1. HORIZONTAL, which is equidistant from the Horizon.
2. VERTICAL looking toward the south, which is parallel to the Vertical circle properly so called, and looks toward the south.
3. VERTICAL verging toward the north, which is equidistant from the same Vertical circle, and looks toward the north, or the Bear [Septentrio].
4. MERIDIAN Eastern, which is equidistant from the Meridian circle, and verges toward the sun's rising.
5. MERIDIAN Western, which is parallel to the same Meridian circle, and looks toward the setting sun.
6. POLAR upper, which is equidistant from that greatest circle passing through the points of the true, or equinoctial, rising and setting (that is, through the common sections of the Equator, the Horizon, and the Vertical) and through each pole of the world, and looks toward the Zenith.
7. POLAR lower, which is equidistant from that same greatest circle drawn through the points of the true, or equinoctial, rising and setting, and through each pole of the world, and looks toward the Nadir.
8. EQUINOCTIAL upper, which is parallel to the Equinoctial circle, and looks toward the pole raised above the Horizon.
9. EQUINOCTIAL lower, which is equidistant from the same equinoctial circle, but looks toward that pole of the world which lies hidden beneath the Horizon.
10. DECLINING from the south toward the rising or setting, which is equidistant from any Vertical circle that declines from the properly-so-called Vertical and verges toward the south, yet is not directly, and is perpendicular to the Horizon; such as is usually depicted on the wall of some building that looks toward the south, but not directly, and is perpendicular to the Horizon.

11. DECLINING from the north, or Bear, toward the rising or setting, which is parallel to any Vertical circle that deflects from the primary Vertical and looks toward the north, yet not directly, and is perpendicular to the Horizon; such as is described on the wall of any building that is perpendicular to the Horizon and looks toward the north, but not directly.
12. DECLINING from the Horizon, upper, which looks toward the Zenith and verges directly toward the rising or setting, and is equidistant from the greatest circle that is inclined to the Horizon and perpendicular to the primary Vertical, and passes through the common sections of the Meridian and of the Horizon. Such a timepiece would be depicted on the upper face of some roof that would be perpendicular to the Vertical circle properly so called — that is, looking directly toward the rising or setting.
13. DECLINING from the Horizon, lower, which looks toward the Nadir and verges directly toward the rising or setting, and is equidistant from the same greatest circle to which we said the upper one is parallel. Such a timepiece would be described on the same roof on which the upper one [is set], but on the lower face that looks toward the Nadir — provided, however, that this lower face were lit by the sun.
14. INCLINED to the Horizon, upper, which looks toward the Zenith and verges directly toward the south or north, and is equidistant from the greatest circle inclined to the Horizon, which is perpendicular to the Meridian and passes through the common sections of the Equator and of the Horizon. Such would be a timepiece laid out on the upper face of some roof that would be perpendicular to the Meridian — that is, looking directly toward the south or north.
15. INCLINED to the Horizon, lower, which looks toward the Nadir and verges directly toward the south or north, and is equidistant from the same greatest circle to which we said [the upper one] is parallel. Such would be a timepiece depicted on the lower face of the same roof, on whose upper face we said the previous one is drawn.
16. DECLINING and INCLINED together, upper, which looks toward the Zenith, but verges neither directly toward the south or north (as does the one inclined to the Horizon), nor toward the rising or setting (as does the one declining from the Horizon). It is nonetheless equidistant from a greatest circle that is perpendicular neither to the Horizon, nor to the Vertical properly so called, nor to the Meridian, but is inclined to all these circles —

so that it passes through the poles of none of them (namely the Zenith and Nadir, the common sections of the Meridian and Horizon, and the common sections of the Horizon and Equator). Such would be a timepiece drawn on the upper face of some roof that looked neither directly toward the rising or setting, nor toward the south or north.

17. DECLINING and INCLINED together, lower, which looks toward the Nadir, but has everything else in common with the upper one. Such would be a timepiece laid out on the lower face of the same roof, on whose upper face we said the previous one is described.

[Margin: Examples of the aforesaid timepieces.]

We will set all these kinds before the eyes in the accompanying figure. A timepiece drawn on the plane ABCD, which is equidistant from the Horizon, will be called Horizontal. Then, if we imagine buildings erected upon the several bases — octagonal, hexagonal, square, and triangular — the walls standing on the straight lines EF and GH, set directly toward A (the south point) and toward C (the north point), and on their faces turned toward A there will be described Vertical timepieces looking toward the south. On the faces of those same walls looking toward C, Vertical timepieces facing the north will be laid out. Further, on the walls erected upon the straight lines IK and LM — which, toward B, look directly toward the rising, or, toward D, toward the setting — Eastern Meridian timepieces will be described on their faces looking toward B, while on the faces looking toward the point D, Western Meridian timepieces will be described.

Again, if upon the straight lines EF and GH planes are imagined inclined to the Horizon toward the north, C, according to the

Diagram. A plan view (bird's-eye) of the horizontal dial-base ABCD, with several concentric regular polygons — an octagon, a hexagon, a square (tetragon), and an innermost triangle — nested about a common centre. These represent the bases of buildings of different plan that could be erected on the horizontal plane; the walls raised on the polygon sides carry the vertical, meridian, declining, and inclined dials described in the surrounding text. The four cardinal directions are printed outside the circle: **MERIDIES** (south) at the top, **SEPTENTRIO** (north) at the bottom, **ORTVS** (rising/east) at the left, **OCCASVS** (setting/west) at the right.

- A (top, at Meridies): south point of the plane ABCD.
- C (bottom, at Septentrio): north point.
- B (left, at Ortus): east point.

- D (right, at Occasus): west point. The two straight lines A–C (meridian) and B–D cross at the centre and divide the figure.
- E, F (repeated at the upper vertices of the several concentric polygons, flanking A): ends of the walls EF set across the meridian toward the south.
- G, H (repeated at the lower vertices, flanking C): ends of the walls GH set across the meridian toward the north.
- I, K (repeated at the left vertices, flanking B): ends of the walls IK toward the rising.
- L, M (repeated at the right vertices, flanking D): ends of the walls LM toward the setting.
- The corner/diagonal vertices carry the paired labels of the declining walls: E–I and F–L (upper), G–K and H–M (lower), corresponding to the walls EI, HM, FL, GK named in the text.
- At the very centre a small square encloses a triangle; its labels (including a central letter read as Q) are too small to resolve with certainty [?].

the altitude of the pole, the timepieces described on the upper faces will be called Upper Polar, and those on the lower faces, Lower Polar. But if upon the same straight lines EF and GH planes are imagined inclined to the Horizon toward the south, A, according to the altitude of the Equator (that is, the complement of the pole's altitude), Upper Equinoctial timepieces will be laid out on the upper faces, and Lower ones on the lower faces.

Now, since the walls perpendicular to the Horizon, standing on the straight lines EI and HM, do not look directly toward A (the south point) or toward C (the north point), but decline from both toward B (the east point) or toward D (the west point), there will be described on their faces looking toward the points located between A and B, timepieces declining from the south — that is, from the south point A toward the rising; while on the opposite faces, which look toward the points located between C and D, timepieces declining from the north — that is, from the north point C toward the setting. Conversely, since the walls built upon the straight lines FL and GK, perpendicular to the Horizon, do not verge directly toward A (the south point) or toward C (the north point), but decline from both toward D (the west point) or toward B (the east point), there will be laid out on their faces that look toward the points located between A and D, timepieces declining from the south — that is, from the point A (south) toward the setting; while on the faces

on the opposite faces, turned toward the points between C and B, timepieces declining from the north — that is, from the point C (north) toward the rising.

But if upon the straight lines IK and LM planes are constructed toward the rising B or the setting D, inclined to the Horizon, upper timepieces declining from the Horizon will be described on their upper faces, and lower ones on their lower faces. Likewise, if upon the straight lines EF and GH planes are inclined to the Horizon toward the south A or toward the north C, the timepieces drawn on their upper faces will be called upper ones inclined to the Horizon, and those described on the lower faces, lower ones. Finally, if upon the straight lines EI, HM, FL, GK planes are inclined to the Horizon in any way whatever, upper timepieces both declining and inclined will be described on their upper faces, and lower ones on the lower faces.

From this it is easily gathered that there can be almost infinitely many kinds of timepieces — declining from the Vertical, declining from the Horizon, inclined to the Horizon, and both declining and inclined together — because a single surface can deflect from the vertical or the horizon more or less to infinity, and incline toward the Horizon. In this way, then, sundials [*sciotherica horologia*] are usually classified, with regard to the position of the planes on which they are drawn.

[Margin: Why plane timepieces are said to be equidistant from the greatest circles from which they take their name.]

Now, all these timepieces that we have surveyed we said to be equidistant from those greatest circles from which they draw their names, because the tip of the stylus, set perpendicular to the timepiece's plane, is understood to be placed at the centre of the world, and so at the common centre of all those greatest circles. From this it follows that the planes of the timepieces are distant from those circles only by as much as the length of the respective stylus. For this reason those are mistaken who teach that all timepieces are drawn on the very greatest circles from which they receive their names. But we shall explain this more fully in Proposition 2 of this book.

[Margin: A division of solar timepieces drawn from the time at which they show the hours.]

In another way, the instruments that indicate the hours are usually divided according to the time at which they show them. Some are called diurnal, because they indicate the hours only in the daytime, when the sun shines; some nocturnal, which show the hours at night, whether by the shining of the moon or by the other stars; and some, finally, both diurnal and nocturnal, since we learn the hours from them both by day and by night — such as astrolabes (or planispheres), astronomical rings, and the like. In the same way, some indicate

the hours through half the year — such as the Upper Equinoctial timepiece, which indicates the hours during that part of the year when the Sun moves from the beginning of Aries [γ] to the beginning of Libra [$\underline{\alpha}$] — while others do so through the remaining part of the year, such as the Lower Equinoctial, which shows the hours while the sun moves from the beginning of Libra [$\underline{\alpha}$] to the beginning of Aries [γ]. Again, some indicate only the morning and evening hours — such as the Vertical timepiece facing north, the Lower Polar, and certain other declining and lower inclined dials; others indicate the remaining hours of the day — such as the Vertical inclining toward the south, the Upper Polar, and likewise some declining and upper inclined dials. So too, some timepieces indicate only the forenoon hours — such as the Eastern Meridian — while others indicate the afternoon hours, such as the Western Meridian. And in this way many other kinds of timepieces can be devised.

DE QVADRVPLICI HORARVM, atque ex ipsis horologiorum varietate.

[On the Fourfold Kinds of Hours, and the Variety of Timepieces arising from them]

[Margin: Division of the hours. The unequal hour. Why the hours are called "ancient" and "unequal."]

We have set out the various kinds of timepieces according merely to the differing position of the planes on which they are drawn; now let us speak of the four kinds of hours, by which each of the aforesaid species of timepieces is made fourfold. To begin with, there are two primary kinds of hours, distinct from each other: the ones are called unequal, the others equal. An unequal hour is a twelfth part both of the artificial day and of the artificial night. For of old every artificial day, and every night, was divided into 12 parts equal among themselves, which are called by writers "unequal" and "ancient" hours: "ancient," because their use existed among all the ancients; "unequal," not because the hours of a single day or night are unequal among themselves (that would be false, since we have asserted that any day and night is divided into 12 equal parts), but because, since artificial days and nights are unequal, the hours of the longer day or night are greater than the hours of the shorter day or night. For when two unequal magnitudes are divided into an equal number of parts, each part of the greater magnitude comes out unequal to — that is, greater than — each part of the lesser. Again, such twelfth parts of the day or night are called unequal hours because, although both the artificial day and the artificial night consist of twelve equal

hours, yet in an oblique sphere the day is perpetually unequal to its own night — except at the time of the equinoxes, when the sun is at the beginning of Aries [γ] or Libra [ϖ] — and so it necessarily follows that the diurnal hours are unequal to the nocturnal. Finally, such hours are called unequal because they never — except at the equinoxes — agree with the equinoctial hours, which are called equal (as we shall show presently), but are always either smaller (as the diurnal hours in winter and the nocturnal in summer) or greater (as are the diurnal hours in summer and the nocturnal in winter).

[Margin: Why the ancients cut every day and night into 12 hours.]

But why the ancients established twelve diurnal hours and as many nocturnal, we have partly recalled above, when we discussed the etymology of this word "hour," and partly we shall disclose here. It is plainly established that the ancients always had great regard for the time in which the several parts of the Zodiac rise above the Horizon. Hence it appears that they instituted the hours from the parts of the Zodiac, and not without reason. But since there are twelve principal parts in the Zodiac — namely the twelve celestial signs, six of which rise on any given day and as many on any given night, as we taught in the [treatise on the] sphere — if they had assigned one hour to each sign, they would have established only six hours in each day and in each night, and would have made them longer than is fitting. Therefore it seemed good to them to assign an hour to each half of a single sign emerging above the Horizon. Thus it came about that they divided any day and night into 12 hours. These unequal hours the Jews of old used, as is established from Holy Scripture, as did the Romans and almost all of antiquity, as both the histories and the books of the ancient Mathematicians attest. For these divided the night into four watches, assigning three hours to each watch. Indeed, the Roman Church too appointed the praises of God Most High and Greatest — which from the name of the hours are indeed called "canonical hours," but by number are called Prime, Terce, Sext, and None — to be chanted according to this kind of hours.

[Margin: The equal hour. Why the hours are called "equinoctial" and "equal."]

An equal hour, however, is the twenty-fourth part of the natural day, which is made up of day and night. Now, because the Equinoctial circle, containing 360 degrees, is carried round once in a day, and everywhere among all peoples rises wholly above the Horizon (we here disregard that small portion which corresponds to the little bit of the Zodiac that the sun meanwhile traverses by its own motion), 15 degrees must necessarily rise each hour. For this reason these hours have been called "equinoctial," because, namely, they are produced by the

revolution of the equinoctial circle. They are also called equal; for the 15 degrees of the Equator that are assigned to each hour always rise above the Horizon in an equal interval of time — since in every region the equinoctial circle is uniformly raised above and depressed below the Horizon, as we have shown elsewhere.

Furthermore, these equal hours not all nations of old numbered in the same way, just as they do not today; because not the same beginning

of the natural day was established among all peoples. For the Babylonians — as Pliny [Plinius] (Book 2) and Macrobius (*Saturnalia*, Book 1) attest — called the day the sun's motion from one sunrise to the next sunrise, whom the inhabitants of the Balearic Islands imitate in our own time. Hence they reckoned the hours from sunrise, and these are called "Babylonian" by most writers, because they were in use among the Babylonians. The Athenians, however — whom now all Italy, together with Bohemia, follows — defined the day from one sunset to the next sunset, and thence numbered the equal hours; these are now called "Italian," from Italy, where their use most flourishes. The Umbrians, next (a custom which all Astronomers also observe), called the whole time from noon to the following noon a day, and reckoned 24 equal hours from noon; and because these are employed by Astronomers in computing the motions of the heavens, they have come to be called "Astronomical." The Egyptians, finally, and — as Macrobius (*Saturnalia*, Book 1) attests — the Roman people, numbered the day from midnight to the next following midnight, and thence observed the elapsed hours. This the Roman Church too observes in the celebration of feasts and fasts. For the rest, from the hours that were in use among the Umbrians, the Astronomers, the Egyptians, and the Romans, the common or ordinary hours — which Germany, France, Spain, and almost all Europe use today — do not much differ. For the peoples of these regions number 12 equal hours from noon until midnight, and as many again from there to the next noon. Hence it happens that in the numbering of the hours from noon to midnight they differ in nothing from the Umbrians or the Astronomers; but from midnight to noon they disagree with them only in the numbering of the hours. For what the Umbrians and Astronomers call the 13th hour from noon, the common European calls the first after midnight; and what for them is the 14th from noon, is called by these the second after midnight, and so on for the rest. In the same way, in the numbering of the hours from midnight to noon they agree with the Egyptians and Romans, but from noon to midnight they disagree with them in the numbering alone. For what among the Romans or Egyptians is called the 13th hour after midnight, is today called by Europeans the first after noon; and what they call the 14th from midnight, is called by Europeans the second after noon, and so forth.

[Margin: The beginning of the day differs among various peoples. The Babylonian hour. The Italian hour. The Astronomical hour. How the common or ordinary hours differ from the Astronomical.]

From this it results that one and the same timepiece shows both the hours counted from noon and the hours counted from midnight, provided you exchange the hour-numbers, as has been said. Nevertheless, in timepieces of this kind the hour-numbers are usually applied according to the common numbering — namely 12 from noon to midnight, and as many from midnight to noon — as will be clear from what follows. Therefore, to sum up everything briefly: since there are two kinds of hours, the one of unequal, the other of equal — and equal hours have their beginning either from sunrise, or from sunset, or from noon and midnight — it comes about that on any timepiece whatever, whether hanging, or concave, or convex, or plane, four kinds of hours can be described: namely, unequal (or ancient) hours; equal hours from sunrise; equal hours from sunset; and equal hours reckoned from noon and midnight. Wherefore, in respect of the hours, every timepiece will be fourfold, and will have these names:

[Margin: In any solar timepiece four kinds of hours can be described. The four kinds of timepieces arising from the variety of the hours.]

ANCIENT, which contains the unequal hours that the ancients used.

BABYLONIAN, which indicates the hours from sunrise, which were in use among the Babylonians.

ITALIAN, which comprises the hours from sunset, which the Italians use.

ASTRONOMICAL, which marks the hours from noon to midnight, and from midnight to noon — which are common not only to almost all Europe, but to all Astronomers as well.

[Margin: The Ancient timepiece. The Babylonian timepiece. The Italian timepiece. The Astronomical timepiece.]

DE INVENTORIBVS SCIOTHERIcorum horologiorum, eorumque scriptoribus.

[On the Inventors of Sundial Timepieces, and their Writers]

[Margin: Anaximenes of Miletus, first inventor of solar timepieces. 4 Kings [2 Kings], chapter 20.]

The first inventor of sundial [sciothericum] timepieces is said to have been Anaximenes of Miletus [Anaximenes Milesius], concerning whom these words are found in Pliny (Book 2, chapter 76): "Anaximenes of Miletus, disciple of Anaximander, discovered the theory of shadows and what they call gnomonics [gnomonicen], and first displayed at Lacedaemon the timepiece that they call a sundial" — thus Pliny. But it has been ascertained by sufficiently clear arguments that the use of timepieces was much older. For we read in Holy Scripture that King Ahaz [Achaz] had a solar timepiece, and he was much older than Anaximenes. For Ahaz reigned about the first Olympiad — that is, in the year 775 before the birth of Christ — or at the least, as others prefer, about the seventh Olympiad, that is, in the year 751 before Christ. Anaximenes, however, flourished about the fiftieth Olympiad, that is, about the year 579 before Christ; so that he was younger than Ahaz by nearly 196 or 172 years. For this reason I would believe that this science of timepieces took its origin from those first Fathers (as Josephus [Iosephus] also affirms concerning the other sciences, in his book *On Antiquity*), and gradually passed to the Egyptians, from these to the Greeks, and finally from the Greeks to the Latins.

[Margin: Various inventors of various timepieces.]

But various inventors of various sundial timepieces are mentioned by Vitruvius (Book 9). For Berosus the Chaldean is said to have invented the hemicycle hollowed out of a square block, on which the lines indicating the hours were drawn. Aristarchus of Samos [Aristarchus Samius] [invented] the scaphe [scaphen], or hemisphere — such as the hemispherical concave timepieces now are. The same man is said to have devised the Disc, that is, a timepiece slightly hollowed in the form of a disc or dish, so that the interior part was not perfectly spherical. Eudoxus the Astrologer is said to have discovered the Arachne — that is, the "spider" — namely a timepiece in the form of a spider's web, such as the horizontal timepiece now is, which contains the astronomical hours and the circles of the sun's altitude, which the Arabs call almucantars [Almucantarath]. Or it may be any timepiece whatever on which both the hour-lines and the arcs of the signs of the Zodiac are drawn. There are those who make Apollonius the inventor of this timepiece. Scopas of Syracuse [Scopas Syracusius] is proclaimed the inventor of the Plinth [Plinthi], or coffer [lacunar] — in the likeness of a certain square beam — on which could be drawn a Vertical timepiece both southern and northern, a Meridian one both Eastern and Western, and also a Horizontal one on the upper plane, such as was set up in the Flaminian Circus. They make Parmenio the inventor of the timepieces that were called πρὸς τὰ ἱστορούμενα [Greek: pros ta historoumena, "for/according to the things inquired

into or recorded"; small type — reading of the middle letters uncertain]; what these were like, we can hardly judge — unless perhaps we should say that on them were contained not only the hour-lines, but also the signs of the Zodiac, the months, and the days, all of which were shown by a pointer, so that those timepieces were like a kind of chronicle. They assert that Theodosius devised the timepiece called πρὸς πᾶν κλίμα [Greek: pros pan klima, "for every clime"], because it served all the climates of the world. Patrocles is related to have discovered the πελεκινον [Greek: pelekinon, "little axe" — a dial in the shape of an axe or double-axe], that is, having the shape of an hour-marker like an axe or a double-axe [bipennis], such a form as the Meridian timepiece now nearly bears, on which the signs of the Zodiac are drawn. Dionysodorus was the inventor, as they say, of the cone, or a timepiece of conical shape. And so various others are recorded by Vitruvius to have devised various forms of timepieces. But Pliny (Book 7, chapter 60) is the authority that the use of timepieces began rather late at Rome. "For in the Twelve Tables," he says, "only sunrise and setting are named; some years later midday too was added, the consuls' attendant [accensus] announcing it, until the first Punic War. Then a solar timepiece — imperfect, however — was set up beside the Rostra on a column by M. Valerius Messala the consul, as M. Varro records, when Catina in Sicily was taken, in the year 477 from the founding of the City; and this they used for ninety-nine years, until Q. Marcius Philippus [Q. Martius Philippus], who was censor together with L. Paulus, [set up a more careful one]...

set up beside it one more carefully arranged, and this service was received most gratefully among the works of the censorship. And Scipio Nasica, the colleague of Laenas, was the first to divide the hours by water — those of the nights equally with those of the days — and he dedicated this timepiece under a roof in the year 595 from the founding of the City. So, more or less, says Pliny.

[Margin: Writers on sundials.]

As for a writer who has treated gnomonics — that is, the theory of sundials — I find none older than Vitruvius, who in Book 9 discusses a few points about the construction of the Analemma, and by this rather hints at how sundials are to be made than actually teaches it. Ptolemy [Ptolemæus], however, published a most penetrating little book on the Analemma, on which Federico Commandino [Federicus Commandinus] wrote most learned commentaries, together with a book on the laying-out of sundials, all of whose demonstrations are drawn from Ptolemy's Analemma. It was from that book that Daniel Barbaro [Daniel Barbarus], in his commentaries on Book 9 of Vitruvius, took everything he

reports about the laying-out of sundials. Ptolemy's *Analemma*, together with Federico Commandino's book on the laying-out of sundials, we shall set out far more clearly and briefly, God willing, in Book 6 of this work. al-Battānī [Albategnius] too, in Proposition 56 of his book *On the Science of the Stars*, teaches very briefly how a sundial of unequal hours may be constructed for any latitude. Among the more recent writers who have illuminated this part of mathematics may be counted: Pedro Nunes [Petrus Nonius Lusitanus], the celebrated Portuguese mathematician, who in his little book *On the Errors of Orontius* shows how horizontal and vertical sundials alone — the rest being omitted — are to be drawn; Federico Commandino, who, as I said, brought out commentaries on Ptolemy's *Analemma* and a little book on the laying-out of sundials; Oronce Finé [Orontius Finæus]; Johann Conrad Ulmer the German [Ioannes Conradus Vlmerus Germanus]; Giovanni Battista Vimercato [Ioannes Baptista Vimercatus] of the Carthusian order, in the Italian tongue; Andreas Schöner of Nuremberg [Andreas Schonerus Norimbergensis]; Giovanni Padovani of Verona [Ioannes Paduanus Veronensis]; Pedro Rodríguez the Spaniard [Petrus Rodericus Hispanus], in the Spanish tongue; Francesco Maurolico [Franciscus Maurolycus], the Sicilian abbot, who wrote three most subtle books on hour-lines; and Giovanni Battista Benedetti [Ioannes Baptista Benedictus], who most recently composed a book on the use of gnomons and of sun-shadows, in which very many things most worth knowing are contained.

[Margin: What the *Analemma* is.]

Therefore, so that we too may bring some light to this so excellent science of gnomonics, we shall begin from the construction of the *Analemma*. This is truly a marvellous invention of the ancients, and the base and foundation of nearly everything we are going to demonstrate in this work. The *Analemma* is a kind of circular figure drawn in the plane of the Meridian — or of any other great circle passing through the poles of the world — described about the centre of that circle, and containing the common sections of the principal circles of the sphere (namely the Equator and its parallels, the Ecliptic, the Horizon, and the vertical circle) with the Meridian, or with that great circle drawn through the poles of the world. This description will be understood most clearly from the first proposition that follows. The ancients called such a figure the *Analemma* — as if a "taking-up" [resumptionem] — because, before they drew the diameters of the other circles, they took, and took up again, certain markings-out of shadows [designationes vmbrarum], in order to place the diameters of the other circles in the required position within the circle of the *Analemma*. This is gathered from what Vitruvius and his interpreter Daniel Barbaro teach in Book 9. That is why Vitruvius in that

place described the Analemma as follows: "The Analemma is a scheme sought out by the course of the Sun, and discovered from observation of the shadow's increase from the winter solstice [Bruma], by which, through architectural reasoning and the drawings of the compass, the effect of the heavens in the world was found."

[Margin: How the Analemma is described by Vitruvius.]

For evidently the ancients — beginning from the course of the Sun and of the shadow cast by the gnomon, starting from the winter solstice [Bruma], that is, from the hibernal solstice (as is gathered from Vitruvius) — marked in the Analemma the diameters of the Sun's parallels according to their several distances from one another. And from this Analemma the effect of the heavens in the world was then found: namely the theory of sundials for any altitude of the pole, the lengths of days and nights, the risings and settings of the Sun, and almost innumerable other things, which it is not the place here to review. But our own description is better suited to the use the Analemma affords us, as will become clear from what follows. Let us therefore now set about describing the Analemma and explaining the other theorems and problems — provided that we first premise the construction of a certain quadrant, which offers us a wonderful usefulness not only in the laying-out of sundials, but also in the construction of the astrolabe and of other instruments pertaining both to Astronomy and to Geometry, and in a certain way makes the work itself both easier and shorter. Anyone will readily learn this from experience itself.

[Margin: Construction of a quadrant having very many uses in the laying-out of sundials and in the building of other mathematical instruments.]

Let there then be two straight lines AB, AC, drawn on some brass or wooden tablet, containing a right angle at the point A. From A as centre, let a quadrant of a circle BC be drawn, and let it be divided into 90 degrees, beginning from the point B. Then from the centre A let straight lines be drawn out to the individual degrees; and finally, from A, let any number of smaller quadrants be drawn, enclosed between the straight lines AB and AC. A quadrant drawn in this way will have uses in mathematics that can scarcely be told. For, quicker than can be said, it gives us all those things that would otherwise have to be sought, through many divisions of circles, with great labour and trouble. I will bring forward here one or two examples of this, for its most abundant fruits will be gathered here and there from what we are going to say throughout this whole work. Take, for example, some figure in which a circle HI has been drawn from the centre G at the interval of the radius GH, and in whose circumference HI — from the point H

toward I — the altitude of the pole is to be marked off, namely 42 degrees, roughly the latitude of Rome. To do this, we shall take with the compass the radius GH, and find on the quadrant a radius equal to it, at whose interval one of the quadrants from A has been drawn (if indeed such a radius can be found). In the given example this is the radius AE, at whose interval the quadrant EF has been drawn. Then in this quadrant EF we shall take with the compass the arc lying between the straight line AB and the straight line AD, which is drawn through the 42nd degree, and we shall transfer it with the same compass from H, along the circumference HI, as far as I. For in this way we shall have the required altitude of the pole, HI — namely 42 degrees — even though we have not divided the circle HI into its degrees. Again, suppose that in the same circle HI the inclination of some plane to the Horizon, amounting to 15 degrees, is to be reckoned. Then if in the same quadrant EF we take with the compass the arc lying between AB and the straight line AO, which is drawn through the 15th degree, and transfer it from H along the circumference HI as far as P, the arc HP will contain 15 degrees. And so, by the help of the quadrant EF, we shall mark off on the circle HI as many degrees as anyone pleases.

But if perchance no radius equal to the radius GH can be found on the quadrant — as almost always happens — we shall take whatever radius we please, say AK, at whose interval the quadrant KL has been drawn; and at the interval of the radius AK so taken we shall draw a hidden arc MN, onto which we shall transfer an arc MN equal to the arc of the quadrant KL that is intercepted between AB and the line AD drawn through the 42nd degree. For the straight line drawn GN will cut the circumference HI at I, and the arc HI will contain 42 degrees, since — by what we wrote in our commentaries on the Sphere near the end of the first chapter — the arcs HI and MN are similar. In the same way, if we take an arc MQ equal to the arc of the same quadrant KL placed between the two straight lines that enclose 15 degrees, the straight line drawn GQ will cut off from the circle HI the arc HP of 15 degrees; and so on for the rest.

[Margin: The use of the quadrant described.]

Moreover, suppose for example that at the straight line GH, at the point G, an angle of the pole's altitude of 42 degrees is to be constructed; likewise an angle of inclination of some plane to the Horizon of 15 degrees, or an angle of any number of degrees whatever — even though no circle is drawn there (a case that not rarely occurs in practice). We shall then take with the compass any radius, such as AE or AK, on the quadrant, and at its interval draw a hidden circumference HI or MN. If in this we take an arc HI or MN equal to the arc of the quadrant EF or

KL that spans 42 degrees, and likewise an arc HP or MQ equal to the arc of the quadrant EF or KL that contains 15 degrees, and so on, and if we draw the straight lines GNI and GQP, then IGH and PGH will be the required angles, and so on.

Diagram. A large graduated quadrant occupying most of the page, with an auxiliary construction to its left. The quadrant proper has its vertex at **A** in the lower-right corner (marked with a small circle representing the sharp pin, *clauiculus*, fixed at the centre). Its horizontal side **AB** runs left along the baseline; its vertical side **AC** rises to **C** at the top-right corner. The outer arc **BC** is finely graduated and labelled in tens: **10, 20, 30, 40, 50, 60, 70, 80, 90** (with 10 near the baseline at B and 90 near the top at C). Two concentric smaller quadrants are drawn from A: the arc **EF** (with E on the baseline AB and F on the vertical AC) and the arc **KL** (with K on the baseline beyond E and L on the vertical). To the left stands the auxiliary "given figure": a centre **G** at the lower left, carrying a vertical plumb-line, from which the circle-arc **HI** is drawn — **H** at the upper left, **I** on the circumference. Radiating lines **GS, GR, GN** run from G; the points **P, R, S** mark where the transferred degrees fall (S near 42°, R near 15°), and the dotted hidden arc through **M, N** (upper-left) illustrates the transfer of an arc equal to a quadrant of the instrument.

- A (lower-right vertex): centre of the quadrant; small circle = the fixed pin
- B (lower-left): end of the horizontal side AB
- C (upper-right): end of the vertical side AC
- E (on baseline AB): foot of radius AE, start of inner arc EF
- F (on vertical AC): end of inner arc EF
- K (on baseline AB, beyond E): foot of radius AK, start of inner arc KL
- L (on vertical AC): end of inner arc KL
- 10, 20, 30, 40, 50, 60, 70, 80, 90 (along arc BC): degree graduations
- G (lower-left, with plumb-line): centre of the target circle HI
- H (upper-left): point on circle HI
- I (on circle HI): where line GN(I) meets the circumference
- P (on the target circle): where the 15° arc HP falls
- R (upper): end of radiating line GR
- S (centre-upper): end of radiating line GS
- M (left): endpoint of the dotted hidden arc MN
- N (lower-left): endpoint of the hidden arc, foot of GN

- e [?] (lowercase, on the dotted arc between M and N): label not fully resolved

You see, then, how much labour this quadrant, constructed in the way we have described, saves us. For if we lacked it, we should always be forced to divide the given circle into its degrees, and everyone knows how laborious and troublesome that is. So, to sum up in brief the whole use of this quadrant: whenever in this gnomonic work the altitude of the pole is to be reckoned, or the declination of some plane from the vertical, or its inclination to the Horizon expressed in a definite number of degrees, or indeed an angle of 20 or 35 or any number of degrees is to be constructed at a given point on some straight line — we shall have recourse to the quadrant constructed here, and from it transfer the required degrees into the given figure, as was done in the examples above, so that we are not forced to divide circles into their degrees, a matter that would be full of labour and trouble.

But now if at the centre A some sharp and very small pin is fixed, and all the parts of the quadrant outside the lines AB, AC and the circumference BC are cut away — leaving, however, a small portion around the centre A to hold the pin, as the figure shows — then this quadrant of ours will have a much handier and quicker use. For if that pin fixed at the centre is placed at the centre G of the proposed figure, and the straight line AB is made to coincide with the straight line GH, we shall at once mark with some sharp stylus, near the 42nd degree, the point S, and near the 15th degree the point R. For the straight lines drawn GS, GR will cut off from the circle HI the arc HI of 42 degrees and the arc HP of 15 degrees, and will contain the angles SGH, RGH of 42 degrees and 15 degrees, and so on. Daily use will teach the rest.

On the other side of the quadrant may be drawn the rays of the signs of the Zodiac, which we shall treat in Proposition 1, now immediately following, so that, when needed, we may transfer them into another figure — the one that must be constructed for drawing the arcs of the signs on sundials, as will appear from what follows.

I have chosen to explain this quadrant here, not because its use is absolutely necessary, but because by means of it we may lay out sundials more easily and quickly, since in this gnomonic work of ours the altitude of the pole, or the declination and inclination of a plane relative to the Equator, must very often be reckoned, and finally an arc of any number of degrees taken, and so on. All of which are accomplished quicker than can be said by means of a quadrant divided in this way, as is manifest from the examples set out.

PROBLEMA PRIMVM. PROPOSIT. PRIMA.

To describe an Analemma for any altitude of the pole.

[Margin: Meridian.] [Margin: Horizon.]

Let there be a Meridian — or rather, in the plane of the Meridian, a circle ABCD — drawn about the centre of the world E, whose common section with the Horizon is understood to be the straight line BD. Then, having reckoned the altitude of the pole for the place for which we are constructing the Analemma, let the diameter FG be drawn from the points B and D in opposite directions as far as G and F; this will be the axis of the world, as can easily be understood if the circle ABCD is set in the plane of the Meridian in such a way that E, its centre, is the same as the centre of the world, and the straight line BD lies in the plane of the Horizon as the common section of the Horizon and the Meridian — with this condition, however, that the point F incline toward the arctic pole and G toward the antarctic. [Margin: Axis of the world.] [Margin: Centre of the world.] For in this way it will come about that the straight line FG, when produced, falls upon each pole, and hence coincides with the axis of the world. This will become plain as follows. [Margin: Poles of the world.] The axis of the world, and the meridian line of the Horizon — that is, the common section of the Horizon and the Meridian — cut off similar arcs from the Meridian circle and from the circle ABCD drawn about the same centre as it, as we showed in our commentaries on the Sphere at the end of the first chapter. Since, therefore, by the construction the arc DF is similar to the arc intercepted in the Meridian between the arctic pole and the Horizon (because the arc DF contains the degrees of the pole's altitude), and the straight line ED is taken as the common section of the Horizon and the Meridian, and the centre E is placed at the centre of the world, then EF will necessarily be the axis of the world, since it cuts off from the circle ABCD the arc DF, similar to the arc of the pole's altitude in the Meridian, as we said. Next let the diameter AC be drawn perpendicular to the Horizon BD; this will be the common section of the Meridian and the vertical circle properly so called.

[Margin: Vertical circle.]

For since the vertical circle stands a quadrant of a great circle away from its own poles, which are at B and D — as is established from the corollary to Proposition 16 of Book 1 of Theodosius, in our edition — and since the arcs AB, AD are quadrants (because of the right angles AEB, AED), the vertical circle will pass entirely through the point A in the Meridian circle; and it also passes through the centre of the world E. Therefore the straight line AC, which we drew through the

centre E perpendicular to BD, will be the common section of the Meridian and the vertical circle properly so called. Again, let the diameter HI be drawn perpendicular to the axis FG; by exactly the same reasoning this will be the common section of the Meridian and the Equator, because the Equator too stands a quadrant of a great circle away from its own poles, which are F and G, as is established from the same corollary to Proposition 16 of Book 1 of Theodosius.

Diagram. The Analemma figure. A large circle **ABCD** about the centre **E**, with **A** at the top, **B** at the left, **C** at the bottom, and **D** at the right. Two perpendicular diameters cross at E: **AC** (vertical, the common section of the Meridian and the vertical circle) and **BD** (horizontal, the common section of the Horizon and the Meridian). The axis of the world **FG** runs obliquely from **F** in the upper right to **G** in the lower left; the Equator's diameter **HI** is drawn perpendicular to FG (**H** toward the upper left, **I** toward the lower right). Parallels **DK** and **BL** are drawn through D and B parallel to HI (the greatest of the always-visible and the always-hidden parallels, with **K** near the top beside A and **L** at the upper left / repeated near the bottom "L C"). At the top the small construction points **M**, **N** (with the auxiliary points **X**, **Y** and further small letters) mark the arcs of greatest declination, and the auxiliary circle **MPN** (points **P**, **Q**) sits toward the upper part of the figure. A dense web of chords fills the disc, with many small italic and Greek labels (the zodiac-parallel construction: points **R**, **S**, Greek β , γ , δ , ϵ on the declination arcs, and lowercase italic **a**, **b**, **c**, **d**, **e**, **f**, **g**, **h** around the lower right marking the parallels through the several signs). Because of the very fine, crowded, and partly rotated lettering, many of these minor labels cannot be resolved with confidence at this resolution.

- A (top): endpoint of vertical diameter AC / near the pole-region point
- B (left): endpoint of horizontal diameter BD
- C (bottom): endpoint of vertical diameter AC
- D (right): endpoint of horizontal diameter BD
- E (centre): centre of the world / of circle ABCD
- F (upper right): pole-end of the axis FG (arctic)
- G (lower left): pole-end of the axis FG (antarctic)
- H (upper left): endpoint of the Equator's diameter HI
- I (lower right): endpoint of the Equator's diameter HI
- K (top, beside A): endpoint of the parallel DK
- L (upper left; also near bottom): endpoint of the parallel BL
- M, N (upper left): endpoints of the arcs of greatest declination (HM, HN)
- P, Q (upper part): points of the auxiliary circle MPN and its diameter

- R, S [?] (division points of the quadrant into signs): partially legible
- β , γ , δ , ϵ [?] (Greek, on the declination arcs): partially legible
- X, Y, Z [?] (top): auxiliary points, partially legible
- a, b, c, d, e, f, g, h [?] (lowercase italic, lower right): parallels through the zodiac signs, not fully resolved

[Margin: Equator (equinoctial).] [Margin: The greatest of the always-visible and of the always-hidden parallels.]

But if through the points D and B we draw DK and BL parallel to HI, these will be the common sections of the Meridian and of those parallels which are, of all the parallels, the greatest of the always-visible and the greatest of the always-hidden respectively [Margin: a. Prop. 16 (Theodosius, Bk. 1) — whence.]; for the Meridian, cutting the Equator and the said parallels, makes their common sections parallel, and the greatest parallel of the always-visible ones touches the Horizon at D, while the greatest of the always-hidden ones touches it at B.

[Margin: How the parallels of the Equator, drawn through the beginnings of the signs of the Zodiac, are described.]

Now, in order to draw the parallels of the Equator that pass through the signs, or degrees, of the Ecliptic — in whose accurate delineation the whole effort and labour of constructing the Analemma is placed, because of the declinations of these parallels from the Equator, which can scarcely be reckoned without error from the Equator's diameter HI on either side, on account of the minutes and seconds that cling to the degrees of declination — we shall use this method handed down by the ancients, as may be seen in Vitruvius, Book 9. Let two arcs HM, HN be taken in the circumference ABCD, each of which is equal to the Sun's greatest declination — that is, contains 23 degrees 30 minutes — and let the straight line MN be joined, cutting HI at O. Now since, when the straight lines EM, EN are drawn, the sides OE, EM of the triangle OEM are equal to the sides OE, EN of the triangle OEN, and they contain equal angles at the centre E (because they stand on the equal arcs HM, HN) [Margin: b. Euclid III.27.], the bases OM, ON will also be equal [Margin: c. Euclid I.4.], and likewise the angles at O — and hence they are right angles. If therefore from O, at the interval OM or ON, a circle MPN is described, and the straight line IH is extended to Q, then the arcs MP, PN, NQ, QM will be quadrants [Margin: d. Euclid III.26.], because, since equal angles at the centre O stand on them — namely right angles — they are equal.

But if each quadrant is cut into three equal parts (and so the whole circle into 12 equal parts, after the manner of the Zodiac, which is divided into 12 equal signs)

at the points R, S, and so on; and if two of these, equally distant from the points P and Q, are joined by straight lines (which will indeed be parallel both to HI and to one another, from what we demonstrated in the scholium on Proposition 27 of Book 3 of Euclid), cutting the arcs HM, HN at the points β , γ , δ , ϵ — then the arcs H β , H γ , H δ , H ϵ will be equal to the declinations of the remaining signs of the Zodiac between Cancer [♋] and Capricorn [♑], as we shall shortly show.

Now if arcs equal to these are cut off — I θ , I λ , I μ , I ξ , I π , I ς — and the straight lines M θ , $\beta\lambda$, $\gamma\mu$, $\delta\xi$, $\epsilon\pi$ are drawn...

let the straight lines $\delta\xi$, $\epsilon\pi$, N ς — or at any rate the parallels XR, YS, and so on — be drawn out. (For the straight lines HI, $\gamma\mu$, $\beta\lambda$, M θ are parallel, as we demonstrated in the scholium on Proposition 27 of Book 3 of Euclid, because of the equality of the arcs H γ , I μ , and $\gamma\beta$, $\mu\lambda$, and so on.) These will be the common sections of the parallels drawn through the beginnings of the signs and of the Meridian circle. For their distances from the straight line HI — the common section of the Equator and the Meridian — are proportional to the distances, in the Meridian itself, of the sections that those same parallels make with the Meridian; since the straight lines drawn from the centre E through the points M, β , γ , and so on cut off from the Meridian, about that same centre E, arcs similar to the arcs HM, H β , H γ , and so on — as follows from what we wrote in the commentaries on the Sphere, at the end of the first chapter.

[Margin: The various positions of the Ecliptic.]

Now the straight lines EM, E β , E γ , and so on are the common sections of the Meridian and of the Ecliptic as it takes up its various positions in the Meridian itself. For EM is a section of this kind when the beginning of ♋ [Cancer] is set in the Meridian; E β , when the beginning of ♊ [Gemini] or of ♌ [Leo] is placed in the Meridian; and E γ , when the beginning of ♉ [Taurus] or of ♍ [Virgo] has occupied the Meridian; and so on — as is evident, provided one understands that the Analemma has its own proper position in the plane of the Meridian. This is very easily grasped from a material sphere as well.

[Margin: The rays of the signs, or of the Zodiac, which are the diameters of the parallels drawn through the points of the Zodiac.]

These straight lines too, when we come to treat of the construction of sundials, we shall call the *rays of the signs* or *of the Zodiac*, because, when the Sun stands at the beginnings of the signs, they represent the rays which at midday the Sun casts through the centre of the world, E. But the straight lines M θ , $\beta\lambda$, $\gamma\mu$, and so on are the diameters of the parallels that run through the beginnings of the signs of the

Zodiac: namely HI, the diameter of the Equator; $\gamma\mu$, the diameter of the parallel of ϑ [Taurus] and of $\mathfrak{M}$ [Virgo]; and so on — just as BD is the diameter of the Horizon, and AD that of the Vertical, and so forth.

[Margin: Another way of describing the parallels of the Equator that pass through the beginnings of the signs.]

Others draw these diameters $M\theta$, $\beta\lambda$, and so on by the following method — and rightly so, in my judgement, because with one effort and one labour they both find the declinations of the parallels and draw those parallels' diameters, HI and the rest, equidistant from one another. Taking arcs HM, HN, I θ , I ϵ , each equal to the Sun's greatest declination, they join the straight lines MN, $\theta\epsilon$, which cut the straight line HI at O and at e. Then about the diameters MN, $\theta\epsilon$ they describe the semicircles MQN, $\theta f\epsilon$ — as much of them as is needed — because, as was demonstrated above, the straight line MN is bisected at right angles at O, and by the same reasoning $\theta\epsilon$ at e. Having divided these semicircles into six equal parts at the points a, z, x, Y, g, h, m, n, they join by straight lines the points that correspond to one another — such as $M\theta$, Yg, Xh, and so on. For these will give the diameters of the parallels, as before, since they are parallel to one another (because the straight lines YS, XR, and so on, together with the semicircle $\theta f\epsilon$, have the same position with respect to the semicircle MQN that the semicircle MPN has, as is manifest).

[Margin: The description of the parallels of the Equator drawn through the individual degrees of the Ecliptic.]

Now if the individual arcs QX, XY, and so on are also bisected, and the same operations are carried out as before, one obtains the common sections of the parallels that are drawn through the half-signs — that is, through every fifteenth degree of the signs. And in the same way the parallels of the individual degrees of the Ecliptic can be investigated, if only the circle MPNQ is divided into single degrees and the rest is done as before. For, in general, the straight lines that are parallel to PQ cut off from the Meridian arcs of declination for those arcs of the Ecliptic which are similar to the arcs of the circle MPNQ — just as the twelve signs of the Zodiac are similar to the arcs QX, XY, and so on. And this we shall demonstrate, by much the same reasoning, together with Pedro Nunes [Pedro Nunes], *On the Art of Navigation*, Book 2.

Diagram. The large construction of the Analemma, occupying the left portion of the page. An outer circle carries the horizontal diameter **B–D** (B at left, D at right) with the centre **E** marked as a small circle at the middle. An inclined inner

circle/ellipse (the plane of the Ecliptic laid into the Meridian) crosses it, with the beginning-of-signs points and the family of parallels of declination drawn as chords, together with their diameters radiating from E. A dense network of chords, radii, and parallel lines fills the figure.

- A, K (upper arc): points near the top of the outer/inner circle
- X, Y (upper left, on the inclined circle): division points
- M (top centre): a beginning-of-signs point (Cancer/Capricorn colure end)
- N (left): division point of the inclined circle
- B (left end of horizontal diameter)
- D (right end of horizontal diameter)
- E (centre, drawn as a small circle)
- F (right side, above D)
- G (lower left), L (bottom), C (bottom centre): points on the lower arc
- W, H (left of centre): [?] interior points
- Numerous small Greek and lower-case point-labels (β , γ , δ , θ , ρ , ϕ , ς , η , μ , λ , and others) mark the chord/parallel intersections across the interior; these are too small to resolve individually on the scan [?].

[This crowded analemma carries many sub-resolution labels]

[Margin: The demonstration of the construction of the Analemma.]

Let a semicircle AMB of the Ecliptic be understood as described about EM, and a semicircle AHB of the Equator about EH, and let the common section of the two be the straight line AB; and let A be the beginning of γ [Aries] and B the beginning of ϱ [Libra]. Now since M is the beginning of ϖ [Cancer] or of $\var�$ [Capricorn] — HM being the portion of the Meridian circle that is the Sun's greatest declination — and since each of these points is distant from the equinoctial points by a whole quadrant, the arcs AM, BM will be quadrants, and therefore the angles AEM, BEM right angles. Now let the straight line XR, drawn in the plane of the Meridian across the arc HM and across the straight lines EH, EM, MO, cut the straight line MO at the point ϕ and the straight line EM at the point C. Let a plane also be understood to be drawn through the straight line XR parallel to the Equator AHB, meeting the straight line EM at C. For since the circle MPNQ, lying in the Analemma in the plane of the Meridian, is perpendicular to the Equator, and QHPE is the common section of the Equator and of that same plane of the Meridian, and the straight line XR is parallel to that section QHPE, a plane can be drawn through XR itself parallel to the Equator...

Diagram. The figure for the demonstration of the Analemma. A large circle (the Meridian, with horizontal diameter along **A–B** at the foot) contains the semicircle **AMB** of the Ecliptic and the semicircle **AHB** of the Equator, together with the inner circle **MPNQ** and its diameters. The centre is **E**, on the baseline.

- X (top): end of a diameter of the inner circle
- Q, ω (upper left): points on the inner circle / its arc
- M (upper centre): beginning of Cancer/Capricorn
- D (left)
- C (centre): intersection of XR with EM
- R (below centre): point on the descending line
- K (right)
- A (bottom left, on the baseline): beginning of Aries
- F (bottom left, near A)
- E (bottom centre): the centre
- B (bottom right, on the baseline): beginning of Libra
- Interior small points near D and the centre (foot O with ϕ , and H on the Equator semicircle) are present but the small labels are hard to resolve [?].

[Interior labels partly sub-resolution]

parallel to the Equator; and this plane will make, in the Ecliptic, the common section DK, a straight line, but in the Sphere the circle D,k — by Proposition 1 of Book 1 of Theodosius — passing through the point γ , where the straight line XR cuts the arc HN of the Meridian.

[Margin: a. Euclid XI.3.]

Since, therefore, as MC is to CE, so is $M\phi$ to ϕO , then, by composition, as ME is to CE, so will MO be to ϕO ; and, by alternation, as ME, the semidiameter of the Ecliptic, is to MO, the semidiameter of the circle MPQ, so is CE to ϕO .

[Margin: b. Euclid VI.2.]

Now CE is equal to the sine of the arc DA — that is, to the straight line DF drawn from D perpendicular to AB.

[Margin: c. Euclid I.34.]

(For AB, DK are the common sections of the parallel planes — namely of the Equator AHB and of the circle D γ K — made by the plane AMB of the Ecliptic, and are therefore parallel;

[Margin: d. Euclid XI.16.]

and likewise CE, DF are parallel.)

[Margin: e. Euclid I.28.]

And ϕO , by the same reasoning, is equal to the sine of the arc QX — that is, to the straight line $X\omega$, which is perpendicular to QE. Therefore the semidiameters ME, MO have the same proportion as the sines DF, $X\omega$, and consequently the arcs AD, QX are similar, as we shall shortly demonstrate in the following lemma.

It remains, then, to show that the arc $H\gamma$, which the parallel XR cuts off from the Meridian, is equal to the arc of declination that the arc AD of the Ecliptic has — the arc AD which we have already shown to be similar to the arc QX of the circle MPQ. This we shall easily accomplish as follows. Let a great circle DG be described through the poles of the world — that is, through the poles of the parallels AHB, $D\gamma K$ — and through the point D; then the arc DG will be the arc of declination of the point D, since it is intercepted between that point and the Equator. Now the arcs of the great circles drawn through the poles of the parallels, intercepted between those same parallels, are equal, by Proposition 15 of Book 2 of Theodosius. But the arcs $H\gamma$, DG belong to great circles drawn through the poles of the parallels AHB, $D\gamma K$, and are intercepted between those parallels; therefore the arc $H\gamma$ will be equal to the arc DG. So in the Analemma the parallel XR cuts off the arc $H\gamma$ equal to the arc of declination of that arc of the Ecliptic which is similar to the arc QX — namely equal to the arc AD. And the same is to be said of the remaining parallels YS, ZT, and αV . It is settled, therefore, that the arcs $H\gamma$, $H\beta$, $H\delta$, and $H\epsilon$ [?] are equal to the declinations of the remaining signs of the Zodiac between $\mathfrak{S}$ [Cancer] and $\mathfrak{V}$ [Capricorn], since the arcs of the signs in the Ecliptic are similar to the arcs QX, XY, and so on in the circle MPNQ — for both alike are twelfth parts of their own circles.

Now since the sections of the parallels made by the plane of the Meridian, drawn through the beginnings of the signs, are parallel to one another, it is plainly evident that those parallels drawn through the points M, β , γ , H, and so on are the diameters of the parallels, since they cut off from the circle AB, CD arcs similar to those which the diameters of the said parallels really cut off from the Meridian, as was said before. And if the circle ABCD were equal to the Meridian in the Sphere, the parallels drawn through the beginnings of the signs would pass entirely through those parallel lines. We shall demonstrate exactly the same thing if, in place of the Meridian, one understands the circle ABCD to be any other great circle drawn through the poles of the world — such as the Colure of the solstices

— as we said above in the definition of the Analemma. We have therefore described the Analemma for any elevation of the pole whatever; which was to be done [recte: *Quod erat faciendum*; the print reads *etat*]. An easier demonstration of this matter you will find in Book 8, chapter 6.

LEMMA.

[Margin: The whole sines are proportional to the sines — both right and versed — of similar arcs, and conversely.]

Whatever proportion the whole sines have — that is, the semidiameters of any circles whatever — the same proportion the right sines, and likewise the versed sines, of similar arcs have. And conversely, arcs whose right sines, and likewise whose versed sines, have the same proportion as the whole sines, are similar.

Let AB, CD be arcs of circles whose semidiameters AE, CF are similar, whose right sines are BG, DH, and whose versed sines are AG, CH. I say that as AE is to CF, so also is BG to DH, and AG to CH. For, if the semidiameters BE, DF are again drawn, then, because of the similarity of the arcs AB, CD, the angles E and F will be equal, from what we showed at Proposition 33 of Book 6 of Euclid; and therefore, since the angles at G and H are also equal — being right angles —

[Margin: a. Euclid I.32.]

the triangles BEG, DFH will be equiangular.

[Margin: b. Euclid VI.4.]

Hence, as BE is to BG, so will DF be to DH; and, by alternation, as BE — that is, AE — is to DF — that is, to CF — so is BG to DH.

Again, since, because of the similarity of the arcs AB, CD, the triangles BEG, DFH are similar in the same way,

[Margin: c. Euclid VI.4.]

it follows that as BE — that is, AE — is to EG, so is DF — that is, CF — to FH; and, by conversion of ratio, as AE is to AG, so is CF to CH; and, by alternation, as AE is to CF, so is AG to CH. Which was the first point.

But let it now be granted that as AE is to CF, so is both BG to DH and AG to CH. I say that the arcs AB, CD are similar. For, if the straight lines BE, DF are again drawn, then, since as AE is to CF, so is BG to DH; and, by alternation, as AE — that is, BE — is to BG, so is CF — that is, DF — to DH; and since the angles at G and H

are equal, being right angles, the triangles BEG, DFH will have the angles at G and H equal, and the sides BE, BG about the angle B proportional to the sides DF, DH about the angle D. Since, then, each of the remaining angles E and F is less than a right angle — because the angles G and H are right angles —

[Margin: d. Euclid I.17.]

the triangles BEG, DFH will themselves be equiangular,

[Margin: e. Euclid VI.7.]

and will have equal the angles B and D, about which the sides are proportional, and therefore also the remaining angles E and F. And so, from what we showed at Proposition 33 of Book 6 of Euclid, the arcs AB, CD will be similar. It is thus settled that arcs whose right sines are proportional to the whole sines are similar.

Diagram. Two figures for the Lemma, drawn side by side. **Left (smaller):** an arc CD with centre F; C at the top, D at the left end of the diameter, and H the foot of the perpendicular CH on the diameter (giving right sine and versed sine), with lines FC, FD and CH drawn. **Right (larger):** an arc AB with centre E; A at the top of the arc, B to its upper left, and the foot of the perpendicular near A (right sine BG, versed sine AG), with radii EA, EB drawn. The foot-point label on the right figure (G) is very small and not cleanly resolved [?].

Then, since as AE is to CF, so is AG to CH, it will follow, by alternation, that as AE is to AG, so is CF to CH; and, by conversion of ratio, that as AE — that is, BE — is to EG, so is CF — that is, DF — to FH. Since, then, the angles at G and H are also equal — namely right angles — the triangles BEG, DFH will have the angles G, H equal, and the sides BE, EG about the angle E proportional to the sides DF, FH about the angle F.

[Margin: a. Euclid I.17.]

Moreover, each of the remaining angles B and D is less than a right angle, because the angles G and H are right angles.

[Margin: b. Euclid VI.7.]

Therefore the triangles BEG, DFH will be equiangular, and will have equal the angles E and F, about which the sides are proportional. For which reason, by what we wrote at Proposition 33 of Book 6 of Euclid, the arcs AB, CD will be similar.

From all this it is clear that arcs whose versed sines are proportional to the whole sines are similar; and the same was just now shown of the right sines. Whatever proportion, then, the whole sines have, and so on. Which was to be demonstrated.

Diagram. The same pair of Lemma figures, repeated at the head of this page.

Left: arc CD, centre F, with C (top), D (left), H (foot of the perpendicular), and lines FC, FD, CH. **Right:** arc AB, centre E, with A (top), B (upper left), the small foot-point near A, and radii EA, EB. As on the preceding page, the right-hand foot-label (G) is too small to resolve cleanly [?].

It is therefore established, from these things, that the arcs AD, QX in the figure of the preceding demonstration are similar — as was assumed in the demonstration of this proposition — since their right sines have the same proportion as the semidiameters of the circles to which the arcs belong. Likewise it is established that the whole sine of the Zodiac is to MO, the whole sine of the circle MPNQ, as the sine of the arc of the Zodiac of 30 degrees is to Oφ, the sine of the arc QX, which likewise contains 30 degrees — because arcs of this kind are similar. And this is what will be of use to us in the following corollary.

COROLLARIUM.

[Margin: The proportion of the whole sine to the sine of the greatest declination is the same as that of the sine of an arc of the Ecliptic reckoned from the equinox to the sine of the declination of the point of the Ecliptic that bounds the said arc. — The computation of the declinations of all the points of the Ecliptic by means of the sine.]

From the demonstration of this proposition it is manifest that, as ME, the whole sine, is to MO, the sine of the Sun's greatest declination, so is CE, the sine of the arc AD of the Ecliptic reckoned from the equinox A, to φO, the sine of the declination that the point D — which bounds that same arc AD — has. For the straight line CE is equal to the sine DF of the arc AD of the Ecliptic; and, by the same reasoning, the straight line φO is equal to the sine γI of the arc Hy, which we demonstrated to be equal to the arc DG that measures the declination of the point D. Hence, with little trouble, the declinations of all the points of the Ecliptic can be computed from a table of sines, as was done by us in the commentaries on the Sphere.

For example, suppose the declination is to be found of the 10th degree of ♈ [Aries], or of the 20th of ♉ [Pisces], or of the 10th of ♎ [Libra], or of the 20th of ♍ [Virgo] — for of these four degrees the first two recede equally from the vernal

equinox on either side, and the latter two from the autumnal; so that all four have the same declination. Let it be arranged that, as the whole sine 100000 is to the sine of the greatest declination 39874, so is the sine of an arc of 10 degrees in the Ecliptic, reckoned on either side from either equinox, 17364, to a fourth term. By the rule of proportion this fourth sine will be found to be about 6923, to which there answers in the table of sines an arc of about 3 degrees 58 minutes. So great, therefore, is the declination of any of the four proposed degrees; and the same reasoning holds for all the rest.

That this is the proportion — the whole sine to the sine of the greatest declination, as the sine of the arc of the Ecliptic begun from either equinox to the sine of the declination of that point in the Ecliptic which bounds the said arc — has been confirmed by an easier and shorter demonstration by Johannes Regiomontanus [Regiomontanus], *Epitome*, Book 1, Proposition 18, and by Pedro Nunes in his book *On Twilights*, and by us too in Lemma 18 of Book 1 of the *Astrolabe*.

[Margin: What the straight lines drawn in the Analemma are.]

It is also perfectly clear that, in the Analemma as described, the diameters passing through the centre E are the common sections of the Meridian and of the great circles — since all the great circles are drawn through the centre of the Sphere, in which we have placed the centre E, and therefore all cut one another there. But the straight lines that do *not* pass through the centre E are not, in reality, the common sections of the Meridian and the *lesser* circles, since in the Meridian these have far greater distances between one another than in the circle ABCD; rather, they cut off from the circle ABCD arcs similar to those which, in the Meridian, the lesser circles — and hence the common sections of those circles and the Meridian — really cut off, as we demonstrated. And if the Meridian of the Sphere were equal to the circle ABCD, then those straight lines not drawn through the centre would indeed be the common sections of the lesser circles and the Meridian, because the arcs of the circle ABCD would be altogether equal to the arcs of the Meridian circle.

SCHOLIVM.

But if we are willing to take as true and granted, as though demonstrated elsewhere, that as the whole sine is to the sine of the greatest declina...

so is the sine of any arc of the Zodiac begun from ♈ [Aries] or ♎ [Libra] to the sine of the declination of that arc. This was demonstrated both by Johannes

Regiomontanus [Regiomontanus], *Epitome*, Proposition 18, Book 1, and by Pedro Nunes [Petrus Nonius] in his book *On Twilights*, and by us too in Lemma 18 of Book 1 of the *Astrolabe*. We shall now show, much more briefly and clearly, how the parallels XR, YS, ZT, and ΦV [?] in the Analemma cut off the arcs of declination from the Meridian, in the following way.

In the Analemma above, the whole sine in the Zodiac is to MO — the whole sine in the circle MPNQ, that is, to the sine of the greatest declination — exactly as (this is clear from the preceding Lemma) the sine of an arc of the Zodiac of 30 degrees, reckoned from the beginning of Υ [Aries] or $\varnothing$ [Libra], is to C ϕ , the sine of the arc QX of the circle MPNQ, which likewise contains 30 degrees. But by what Johannes Regiomontanus [Regiomontanus] and Pedro Nunes [Petrus Nonius] have demonstrated — as was said, and as we take for true and granted — the whole sine of the Zodiac is to the sine of the greatest declination just as the sine of an arc of the Ecliptic of 30 degrees, begun from the beginning of Υ or $\varnothing$, is to the sine of the declination of that same arc of 30 degrees. Therefore the sine O ϕ is equal to the sine of the declination of that arc of the Ecliptic which spans 30 degrees, and it is similar to the arc QX. Hence the arc Hy is equal to the arc of declination of that arc of the Ecliptic of 30 degrees, which is similar to the arc QX of 30 degrees. The same reasoning holds for all the other arcs of the Zodiac, which was to be demonstrated.

[Margin: Another demonstration of the way the parallels of the Equator are drawn through the points that fall along the Ecliptic.]

The declinations of all the signs of the Ecliptic can also be found in this way. Let the circle of the Analemma, ABCD, be divided into 12 equal parts, beginning from the point M, the point of greatest declination; and let each pair of division-points equally distant from M be joined by straight lines. In the Analemma these are the lines marked by the points, and they cut the straight line M ϕ at the points l, p, E, q, u; by the scholium of Proposition 27, Book 3 of Euclid, they will all be parallel to one another. Where these lines cut the straight line M ϕ — namely at the points l, p, E, q, u — through those points the straight lines $\beta\lambda$, $\gamma\mu$, and so on, are to be drawn parallel to the equinoctial line HI, to serve as the diameters of the parallels described through the beginnings of the signs, so that in turn the arcs H β , Hy, and so on, are the declinations of the signs of the Zodiac.

To demonstrate this, we must understand the circle ABCD to be the Ecliptic, whose sign-beginnings lie at those 12 division-points, so that M and ϕ are the beginnings of $\var�$ [Cancer] and $\var�$ [Capricorn]. Then, keeping this Ecliptic fixed and in the position it holds in the Sphere — with the beginning of $\var�$ (the point M)

placed on the Meridian circle above the Horizon, and the beginning of γ (the point ϕ) on the same Meridian below the Horizon — we must imagine this same circle turned about the diameter $M\phi$, like a Colure of the solstices, until it stands at right angles to the plane of the Ecliptic, with the point F facing straight toward the north pole and G toward the south pole. In this way the Equator, drawn at right angles to this Colure along the straight line HI, will [a] produce in the plane of the Ecliptic a common section — the straight line marked by the points — which cuts $M\phi$ itself at right angles at the centre E.

[Margin: (a) Euclid, Elements XI.3.]

For since both the plane of the Ecliptic and that of the Equator are at right angles to the Colure, [b] their common section will likewise be at right angles to the same Colure, and therefore also to the straight line $M\phi$, which lies in that same Colure. Suppose, then, that through the point p, for example, we imagine a plane parallel to the Equator to pass: it will make in the plane of the Ecliptic a straight line marked by the points and passing through p, [c] parallel to the other straight line drawn through E and marked by its points — this because these lines drawn through E and through p are the sections that a plane parallel to the Equator makes with the plane of the Ecliptic. But in the Sphere, by Proposition 1, Book 1 of Theodosius, this plane will trace [d] a circle parallel to the Equator, whose diameter — running through p — will be parallel to the diameter HI of the Equator; for HI and the diameter of this circle are the sections that the parallel planes (namely the Equator and the plane equidistant from it) make with the plane of the Colure of the solstices.

[Margin: (b) Euclid XI.19. (c) Euclid XI.16. (d) Euclid XI.16.]

Therefore the straight line $\gamma\mu$, drawn through p parallel to HI, is the diameter of that parallel which, in the Ecliptic, passes through the points bounding the straight line marked by the points and drawn through p — namely through the arcs of 30 degrees reckoned from the equinoctial points; and these equinoctial points are bounded by that marked straight line drawn through the centre E. Hence, since the arc of the Colure of the solstices intercepted between the Equator and any parallel circle measures the declination of that parallel from the Equator, the arc $H\gamma$ will be the declination of the parallel whose diameter is $\gamma\mu$, which runs through those points on the Ecliptic bounded by the marked straight line drawn through the point p. The same reasoning holds for the rest. And if the circle ABCD is divided not merely into 12 parts but into single degrees as well, and the same operations are performed as before, we shall by the same device

describe the diameters of the parallels passing through the individual degrees of the Ecliptic.

[Margin: Another description of the parallels passing through the points of the Ecliptic.]

Finally, if the declinations of the signs, or of any points whatever of the Ecliptic — found by the doctrine of sines, as we taught in the corollary of this proposition — are laid off from the Equator's diameter HI toward either side in the circle of the Analemma, and through the endpoints of these measurements lines are drawn parallel to HI, these will again be the diameters of the parallels passing through the beginnings of the signs, or through given points of the Ecliptic, as before. Yet, as we said at the outset, the description of the Analemma by this route is uncertain, because of the declinations, which can scarcely be laid off without error in the circle ABCD, since minutes and seconds of degrees cannot be marked out in it.

[Margin: Knowledge of the altitude of the pole is necessary for the description of the Analemma.]

For the rest — by what procedure the elevation of the pole in any region whatever is to be investigated, which is indeed required for a correct construction of the Analemma (for the axis FG cannot be drawn if it is unknown how great the arc DF of the pole's altitude ought to be) — we have shown both in the *Use of the Astrolabe*, and in the *Cosmography*, and also in our commentaries on the *Sphere*, where we treated of the offices of the Meridian circle. Nevertheless we shall find that same altitude of the pole by another method, by means of the Analemma, in Scholium 2 of Proposition 28 of this book.

Diagram. A large, densely worked Analemma: a great circle (the Meridian, with the equinoctial diameter HI through its centre) carrying a second, obliquely inclined great circle (the Ecliptic/oblique circle) drawn as an ellipse across it, together with a dense pencil of straight chords and dotted lines representing the parallels, colures, and common sections discussed in the text. The centre is marked E. This figure is heavily labelled with a mixture of Roman capitals, Greek letters, and lowercase italics around the rim and interior; many peripheral labels are too small to resolve at this resolution.

- E (centre): centre of the Analemma / Meridian
- B (left end of horizontal diameter) and D (right end): endpoints of the horizontal diameter BD

- H, I: endpoints of the equinoctial line/diameter HI (the equinoctial diameter through E)
- F (upper right, on the oblique circle) and G (lower left): the poles of the Ecliptic / axis endpoints, F toward the arctic and G toward the antarctic pole
- M, φ : beginnings of ϖ [Cancer] and φ [Capricorn] on the oblique circle (φ near lower region)
- Upper rim (left to right): N [?], X [?], Y, M, A, K [?]
- Interior division/section points named in the text: l, p, E, q, u (on the line M φ); β , λ , γ , μ (diameters of parallels)
- Lower-right rim carries a series of small italic/Greek labels (b, g, h, f, n, and further symbols) that are not legible at this resolution [?]
- L, C (lower centre): rim points

[Continuation — Liber Primus]

This figure, then, which we have constructed up to this point, containing the common sections of the said circles with the Meridian circle, was called the *Analemma* by the ancients and especially by more recent writers — though they have not all defined it in one and the same way, since each had a different aim in defining it. We, however, have chosen to explain it through the common sections which the principal circles of the sphere make in the plane of the Meridian.

[Margin: Other circles besides those mentioned can also be described in the *Analemma*.]

Now the sections of other circles too with the same Meridian (such as the parallels of the Horizon, the parallels of the Ecliptic, and so on) can be described in that same Meridian, as is done in the description of the Astrolabe, and as will sometimes be done in what follows. Indeed, even a circular figure whose circle stands for some other great circle besides the Meridian, containing the common sections of other circles with that great circle, has customarily been called an *Analemma*, as we shall teach in its proper place.

[Margin: A different acceptance of the *Analemma*. — Which lines of the *Analemma* stay the same in every clime, and which do not. — How the drawing of the *Analemma* begins from the parallels passing through the signs of the Zodiac.]

Moreover, the *Analemma* as thus far constructed, so far as concerns the parallels found through the circle MPNQ, serves all the climes of the world. For these

parallels never change, in whatever Horizon the Analemma is set up, unless the greatest declination of the Sun has first changed — since their description depends on this greatest declination alone, as is evident. The other sections, or straight lines, however, vary with the varying altitude of the pole above the Horizon; for the same altitude of the pole above the Horizon is not found everywhere. Hence, if the parallels drawn through the signs of the Zodiac are first described in the Analemma — as being unchangeable in any clime (namely by first drawing, for the Equator's diameter, the straight line HI, and then working out the greatest declinations of the Sun, HM, HN, and so forth) — we shall complete its remaining parts for a given altitude of the pole in this way. Through the centre E, draw FG perpendicular to the Equator's diameter HI, for the axis of the world. Then from the points F and G, in opposite directions, with the altitude of the pole marked off up to D and B, draw the diameter BD for the Horizon; and for the Vertical draw another diameter, AC, cutting BD at right angles. Finally, from the points D and B draw DK and BL parallel to the Equator's diameter HI, to serve as the diameters of the parallels which — between the everlastingly visible and the hidden ones — are the greatest.

[Margin: The various uses of the Analemma.]

Furthermore, it is incredible how manifold and varied a use the Analemma has in matters of Astronomy. For by means of it, not only is the construction of the Astrolabe (which Ptolemy calls the *planisphere*) carried through by geometrical demonstrations, but also nearly everything that pertains to demonstrating the phenomena of the primum mobile is drawn out without great labour — which it is not the place to explain here. In this our Gnomonic work too its excellence and remarkable usefulness will shine out plainly, since almost all the demonstrations employed in the description of sundials are elicited from the Analemma, as will become clear from what follows — especially when we come to treat of Ptolemy's Analemma, from which sundials are laid out with wonderful ease. For now I shall be content if I briefly show how readily, from the Analemma, one may come to know the lengths of the days and nights; the time of sunrise and sunset in terms of Italian and Babylonian hours, and the time of noon; likewise the time of rising and setting reckoned by astronomical hours; and also the rising- and setting-amplitudes of all points of the Ecliptic at any time of the year, and for any latitude of place whatever.

Diagram. A large circle graduated into 24 equal hour-divisions by tick-marks around its rim, with a vertical and a horizontal diameter crossing at a small central mark. Two concentric series of numerals run round the rim: an outer

series and an inner series, so that each division carries two numbers (the Italian/Babylonian reckoning against the astronomical reckoning). At the top, on the vertical diameter, is a symbol flanked by "16" (left) and "17" (right); the numbers run round the circle in sequence from there. Because this is a numeral-dense figure, individual rim numbers are read below only where legible.

- Top (vertical diameter, meridian): symbol [☿?] with 16 to its left and 17 to its right
- Upper left: 15, then a symbol with a small numeral [?]
- Upper right, descending: 18, 19
- Right side, inner/outer pairs descending: 4 / 20, 3 / 21, 2 / 22, 1 / 23, then 24 at the horizontal
- Lower rim numbers (20, 21, 3, 4, 5) and left rim numbers (9, 10, 11, 12, 13, 14) are partly legible; the full sequence is not resolved cell-by-cell [?]

Diagram. To the right, a smaller circle (the parallel-circle $M\theta$ of the following demonstration) with a vertical diameter and a horizontal diameter. Dotted straight lines run down from its lower left to a point G below and to the left, linking it to the large hour-circle. The rim is graduated with small numerals (roughly 1–12 on each side).

- A (top of vertical diameter)
- E (centre)
- F (on the vertical diameter, just below the centre E)
- C (foot of the vertical diameter)
- D (right end of the horizontal diameter)
- H (lower left, below the horizontal)
- V (left, on/near the horizontal diameter)
- G (below and to the left, meeting-point of the dotted lines)

Then let it be proposed to learn all this thoroughly, for the case when the Sun runs through the parallel of ☊ [Cancer], or of ♊ [Capricorn], by the motion of the primum mobile. About the diameter of the parallel of ☊, namely $M\theta$ (or of ♊, namely $N\rho$), from the centre b — for since the axis FG [a] cuts all the parallels at right angles (because it cuts the Equator's diameter, to which they are equidistant, at right angles), [b] and therefore bisects them, the point b will be the centre of the circle to be described about $M\theta$ — let a separate circle be described about $M\theta$. Taking the straight line Ma equal to the Ma in the Analemma, draw through a, perpendicular to $M\theta$, the line de, which will be the common section of the Horizon and of the proposed parallel.

[Margin: The finding of the diurnal and nocturnal arcs from the Analemma, and of the hour of sunrise and sunset. — (a) Euclid I.29. (b) Euclid III.3.]

For since both the Horizon and the parallel of $\mathfrak{S}$ are at right angles to the Meridian, [c] their common section will likewise be at right angles to the same Meridian; and therefore, by Definition 3 of Book 11 of Euclid, it is perpendicular to the straight line $M\theta$ (which lies in the Meridian of the Analemma) at the point a , where the Horizon and the parallel cut one another in the Meridian. Hence the straight line de , which is drawn in the circle $Md\theta e$ through a perpendicular to $M\theta$, will be the common section of the Horizon and the parallel of $\mathfrak{S}$. So that, if the circle $Md\theta e$ is imagined to be turned about the diameter $M\theta$ in the Analemma until it stands at right angles to the plane of the Meridian — and therefore the straight line de of this separately described circle is likewise perpendicular to that plane — the Horizon, standing at right angles to that same plane of the Meridian, will pass through the points d and e , and so along the straight line de . We shall take up this same reasoning again in Proposition 33 of this book, where it will perhaps become clearer, since there the Sun's parallel is described in the Analemma itself about its own diameter. Thus the arc dMe will be the diurnal arc of $\mathfrak{S}$ (namely the part that stands above the earth), and $d\theta e$ the nocturnal; or that same arc will be the nocturnal arc of $\mathfrak{V}$ and this the diurnal. Hence if the whole circle $Md\theta e$ is divided into 24 equal hours, beginning from the point d or e — we have begun from e , because it now marks...

[Margin: (c) Euclid XI.19.]

the point of rising in the Horizon for Babylonian hours, and the point of setting for Italian hours — it will at once appear how many hours both the arc dMe and the arc $d\theta e$ comprehend. Thus you see that the diurnal arc of $\mathfrak{S}$, dMe , comprehends fifteen hours and a little more, while the nocturnal arc $d\theta e$ comprehends not quite 9 hours, but a little less. So too you understand that in the former arc the Sun sets, in the manner of hours reckoned from sunrise, a little after the fifteenth hour, and rises a little before the ninth hour, in the manner of hours reckoned from sunset, and so on. The outer hours in the diurnal arc of $\mathfrak{S}$, dMe , and the nocturnal arc $d\theta$, belong to the Italian hours, and the inner ones to the Babylonian. By contrast, in the diurnal arc of $\mathfrak{V}$, $d\theta$, and the nocturnal arc dMe , the outer hours belong to the Babylonian and the inner ones to the Italian. Yet the point e is always taken for the Sun's rising, if we are speaking of hours reckoned from sunrise, and the point d for its setting; and conversely, if the talk is of hours reckoned from sunset, the point e is to be taken for the Sun's setting and d for its rising, as the numbers of the hours show.

The same may be seen in astronomical hours, if the division of the circle begins from the point M, the point of noon — as is plain in the other, smaller circle ABCD described about the centre E, which is divided by the straight line BD in the likeness of the circle Mdθe, so as to stand for the parallel of ☊ (or of ☋) described from some smaller Analemma. Here too, then, you perceive that the diurnal arc of ☊, BAD, comprehends fifteen hours and more, while the nocturnal arc BCD comprehends a little less than 9 hours. Likewise, in the former case the Sun rises at D a little before 4½ hours after midnight, and sets at B a little after 7½ hours after noon, and so on.

All this may be tested in every other parallel of the Sun, and in any clime whatever, provided the Analemma is set up for the altitude of the pole in the given clime.

But let us teach by what art that smaller circle ABCD — or any other, even a larger — is to be divided, by the aid of the Analemma, into two portions, of which one is similar to the diurnal arc and the other to the nocturnal, when the Sun stands at the beginning of ☊ (or at any other degree of the Ecliptic). This will prove of excellent use in describing the hours reckoned from sunrise or sunset, as will be clearly established from what follows.

[Margin: How a given circle is divided into two portions, of which one is similar to the diurnal arc and the other to the nocturnal, when the Sun stands at any degree whatever of the Ecliptic. — (a) Euclid VI.2.]

Suppose, then, for example, that the circle ABCD is to be divided into the diurnal and nocturnal arc of ☊, just as the circle Mdθe was divided. Having drawn the diameter AC at pleasure, draw from A the straight line AG making any angle with AC, and from it cut off AG equal to the diameter of the parallel of ☊, Mθ, in the Analemma, and again the straight line AH equal to the portion Ma of that same diameter. Then, joining the straight line CG, draw through H the line HF parallel to it, cutting the diameter AC at F; and through F erect the perpendicular BD to AC. I say that the arc BAD is similar to the diurnal arc of ☊, and the arc BCD to the nocturnal — that is, that the arc BAD is similar to the arc dMe in the larger circle, and the arc BCD to the arc aθe. [a] For since AH is to HG as Ma is to aθ, and as AF is to FC, then by composition Mθ is to aθ as AC is to FC; and by alternation, Mθ is to AC as aθ is to FC. But as Mθ is to AC — diameter to diameter — so is Mb, the semidiameter, to the semidiameter AE. Therefore, likewise, as Mb the semidiameter is to the semidiameter AE, so is aθ, the versed sine of the nocturnal arc of ☊, dθ, to FC, the versed sine of the arc BCD. By the lemma given above, then, the nocturnal arc of ☊, dθe, and the arc BCD are similar; and consequently

the arc BCD will comprehend as many hours of its own circle as are contained in the arc d θ e. For this reason the remaining arc BAD will likewise be similar to the remaining diurnal arc dMe, which was the proposition.

[Margin: The finding of the rising- and setting-amplitude from the Analemma.]

Now the rising- or setting-amplitude will be found from the Analemma in this way. From the point a, where the parallel cuts the Horizon, draw the perpendicular ad to the Horizon's diameter BD. I say that the arc dA is the rising- or setting-amplitude. For since, as we demonstrated a little earlier, the common section of the parallel and the Horizon is at right angles to the plane of the Meridian — and therefore, by Definition 3 of Book 11 of Euclid, perpendicular to the straight line BD lying in the plane of the Meridian — it comes about that, if the circle ABCD of the Analemma is taken for the Horizon, the straight line ad in the Horizon is the common section of the Horizon and of the Sun's parallel; so that the Sun rises or sets at d, if the Horizon has its proper position, such that BD is the Meridian line (that is, the common section of the Horizon and the Meridian), and AC the common section of the Horizon and the Vertical, and therefore also of the Equator — so that the Sun, when it is on the Equator, rises or sets at A. Hence the arc dA of the Horizon, between d (the rising or setting of the Sun's parallel) and A (the rising or setting of the Equator), will be the rising- or setting-amplitude, the Sun describing the parallel of the diameter M θ . The same reasoning must be applied to the rest. And ad in the Analemma will always be equal to the straight line ad, or ae, in the parallel Md θ e, because each is a common section of the Horizon and the parallel, running out from a up to the surface of the Sphere, where they coincide with one another, if both the Horizon and the parallel are conceived in their proper position.

THEOREMA PRIMVM.

PROPOS. SECVNDA.

In any sundial the tip of the gnomon must be reckoned as the same thing as the centre of the world; but the plane of the sundial itself is to be understood as distant from the centre of the world by only as much as the length of the gnomon, and as equidistant from the great circle to whose plane the gnomon stands perpendicular, and from which the sundial takes its name.

[Margin: The tip of the gnomon of any sundial is the centre of the world, but the plane of the sundial lies outside the centre of the world.]

Let AB be the gnomon of some sundial, standing at right angles to the plane of the sundial, which we understand to be drawn by the straight line CD. Now since the whole earth, compared with the Sphere of the Sun, is like a point and a centre — as we have shown in the commentaries on the *Sphere*, following Ptolemy and other astronomers — the centre of the world will differ in nothing from the point A, the tip of the gnomon or style; seeing that from the tip A to the centre of the earth (which is the same as the centre of the world), as we taught in those same commentaries, there is no appreciable distance, when it is compared with the distance the Sun has from that same tip. And so the circle drawn through the tip A, equidistant from the plane of the sundial drawn by CD, may not unfittingly be taken for a great circle. Hence with fullest right those who treat of the description of sundials — in order to be able, by the theory of the shadows which the Sun casts at every moment of time, to demonstrate their results — conceive the tip of the style to be set at the centre of the world, onto which all the incident rays of the Sun project through...

Diagram. A large circle representing a great circle of the world (the Sphere), with the Sun shown at the upper left as a radiating face. Inside, a horizontal diameter and a set of lens-shaped (vesica) curves span the circle. The gnomon stands vertically at the centre. A dotted ray runs from the Sun down through the gnomon's tip.

- H (upper left, radiating face): the Sun
- E (left end of the horizontal diameter) and F (right end): endpoints of the horizontal great-circle diameter EF
- A (centre, tip of the gnomon): the tip of the style / centre of the world
- B (below A, foot of the gnomon): the base of the gnomon AB
- C (lower left) and D (lower right): endpoints of the straight line CD, the plane of the sundial
- G (bottom, between B and D): point on the sundial-plane line

projecting, through the tip of the gnomon, the shadow onto the plane of the sundial — as the figure shows, in which the shadow is BG on the plane of the sundial, the Sun having the altitude EH above the great circle EF, to which the plane CD, on which the shadow falls, is parallel. For when HAG, the ray of the Sun at the point H, reaches the point G, and the style is opaque, the whole triangle ABG will be in shadow, since the rays of the Sun do not fall within its area; and so BG will be the length of the shadow on the plane of the sundial, while all the remaining parts — such as GD and BC — are lit by the Sun. In the same way we shall be able to investigate the length of the shadow at any time, once we have

found the altitude of the Sun above the great circle that is parallel to the plane of the sundial, as we shall say in its place. From this it is clear that the plane of the sundial, drawn along the line CD, is distant from the centre of the world by only as much as the length of the gnomon AB, since the tip A is placed at the centre, as we said. And if a great circle is understood to be drawn along the line EAF, to which the gnomon AB is perpendicular, the plane of the sundial will be parallel to this circle — since the gnomon AB is set perpendicular both to the plane of the circle along the line EF and to the plane of the sundial along the line CD.

[Margin: (a) whence 14 — i.e. see Prop. 14.]

Diagram. A large circle representing a great circle of the world. At the upper left is the Sun, drawn as a radiating face. A horizontal diameter EF runs across the circle; the gnomon stands vertically at the centre with its tip at A and its foot at B. Below, the line CD represents the plane of the sundial, parallel to EF, and G marks the point where the shadow ends. A dotted ray runs from the Sun H down through the tip A to G (the ray HAG). Several lens-shaped (vesica) curves span the circle, representing the circles/parallels.

- H (upper left, radiating face): the Sun
- E (left end of horizontal diameter) / F (right end): endpoints of the great-circle diameter EF, to which the dial plane is parallel
- A (centre): tip of the gnomon (= centre of the world)
- B (below A): foot of the gnomon; AB is the gnomon
- C (lower left) / D (lower right): endpoints of the line CD, the plane of the sundial
- G (bottom, between B and D): end of the shadow; BG is the shadow

Now the sundial takes its name from the circle of the diameter EF to which it is parallel. For if that circle is the Horizon, the sundial is called Horizontal; if it is the Vertical, Vertical; if the Meridian, Meridian; if the Equinoctial, Equinoctial — and so with the rest, as we said above when we set out the various kinds of sundials. For as many sundials can be made as there are great circles that can be drawn in the Sphere through the centre of the world, since to each of them parallel planes can be drawn at the distance of the style's length, on which the sundials are described, as is clear. In every sundial, therefore, the tip of the style, and so on — which was to be shown.

[Margin: Every sundial takes its name from the greatest circle to which it is parallel.]

THEOREMA 2. PROPOS. 3.

[Margin: The Sun, situated on the Equator, describes with its ray the equinoctial circle; but off the Equator, two conic surfaces.]

The ray of the Sun, when the Sun is on the Equator, describes by the daily motion about the centre of the world a circle — namely the Equator itself. But when the Sun is set outside the Equator, its ray describes two conic surfaces joined at the centre of the world as at a common vertex: the base of the one being the parallel traced from the centre of the Sun, and of the other the parallel opposite to this; and the axis of both is the same, namely the axis of the world.

In the Analemma ABCD, whose centre is E, let the axis of the world be DB; let the common section of the Equator and the Meridian be the line AC; and the common sections of the Meridian with two opposite parallels the lines FG, HI, cutting the axis at the points Q and R. These will be the centres of those parallels, by Prop. 10 of Book 1 of Theodosius [*Sphaerica*], since the axis is drawn through their poles and therefore, by that proposition, passes through their centres. Let there also be understood, described about the diameters AC, FG, HI, the circles — namely the Equator AKCL and the two parallels FM, GN, HOIP — at right angles to the Meridian. For in the Sphere the Equator and its parallels are perpendicular to the plane of the Meridian, by Prop. 15 of Book 1 of Theodosius, since the Meridian circle cuts them through their poles. Since, then, when the Sun is on the Equator — that is, at the point A — its centre does not depart from the circumference of the Equator AKCL, nor does the radius AE (which reaches to the centre of the world) depart from the plane of that same Equator (which is likewise drawn through the centre of the world), but is carried round always within it by the daily motion (for we here disregard the declination that the Sun acquires by its own proper motion): it is clear, from the definition of a circle, that a circle — namely the Equator AKCL itself — is described by the ray of the Sun, whose circumference the centre of the same describes.

But when the Sun is set outside the Equator, as at the point F, its radius FE, reaching to the centre of the world and produced straight on and continuously, is turned round (the point E remaining fixed) about the circumference of the circle FMGN — since in the daily motion the centre of the Sun does not depart from it — and, on the other side, about the circumference of the circle HOIP, which is equal and opposite to it. Therefore the radius of the Sun FE, produced to I, describes the conic surfaces EFG, EIH, fitted to the centre E, whose bases are the opposite

Diagram. The Analemma ABCD: a large circle with a vertical axis DB (D at top, B at bottom) and a horizontal diameter AC (A at left, C at right), crossing at the centre E. Several chords drawn parallel to AC represent the equator and the parallels seen edge-on (FG, HI, and the further parallels through S and Y); each is accompanied by lens-shaped (vesica) curves representing those circles projected. A dense web of straight lines runs from the centre and between the peripheral points. This is a crowded analemma projection with about two dozen labelled points; several small peripheral labels (including the Greek letters) are hard to resolve at this resolution.

- D (top) / B (bottom): endpoints of the world-axis DB
- A (left) / C (right): endpoints of AC, the common section of Equator and Meridian
- E (centre): centre of the analemma (centre of the world)
- F (left) / G (right): endpoints of parallel-section FG; Q (on axis, upper): its centre
- H (lower left) / I (lower right): endpoints of parallel-section HI; R (on axis, lower): its centre
- K (lower left) / L (lower right): points on the Equator circle AKCL
- M / N: points on the parallels FM, GN
- O / P: points on the parallel HOIP
- S (upper left) / V (upper right): points of the greatest ever-apparent parallel; T (left) and X (upper): further points of the circle STVX
- Y (lower left) / Z (bottom): points of the greatest ever-hidden parallel; horizon YV
- α (bottom) [?] / β (bottom) [?]: Greek-letter labels on the ever-hidden parallel YZ $\alpha\beta$ (glyphs not fully resolved)

[Diagram note: very dense analemma; 2 Greek labels flagged]

—opposite [parallels] FMGN, HOIP; the common vertex is E, the centre of the world; and the axis of both is EQ, ER, the same as the axis of the world, since Q and R are the centres, as we showed, of the circles FMGN, HOIP. All of which is clear from the definitions of Apollonius of Perga [*Conics*].

The same conic surfaces will be described when the Sun is set at the opposite point I, as is plain.

Finally, if from any point of the heavens outside the Equator a straight line is drawn through the centre of the world, that line, carried round by the daily

motion, will describe two conic surfaces connected at the centre of the world, whose bases are described by that point and its opposite, and whose axes are portions of the axis of the world. Thus if from the point S — of the greatest of the ever-apparent parallels — the straight line SE is extended through the centre of the world, there will be described by the daily motion the conic surfaces ESV and E[α]Y[?], fitted to the centre E as to a common vertex, whose bases are the parallels described from the point S and its opposite [α][?]. Of these, STVX is the greatest of those that always appear, while YZ $\alpha\beta$ is the greatest of those that never appear above the Horizon YV. And the same reasoning holds for the other points of the heavens. Therefore the ray of the Sun, when the Sun is indeed on the Equator, by the daily motion, and so on — which was to be demonstrated.

SCHOLIVM.

[Margin: What the conic surface of light is; what the conic surface of shadow is.]

Some writers — and rightly — are accustomed to call that conic surface whose base is described by the centre of the Sun the *conic surface of light*, because it is traced by the ray of the Sun; and the other, whose base is described by the point opposite the centre of the Sun, the *conic surface of shadow*, because it is traced by the shadow which the centre of the world projects. Thus, when the Sun is at the point F, the surface of light is EFG, because it is wholly illuminated by the Sun, while the surface of shadow is EIH, because it is described by the shadow of the centre E, projected along the straight line EI. Conversely, when the Sun occupies the point I, the surface of light is called EIH, and the surface of shadow EFG. For we here suppose the centre E to have the power of projecting a shadow; because, as we said in the preceding proposition, the centre of the world is understood in every sundial to be the tip of the style, which — being an opaque body — projects a shadow, as is manifest.

THEOREMA 3. PROPOS. 4.

[Margin: A sundial plane parallel to the bases of the conic surfaces produces a circle on the other of the surfaces.]

The common section of two conic surfaces — joined at the centre of the world as at a common vertex, whose two bases are opposite and equal parallels of the Sphere described by the daily motion about the poles of the world — and of a sundial plane parallel to the great circle that is parallel to the bases of the conic surfaces, is a circle, having its centre on the axis of the world.

In the Sphere whose centre is A, let there be two conic surfaces ADE, AFG, joined at the centre of the world A as at a common vertex, whose bases — described by the daily motion, opposite and equal — are DE, FG; and let the axis be BC. Let there also be HI, a great circle in the Sphere parallel to the bases DE, FG of the said conic surfaces. Let the sundial plane KL be parallel to this circle, making on the conic surface AFG the section MN. I say that MN is a circle having its centre on the axis of the world. For since the planes FG, KL are set parallel to the plane HI, they will also be parallel to one another, by what we demonstrated on Prop. 16 of Book 11 of Euclid. Therefore, since the conic surface AFG is cut by the plane KL, which is parallel to the base FG, the section MN thus made will — by Prop. 4 of Book 1 of Apollonius — be a circle having its centre on the axis BC, namely where the plane of the sundial meets the axis. In the same way, if a plane parallel to the circle HI cuts the conic surface ADE, the section will be a circle. Therefore the common section of the conic surfaces, and so on — which was to be demonstrated.

Diagram. A sphere with centre A, drawn as a circle. Two opposite lens-shaped bands (vesica curves) represent the two conic surfaces ADE and AFG joined at A; their bases DE (upper) and FG (lower) are the opposite parallels, and BC is the vertical axis. The great circle HI is drawn horizontally through the centre, and the sundial plane KL below it cuts the lower cone in the section MN. All labels resolve clearly.

- B (top) / C (bottom): endpoints of the axis BC
- A (centre): centre of the world / common vertex of the cones
- D (upper left) / E (upper right): endpoints of the base DE (upper cone)
- H (left) / I (right): endpoints of the great circle HI
- K (lower left) / L (lower right): endpoints of the sundial plane KL
- M / N (lower centre): points of the section MN made on the cone AFG
- F (lower left) / G (lower right): endpoints of the base FG (lower cone)

COROLLARIUM.

[Margin: An equinoctial sundial cutting a conic surface whose base is a parallel of the Equator produces a circle.]

Hence it follows that the common section of the plane of an Equinoctial sundial and of the conic surfaces — whose bases are any parallels described by the Sun, opposite and equal, or any others parallel to these (such as also are the greatest of the ever-apparent and of the ever-hidden parallels) — is a circle; because the

equinoctial circle, to which the plane of the sundial is parallel, is parallel to the bases of conic surfaces of this kind.

THEOREMA 4. PROPOS. 5.

[Margin: A sundial plane parallel to the great circle that touches the bases of the conic surfaces produces a parabola on the other of the surfaces.]

The common section of the same conic surfaces and of a sundial plane parallel to the great circle that touches the bases of the conic surfaces is a parabola.

Let there be in the same Sphere two conic surfaces, as before; and let EF be the greatest circle touching the opposite bases at the points E and F. Let the sundial plane HI be parallel to this circle, making on the conic surface AFG the section KLM. I say that KLM is a parabola. Through the poles of the parallels B, C, and through the point of contact E, let the great circle BDCG be drawn, by Prop. 20 of Book 1 of Theodosius. This circle also necessarily passes through the poles of the circle FE (by Prop. 5 of Book 2 of Theodosius), and therefore through the poles of the circle HI — which the plane of the sundial produces in the Sphere by Prop. 1 of Book 1 of Theodosius — since (by Prop. 1 of Book 2 of the same) the parallels FE, HI have the same poles; it will therefore pass through them. And so, by Prop. 15 of Book 1 of Theodosius, it will cut both the circle FG and the circle HI — along the straight lines FG, HI, which cut one another at N — in half and at right angles (for the lines FG, HI will indeed cut one another, since they lie in the same plane of the circle BDCG), and it will make the common sections of the parallel planes FE, HI parallel [to one another]. Let the same circle BDCG also, since it proceeds through the axis BC, make the triangle-through-the-axis AFG, cutting the line HI and the conic section at

Diagram. A sphere drawn as a large circle, with a network of chords and vesica curves. The vertical diameter has B at the top and C at the bottom; the great circle BDCG is inscribed through B, D, C, G. The two conic surfaces meet at the centre A; the bases (opposite parallels) run through D–E (upper) and F–G (lower). The sundial plane HI is drawn across, and the parabolic section KLM is formed on the lower cone near F–G, with M and N marked near the foot and a small point (L) toward the lower centre.

- B (top) / C (bottom): endpoints of the vertical axis / circle BDCG
- D (upper left) / E (upper right): endpoints of the upper base and points on circle BDCG
- A (centre): centre of the world / common vertex

- I (right) / H (lower left): endpoints of the plane HI
- K (mid right, on the cone): a point of the parabolic section
- F (lower left) / G (lower right): endpoints of the lower base FG
- L (lower centre) [?]: a further point of the section (small, near the axis)
- N (bottom centre) / M (bottom centre, below N): points of the section / intersection
- I (small, lower centre) [?]: a small label near the foot of the axis (possibly duplicate label)

[Diagram note: two small foot-of-axis labels (L and a lower I) not fully resolved]

k: Let the plane HI also cut, along the line KN passing [through the point N], the circle FG along the line MNL, which passes through the point N. For since the plane drawn through KN passes through the point N (which lies in the plane GF), the line LM — the common section of the planes HI, FG — will also pass through the point N. Since, then, the planes FG, HI are perpendicular to the plane of the circle BDCG, their common section LM will likewise be perpendicular to that same plane at the point N, and so also perpendicular to the line FG, the base of the triangle-through-the-axis, by Definition 3 of Book 11 of Euclid. Therefore, since the cone AFG is cut by the plane BDCG through the axis, and is also cut by the other plane HI — which cuts the base of the cone along the straight line LM, perpendicular to FG (the base of the triangle-through-the-axis) — and since KN, the diameter of the section, is parallel to the side AF of the triangle-through-the-axis: the section KLM will, by Prop. 11 of Book 1 of Apollonius, be a parabola. Therefore the common section of the same surfaces, and so on — which was to be demonstrated.

[Margin: (a) whence 16 — see Prop. 16.]

COROLLARIUM.

And so, since any oblique Horizon touches two parallels — one the greatest of those that ever appear, the other the greatest of those that are ever hidden beneath the earth — the common section of the plane of a Horizontal sundial and of the cone whose base is the greatest of the hidden parallels will be a parabola (for the other cone, whose base ever appears, is not cut, since it lies wholly above the Horizon). The same will happen in a Vertical sundial at latitude 45°. Likewise in a sundial whose plane is parallel to the circle of any hour from sunrise or sunset. For both the Vertical circle of latitude 45° and the circle of any hour from

sunrise or sunset touch, in every Horizon, the greatest parallel of those that stand wholly above the Horizon, as will be demonstrated at Prop. 10 of this book.

Finally, the common section of any sundial and of the cone whose base declines from the Equator toward the South by as much as the complement of the altitude of the arctic pole above the great circle to which the plane of the sundial is parallel, will be a parabola. Such will be the section of the cone having as its base the parallel ♄ [?] (the Tropic of Capricorn — the parallel declining $23^{\circ}30'$ to the south), and of a Horizontal sundial at northern latitude $66^{\circ}30'$. For the complement of this latitude amounts to $23^{\circ}30'$, which is precisely the declination of the parallel ♄ [?]. Such too will be the section of the cone having as its base the parallel ♊ [?] (the Tropic of Cancer),

[Margin: (continuation of the note begun on the previous page) ...the sundials make on the conic surfaces whose bases are any of the parallels of the Sun, parabolas.]

and of a horizontal sundial at the northern latitude of $69^{\circ}48'$. For the complement of this latitude — namely $20^{\circ}12'$ — equals the declination of the aforesaid parallel [♄ [?]; the parallel of $20^{\circ}12'$ declination, per the stated complement of latitude — glyph worn]. In the same way, the section of the cone whose base is the parallel ♏ [?] [Scorpio] and ♐ [?] [Pisces (♊)], together with a Horizontal sundial at the northern latitude of $78^{\circ}30'$, will be a parabola; for the complement of this latitude — that is $11^{\circ}30'$ — equals the declination of the parallel ♏ [?] and ♐ [?]. Say the same of the cones whose bases are the northern parallels opposite to the aforesaid — namely the parallel ♋ [?] [Cancer]; ♊ [?] [Gemini] and ♌ [?] [Leo]; ♉ [?] [Taurus] and ♍ [?] [Virgo] — where, however, the antarctic pole is raised above the Horizon.

From these it will be easy to judge which sundial-planes produce parabolas, whatever parallel the Sun happens to occupy. For if the Sun stands in a northern parallel which the great circle equidistant from the sundial-plane touches, then the common section of the sundial and of the cone of shadow whose base is the opposite southern parallel will be a parabola — namely wherever the arctic pole is raised above the sundial's plane. But if, on the contrary, the antarctic pole is seen above the sundial's plane, and the Sun occupies the southern parallel which the great circle equidistant from the sundial-plane touches, then a parabola will arise in the cone of shadow whose base is the opposite northern parallel, as is clear from what has been said.

For in the upper figure, if B is taken as the arctic pole and the Sun stands in the northern parallel DE, the Sun's ray will indeed describe the cones ADE and AFG;

but the sundial's plane HI, set opposite — within the cone of shadow AFG, whose base FG is parallel to the Sun's parallel DE — will produce the parabola KLM. And if B is taken instead as the antarctic pole and the Sun runs through the southern parallel, the sundial-plane will in the same way produce a parabola in the northern cone of shadow AFG, and so on.

In the same figure you also see that the arctic pole B is raised above the plane FE — which touches the northern parallel DE — by exactly as much as the complement of the declination of the opposite southern parallel FG, and so forth; since the altitude of the pole is the arc BE, while the complement of the declination is the arc CF, ^awhich is equal to it because of the equal vertical angles at the center A on which they stand. For, universally, any great circle touches that parallel whose declination equals the complement of the altitude of the pole above that great circle — or, what is the same, whose complement of declination equals the altitude of the pole above the great circle — as the figure sufficiently shows.

[Margin: (a) 26 of the third.]

THEOREMA 5. PROPOS. 6.

[Margin: The plane of a sundial equidistant from the greatest circle, which cuts the bases of the conic surfaces, produces two opposite and equal hyperbolas.]

The common sections of the same conic surfaces and of the plane of a sundial equidistant from the greatest circle — the plane which cuts the bases of the conic surfaces — are opposite and equal hyperbolas.

Diagram. A large circle (the sphere seen edge-on, representing the meridian) with center A, carrying the double cone and the cutting plane. Readable labels:

- B (top, just left of apex): pole
- I (top, right of B)
- D (upper left, on the circle)
- E (upper right, on the circle)
- L (right side, below E)
- Q, T, R, P (small cramped cluster of points near E, marking the upper hyperbola section PQR) — labels crowded, positions uncertain [?]
- A (center): vertex of the two cones
- M (interior, mid-lower right)
- N (interior, lower center)

- S (below N)
- O (bottom center, below the circle's foot)
- F (lower left, on the circle)
- G (lower right, on the circle)
- H (bottom left)
- C (bottom center)
- K (bottom, right of C)

The two cones are ADE (upward) and AFG (downward) sharing vertex A; HI is the great circle cutting both bases; KL is the trace of the sundial-plane; and MNO (lower) and PQR (upper, near E) are the two opposite hyperbola sections. Several peripheral labels (Q, T, R, P) are crowded and worn

Let there be, in the same Sphere, the two conic surfaces as before, and let HI be the greatest circle cutting each of the two bases. Let the sundial-plane KL be equidistant from this circle, producing in the conic surfaces the sections MNO and PQR. I say that the sections MNO and PQR are opposite and equal hyperbolas. For since the conic surfaces ADE and AFG, joined at the vertex A, are cut by the plane KL not through the vertex, there will be in each of the surfaces — by Prop. 14 of Book 1 of Apollonius — a section called a hyperbola, and the two sections will have the same diameter KL, and so on. Therefore MNO and PQR are hyperbolas, and they are opposite and also equal, as is drawn from the said Prop. 14 of Book 1 of Apollonius. So the common sections of the same conic surfaces, and so on — which was to be demonstrated.

Diagram. Left-hand figure: a sphere (center A) with a single cone opening upward above it, the augmented surface of the Scholium (figure BDCE). Readable labels: D (upper left), Q, T, R (small cluster at the upper apex, near E) [?], E (upper right), B, I (upper interior on the sphere), P, L (right interior), A (center), N, M (lower interior), S, O (bottom), F (lower left), G (lower right), H, C, K (bottom row). Several apex-cluster labels are crowded [?]

Diagram. Right-hand figure: a double (hourglass) figure — two full cones, one opening upward and one downward, above and below the central sphere (center A), showing both conic surfaces augmented until the plane KL cuts them. Readable labels: at the top C/Q, T, R with E (upper apex and rim); D, E (upper on sphere); B, I; P, L; A (center); M, G (mid-right); N, S; F (left), G (right, at the wide lower rim); H, C, O (bottom). This crowded figure has many small worn labels

SCHOLIVM.

[Margin: The plane of a Meridian sundial, and of one equidistant from any hour-circle from noon or midnight — indeed of a Vertical sundial at a latitude greater than 45° — produces, on the conic surfaces whose bases are the ever-apparent greatest parallel and the ever-hidden greatest parallel, two opposite and equal hyperbolas. Such sundials, on the conic surfaces whose bases are any parallels of the Equator, produce opposite and equal hyperbolas. The plane of a sundial equidistant from the greatest circle, which neither is equidistant from the bases of the conic surfaces nor touches nor cuts them, produces on one of the two surfaces an ellipse.]

If it should happen that the plane KL — equidistant from the greatest circle HI — lies so far from the center A that (as in the figure BDCE) it does not cut both conic surfaces but only one, or neither, then each surface must be extended until it is cut by the plane KL, as you see in the two adjoining figures.

COROLLARIVM.

Since, therefore, both the Meridian and the circle of any hour from noon or midnight (as we shall say at Prop. 9) — or indeed any great circle drawn through the poles of the world, and even the Vertical circle of a latitude greater than 45° — cut both parallels (of which one is the greatest of those that ever appear, the other the greatest of those that are ever hidden): the common sections of the conic surfaces whose bases are these parallels, made by the planes of sundials equidistant from those greatest circles, will be opposite and equal hyperbolas.

Likewise, the common sections of any sundial and of the cones whose bases are parallels of the Sun having a declination smaller than the complement of the altitude of the pole above the greatest circle from which the sundial-plane is equidistant, will be opposite and equal hyperbolas. Such will be the sections of the cones whose bases are the parallels $\mathfrak{S}$ [?] [Cancer] and $\mathfrak{V}$ [?] [Capricorn] — and hence of all other parallels between these (since all the others have a smaller declination than those two) — together with a Horizontal sundial at a latitude smaller than $66^\circ 30'$; because in this case the complement of the pole's altitude will be greater than $23^\circ 30'$, which is the declination of $\mathfrak{S}$ and $\mathfrak{V}$. Say the same of the sections of the same cones and of any sundial equidistant from a greatest circle above which the pole of the world is raised by fewer than $66^\circ 30'$.

From these things you will easily recognize which sundial-planes produce hyperbolas, whatever parallel the Sun runs through. For if the Sun stands in a parallel which the great circle equidistant from the sundial-plane — and

therefore its opposite as well — cuts, then the common sections of the sundial and of the cones whose bases are that parallel and its opposite will be hyperbolas. All of which can easily be understood from the figure above. For in general, any great circle cuts that parallel whose declination is smaller than the complement of the pole's altitude above that great circle, or whose complement of declination is greater than the altitude of the pole above the great circle, as the figure indicates.

THEOREMA 6. PROPOS. 7.

[Margin: The plane of a sundial equidistant from the greatest circle among the bases of the conic surfaces, which neither is equidistant from those bases nor touches nor cuts them, produces on one of the two surfaces an ellipse.]

The common section of the same conic surfaces and of the plane of a sundial equidistant from the greatest circle — a plane which neither is equidistant from the bases of the conic surfaces, nor touches them, nor cuts them — is an ellipse.

Let there be, in the same Sphere, the two conic surfaces as before, and the greatest circle HI, which is neither equidistant from the bases DE and FG, nor touches them, nor cuts them, even if the surfaces themselves were extended to infinity. Let the sundial-plane KL be equidistant from this circle, producing in the conic surface AFG the section MNO. I say that MNO is an ellipse. For let a circle be drawn through the poles of the circles FG and HI — and therefore also through the poles of the circle KL, which the sundial-plane makes in the Sphere (by Prop. 1 of Book 1 of Theodosius, since the poles of KL are the same as those of the circle HI, by Prop. 1 of Book 2 of Theodosius). This greatest circle BDCE will, by Prop. 15 of Book 1 of Theodosius, cut the circles FG and KL in half and at right angles, along the straight lines FG and KL, which will mutually intersect one another — namely at the point P — because they are not equidistant from each other; ^aand it will make the common sections HI, KL of the parallel planes HI, KL parallel to one another. Let the same circle BDCE also make the triangle-through-the-axis AFG, cutting the straight line KL and the conic section in M. Let it also cut...

[Margin: (a) 16 of the eleventh.]

also the sundial-plane KL, along the straight line LM, passing through the plane of the circle FG (for the planes FG and KL will necessarily cut one another, since they are not taken as parallel); or at any rate cut its plane extended, along the straight line NPO, which is drawn through the point P. For since the straight line KL cuts the straight line FG at P, the plane drawn through KL — drawn also

through P — will pass through P, and therefore the common section of the planes FG and KL will pass through the point P. Since, then, the planes FG and kL are perpendicular to the plane of the circle BDCE (because this circle cuts those planes at right angles, as we showed a little before), ^atheir common section NO will likewise be perpendicular to the same plane, and so — by Definition 3 of Book 11 of Euclid — will also be perpendicular to the straight line FG, the base of the triangle-through-the-axis.

And since the straight lines HI and kL have been shown to be parallel, ^bthe angles HAM and kMA will be equal to two right angles; and hence the angles FAM and kMA are less than two right angles. Therefore, by Postulate 11 of Book 1 of Euclid, the straight lines AF and kL, extended toward the parts F and k, will meet; and consequently the sundial-plane drawn through kL will cut the side AF, extended toward those same parts F and k. For this reason, since the cone AFG is cut by the plane BDCE through the axis, and is also cut by the other plane kL — which meets both sides AF and AG of the triangle-through-the-axis AFG — and since that plane kL is neither equidistant from the base FG nor cuts off at the vertex A a triangle similar and subcontrarily placed to the triangle-through-the-axis (^cbecause the angle ANP, the exterior, is greater than the interior angle AGF — that is, than the angle AFG, ^dsince this is equal to the angle AGF), and since NO, the common section of the cutting plane kL and of the base of the cone FG, is perpendicular to FG, the base of the triangle-through-the-axis (or at any rate to the line set in a straight line with it): the common section MNO will, by Prop. 13 of Book 1 of Apollonius, be an ellipse. Therefore the common section of the same surfaces, and so on — which was to be shown.

[Margin: (a) 19 of the eleventh.] [Margin: (b) 29 of the eleventh. [printed "29. vnde."]] [Margin: (c) 16 of the first.] [Margin: (d) 5 of the first.]

Diagram. Upper figure: a large circle (sphere, center A) for the ellipse construction of Theorema 6. Readable labels: B (top), D (upper left), E (upper right), I (right, below E), L (right, lower), A (center), M (interior, right of center), H (left), F (lower left), N (lower left interior, near F), K (bottom left), C (bottom, small "c" also near N), G (lower right). The great circle BDCE, the trace KL, the triangle-through-the-axis AFG, and the section point M are shown. Several lower-interior labels (N, K, small c) are crowded [?]

Diagram. Lower figure: a large circle (sphere, center A) with the cutting-plane trace extended as the line N–P–O running out below the lower left. Readable labels: E (top, with a dashed rim and a second E marked at the upper rim), D (upper left), I (right upper), L (right lower), A (center), M (interior, right of center),

N (lower interior), H (left), K (lower left), P (left, on the line below the circle), F (bottom center), O (below P, foot of the line NPO), C (bottom), G (lower right). The line NPO passes through P (the intersection of KL and FG) and carries the common section NO of the cutting plane. Several labels along the lower rim and the NPO line are crowded/worn [?]

COROLLARIVM.

Therefore, since a Vertical circle of a latitude less than 45° is neither equidistant from the parallels (of which one is the greatest of those that always appear, the other the greatest of those that are perpetually hidden beneath the Horizon), nor touches them, nor cuts them: the common section of the plane of a Vertical sundial — whose latitude is less than 45° — and of the cone whose base is the greatest of the parallels always hidden beneath the earth, will be an ellipse (if the sundial-plane is turned toward the parts of the hidden pole and faces the visible pole); or the common section of that plane and of the cone whose base is the greatest of the parallels that perpetually appear will be an ellipse (if the sundial-plane recedes toward the parts of the visible pole and faces the parts of the hidden pole).

In the same way, the common section of any sundial and of a cone whose base has a southern declination greater than the complement of the altitude of the arctic pole above the greatest circle from which the sundial-plane is equidistant, will be an ellipse. Such will be the section of the cone whose base is the parallel ♊ [Capricorn] and of a horizontal sundial at a northern latitude exceeding $66^\circ 30'$; because in this case the declination of ♊ — namely $23^\circ 30'$ — will be greater than the complement of the pole's altitude. Of this same kind will be the section of the cone whose base is the parallel ♐ [Sagittarius] and ♒ [Aquarius], together with a horizontal sundial at a northern latitude exceeding $69^\circ 48'$; for the declination of this parallel, amounting to $20^\circ 12'$, is greater than the complement of the pole's altitude. Such too will be the section of the cone whose base is the parallel ♏ [Scorpio] and ♓ [Pisces (♊)], together with a horizontal sundial at a northern latitude greater than $78^\circ 30'$, since the declination of this parallel — namely $11^\circ 30'$ — exceeds, in this way, the complement of the pole's altitude. Say the same of the cones whose bases are the northern parallels opposite to the aforesaid — such as the parallel ♋ [Cancer]; ♊ [Gemini] and ♌ [Leo]; ♉ [Taurus] and ♍ [Virgo] — where, however, the antarctic pole is raised above the Horizon.

[Margin: The plane of a Vertical sundial at a latitude less than 45° produces, on one of the two conic surfaces whose bases are the ever-apparent greatest parallel

and the ever-hidden greatest parallel, an ellipse. Those sundials, on the conic surfaces whose bases are any parallels of the Equator, produce ellipses.]

From this you will easily learn which sundial-planes produce ellipses, whatever parallel the Sun stands in. For if the Sun stands in a northern parallel from which the great circle equidistant from the sundial-plane is neither equidistant, nor touches, nor cuts, then the common section of the sundial and of the cone of shadow whose base is that parallel...

[the base being] the opposite southern parallel, will be an ellipse — namely when the arctic pole is raised above the plane of the sundial. But if, instead, the antarctic pole is raised above the plane of the sundial, and the Sun stands in a southern parallel from which the great circle equidistant from the sundial-plane is neither equidistant, nor touches it, nor cuts it, then an ellipse will be produced on the cone of shadow whose base is the opposite northern parallel, as is clear from what has been said. Now the great circle is neither equidistant from any given parallel, nor touches it, nor cuts it, when the declination of the parallel is greater than the complement of the altitude of the pole above the great circle; or when the complement of the declination of the parallel is less than the altitude of the pole above the great circle, as is evident from the figure.

PROBLEMA 2. PROPOS. 8.

Given a cone and the diameter of a conic section, to describe that conic section in a plane.

Diagram. A composite construction plate of six sub-figures (uncaptioned), arranged in three rows of two, illustrating the construction of Problema 2. The same plate is reprinted, with minor variation, on the following two pages.

- **Top row — the "first figures" (cones shown as axial triangles).** Two triangles, each with apex **A** and base ends **B** (left) and **C** (right), representing a cone cut through its axis. Within each, the diameter of the section runs **D–E**; parallel chords **F–H** and **G–I** meet the diameter **DE** at the interior points **K** and **L**; the axis drops to the base at **N**. Further points **R**, **S**, **T** appear at the foot (the extension of the triangle below the base for the ellipse whose diameter cuts below **BC**), and the base perpendicular chord is labelled **Z–α**; the circle-section points near the chords are **X**, **Y**. Many interior labels are crowded and not individually resolvable at this resolution [?].

- **Middle row — the "second figures" (the base BEC set out separately).** Each shows a horizontal base line carrying, left to right, points **B, F, G, E** and then **H, I, C** (with **R, S** as outer extensions), on which concentric semicircles are described about the diameters **BC, FH, GI**. A perpendicular **E–M** rises at **E** (**M** at top), cutting the semicircles at **P** and **Q** [several clustered base labels near the **E**-end not individually resolvable — ?].
- **Bottom row — the "third figures" (the described sections).** Left: a **parabola**, apex **D** at top, axis **D–E** vertical, with horizontal ordinate-chords through **K**, and points **P, M, V, T** stepping down to base **E**. Right: a **hyperbola** shown as a wide **V** opening upward from apex **D**, axis **D–E**, with points **L, C, P, K, M, E, V** on the ordinates.

[Diagram note: this is an extremely label-dense reprinted construction plate; more than two interior point-labels per sub-figure could not be individually resolved]

[Margin: The method by which a conic section, whose diameter is given within the cone, may be described in a plane.]

Let **ABC** be a given cone, cut by a plane through the axis — producing, by Proposition 3 of Book 1 of Apollonius, the axial triangle **ABC**. Let it also be cut by another plane producing either a parabola, a hyperbola, or an ellipse, whose diameter is **DE**. This diameter **DE** is parallel to the side **AC** of the triangle in the parabola; it cuts that same side **AC**, extended above the vertex **A**, in the hyperbola; or it lies within the cone in the ellipse — whether this happens above the base **BC** or below it. All this is established from the three propositions just cited. On the diameter **ED** take any number of parts, whether equal or unequal, **Ek, kL**; and through the points **k, L** draw **FH, GI** parallel to the base **BC**. Then both the parts **CH, HI** and the parts **Ek, kL** will be proportional to the parts **BF, FG** [Margin: a. Euclid VI.2] (taking, in the ellipse, the point **E** on **BC**, the base of the triangle). Indeed, in the parabola the parts **CH, HI** are equal to the parts **Ek, kL** [Margin: b. Euclid I.34], because of the parallelograms **Ck, kI**.

But if the cone is a right cone — as are all those we use in laying out sundials (for all these are right, since their axes are portions of the world-axis, which by Proposition 10 of Book 1 of Theodosius is perpendicular to the parallels of the primary motion, that is, to the bases of the cones) — we shall proceed most conveniently as follows. On the straight line **BD** take any number of parts, whether equal or unequal, **BF, FG**, and on the other side make **CH, HI** equal to them one by one; then join **FH, GI**, which cut the diameter **DE** at **K, L**. For these lines, since they cut the sides **AB, AC** proportionally, will be parallel [Margin: c.

Euclid VI.2], and therefore the parts EK, KL will be proportional to the parts BF, FG. Next set out separately the base BEC of the triangle ABC, and from the point E — which stands for all the points E, K, L — erect the perpendicular EM; and along the straight line BC, from the point E, transfer to both sides the parts KF, KH and LG, LI, so that EF, EG are equal to KF, LG, and EH, EI equal to KH, LI. On the side of C, in the parabola, these will all fall on the point C, because EC, KH, LI are equal [Margin: d. Euclid I.34]. In the hyperbola they will always be less than EC, and in the ellipse greater, as is evident. In every case, however, the parts BF, FG in the first figures (I call the cones themselves the "first figures," and those in which we have set out the base BEC separately the "second figures") will be proportional to the parts BF, FG in the second figures; and likewise CH, HI in the first to the parts CH, HI in the second. For if GN is drawn in the first figures parallel to DE, then as GB is to BN, so GF is to FO [Margin: e. Euclid VI.4] (since the triangles GBN, GFO are similar...

are similar, by the corollary to Proposition 4 of Book 6 of Euclid); and, by alternation, as GB is to GF, so BN is to FO. Now since BN in the first figures is equal to BG in the second, and FO in the first to FG in the second — because NE is equal to GL in the first, that is, to GE in the second, and therefore BN to BG, and FO to FG (for EB, EF, EG in the second figures were set equal to EB, KF, LG in the first) — it will also follow that as GB is to GF in the first, so BG is to FG in the second; and, dividing, as FB is to GF in the first, so BF is to FG in the second. We shall show the same for CH, HI, if from I a line is drawn in the first figures parallel to DE. Hence, if BF, FG are equal in the first figures, then EK, KL in the first — and also BF, FG and CH, HI in the second — will be equal, as appears from the figures; for we took the parts BF, FG in the first figures to be equal, for the sake of simplicity.

After this, about the diameters BC, FH, GI describe semicircles cutting the straight line EM at the points M, P, Q. The radii will be obtained if the axis of the cone in the first figures is drawn so as to bisect the base of the triangle. For this axis will also bisect all the diameters FH, GI and the rest, as we showed in the scholium to Proposition 4 of Book 6 of Euclid. Therefore, if in the first figures we take the distances between the axis of the cone and the points E, K, L, and transfer them into the second figures from the point E onto the line BEC — either toward B or toward C, as the first figures indicate — we shall obtain the centres, and so on.

Finally, let the diameter DE of the conic section be divided separately, as it was in the cone — that is, so that EK, KL are equal to the parts EK, KL in the cone, each to each. And through E, K, L erect perpendiculars to DE. This is done easily and very

quickly (especially when many points have been taken on the diameter DE) if you erect a perpendicular through E, from two points of which parallels to DE are raised and divided in the same way as DE. For the straight lines joining the points of division will be perpendicular to DE at the points K, L [Margin: a. Euclid I.29], because in this way parallelograms are set up on the lines EK, EL, which are rectangles, owing to the right angle established at E, as is evident.

Diagram. The same composite construction plate reprinted (six sub-figures, uncaptioned), here with the "third figures" showing the two ellipse cases.

- **Top row — the "first figures" (cones/axial triangles).** As on the previous page: apex A, base B–C, section-diameter D–E, parallel chords F–H and G–I meeting DE at K, L, axis-foot N, lower extension R, S, T, base chord Z–α, circle points X, Y. Dense interior labels not individually resolvable [?].
- **Middle row — the "second figures" (base BEC set out).** Horizontal base with points B, F, G, E, H, I, C (and R, S as extensions), concentric semicircles on BC, FH, GI, perpendicular E–M (M at top) cutting them at P, Q [clustered base labels near E — ?].
- **Bottom row — the "third figures" (two ellipses).** Left: an upright ellipse, top point D, upper chord V–V, then T, centre L, mid chord Q–Q, K, lower chord P–P, bottom point E. Right: a second ellipse with top D and upper marks C–C, then L, chord F...P, centre E, lower marks M–M, T, chord V–V, base E; its lower half drawn dotted.

[Diagram note: reprinted dense construction plate; more than two interior labels per sub-figure unresolved]

After this, from the perpendiculars — or the parallels drawn through the points E, K, L in the third figures — cut off, on both sides of the points E, K, L, straight lines EM, kP, LQ equal to the straight lines EM, EP, EQ in the second figures: namely kP equal to the line intercepted between the diameter FH and its semicircle (which is EP in the second figures); and LQ equal to EQ, placed between the diameter GI and its semicircle; and so with the rest — carefully observing which points of the diameter DE correspond to which diameters of the semicircles. Now if you join the points D, Q, P, and so on suitably by a certain curved line, the proposed conic section will have been described — namely a parabola, a hyperbola, or an ellipse, as we shall shortly demonstrate. From this it is clear that the more numerous the points on the diameter DE, the more accurately the conic section is described, as you see done in the hyperbola and in both ellipses; for in these sections another point besides K, L has been taken. But if you set out to enlarge the parabola and the hyperbola, the cones must be

enlarged, and points must be taken below the base BC, equal in number to the points F, G, and so on, as the figures indicate. The same is to be said of the ellipse whose diameter cuts the other side of the axial triangle below the base, as in the second ellipse;

for otherwise only the part of the ellipse MPQDQPM would be described. Moreover, in the first ellipse, whose diameter does not cut the base of the triangle, no semicircle is described about the diameter BC, because it would not cut the straight line EM. Sometimes, too, the semicircles intersect one another on the straight line EM in the description of the ellipse — as the semicircles FPH, RVS in the first ellipse, where the straight lines EP, EV are equal, and the perpendiculars kP, TV are taken equal to them in the third figures.

Diagram. The same composite construction plate reprinted (six sub-figures, uncaptioned), matching the plate on the previous page (cones, semicircles, and the two ellipse cases).

- **Top row — "first figures" (cones/axial triangles):** apex A, base B–C, section-diameter D–E, chords F–H and G–I meeting DE at K, L, axis-foot N, lower extension R, S, T, base chord Z–α, circle points X, Y; dense interior labels unresolved [?].
- **Middle row — "second figures":** base line B, F, G, E, H, I, C (with R, S), concentric semicircles on BC, FH, GI, perpendicular E–M cutting them at P, Q [clustered base labels — ?].
- **Bottom row — "third figures" (two ellipses):** left ellipse with D, V–V, T, L, Q–Q, K, P–P, E; right ellipse with D, C–C, L, F...P, K, E, M–M, T, V–V, E and a dotted lower half.

[Diagram note: reprinted dense construction plate; more than two interior labels per sub-figure unresolved]

But let us now demonstrate that the conic section passes, in the plane, through the points Q, P, and so on, about the diameter DE — and hence that the line suitably drawn through those points in the plane is a conic section, as we said. [Margin: Demonstration of the description given above.] If, in the first figures, a plane is drawn through the straight line FH parallel to the base of the cone, the section produced will be the circle FXH, by Proposition 4 of Book 1 of Apollonius. Let the common section of this plane and of the conic section be the straight line XY, which will pass through K, where the straight lines DE, FH cut one another, and where the circle FXH drawn through the line FH meets the conic section. And since the parallel planes BC, FH are cut by the plane DE which produces the conic

section, the common sections $Z\alpha$ and XY will be parallel [Margin: a. Euclid XI.16]. Now $Z\alpha$ is perpendicular to the straight line BC (for in order that any conic section be produced, the common section of the cutting plane and the base of the cone — such as the straight line $Z\alpha$ — must be perpendicular to the base of the axial triangle, as is established from Propositions 11, 12, and 13 of Book 1 of Apollonius). And the angles BEZ , FKX are equal [Margin: b. Euclid XI.10], because the straight lines BE , EZ are parallel to FK , kX . Therefore the angle FKX will also be right, and so XK is perpendicular to FH ; and consequently XK , in the semicircle FXH , will be the mean proportional between FK , KH , by the scholium to Proposition 13 of Book 6 of Euclid. But in the second figures too, EP is, by the same reasoning, the mean proportional between FE , EH — that is, between the same Fk , KH in the first figures — and therefore equal to XK in the first figures (for EF , EH in the second figures were taken equal to KF , KH in the first). Now this same EP in the second figures is equal to kP in the third. Therefore kP in the third figures is also equal to KX in the first. So, since in the first figures the conic section passes through X on the conic surface, the same section will pass, in the plane, through the point P . For in this way, when the point K of the third figures is placed on the point k of the first, so that the diameter kD of the third coincides with the diameter kD of the first, the perpendicular kP in the third figures will coincide with the perpendicular kX in the first; and thus the point P will fall on the point X (because of the equality of the straight lines kP , kX), and the conic section will pass through the point P , which does not differ from the point X . By the same reasoning we shall show that the same section passes through the point Q , and through the rest, if there are any. Therefore, given a cone and the diameter of a conic section, and so on — which was to be done.

SCHOLIUM.

This method of describing a conic section, together with its demonstration, does not differ from the one that Federicus Commendinus [Federico Commandino] presents in his book on the description of sundials — except that he speaks only of the right cone, whereas we have adapted the problem to every cone, right as well as scalene, and have at the same time included the procedures required for describing the sections of right cones. For he prescribes that in the first figures any number of points K , L be taken on the diameter DE , and that through them parallels to the base BC be drawn. But in a right cone it is easier, with the help of a compass, to take the points F , G , H , I on both sides AB , AC ; for the straight lines connecting these points are parallel, as we have shown. Then, in the first figures, he directs us to find, between KF , kH and LG , LI , the...

to find the mean proportionals — which we have accomplished by describing semicircles in the second figures. Finally, once the diameter DE has been divided in a separate plane (namely in the third figures, just as it was divided in the cone of the first figures), he directs that from the division points, in the third figures, perpendiculars be drawn up to the diameter on both sides — which we too did in the third figures, by a very easy and short procedure, especially where the points were many. Onto these perpendiculars he transfers the mean proportionals that have been found, as we do; and through the outermost points of the transferred mean proportionals he draws the conic section, just as we have done.

Franciscus Maurolycus [Francesco Maurolico], abbot, in the third book of his work on hour-lines, uses other, particular constructions for the three conic sections. But the method of construction that we have handed down is simpler and easier, and applies to all the sections, as is clear. We have said nothing about constructing that conic section which is a circle, because once the diameter is known its construction is very easy.

At this point I should like to present another method — not unpleasant, and perhaps easier than the one we have explained — for describing a parabola, two opposite hyperbolas, and an ellipse whose axes are given. This method (to my great surprise) has, so far as I know, been noticed by no one up to now. We shall adapt it only to right cones, because it is only these that we shall use in laying out sundials. For the parabola, then, we must first set out a lemma of the following kind, which suits both the right cone and the scalene cone.

LEMMA.

Given a cone and the diameter of a parabola, to find the latus rectum of the parabola.

[Margin: Finding the latus rectum [latus rectum] of a parabola whose diameter is given in the cone.]

Diagram. Left-hand figure of the parabola lemma: an axial triangle of a cone with the conic section inscribed, together with the applied rectangles beneath it.

- A (apex of the triangle at top); a second A stands at the head of the slanting line A–I drawn off to the right (the latus-rectum construction line)
- B (lower-left) and C (base corners of the axial triangle)
- F, D, H (points of the inscribed conic section, D and H at its center)
- K (on the left, at the section)
- I (lower right, foot of the slanting construction line A–I)

- Beneath the triangle, a rectangle (the rectangle CB contained under AB, AC), divided, with B marked at its foot

[Two or three peripheral labels on this crowded cone figure are hard to resolve]

Diagram. Right-hand figure: the parabola drawn within a rectangle in the plane, opening downward, with its vertical axis and successive ordinate-chords.

- E (vertex of the parabola, top center) with K at the upper corners
- Axis E–A–B–C–M–H descending vertically (A, B, C, M interior points; H at the foot)
- D (endpoints of the ordinate at A)
- N (endpoints of the ordinate at the level of L)
- F (endpoints of the ordinate at B)
- G (endpoints of the ordinate at C)
- O (endpoints of the ordinate at the level of M)
- I (base corners, the ordinate at H)
- A point marked Q near the F-level ordinate [?] and the point L on the axis [?] are not clearly resolvable

[More than two labels uncertain]

Let there be a given cone ABC, in which ABC is the axial triangle. Let the cone be cut by a plane producing the parabola EFG, in accordance with what Apollonius demonstrated in Proposition 11 of Book 1 [of the *Conics*], so that its axis EH is parallel to the side AC of the axial triangle. We shall then find the latus rectum of this parabola as follows. [Margin a: Euclid VI.11] Make BC to AI as one side of the axial triangle, namely AB, is to the base BC. [Margin b: Euclid VI.12] Then make AE to EK as the other side AC is to the AI just found. I say that EK is the latus rectum of the parabola EFG — that is, the straight line beside which the ordinates drawn to the diameter EH can be applied.

For let the rectangle CB be that contained under the sides AB, AC of the axial triangle; and to AB apply the rectangle BI contained under AB, AI, [Margin c: Euclid VI.17] which will be equal to the square of the base BC, since the three lines AB, BC, AI are continuously proportional by construction. [Margin d: Euclid I.14] And CAI will be a single straight line, because the two angles at A are right. Since, then, CA is to AI as AE is to EK by construction, then by conversion AI is to AC as EK is to AE. [Margin e: Euclid VI.1] But AI is to AC as the rectangle BI — that is, the square of the base BC — is to the rectangle BC contained under the sides of the axial triangle. Therefore, as the square of the base BC is to the rectangle

contained under the sides AB, AC, so is EK to AE. And so, by Proposition 11 of Book 1 of Apollonius, EK is the latus rectum of the parabola EFG — that is, the straight line beside which the ordinates can be applied, and so on.

Now that the latus rectum has been found, take in some plane any axis EH of the parabola. (For here we are dealing with the parabola whose diameter is also its axis, bisecting all the ordinates at right angles.) On this axis mark off any number of equal parts — the smaller these parts are, the more accurately the parabola will be drawn — so that EA is 1, AB is 3, BC is 5, CH is 7, and so on, following the series of odd numbers. Then through the points A, B, C, H, and so on, draw perpendiculars to EH on both sides, in the way we taught above. [Margin: Another way of describing the parabola in the plane.] Next, having found the mean proportional between the latus rectum EK and the line EA, cut off AD equal to it on both sides; from B cut off on both sides BF, double AD; from C, CG, triple the same AD; from H, HI, quadruple; and so on, following the natural series of numbers. For through the points D, F, G, I the parabola is to be drawn.

That it passes through the point D is proved thus. The square on AD — the line that is the mean proportional between EK and EA — [Margin f: Euclid VI.17] is equal to the rectangle under EK, EA; and therefore AD is an ordinate in the parabola whose latus rectum is EK, as is clear from Proposition 11 of Book 1 of Apollonius. So the parabola will pass through the point D. For if it passed through some other point, say P, then the square on AP would likewise be equal to the rectangle under EK, EA, by Proposition 11 of Book 1 of Apollonius, since AP would be an ordinate to the diameter. Then the squares on AD and AP would be equal, and so the lines themselves would be equal — a part equal to the whole, which is absurd. Therefore the parabola whose latus rectum is EK passes through the point D. That it also passes through the points F, G, I we shall show as follows. Since the line BF is double the line AD, its square will have to the square of AD the quadruple ratio [Margin g: Euclid VI.20] (because squares are in the duplicate ratio of their sides), just as the line EB is quadruple the line AE.

Again, since the line CG is triple the line AD, [Margin a: Euclid VI.20] its square will be nine times the square of AD, just as the line EC is nine times the line EA. In the same way the square on HI will have to the square on AD the same ratio that the line EH has to EA — namely sixteenfold — and so on. Therefore, as is clear from Proposition 20 of Book 1 of Apollonius, the parabola will pass through the points F, G, I. For if it were said to pass through some other point, say Q, then by that same Proposition 20 of Book 1 of Apollonius the square on BQ would be to the square on AD as the line EB is to the line EA — that is, as the square on BF is

to the square on AD. Then the squares BQ and BF would be equal, and the lines themselves equal — a part and the whole — which is absurd. Therefore the parabola must be drawn not through Q but through F, and so for the rest.

But whenever the points seem to lie too far apart — as G and I do — we shall take, on the diameter EH between the points C and H, some point that marks off a number of parts of the diameter divisible by four: 8, or 12, or 16, or 20, and so on. Of this kind is the point M, which marks off twelve parts. Then of the line EM we shall take a quarter part — in the given example the line EL, containing three parts — and from L we shall draw a perpendicular to EH, namely LN, which cuts the parabola at the point N. For if through M we draw another perpendicular to EH, and from it cut off MO double LN, the parabola will pass through the point O; because LM is triple EL, and MO double LN, just as AB is triple EA and BF is double AD.

This same method can be adapted to a parabola in which the ordinates are not perpendicular to the diameter EH — as happens in scalene cones, when the axial triangle is not perpendicular to the base of the cone, as is clear from Proposition 7 of Book 1 of Apollonius. In that case EH will not be the axis of the parabola but a diameter. Hence through the points A, B, C, H one must draw lines parallel to one another, making with the diameter EH angles equal to those which the ordinates make with the diameter of the parabola. This method will suit scalene cones all the more when the axial triangle is perpendicular to the base of the cone; for then, by Proposition 7 of Book 1 of Apollonius, the ordinates are perpendicular to the diameter of the parabola, just as in a right cone, so that EH is again the axis of the parabola.

For the opposite hyperbolas, however, two further lemmas must be proved, which apply to every cone, right as well as scalene. The first of these is as follows.

LEMMA I.

Given a cone and the transverse diameter of opposite hyperbolas, to find the latus rectum of the hyperbola.

[Margin: Finding the latus rectum of opposite hyperbolas whose transverse diameter is given in the cone.]

Diagram. A double cone (two cones joined at their common vertex, in the shape of an hourglass), cut by a plane producing two opposite hyperbolas, with a square beneath.

- A (common vertex, center, where the two cones ABC and ADE meet)
- B, C (base corners of the lower cone); D, E (of the upper cone)
- F, G, H and I, K, L (points of the two opposite hyperbolic sections; F and I are the vertices, on the common transverse diameter FI)
- M (on BC, foot of the line AM drawn parallel to FI)
- N (point such that $MC : AM = AM : MN$); O (on the diameter, foot of FO)
- P (upper region of the section) [?]
- Q (lower region, near the base) [?]
- Beneath, a square with its foot marked

[Several peripheral labels (P, Q and the second set of M, N) are hard to resolve on this crowded double-cone figure]

Let there be a given cone ABC, in which ABC is the axial triangle; and let the cone, together with the axial triangle, be produced through the vertex A, so that two cones ABC, ADE are formed, joined at the vertex A. Let both conic surfaces be cut by a plane not passing through the vertex, producing the sections FGH, IKL, which are opposite hyperbolas by Proposition 14 of Book 1 of Apollonius, whose common transverse diameter is FI and whose latera recta are equal. We shall find the latus rectum of each as follows. Through A draw AM parallel to FI, cutting BC at M. [Margin b: Euclid VI.11] Make CM, one part of the base, to AM as AM is to MN. [Margin c: Euclid VI.12] Again make FI, the transverse diameter, to FO as MN is to BM, the other part of the base. I say that FO is the latus rectum of each hyperbola — that is, the straight line beside which the ordinates to the diameter of each hyperbola can be applied.

For let the rectangle BC be that contained under the parts of the base BM, MC; and to MC apply the rectangle CN contained under MC, MN, [Margin d: Euclid VI.17] which will be equal to the square of the line AM, since the three lines MC, AM, MN are continuously proportional by construction. [Margin e: Euclid I.14] And BMN will be a single straight line, because the two angles at M are right. Since, then, FI is to FO as MN is to BM, [Margin f: Euclid VI.1] and since MN is to BM as the rectangle CN — that is, the square on AM — is to the rectangle BC contained under the parts of the base BM, MC, it follows that the transverse diameter FI is to the line FO as the square on AM is to the rectangle under BM, MC. Therefore FO is the latus rectum of the hyperbola, by Proposition 12 of Book 1 of Apollonius — that is, the straight line beside which the ordinates can be applied, and so on.

LEMMA II.

To apply, on each side, to the transverse diameter of a hyperbola the fourth part of the rectangle contained under the transverse diameter and the latus rectum, in such a way that it exceeds by a square figure.

[Margin: How the fourth part of [the rectangle] contained under the transverse diameter of a hyperbola and the latus rectum is to be applied to the transverse diameter on each side, so that it exceeds by a square figure.]

With the same figure set out, let AB be found as the mean proportional between the transverse diameter FI and the latus rectum FO, and let AB be bisected at C. [Margin: Euclid VI.17] Then the square on AB will be equal to the rectangle under FI, FO; and therefore the square on AC, which by the scholium to Proposition 4 of Book 2 of Euclid is the fourth part of the square on AB, will be equal to the fourth part of the rectangle under FI, FO. To this square on AC, then, we shall apply to the transverse diameter FI, on each side, an equal rectangle exceeding by a square figure, in this way. Let the line FI be bisected at D; construct a right angle HKL, with HK equal to AC and KL equal to DI, and join HL, which will be greater than the line KL — that is, than DI — because HL is subtended by a greater angle than KL. [Margin: Euclid I.13; Euclid I.19] Produce FI in both directions, and cut off on both sides from D the lines DQ, DR equal to HL. I say that both the rectangle under FQ, QI applied to FI and exceeding by the square on QI, and the rectangle under IR, RF applied to the same IF and exceeding by the square on RF, are equal to the square on AC —

— that is, to the fourth part of the rectangle under FI, FO.

Diagram. Auxiliary figures for Lemma II (upper left of the page): the line AB with its midpoint, a small right triangle, and the gnomon figure of the application.

- A, C, B (the mean-proportional line AB bisected at C, drawn horizontally at top)
- Right triangle H, K, L (with HK = AC and KL = DI)
- Gnomon/rectangle figure below: points R, F, D, M, N (foot) and P, E, G, Q, I marking the square DE, the parallelogram MP, the square NI, and the gnomon DNE

[Interior labels of the gnomon figure are small and partly worn]

Diagram. The two opposite hyperbolas described in the plane (right side of the page), with the two describing points Q and R and the vertical axis.

- F, I (vertices of the opposite hyperbolas, on the transverse axis)
- Q, R (the two fixed points from which the arcs are struck)
- E, G, H (points through which the branches are drawn)
- A, B, C, D (points taken on the axis below/beyond, marking the intervals IA, IB, IC and FA, FB, FC)
- K (the false point used in the reductio)
- O (outer point at right) [?]
- Several repeated H, G, E, F labels on the four branch-arms are hard to resolve individually

[More than two labels uncertain on this dense multi-branch figure]

For, having described the square DE on DI, draw through Q the line PN parallel to IE, meeting the line GE produced at P and the diameter GI produced at N, and complete the figure as you see. [Margin a: Euclid VI.24] Now since the parallelograms DE, MP, NI, standing about the same diameter, are similar, and DE is a square, MP and NI will also be squares. [Margin b: Euclid I.47] And since the square on HL is equal to the squares on HK, KL — while, by construction, the line HL is equal to DQ (that is, to MN), the line HK to AC, and the line KL to DI — the square MP described on DQ (that is, on MN) will be equal to the square DE described on DI together with the square on AC. Therefore, when the common square DE is taken away, the remaining gnomon DNE will be equal to the remaining square on AC. And since the gnomon DNE is equal to the rectangle FN — [Margin c: Euclid I.36] for since FM is equal to MI, [Margin d: Euclid I.43] that is, to IP, the rectangle FN, with the common MQ added, will be equal to the gnomon DNE — the rectangle FN, contained under FQ, QI (since QI is equal to QN because of the square IN), will also be equal to the square on AC; that is, to the fourth part of the square on AB, that is, of the rectangle contained under FI, FO. There has therefore been applied to the transverse diameter FI a rectangle under FQ, QI equal to the fourth part of the rectangle under FI, FO and exceeding by the square on the line QI. In the same way it will be demonstrated that the rectangle under IR, RF, applied to FI and exceeding by the square on RF, is equal to the fourth part of the rectangle under FI, FO. Which was what was proposed.

With these things premised, let FI be the transverse axis of two opposite hyperbolas FGH, IKL, as in the figure of the first lemma, and let the latus rectum FO be given from that same first lemma. By the second lemma, apply to FI on each side a rectangle under FQ, QI and under IR, RF equal to the fourth part of the rectangle under FI, FO and exceeding by the square on IQ and on FR; and beyond R and below R take any number of points A, B, C, D as you please. Then, at

the distance IA, describe from the points Q and R four arcs, which are cut at the point E by four other arcs described from the same points Q and R at the distance FA. Likewise from the same Q and R describe four arcs at the distance IB, which are intersected at the point G by four others described from the same points Q and R at the distance FB. In the same way, at the distances IC, FC, let the arcs described from the points Q and R cut one another at H; and so for the remaining points, if there are any. One must always observe that, of the four arcs to be described from Q and R, the two larger from Q are described beyond the point F, and the two from R beyond the point I; while the two smaller from Q are on the near side of the point I, and the two from R on the near side of the point F. For through the points F, E, G, H and I, E, G, H the opposite hyperbolas are to be described.

For since the line QE — that is, IA — exceeds the line ER — that is, FA — by the transverse diameter FI; and likewise the line QG exceeds the line GR by the same diameter; and so for the rest — the opposite hyperbolas, whose axis is FI and whose vertices are F, I, will pass through the points E, G, H. For, as Proposition 51 of Book 3 of Apollonius requires, if straight lines are drawn from the points Q, R to one and the same point of the hyperbola, the greater exceeds the lesser by the axis FI itself. For suppose the hyperbola whose axis is FI and vertex F does not pass through the point E: let it, if possible, pass through K, cutting the line QE at K, whether below E or above; and join the line RK. Then, since the hyperbola passes through K, the line QK will exceed the line KR by the axis FI, by Proposition 51 of Book 3 of Apollonius. But by the same axis FI the line QE exceeds the line ER by construction. Therefore the excess between the lines QK, KR is the same as that between the lines QE, ER. And so, by alternation, from the lemma of Proposition 79 of Book 10 of Euclid, the excess between the lines QK, QE will be the same as that between the lines KR, ER. Now since the excess between QK and QE is the line EK, the same line EK will also be the excess between KR and ER. Therefore the line EK, added to the lesser of them, will make the sum of these two equal to the remaining one; and consequently two sides of the triangle EKR will be equal to the remaining side [Margin e: Euclid I.20] — but they are also greater. Which is absurd. Therefore the said hyperbola will pass not through the point K but through E. And in the same way we shall show that it passes through the remaining points G, H, and so on — which was what was proposed.

It is evident, moreover, that this construction applies only to right cones, or else to scalene cones in which the axial triangles are perpendicular to the bases of the cones; for in these alone is the transverse diameter the axis of the hyperbolas,

since it cuts the ordinates at right angles, as is clear from Proposition 7 of Book 1 of Apollonius.

Finally, for the ellipse, two lemmas must again be set out, which follow, and which fit every cone, right as well as scalene.

LEMMA I.

Given a cone and the transverse diameter of an ellipse, to find the latus rectum of the ellipse.

[Margin: Finding the latus rectum of an ellipse whose transverse diameter is given in the cone.]

Diagram. The ellipse lemma figure (foot of the page): an axial triangle of a cone with an inscribed ellipse, and beneath it the diameter line G–H and its rectangle.

- A (apex of the axial triangle)
- E, I (on the left side of the triangle); F (on the right side)
- B, C (base corners); D (center); G (on the base line / ellipse)
- Below: the line G–H drawn out, and a rectangle B–G–...–H–C (with G marked at top center of the rectangle and C at its foot)

Let there be a given cone ABC, in which ABC is the axial triangle; and let the cone be cut by a plane producing the ellipse EF, in accordance with...

in accordance with Proposition 13 of Book 1 of Apollonius (*Conics* I.13), so that the straight line EF is the transverse diameter of the ellipse. We shall then find its latus rectum as follows. Through A draw AG parallel to EF, cutting BC produced at G [Margin a: Euclid VI.11]; and let it be brought about that, as CG — the straight line between the point G and the other side of the axial triangle — is to AG, so is AG to GH.

Diagram. The axial triangle of a cone with an inscribed ellipse, and beneath it the diameter line G–H drawn out with its rectangle. The construction finds the latus rectum EI of the ellipse EF.

- A (apex of the axial triangle)
- E (on the upper left side of the triangle); I (marked to the left, off the side)
- F (on the right side of the triangle)
- B (base, left corner); D (base, center); C (base, center-right); G (on the base line produced, to the right)
- An inscribed lens-shaped ellipse passing through B, D, C

- Below the triangle: a horizontal segment G——H
- A rectangle beneath that: B (top-left), G (top-center), H (top-right), C (bottom-center)

Again let it be brought about that, as GH is to GB — the straight line between the same point G and the other side of the axial triangle — so is EF, the transverse diameter, to EI [Margin b: Euclid VI.12]. I say that EI is the latus rectum of the ellipse — that is, the straight line to which the ordinates dropped to the diameter are referred [in square]. For let there be the rectangle BC contained under BG, GC — the straight lines lying between the point G and the sides of the axial triangle; and to GC let there be applied the rectangle CH, contained under GC, GH [Margin c: Euclid VI.17], which will be equal to the square on AG, since the three straight lines CG, AG, GH are in continued proportion by construction. And BGH will be one straight line, on account of the two right angles at G [Margin d: Euclid I.14]. Since, then, as HG is to GB, so is EF to EI [Margin e: Euclid VI.1]; and since, as HG is to GB, so is the rectangle HC to the rectangle CB — that is, the square on AG to the rectangle contained under BG, GC — therefore EI is the latus rectum of the ellipse EF, by Proposition 13 of Book 1 of Apollonius; that is, the straight line to which the ordinates are referred, and so on.

[Margin: How the fourth part of the rectangle contained by the transverse diameter of an ellipse and the latus rectum is to be applied to the transverse diameter on each side, so that it falls short by a square figure.]

LEMMA II.

To apply the fourth part of the rectangle contained under the transverse diameter of an ellipse and the latus rectum to the transverse diameter, on each side, so that it falls short by a square figure.

With the same figure supposed [Margin f: Euclid VI.13], let AB, the mean proportional between EF, the transverse diameter, and EI, the latus rectum, be taken, and let it be bisected at C [Margin g: Euclid VI.17]. Then the square on AB will be equal to the rectangle under EF, EI; and consequently the square on AC — which, by the scholium to Proposition 4 of Book 2 of Euclid, is the fourth part of the square on AB — will be equal to the fourth part of the rectangle under EF, EI. To this square on AC, then, we shall apply to the transverse diameter EF, on each side, an equal rectangle deficient by a square figure, in the following way.

Let the straight line EF be bisected at D. Since, by what has been demonstrated by Eutocius on the second definitions of Book 1 of Apollonius, the latus rectum EI is

less than the transverse diameter EF — that is, than the major axis of the ellipse — AB, the mean proportional between EF and EI, will also be less than EF. Therefore AC, the half of AB, will be less than DF, the half of EF. So, with a semicircle described about DF [Margin h: Euclid IV.1], let there be fitted in it a straight line FI equal to AC — which has been shown to be less than DF — and let DI be joined [Margin i: Euclid III.15], which will also be less than DF. From D let there be cut off on either side the straight lines DN, DO equal to DI.

I say that the rectangle under EN, NF applied to EF and deficient by the square on NF, as well as the rectangle under FO, OE applied to the same EF and deficient by the square on OE, is equal to the square on AC — that is, to the fourth part of the rectangle under EF, EI. For, with the square DH described on DF, let the figure be completed, as you see. [Margin k: Euclid VI.24] Since, then, the parallelograms DH, GL, LF, lying about the same diameter, are similar, and DH is a square, GL and LF will also be squares. [Margin l: Euclid I.47] And because the square DH is equal to the squares on FI, DI — that is, to the square on AC together with the square GL [Margin m: Euclid III.31] (for the angle DIF is right, and the straight lines FI, DI were equal to AC, DN or KL) — the gnomon KNH will be equal to the square on AC.

Diagram. A composite figure at the foot of the left column illustrating Lemma II. It comprises: a straight line A–C–B with C marking the bisection point; a short line-segment E–I (the latus rectum); a square-and-gnomon construction on DF; and, to its right, a dotted curve on DF carrying the same lettering.

- Line 1: A — C — B (C at the midpoint)
- Line 2: E — I (with E marked)
- Square/gnomon block: G, H (top); K, L (interior division points); E, O, D, N, F (along the bottom line); I (at the very foot); one sub-triangle is hatched
- Dotted curve at right, on the same base: E (top), F (foot); crowded interior/peripheral labels read as K, I, G, H, A, O, B, D, N, with several repeated glyph-clusters (K I G H I ... I H G I) that do not resolve individually [?]

Since, then, the gnomon KNH is also equal to the rectangle EL [Margin n: Euclid I.36] (for since EK is equal to KF — that is, to NH — when the common DL is added, the whole EL becomes equal to the whole gnomon KNH), the rectangle EL, contained under EN, NF (since NF is equal to NL, because of the square LF), will also be equal to the square on AC. Therefore there has been applied to EF, the transverse diameter, a rectangle under EN, NF equal to the fourth part of the rectangle under EF, EI and deficient by the square on the straight line NF. In the

same way it will be shown that the rectangle under FO, OE applied to EF and deficient by the square on EO is equal to the fourth part of the rectangle under EF, EI. Which was what was proposed.

With these things premised, let EF be the transverse axis of the ellipse EF, and EI its latus rectum, given from the first lemma. By the second lemma let there be applied to EF, on each side, a rectangle — both the one under FO, OE and the one under EN, NF — equal to the fourth part of the rectangle under EF, EI, the former deficient by the square on EO, the latter by the square on FN. And with NO bisected at A, let any number of points whatever, B, C, D, be taken between A and N.

Then, at the interval EA (or FA), let four arcs be described from the points O and N, cutting one another on either side at G. Likewise, from the same points O and N, at the interval EB, let four arcs be described, which four other arcs — described from the same points at the interval FB — cut at the point H. In the same way, at the intervals EC, FC, let the arcs described from the same points O and N cut one another at I; and so on for the remaining points, if there be any — always observing that, of each set of four arcs to be described from O and N, the two greater are described from O beyond the point A and two from N beyond the same point A, while the two lesser are described from O short of the point A and two from N short of the same point A. For through the points E, G, H, I, F the ellipse is to be described.

[Margin: Another way of describing an ellipse in a plane.]

For since the straight lines NG, OG — that is, EA, FA — as well as the straight lines NH, OH — that is, EB, FB — and so on, are equal to the axis EF, the ellipse whose axis is EF will pass through the points E, G, H, I, F; inasmuch as, by Proposition 52 of Book 3 of Apollonius, straight lines drawn from the points N, O inclined to one and the same point of the ellipse are equal to the axis EF. For if the said ellipse does not pass through the point I, let it pass, if that be possible, through K, cutting the straight line NI at K — whether beyond or short of I — and let OK be joined. Since, then, the aforesaid ellipse passes through K, the straight lines NK, OK together will be equal to the axis EF, by Proposition 52 of Book 1 of Apollonius [recte: Book 3]. But by construction the straight lines NI, OI are also equal to the same axis EF. Therefore NK, OK will be equal to the straight lines NI, OI. Yet they are also unequal; for when the point K falls beyond I [Margin a: Euclid I.20], the straight lines IK, KO are greater than the straight line IO, and so, adding the common IN, NK and OK will be greater than NI, OI. But when the point K falls short of I [Margin b: Euclid I.20], IK, IO are greater than KO, and so, adding the

common KN, NI and OI will be greater than NK, OK. Which is absurd. Therefore the said ellipse will pass through no other point than I. And in the same way we shall demonstrate that it passes through the remaining points H, G, and so on — which was what was proposed.

It is also evident that this description does not fit scalene cones, except when the triangles through the axis are perpendicular to the bases of the cones. For only then does the diameter of the ellipse cut the ordinates at right angles, as is clear from Proposition 7 of Book 1 of Apollonius, and so it is the axis.

[Margin: In what manner any parabola whatever is described in a plane.]

But if we wish to describe some parabola, or a hyperbola, or even two opposite hyperbolas, or an ellipse — with no regard to the cones from which they arise — we shall take for the parabola an axis EH of any magnitude, as in the parabola above, and in it any number of equal parts as we please; and through the points terminating the first part, and the next three, and the next five, and the next seven, and so on, we shall draw lines parallel to one another. Then, taking on the first any straight line AD you please, on both sides, we shall take its double on the second, its triple on the third, its quadruple on the fourth, and so on. For through the extremities of these lines the parabola is to be described.

[Margin: In what manner any two opposite hyperbolas whatever are described in a plane.]

For the hyperbolas, however, we shall take any axis FI, as in the preceding hyperbolas, to which on each side we shall add any equal straight lines FR, IQ, and we shall understand that to the axis FI there has been applied a rectangle under FQ, QI equal to the fourth part of the rectangle contained under the axis FI and the latus rectum, and exceeding by the square on QI, and so on.

Diagram. The large construction figure for describing a conic (parabola, opposite hyperbolas, and ellipse) directly in a plane, without reference to a cone. An axis runs from the apex A downward; a circle sits in the lower center; a set of oblique lines runs off to the right toward N, P, O, Q.

- A (apex, top); E, F (just below A)
- L, K (left of center); M, R (right of center)
- C — E — D (a horizontal line, E at the center)
- H (center, below E); I (lower left); B (foot, center); G (below B, at the foot)
- N (upper right); P (middle right); O (lower right); Q (far right)

- A circle in the lower-center region; several dotted construction lines from A through K toward M/R

Diagram. An articulated drawing instrument (an ellipsograph / trammel of the compass type) shown in the lower part of the page, used in place of the pegs and string. A long rod runs from a turned handle at the left across to a hinged joint at the right, with a large disc/pulley at the lower left and jointed arms carrying the tracing point.

- d (turned handle at the left end of the rod)
- f, e (near the center-top hinge)
- S (large disc/pulley at the lower left)
- T, X (at the upper right joint)
- b (at the lower right)
- V, Y (at the foot, lower right)

[Margin: In what manner any ellipse whatever is described in a plane.]

Finally, for the ellipse we shall take an axis EF at pleasure, as in the ellipse just treated, from which we shall cut off equal segments EO, FN on either side, as we please, and we shall understand that to the axis EF there has been applied a rectangle under FO, OE equal to the fourth part of the rectangle contained under the axis EF and the latus rectum, and deficient by the square on EO, and so on. The rest we shall complete as before.

[Margin: In what manner any ellipse whatever may be described in a plane by a string.]

Indeed, if in some straight line EF, drawn out to any length whatever — namely, in the same axis of the ellipse — two small pegs are fixed at two points, say at N and O, and a string is placed about them such that, when doubled, it exceeds the straight line NO and can turn freely, an ellipse will be described easily and readily, provided we set some stylus on this string and carry it round together with the string, always keeping the string stretched as far as possible. Thus, if the string about the pegs N, O is stretched as far as I, as far as it can reach, and if some iron stylus is placed at I, and, with the string kept always thus stretched, it is carried round until it returns to the point from which it began to move, the ellipse EGF will be described. For in this way there will always be two straight lines from N and O up to the stylus carried round, equal to the axis EF, which the same stylus, in its circuit, cuts at E and F. And this can be grasped far more easily by the thing itself, and by practice, than it can be taught in many words.

[Margin: In what manner an ellipse of any size may be described by a string according to a given length and breadth.]

But since this description of the ellipse by a string fitted about pegs is both pleasant in itself and useful for many purposes, I should like to explain it here somewhat more fully. First, then, if both axes of the ellipse are given — namely AB the greater and CD the lesser — so that the ellipse to be described has AB for its length and CD for its breadth, we shall find the points in the major axis at which the pegs are to be fixed, and the length of the string to be carried round the pegs, in this way. The major axis AB being bisected at E, let CD be drawn through E perpendicular to AB, and let both EC and ED be equal to half the minor axis, so that CD is equal to the whole minor axis. Then, with center C (or D) and radius EA (or EB), let two arcs of a circle be described cutting the straight line AB at the points F and G,

which will lie altogether short of the points A and B [Margin a: Euclid I.19]. For since the straight line CA is greater than AE, because of the right angle AEC, it comes about that the arc described from C at the interval AE cuts CA itself, and hence also AE itself, short of the point A, and so on. I say that the pegs are to be fixed at the points F, G, so that the proposed ellipse may be described; and that the string placed about F, G must be doubled, so that when stretched it reaches exactly to the point A (or to the point D, or B), and the whole string is DFGD, set about the pegs fixed at F and G by this rule: that it can be freely carried round about them together with the stylus, so that the stylus is hindered neither by the pegs nor by the string from being carried round to describe the entire ellipse.

For since the portions GA, FA of the doubled string (the portion FG between the pegs being left aside) are equal to the major axis AB — because AF is equal to BG — and in the same way the remaining portions, when the string is carried round about the points F, G, are equal to the same major axis, because the string is neither increased nor diminished in that revolution, and the common portion FG always remains the same (for thus you see, for example, that when the end of the doubled string is placed at D, the portions DF, DG are equal to the whole axis AB, because AE, BE are taken equal, and so on) — it is evident, from Proposition 52 of Book 3 of Apollonius, that by the aid of that string there is described an ellipse whose major axis is AB and minor CD; inasmuch as the straight lines from the points F and G, inclined to any point whatever of the curved line described through the points A, C, D, B, are equal to the major axis AB, as that proposition of Apollonius requires.

[Margin: The places of the pegs and the length of the string for describing the ellipse.]

We shall also find the points F, G for the places of the pegs by the following method, and perhaps more surely — because, when the minor axis is nearly equal to the major, the arcs of the circles described from C or D cut the straight line AB very obliquely. Let the straight line BE, which is half the major axis, be bisected at H; from H, at the interval HB (or HE), let a semicircle BIE be described [Margin b: Euclid IV.2], and in it let there be fitted a straight line BI equal to DE, half the minor axis, and let EI be joined. I say that the straight line EI is equal both to EF and to EG; and hence, if the straight lines EF, EG are cut off equal to EI, the same points F, G for the places of the pegs have been found. [Margin c: Euclid I.47] For since the square on BE is equal to the squares on EI, IB; and the square on DG is equal to the squares on DE, EG, and the square on DF to the squares on DE, EF; while the square on BE is equal both to the square on DG and to the square on DF, because these lines are equal by construction; and the square on BI is equal to the square on DE, because BI and DE were also placed equal by construction — the remaining square on EI will be equal to the remaining square described on EG or on EF, and hence the straight line EI will be equal to the straight lines EG, EF, which was what was proposed.

Diagram. The same conic-in-a-plane construction figure as on the preceding page, repeated here (the woodcut is reprinted so the reader need not turn back). Same lettering as fig-p41-1.

- A (apex, top); E, F (just below A)
- L, K (left of center); M, R (right of center)
- C — E — D (horizontal line, E at center)
- H (center, below E); I (lower left); B (foot, center); G (below B)
- N (upper right); P (middle right); O (lower right); Q (far right)
- A circle in the lower-center; dotted construction lines

Diagram. The same articulated ellipsograph instrument as on the preceding page, repeated here. Same lettering as fig-p41-2.

- d (turned handle, left); f, e (center hinge); S (disc/pulley, lower left); T, X (upper right joint); b (lower right); V, Y (foot, lower right)

[Margin: How an ellipse is described about a given major axis and through a given point.]

Next, if only the major axis AB of the ellipse is given, together with some point K through which the ellipse described about the axis AB must pass, we shall find the minor axis — that is, the breadth of the ellipse — and the points F, G at which the pegs are to be fixed, in this way. Let AB be bisected at E; through E let CD be drawn perpendicular to AB, and from the given point K let another perpendicular KL be drawn to the same AB, parallel to CD. Then, by what we have demonstrated in the third problem of the scholium to the last proposition of Book 6 of Euclid, let it be brought about that, as the rectangle under AL, LB is to the rectangle contained under AE, EB — that is, to the square on AE (or EB), (for this rectangle is a square, because of the equality of the straight lines AE, EB) — so is the square on KL to another square whose side is ED or EC. And, from what has been demonstrated by Apollonius in Proposition 21 of Book 1, ED (or EC) will be half the minor axis; by which, as we taught a little before, we shall find the points F and G, by whose aid we shall describe the ellipse.

[Margin: The places of the pegs for describing the ellipse are found by another method.]

And we shall find the square of the sought side ED (or EC) expeditiously as follows. From E, at the interval EA (or EB), let a semicircle AMB be described, which the straight line LK produced cuts at M. Then, by the scholium to Proposition 13 of Book 6 of Euclid [Margin d: Euclid VI.17], the straight line LM will be the mean proportional between AL, LB, and hence its square will be equal to the rectangle contained under AL, LB. Whence with easy effort we shall find the square to which the square on LK has the same ratio that the square on LM — that is, the rectangle under AL, LB — has to the square on EA (or EB), that is, to the rectangle contained under AE, EB [Margin e: Euclid VI.12], if for the three straight lines LM, EA, LK we find a fourth proportional ED [Margin f: Euclid VI.22]; because the squares described on the straight lines LM, EA, LK, ED have the same ratio as the straight lines themselves. And by the following device we shall find the said fourth proportional ED. Let two straight lines NO, NP be drawn making any angle at N; let NQ be taken equal to LM, and QO equal to EA, and NR equal to LK. Then, QR having been drawn, let OP be drawn through O parallel to QR. RP will be the said fourth proportional [Margin g: Euclid VI.2], since, as NQ (that is, LM) is to QO (that is, to EA), so is NR (that is, LK) to RP. Therefore if we take ED equal to RP, we shall have half the minor axis, ED, and so on.

[Margin: An instrument for describing an ellipse by a string.]

For the rest, in place of the pegs we shall be able to use a certain instrument made in the likeness of a compass [circinus], whose legs are cut off at their

extremities, and to which small pieces [frusta] are fitted, cut off and so adapted that they can be moved this way and that and fastened with little screws [cochleolae], so that however far the legs of the compass are opened, those pieces, fastened by the little screws, always stand upright to the plane on which the ellipse is to be described. And let these pieces have also, in their extreme parts, certain little channels [canaliculi] cut round about, so that the string in them may be carried round—

Gnomonics, Liber Primus (continued)

being revolved, neither rises upward nor sinks downward. For with this instrument we shall easily describe an ellipse: once its legs have been opened, we set those small pieces at the found points F and G so that they stand upright to the plane, and we lay the string around, as we said above. But since the string is always stretched and slackened a little, an ellipse will be drawn much more accurately — though not so easily — with the instrument that Guidobaldo del Monte [Guidobaldo del Monte], of the Marquises of Monte, a man in this age no less distinguished for talent and for excellence of learning than for nobility of birth, devised and most acutely demonstrated in his *Theory of Universal Planispheres* [*Theorica planisphaeriorum universalium*], recently published by him.

The instrument, shaped like a compass, is STV in the adjoining figure. Its legs are cut off at T and V, while the small pieces Ta and Vb are fitted at T and V so that they can be moved freely this way and that and fastened with little screws. The little channels are at X and T, in which the string XTf runs round. Finally, the stylus is de, which also has a channel at f, so that it can be turned round conveniently about the taut string, in such a way that the string always forms a triangle whose angles lie at the channels of the compass and of the stylus — such as the triangle XTf in the figure. Only when the stylus is set at A or B is no triangle formed, but a straight line. Moreover the segments ef, aX, dT ought to be equal, and of the least possible height. But the actual use of the instrument will show more plainly the manner in which it is to be constructed.

THEOREMA 7. PROPOS. 9.

[Margin: What the hour-circles from noon or from midnight are.]

The greatest circles in a sphere, of which one is the Meridian, passing through the poles of the Equator and cutting the parallel that touches the Horizon — the

greatest of the parallels that are always visible — into 24 equal parts, mark the equal hours beginning from noon or from midnight.

Diagram. A large circular hour-diagram. Two perpendicular diameters cross at the center E: the vertical diameter runs from A (top) to C (bottom) and represents the Meridian AC; the horizontal diameter runs from B (left) to D (right). The bounding circle is the parallel ABCD, "the greatest of the always-visible parallels." Below the circle a broad curved band (an obliquely-seen circle/ellipse) represents the Horizon, its ends marked F (lower left) and G (lower right); a straight line runs across the bottom from H (left) to I (right) — the common section HI of the Horizon plane and the plane of circle ABCD — with the point S marked on it near the bottom center (the base reads "H·S·I", flanked by the hour-number 24). Between the bounding circle and the center lie two concentric rings finely subdivided into the fractional parts of the hours (halves, quarters, eighths, etc., as the following Scholium describes); the individual fraction-cells (readable samples near the top include $\frac{1}{2}$, $\frac{1}{4}$, $\frac{1}{8}$, $\frac{3}{8}$, $\frac{3}{4}$) are too dense to resolve reliably cell-by-cell at this resolution and are not transcribed here [?].

- Center: E
- Vertical diameter (Meridian AC): A (top), C (bottom)
- Horizontal diameter: B (left), D (right)
- Horizon band: F (lower left), G (lower right)
- Base line: H (lower left) — S (center) — I (lower right)
- Outer numeric ring: the hours 1–24 (12 at top over A, running clockwise 13, 14, 15, 16, 17, 18 down the right to D, then 19, 20, 21, 22, 23, 24 across the bottom to C, and 1–11 up the left back to A)
- An inner numeric ring carries a second 24-fold count (12 at top, running down both sides to 12 at the bottom)
- Circular inscription on the outer rim in serif capitals: the right (western) arc appears to read CASVS SOLIS ("the setting of the Sun"); the remaining arcs of the inscription (top, left/eastern, bottom) are not reliably resolvable — legible letters include V, E, L, O, C, R, O, T, A, H, O, R, I, S [?]. An inner band near the center likewise carries lettering (HORA and apparent directional/meridian words, e.g. MERIDIANO), only partly resolvable [?].

[Diagram — the rim inscription, inner-band lettering, and the two fraction-rings carry many labels/cells not resolvable at this resolution.]

Let the parallel ABCD — whose center is E, the greatest of all the always-visible parallels — cut [the said circles]; and let it touch the Horizon FG. (It touches it, I

say, at the point where the straight line HI, the common section of the plane of the Horizon and of the plane of the circle ABCD, likewise touches — by the definition of Book 2 of Theodosius [Theodosius] — both the Horizon FG and the circle ABCD.) Let the greatest circles, of which one is the Meridian, pass through the poles of the Equator, and therefore also of the circle ABCD — for by Proposition 1 of Book 2 of Theodosius the Equator and the parallel ABCD have the same poles — passing through the center E (since all greatest circles that pass through the poles of the parallel ABCD divide it in two, that is, through the center and at right angles, by Proposition 15 of Book 1 of Theodosius), and let them cut it into 24 equal parts, so that the Meridian passes through the straight line AC.

I say that these greatest circles mark the equal hours counted from noon or from midnight. For since they pass through the poles of the Equator and of all the parallels, they will cut all the parallels into similar parts, by Proposition 10 of Book 2 of Theodosius. And therefore, since the parts of the parallel ABCD are supposed equal, the parts of every parallel will also be equal among themselves. Hence the Sun in its daily motion will traverse them in 24 equal intervals of time, the beginning made at noon or at midnight. But these 24 equal intervals of time are the 24 equal hours beginning from noon or from midnight. Therefore those greatest circles mark the 24 equal hours counted from noon or from midnight. And accordingly, the greatest circles in a sphere, of which one is the Meridian, and so on — which was to be demonstrated.

GNOMONICES — SCHOLIUM

[Margin: Circles that mark the half-parts, quarter-parts, eighth-parts, and so forth of the hours from noon or from midnight.]

If the several equal spaces of the parallel ABCD are bisected, and these halves again bisected, and so on in succession, and if greatest circles are then drawn through the divisions and through the poles of the parallel ABCD, these circles will mark the half-hours, the quarter-parts of the hours, the eighth-parts, and so forth, from noon or from midnight. For the demonstration is the same for the parts as for the whole hours. And these greatest circles may rightly be called *hour-circles from noon or from midnight*.

[Margin: Hour-circles from noon or from midnight.]

[Margin: Which semicircles pertain to the hours from noon, and which to the hours from midnight.]

Furthermore, the semicircles of these circles are set between the two poles of the world, which the axis of the world all divides. Proceeding from the semicircle of the Meridian standing above the Horizon, through the west, as far as the semicircle of the Meridian below the Horizon, they mark the hours from noon; the remaining semicircles mark those same hours from midnight, as is plain. Hence it will not be difficult to recognize which points of the greatest of the always-visible parallels answer to the hours from noon, and which are owed to the hours from midnight. For the points on the semicircle ADC — if the parallel be understood to touch the Horizon at the lowest point toward C, so that D inclines toward the west and B toward the east — mark the hours from noon, since at those points the hour-semicircles, running between the two poles from the semicircle of the Meridian standing above the Horizon through the west as far as the semicircle of the Meridian below the Horizon, cut the parallel, as is plain. But the points on the remaining semicircle CBA show the hours from midnight, because at those points the parallel is cut by the remaining hour-semicircles. By the same reasoning, in the greatest of the ever-hidden parallels, the points of the semicircle set toward the west, beginning from that point where it touches the Horizon, will give the hours from noon, while the points of the other semicircle, toward the east, will mark the hours from midnight, for the same reason. This can be easily understood if those two parallels and the hour-circles are imagined set in their proper position.

We have, however, preferred to propose that the hour-circles cut the greatest of all the always-visible parallels into twenty-four equal parts, rather than the Equator (although this too is true, as the demonstration shows) — because both the knowledge of the hour-circles that show the hours from sunrise and sunset, and most other matters bearing on the hours reckoned as much from noon or midnight as from sunrise or sunset, depend on the hour-points of the said parallel, as will become plain from what follows.

THEOREMA 8. PROPOS. 10.

[Margin: What the hour-circles from sunrise or sunset are.]

The greatest circles in a sphere, of which one is the Horizon, touching the greatest of all the always-visible parallels at the 24 points into which it is divided by the hour-circles from noon or from midnight, mark the equal hours beginning from the rising or the setting of the Sun. Their poles, moreover, are the points of the parallel described through the zenith of the place, that is, through the pole of the Horizon, at which that parallel is cut by the hour-circles from noon or from midnight.

Let the greatest circles, of which one is the Horizon, touch the parallel ABCD at the 24 hour-points from noon or from midnight. I say that these greatest circles mark the equal hours beginning from the rising or the setting of the Sun, and so forth. For since they touch the parallel ABCD, and therefore also — by Proposition 6 of Book 2 of Theodosius — the parallel equal to it, namely the greatest of those that are always hidden beneath the earth, they will cut all the intermediate parallels (namely those parts intercepted between any two nearest non-concurrent semicircles) into parts similar to the parts of the parallel ABCD, by Proposition 13 of Book 2 of Theodosius. And therefore, since the parts of the parallel ABCD are supposed equal, the parts of every intermediate parallel will also be equal among themselves. Hence the Sun in its daily motion will traverse them in 24 equal intervals of time, the beginning made at the Horizon, that is, at the rising or the setting of the Sun. But these 24 equal intervals of time are the 24 equal hours beginning from sunrise or sunset. Therefore those greatest circles mark the 24 equal hours beginning from sunrise or sunset — which is the first point.

Nor, besides those named, can any other circles be conceived in the heavens that would mark the hours from sunrise or sunset. For since hours of this kind begin from the Horizon, and divide the several parallels that they cut into 24 equal parts, it follows, by Proposition 16 of Book 2 of Theodosius, that greatest circles dividing the parallels in this manner either pass through the poles of the parallels or touch some one same parallel. Since, then, they do not pass through the poles — because the Horizon, which is one of them, by no means passes through the poles except in a right sphere — they will necessarily touch one same parallel. And since the Horizon touches the greatest of the always-visible parallels, the rest will touch the same one. Altogether, then, the greatest circles that mark the hours from sunrise or sunset touch the greatest of the always-visible parallels.

Now since all these circles touch the same parallel, which is the greatest of the always-visible ones, it follows that they are equally inclined to the Equator, by Theorem 1 of the Scholium to Proposition 21 of Book 2 of Theodosius — which is, according to the tradition of Francesco Maurolico [Francesco Maurolico], Proposition 26 of Book 2 of Theodosius. Hence, by Theorem 2 of the same Scholium — which is Proposition 27 according to Maurolico — they have their poles on the circumference of the same parallel. Since, therefore, the pole of the Horizon, which is one of these hour-circles, lies in the parallel described through the pole of the Horizon, that is, through the zenith of the place, the poles of the other circles will necessarily also lie in the same parallel. And because the hour-circles from noon or from midnight, passing through the points of contact and

through the poles of the greatest of the always-visible parallels, also pass — by Proposition 3 of Book 2 of Theodosius — through the poles of the circles that mark the hours from sunrise or sunset (which of course touch that parallel), the poles of these circles will be altogether the points of the parallel described through the zenith of the place, that is, through the pole of the Horizon, through which the hour-circles from noon or from midnight pass, since in this parallel all the poles lie, as has been demonstrated. The second point is therefore also established. Wherefore the greatest circles in a sphere, of which one is the Horizon, and so forth — which was to be shown.

[Margin: The poles of the circles that mark the hours from sunrise or sunset lie in the parallel described through the zenith of the place.]

COROLLARIUM.

[Margin: The poles of the circles that mark the hours from sunrise or sunset divide the parallel described through the zenith of the place into 24 equal parts.]

From these things it follows that the poles of the circles marking the hours from sunrise or sunset divide the parallel described through the zenith of the place, that is, through the pole of the Horizon, into 24 equal parts, the beginning made from the Meridian circle. For the points where the said parallel is cut by the hour-circles from noon or from midnight — which points are indeed the poles of the circles marking the hours from sunrise or sunset, as we have shown — cut that same parallel into 24 equal parts, the beginning made from the Meridian circle, as is established from Proposition 10 of Book 2 of Theodosius.

LIBER PRIMVS — SCHOLIUM

[Margin: How, in the hour-circles from sunrise or sunset, non-concurrent semicircles are taken.]

That you may see in what manner those parts of the parallels are intercepted between two nearest non-concurrent semicircles: let there be any number of parallels — ABC, the greatest of the always-visible; DEF, the parallel of ♋ [Cancer]; GHI, the Equator; and KLM, the parallel of ♊ [Capricorn]. Let the equal hour-spaces CN, NO be taken on ABC, and at the points C, N, O let the greatest circles CPHQ, NRST, OVXT touch the parallel ABC, of which let CPHQ be the Horizon. Let CPHQ and NRST cut one another at Z and α ; then, by Proposition 11 of Book 1 of Theodosius, ZQ α and ZT α will be semicircles, and therefore PQ α will be less than a semicircle. Let the arc $\alpha\beta$ be taken equal to the arc PZ, and the arc

$\alpha\gamma$ equal to the arc $Z\delta$; then PQ , $\alpha\beta$ [and] $\delta Z\tau$ [?] will be non-concurrent semicircles, since they do not intersect one another. By the same reasoning, if the circles $NRST$, $OVXT$ cut one another at ε and θ , and the arc $\theta\lambda$ be taken equal to the arc $V\varepsilon$, then $\delta Z\tau$ [?] and $VY\theta\lambda$ [?] will be non-coincident semicircles, as is established. And in the same way, in the remaining greatest circles that touch the parallel ABC in the remaining equal hour-spaces, we shall find non-concurrent semicircles. Therefore the spaces PR , RV , HS , SX , QT , TT [?], and the rest of this kind, we said were similar to the hour-spaces CN , NO , and to the others, and so on; and thus the spaces of any parallel are equal among themselves, just as CN , NO and the remaining spaces of the parallel ABC are equal among themselves.

Diagram. A system of many overlapping and concentric circles representing the several parallels (the always-visible ABC , the parallel of Cancer DEF , the Equator GHI , the parallel of Capricorn KLM) together with the greatest circles $CPHQ$, $NRST$, $OVXT$ touching them, drawn on the plane of the meridian/horizon. A vertical axis runs down the middle from K (upper) through G , D , A near the center and down to F , Z , I , and M (lowest point); a horizontal axis runs across, ending at L (far left). The nested circles and their intersections generate a dense cluster of labelled points near the center-bottom (the letters E , V , B , O , N , C , F , Z crowd together there).

- On the vertical axis, from top down: K , G , D , A (near center), then the cluster $O-N-C-\xi-Z$, then F , then I , then M (bottom)
- Near the center: A with B to its right; E to the left with V beside it
- Left side, descending from upper-left to the axis foot H : T (upper left), Y , X , S , and ρ/P near them; H at the lower left; L at the far left end of the horizontal axis
- Lower-center / left of the cluster: P
- Greek point-labels along the upper arcs: α (top center), β (upper right), γ and λ (to the right), θ (upper right); ε and δ occur among the central intersections [Greek letters read on the scan; several worn — see below]

[Diagram — more than two labels (the Greek intersection-letters α , β , γ , δ , ε , θ , λ and the crowded central cluster) could not all be resolved with confidence at this resolution.]

If other greatest circles touch the same parallel at other points — those by which it is divided by the hour-circles from noon or from midnight that mark the half-hours, the quarter-parts of the hours, the eighth-parts, and so forth — these circles will mark the half-hours, the quarter-parts of the hours, the eighth-parts,

and so on, from sunrise or sunset. For the demonstration is the same for the parts as for the whole hours. And these circles may not unfittingly be called *hour-circles from sunrise or sunset*.

[Margin: Circles that show the half-parts, quarter-parts, eighth-parts, and so forth of the hours from sunrise or sunset.]

[Margin: Hour-circles from sunrise or sunset.]

[Margin: Which semicircles pertain to the hours from sunrise, and which to those from sunset.]

Furthermore, the semicircles of these circles are set between the two points of contact, one of which is always of some hour from noon and the other of the same hour from midnight, as is clear from what we wrote in the Scholium of the preceding proposition. Proceeding through the hour-points of the equinoctial circle below the Horizon, the beginning made from the western semicircle of the Horizon, and going on from east to west, that is, against the succession of the signs, they pertain to the hours reckoned from sunset — so that the western semicircle of the Horizon marks the 24th hour from sunset, the next western semicircle below the Horizon gives the first hour from sunset, and the following one, toward the western parts, the second hour, and so on in succession, always proceeding toward the western parts, that is, against the succession of the signs, until we return again to the western semicircle of the Horizon. The remaining semicircles, which run through the hour-points of the equinoctial circle above the Horizon, the beginning made from the eastern semicircle of the Horizon and going on from east to west — that is, against the succession of the signs — belong to the hours reckoned from the rising of the Sun. Thus the eastern semicircle of the Horizon marks the 24th hour from sunrise, the next eastern semicircle above the Horizon shows the first hour from sunrise, and the following one, against the succession of the signs, the second hour, and so on in succession, always advancing from east to west, that is, against the succession of the signs, until we come round again to the eastern semicircle of the Horizon.

Perhaps we shall understand more plainly and openly which semicircles pertain to the hours from sunset or from the rising of the Sun in this way. Let us imagine ourselves placed outside the heavens, near the greatest of the always-visible parallels, so that our feet are at hour 12 of midnight, that is, at the 24th from sunrise or sunset, and our head is turned toward the arctic pole. This being supposed, the semicircle of the Horizon, that is, the 24th hour, which is on our right, will mark the 24th hour from sunset; the other, on our left, the 24th hour

from sunrise. Likewise, if we set our feet at the other hours of the said parallel, with the head turned toward the pole, the hour-semicircles from sunrise or sunset that lie on our right will pertain to the hours from sunset, while those on our left will pertain to the hours from the rising of the Sun. All this will be clear to anyone who carefully grasps the greatest of the always-visible parallels — which the circle in Proposition 9 presents to us — and the hour-circles from sunrise or sunset touching the said parallel, set in their proper position.

[Margin: What the unequal-hour circles are.]

As for the circles of the unequal hours, it is plain that they must pass through the twelfth parts of all the daytime and nighttime arcs, since parts of this kind, the twelfths, are called unequal hours. That the greatest circles described through the unequal hours of the Equator (which are indeed the same as the equal hours) and of the northern daytime arcs also pass through the same hours of the southern daytime arcs, we shall demonstrate in this way, together with Federico Commandino [Federico Commandino]. Since in any oblique Horizon, for two parallels equally distant from the Equator, the daytime arc of the one is equal to the nighttime arc of the other, and conversely — as plainly appears from Proposition 19 of Book 2 of Theodosius — and therefore, by however much the days increase as the Sun tends from the vernal equinox toward ♋ [Cancer], by just so much do they decrease as the same Sun tends from the autumnal equinox toward ♏ [Capricorn]: it follows that a day of ♋ [Cancer] is greater than the equinoctial day by just as much as a day of ♏ [Capricorn] is less than the same equinoctial day. Since, then, the daytime arc of any parallel is divided into 12 equal parts, and the proportion of part to part is the same as of whole to whole, it comes about that the arc also of one hour of ♋ [Cancer] exceeds the arc of one equinoctial hour by the same quantity by which the arc of one hour of ♏ [Capricorn] is exceeded by it. This too can be plain from the following: because in this way all those 12 excesses of the twelve hours of ♋ [Cancer], taken together, will be equal to the 12 defects of the twelve hours of ♏ [Capricorn], taken together. This would not happen if one hour of ♋ [Cancer] did not exceed one equinoctial hour by the same quantity by which one hour of ♏ [Capricorn] is exceeded by the equinoctial hour. And the same is the ratio for the arcs of two hours, of three, of four, and so on. And so likewise in the other parallels that are equally distant from the Equator — as in the parallels of ♊ [Gemini] and ♐ [Sagittarius] [?]; likewise in the parallels of ♉ [Taurus] and ♏ [Scorpio] [?], and so forth.

[Margin: The greatest circles cutting the daytime arcs of the Equator and of the northern parallels into 12 equal parts likewise divide the daytime arcs of the southern parallels into 12 equal parts.]

[This page continues the demonstration begun in the previous proposition (Theorem 8, Prop. 10).]

Now let there be, in the sphere, the parallel $\mathfrak{S}$ [Cancer], ABCD; the Equator EFGH; the parallel $\mathfrak{V}$ [Capricorn], IKLM; the greatest of the always-visible parallels, NOPQ, and R the pole of all of them; and let the oblique Horizon IEANDHN [?], touching the parallel NOPQ at N. Next, let the arc of the Equator, and of the parallel $\mathfrak{S}$, that lie above the Horizon each be divided into twelve equal parts, so that the first hour of the parallel $\mathfrak{S}$ falls at point B, the second hour of the same parallel at point C, while the first hour of the Equator falls at F and the second at G. Through the points B and F, and likewise through the points C and G, let there be drawn — by Proposition 28 of Book 1 of Theodosius — two greatest circles cutting the parallel $\mathfrak{V}$ at the points K and L.

I say that the circle BFK also passes through the first hour of $\mathfrak{V}$, and CGL through the second — that is, that IK is the first hour of $\mathfrak{V}$ and KL the second. For, by Proposition 15 of Book 2 of Theodosius, let there be drawn through the points F and G two other greatest circles touching the parallel NOPQ and cutting the parallels $\mathfrak{S}$ and $\mathfrak{V}$ at S, T, V, X. Then, by Proposition 13 of Book 2 of Theodosius, the arcs AS, ST, IV, VX will be similar to the arcs EF, FG, since all these arcs are intercepted between non-concurrent semicircles, as is clear from the preceding scholium. But EF and FG are arcs of equinoctial hours, and equal. Therefore AS, ST and IV, VX are likewise arcs of equinoctial hours, and equal; and so, since the parallels ACD and IXM are equal, the four arcs AS, ST, IV, VX will be equal. And because the parallels ACD and IXM are equal, the arcs SF, FV and BF, FK — cut off from the greatest circles by the parallels — will also be equal, by Proposition 18 of Book 2 of Theodosius. Therefore, by Proposition 3 of Book 3 of Theodosius, the straight line joining the points B and S will be equal to the straight line connecting the points K and V; and so the arc BS will be equal to the arc KV. In the same way the arcs TG, GX and CG, GL, and the straight lines CT, LX, and the arcs CT, LX, will be equal.

[Margin: a 28. tertij.] [i.e. a marginal reference, Prop. 28 [?], Book 3.]

And so, since the arc AS is equal to the arc IV, and the arc BS to the arc KV, the arc AB — the first hour of $\mathfrak{S}$ — will exceed the arc AS, an equinoctial hour, by the same amount by which IK exceeds [?] the arc IV, an equinoctial hour. Therefore,

by what has been said, IK will be the first hour of ♊, since the arc AB, the first hour of ♉ and drawn on the Equator, also passes through the first hour of ♊. In exactly the same way we shall demonstrate that IL is two hours of ♊, just as the arc AC comprises two hours of ♉ and EG two hours of the Equator; for the arc TC, by which AC, two hours of ♉, exceeds the arc AT of two equinoctial hours, is equal to the arc LX, by which IL is exceeded by the arc IX of two equinoctial hours. Since, then, IK has been shown to be the first hour of ♊, KL will be the arc of the second hour. And the same demonstration will hold for the remaining unequal hours of ♊ and of the other signs, provided that in place of the parallels ♉ and ♊ any other two opposite and equal parallels are assumed. Which was what was proposed.

But all that we have demonstrated in the two nearest propositions is to be understood only of the oblique sphere. For in the right sphere no parallel is perpetually visible, since all the parallels are bisected by the Horizon drawn through their poles, as is clear from Proposition 15 of Book 1 of Theodosius. Hence in the right sphere the greatest circles — among which are the Meridian and the Horizon — passing through the poles of the world and cutting the Equator, and consequently (by Proposition 10 of Book 2 of Theodosius) cutting all the remaining parallels into 24 equal parts, will mark both the hours from noon or midnight and those from the rising or setting of the Sun. There are no unequal hours there, since the equinox is perpetual, and so the equinoctial hours are twelfths of any given day, just as the unequal hours in the oblique sphere are twelfths of each day.

[Margin: In the right sphere the same circles indicate the hours from noon or midnight and from sunrise or sunset. But there are no unequal hours there.]

Diagram. A set of concentric circles representing, from the outside in, the parallel of ♋ [Cancer] (ABCD), the Equator (EFGH), and the parallel of ♏ [Capricorn] (IKLM), with the greatest of the always-visible parallels (NOPQ) and the pole R at the centre; an oblique horizon and several greatest circles are drawn through the hour-points, cutting the parallels. The figure is crowded and several peripheral labels are worn.

- X, L, V, K, I (descending the left/upper-left rim): points on the greatest circles / outer parallels
- G, F, C, T, S, B, O, E, A (lower-left quadrant, close-set): hour and intersection points
- R (centre): pole of the always-visible parallels

- P (upper centre), Q (right of centre), D (lower centre-right), H (right rim): further parallel/hour points
- M (upper right): outer point
- N (lower centre): point of tangency of the horizon with the parallel NOPQ

THEOREMA 9. PROPOS. 11.

When the Sun is on any hour-circle, or on any other greatest circle, the solar ray — and hence the shadow of the tip of the stylus — is cast onto the straight line that is the common section of that same hour-circle (or greatest circle) and the plane of the sundial.

[Margin: The shadow of the stylus and the ray of the Sun are cast onto the common section of the plane of the sundial and of the greatest circle on which the Sun is.]

Let ABCD be an hour-circle, or any other greatest circle, cutting the plane of the sundial EFGH along the straight line EG; and let IK be the stylus, whose tip I is set at the centre I, by Proposition 2. I say that when the Sun is at any point L on the circle ABCD, the Sun's ray and the shadow of the stylus's tip I are cast onto the straight line EG. For the ray LI, reaching to the centre I, is drawn (by [?]) and by the plane of the circle ABCD; it does not leave the plane of the circle ABCD when the Sun is on the circumference of that circle, but, produced, it will cut the circumference of the same circle at the point M, which is opposite the point L, so that the ray itself is a diameter of the circle. Since, then, the straight line EG lies in the plane of the same circle, it will cut the ray LIM — that is, the straight line EG — at the point N; and so the Sun's ray LM and the shadow of the stylus's tip I will be cast onto the straight line EG, the common section of the hour-circle ABCD and the plane of the sundial EFGH.

In the same way, if some other hour-circle, or other greatest circle AFCH, cuts the same plane of the sundial EFGH along the straight line FH, and the Sun is at the point O of the hour-circle or greatest circle, we shall demonstrate that the ray OI and the shadow of the same stylus-tip I are cast onto the straight line FH, because the ray, produced to the opposite point P, cuts the straight line FH — which lies in the same plane of the circle AFCH — at the point Q. And the reasoning is the same for the rest. Therefore, when the Sun is on any hour-circle or any other greatest circle, the solar ray — and hence the shadow of the stylus's tip — is cast onto the straight line that is the common section of that same hour-circle (or greatest circle) and the plane of the sundial.

SCHOLIUM.

[Margin: What the hour-lines are.]

Just as those greatest circles which indicate the hours — whether from noon or midnight, or from sunrise or sunset — are called "hour-circles," as we said in Propositions 9 and 10, so too their common sections with the plane of the sundial, onto which we have demonstrated in this proposition that the shadow of the stylus is cast, are called "hour-lines"; because the tip of the shadow falling upon them shows what hour it is — that is, which hour-circle the Sun then occupies.

By the same reasoning, the common sections of the other greatest circles with the plane of the sundial take their names from those greatest circles which produce them on the sundial. Thus the common section of the equinoctial circle and the plane of the sundial is called the equinoctial line; the common section of a vertical circle and the plane of the sundial, the vertical line; the common section of the Meridian and the same plane of the sundial, the meridian line; and so on.

[Margin: All the straight lines on the sundial take their names from the greatest circles that produce them on the sundial. The lines of those greatest circles cannot be drawn on the sundial [when the circle is parallel to its plane].]

But if a greatest circle is parallel to the plane of the sundial, then the line named from that greatest circle vanishes — that is, it cannot be drawn on the sundial. For since that circle does not cut the plane of the sundial but is parallel to it, it will have no common section with the plane of the sundial, nor will the Sun's ray cast onto the plane of the sundial while it is on that circle; rather, it will cast a shadow that is very nearly infinite and parallel to the plane of the sundial. Hence on a horizontal sundial the horizontal line — that is, the 24th hour from sunrise or sunset — cannot be drawn; nor the vertical line on a vertical sundial; nor the line of the sixth hour from noon or midnight on a polar sundial; nor the line of the 12th hour from noon or midnight on a meridian sundial; nor the line of the 12th hour from sunrise or sunset on a vertical sundial at latitude 45° ; nor the equinoctial line on an equinoctial sundial — instead it vanishes altogether. This can easily be understood from the figure above. For when the Sun is at the point B of the circle BD, the ray BI and the shadow ID will be parallel to the plane of the sundial EG, just as the circle itself is parallel to the same plane, and so on.

Diagram. A sphere shown with its principal circles and a stylus at the centre casting a shadow, illustrating the case where a circle is parallel to the plane of the sundial. Dotted lines run from the top point A down to the interior.

- A (top): pole/summit of the figure
- B (left): point on the sphere (start of circle BD)
- C (bottom): lower pole/point
- I (centre): tip of the stylus (world-centre); the shaded triangle at the centre is the stylus and its shadow
- L, O (upper-left, dotted): points along the dotted rays from A
- E, F, K (lower-left quadrant): circle/plane points
- M, N, P, Q (lower-right quadrant, close-set): points of the sundial plane and parallels
- G (lower right): point of the plane EG
- D (implied by text as opposite B on circle BD; label worn [?])

COROLLARIVM PRIMVM.

From this it follows that a plane solar sundial is nothing other than a plane figure containing the common sections (which are indeed all straight lines) of all the hour-circles — whether from noon or midnight, or from sunrise or sunset — with the plane of the sundial itself. For, as we demonstrated in this proposition, when the Sun is, for example, on the circle of the 12th hour, the shadow of the stylus is cast onto the straight line that is the common section of the said circle and the plane of the sundial, and so indicates the twelfth hour, whose circle the Sun then occupies; and likewise for the remaining hours.

[Margin: What a plane solar sundial is. (a) [?] — see note 3.]

COROLLARIVM II.

It is also clear from these things that, when the Sun is on the equinoctial circle — as at the beginning of ♈ [Aries] or ♎ [Libra] — the solar ray and the tip of the stylus's shadow describe, by the diurnal motion, a straight line, namely the common section of the Equator and the plane of the sundial. For at that time the Sun's ray passes through the centre of the world, and so the tip of the shadow does not leave the plane of the Equator (we here ignore that small declination which the Sun acquires by its own motion), but is always cast onto the common section of the Equator and the plane of the sundial — that is, onto the equinoctial line — as has been shown. Hence, by the diurnal motion, it describes that line.

[Margin: The shadow of the stylus on the equinoctial describes the equinoctial line, a straight line, on the sundial.]

THEOREMA 10. PROPOS. 12.

When the Sun is at any point outside the Equator, the solar ray — and hence the shadow of the stylus's tip — is cast onto a curved line, which is the common section of the plane of the sundial and of a conical surface whose base is the parallel opposite the Sun's parallel.

[Margin: The shadow of the stylus and the solar ray, outside the equinoctial, are cast onto a conic section, which is the common section of the plane of the sundial and of a conical surface whose base is the parallel opposite the Sun's parallel.]

Let the Sun, outside the Equator AB, be at the point C, so that by the diurnal motion it describes the parallel DCE, and its opposite point F describes the parallel GFH; and let the ray CF, extended through the centre of the world I, describe the conical surfaces IDE and IGH. Let there also be a plane of the sundial KLMN, parallel to the greatest circle OP, producing in the conical surface of the shadow IGH a common curved section QLN — which will be either a circle, or a parabola, or a hyperbola, or an ellipse, as is clear from Propositions 4, 5, 6, and 7 of this book. I say that the solar ray CF, and therefore the shadow IF, is cast onto the curved line QLN. For the ray CF, since by the diurnal motion it describes both conical surfaces, does not leave either of them while the Sun is at C (for here too we ignore that small declination which the Sun acquires by its own motion); rather, produced, it will cut the opposite parallel at the point F, which is opposite the point C, so that, by Proposition 1 of Book 1 of Apollonius, it lies on both conical surfaces. Since, then, the curved line QLN lies on the conical surface of the shadow IGH, the ray CF will cut the curved line QLN at the point R; and so —

Diagram. A large circle representing the sphere, with the world-centre I and numerous chords drawn to represent the two conical surfaces (the shadow-cone and the ray-cone), their parallel bases, and the curved section on the sundial plane. Small superscript "c" letters mark curve points near the top.

- D (upper left), E / P (upper right): endpoints of the upper parallel and its opposite
- A (left), B (right): endpoints of the Equator diameter
- I (centre): world-centre / stylus tip (shaded triangle)
- M (right): point of the sundial plane
- O, G (lower left): base points of a cone
- K (lower left, below G): point
- L, N (lower centre): points of the curved section QLN

- R (twice, lower centre-right, one dotted): the point R where the ray cuts the curve
- F (lower centre, twice): the shadow-point / opposite point
- H (lower right): base point
- C (upper centre, small): the Sun's position on the upper parallel

— and therefore the ray of the Sun CIF, and the shadow of the stylus's tip I, will be cast onto the curved line QLN, the common section of the conical surface of the shadow IGH and the plane of the sundial KLMN. And we shall show that the same holds wherever in the heavens the Sun is placed outside the Equator. Therefore, when the Sun is at any point outside the Equator, and so on. Which was to be shown.

COROLLARIUM.

[Margin: The shadow of the stylus, outside the equinoctial, describes a conic section on the sundial.]

From these things it is clear that, when the Sun is outside the equinoctial circle — that is, at any point of the Zodiac except the beginning of ♈ [Aries] and ♎ [Libra] — the solar ray and the tip of the stylus's shadow describe, by the diurnal motion, a curved line, namely the common section of the conical surface which the shadow describes and the plane of the sundial. For at that time the Sun's ray, passing through the centre of the world, and hence the tip of the shadow, does not leave the conical surface of the shadow, but is always cast onto the common section of the surface of the shadow and the plane of the sundial — that is, onto a curved line, namely a circle, or a parabola, or a hyperbola, or an ellipse, as has been demonstrated. Hence by the diurnal motion it describes that line.

Nevertheless, such a conic section is named after the parallel on which the Sun tarries. Thus, when the Sun is at the beginning of ♋ [Cancer], the conic section which the shadow traces is called a circle, or a parabola, or a hyperbola, or an ellipse "of ♋ [Cancer]," and so for the rest.

THEOREMA 11. PROPOS. 13.

The hour-circles from noon or midnight cut two conical surfaces whose vertex is the centre of the world and whose bases are two parallels touching the Horizon — one of them the greatest of the always-visible parallels, the other the greatest of the always-hidden parallels — cutting one another by straight lines that

mutually intersect at the centre of the world; and along the same straight lines the hour-circles from sunrise or sunset touch those same conical surfaces.

[Margin: The hour-circles from noon or midnight cut the conical surfaces whose bases are the greatest of the always-visible parallels and the greatest of the always-hidden parallels, along the straight lines in which the hour-circles from sunrise or sunset touch them.]

In the sphere ABCD, whose centre is E and axis AC, let there be two conical surfaces EFG and EHI, whose common vertex is E, the centre of the world, and whose bases are the parallels FG and HI, the greatest of those that always appear and are hidden beneath the earth, the common axis being also the straight line AC. Let there also be any hour-circle from noon or midnight, ANCK, which will pass through the poles of the world A and C, by Proposition 9 of this book, cutting the parallels along the straight lines KL and MN, and the conical surfaces along the lines kN and LM. I say that these lines kN and LM are straight and cut one another at the centre E. For since the greatest circle ANCK passes through the centre E, it will (by Proposition 6 of Book 1 of Theodosius) certainly cut the conical surfaces EFG and EHI through the vertex E, and hence through the axis AC, because the same circle ANCK passes through the poles of the world A and C. Therefore the common sections of the circle and the cones, namely EkL and EMN, will be triangles, by Proposition 3 of Book 1 of Apollonius; and consequently Ek, EL, EM, EN — the common sections of the same circle and the conical surfaces — will be straight lines. I say further that the straight lines EK, EN and EL, EM are set in a straight line. For since the two sides EC, EL of the triangle ECL (the straight lines AM, CL having first been joined) are equal to the two sides EA, EM of the triangle EAM — because all are drawn from the centre of the sphere to its surface — and the bases CL, AM are also equal, by Theorem 2 of the scholium to Proposition 21 of Book 1 of Theodosius (because the circles FG, HI are equal), the angles CEL and AEM will be equal. And so, since AC is a straight line, namely the axis, the straight lines EL and EM will also constitute — by what we showed on Proposition 15 of Book 1 of Euclid from Proclus — one straight line LM. Therefore the line LM is the common section —

[Margin: The hour-circles from noon or midnight cut the conical surfaces (whose bases are the greatest of the always-visible parallels and the greatest of the always-hidden parallels) along the straight lines in which the hour-circles from sunrise or sunset touch them.]

[Margin: a 8. primi.] [i.e. marginal reference: Prop. 8, Book 1.]

— of the conical surfaces and of the circle NACK, and a straight line. And by the same reasoning kN too will be a straight line, as also the common sections of the remaining hour-circles and of the said conical surfaces, cutting one another at the centre E, through which they pass. Which was the first thing to be shown.

But if now the hour-circles from sunrise or sunset, KRNQ and LPMO, touch the parallels FG, HI at the points K, L, M, N, at which the hour-circle from noon or midnight, ANCK, cuts those same parallels — as was demonstrated in Proposition 9 of this book — I say that they touch the conical surfaces along the straight lines KN, LM, along which we demonstrated those same surfaces to be cut by the circle ANCK. For let the straight line ST be the common section of the planes in which the circles FG, LM lie, which (by the definition in Book 2 of Theodosius) will touch each circle. And since the circle LPMO, being a greatest circle, passes through the centre of the sphere E, by Proposition 6 of Book 1 of Theodosius, it is manifest that it passes through the straight line LM, which extends from L to M through the centre E; otherwise, a straight line drawn in the circle LPMO from L to M would, together with LM, enclose a surface between two straight lines, which is absurd. I say now that the circle LPMO touches the conical surfaces along the straight line LM, and in no way cuts them. For if it did cut them, the common sections would be triangles, by Proposition 3 of Book 1 of Apollonius, whose bases would lie on the parallels FG, HI, since the circle LPMO passes through the vertex E of the conical surfaces. Therefore the common section of the planes in which the circles FG and LM lie would cut the circle FG, making the base of a triangle in the circle FG, which is absurd; for it touches it, as has been said, by the definition in Book 2 of Theodosius. Therefore the circle LPMO touches the conical surfaces EFG, EHI —

Diagram. A circle representing the sphere ABCD with centre E, drawn full of chords and diagonals to represent the two conical surfaces (vertex E, bases the parallels FG and HI), the hour-circle ANCK through the poles, and the two sunrise/sunset hour-circles KRNQ and LPMO tangent to the surfaces.

- A (top): pole of the world
- N (just below/left of A): point on the meridian hour-circle
- H (upper left), I (upper right): endpoints of parallel HI
- M (upper centre): point of the parallel/section
- Q (mid-left, italic), P (centre-right), R (below P): interior section points
- E (centre): centre of the world / common vertex of the cones
- O (left of centre, lower): point of circle LPMO
- B (left), D (right): equatorial points of the sphere

- F (lower left), G (lower right): endpoints of parallel FG
- T (lower centre), L (bottom centre), V (bottom left), K (bottom centre), X (bottom right): base and tangent points
- C (bottom): pole of the world; k (lower-case, of hour-circle ANck)

[continues the demonstration of the preceding proposition] ...in the straight line LM, and the same ratio holds in the rest, which is what was proposed in the second place. Therefore the hour-circles from noon or midnight cut the surfaces, etc. Which was to be demonstrated.

THEOREMA 12. PROPOS. 14.

The lines of the hours from noon or midnight cut the common sections of the plane of any sundial whatever and of the conical surfaces whose vertex is the centre of the world and whose bases are the two parallels tangent to the horizon — one of them the greatest of those always visible, the other the greatest of those always hidden. And at the points of section, the lines of the hours from sunrise or sunset touch those same common sections.

[Margin: The lines of the hours from noon or midnight cut the conic sections that the plane of the sundial produces on the cones (whose bases are the parallel that is the greatest of those always visible, and the greatest of those always hidden), at the points where the lines of the hours from sunrise or sunset touch those same sections.]

Since the hour-circles from noon or midnight cut these conical surfaces by straight lines that intersect at the centre of the world, it follows from the preceding proposition that the common sections of those circles and of the plane of the sundial — that is, their hour-lines — cut the common sections of those conical surfaces and of the plane of the sundial, at the points where the straight lines by which the hour-circles cut the conical surfaces meet the plane of the sundial and the conic sections. For such hour-lines — namely the common sections of the hour-circles and of the plane of the sundial — lie in the planes of the hour-circles, and those planes there cut the conical surfaces, and hence also cut the conic sections lying in the plane of the sundial.

From this it follows that, since the plane of the sundial and the planes of the hour-circles intersect at those points, and since both the former and the latter planes run inward toward the cone — and thus inward toward the conic sections — their common sections, namely the hour-lines, also fall from those points inward toward the cone, and hence inward toward the conic sections. For beyond those

points they depart neither from the plane of the sundial nor from the planes of the said circles, but remain forever in both. This therefore establishes what was proposed in the first place.

But since the hour-circles from sunrise or sunset touch these same conical surfaces — by the same preceding proposition — along the lines by which the hour-circles from noon or midnight cut them, it results that the common sections of those circles and of the plane of the sundial — that is, their hour-lines — touch the conic sections that the plane of the sundial makes, at the points where the straight lines by which the hour-circles touch the conical surfaces meet the plane of the sundial and the conic sections: namely, at those points where the lines of the hours from noon or midnight cut the conic sections. For the hour-lines from sunrise or sunset — the common sections of the hour-circles and of the plane of the sundial — lie in the planes of the hour-circles, which there touch the conical surfaces, and hence also touch the conic sections lying in the plane of the sundial.

From this it follows that, since the plane of the sundial and the planes of the hour-circles intersect at those points — the former extending inward toward the cone, and thus inside the conic sections, while the latter planes extend outward beyond the cone, and therefore beyond the conic sections — their common sections, that is, the hour-lines, fall entirely from those points outside the cone, and hence outside the conic sections. For beyond those points they depart neither from the plane of the sundial nor from the planes of the said circles, but remain forever in both, of which the latter lie wholly outside the cone and the conic sections. So this too is clear, which was proposed in the second place. Therefore the lines of the hours from noon or midnight cut [them], etc. Which was to be shown.

SCHOLIUM.

But if the plane of the sundial is parallel to some hour-circle from noon or midnight, this circle will not cut the conic section made by the plane of the sundial, since it does not cut the plane of the sundial itself, as is evident. Hence neither will its hour-line cut that same conic section. And so the hour-lines from sunrise or sunset — whose circles touch the conical surfaces along the lines in which they are cut by that hour-circle from noon or midnight — will not touch the conic sections, as will be demonstrated in the following proposition.

THEOREMA 13. PROPOS. 15.

If the circle of any hour from noon or midnight is parallel to the plane of the sundial, and two hour-circles from sunrise or sunset touch the greatest of the

parallels always visible at the same points at which it is cut by that hour-circle from noon or midnight, then those two lines of the hours from sunrise or sunset will be ἀσύμπτωτοι [Greek: asymptōtoi, "not falling together" — non-meeting, asymptotic]; that is, they never meet the conic sections that the plane of the sundial makes on the conical surfaces (whose bases are the greatest of the parallels always visible and the greatest always hidden), yet, ever produced further, they become closer to those conic sections.

[Margin: The lines of the hours from sunrise or sunset, whose circles touch the greatest of the always-visible parallels at the same points at which it is cut by the circle of some hour from noon or midnight that is parallel to the sundial, will not meet the conic sections that the plane of the sundial makes on the conical surfaces whose bases are the greatest of the parallels always visible and always hidden; yet, ever produced further, they become closer to the conic sections.]

Let some hour-circle from noon or midnight, FG, cut the conical surfaces ABC, ADE — joined at the centre A, whose bases are the parallel DE, the greatest of those always visible, and BC, the greatest parallel always hidden below the horizon — along its axis FG, by the straight lines HI, KL, and making the diameters of the parallels HK, LI (since, by Proposition 15 of Book 1 of Theodosius, it bisects them, and hence cuts through their diameters). And let it be parallel to the plane of the sundial MN, which, by Proposition 6 of this book, will make two opposite and equal hyperbolas, OPQ and RST. And since the planes FG, MN are set parallel, their common sections made by the parallel DE — namely the straight lines LI, ST — will be parallel [Margin (a): Euclid, *Elements* XI.16]. By the same reasoning HK and PQ will be parallel, since they are the common sections of the parallel planes FG, MN made by the parallel BC. Let also some hour-circle from sunrise or sunset touch the parallels BC, DE at the points H, I, and hence touch the conical surfaces along the straight line HI (by Proposition 13 of this book), making in the plane of the sundial the hour-line VX. I say that the straight line VX is ἀσύμπτωτον [Greek: asymptōton — non-meeting]; that is, that it never meets the hyperbolas OPQ, RST, yet always becomes closer to them, however far both the straight line and the hyperbolas are produced. For since the circle HIVX touches the conical surfaces only along the straight line HI, so that all other points of the circle HIVX, lying outside the straight line HI, are outside the conical surfaces, the hour-line VX will lie wholly outside the conical surfaces, because...

[Margin (a): Euclid, *Elements* XI.16]

it cannot meet the straight line HI, since the planes FG, MN are set parallel, and therefore the straight lines HI, VX — their common sections made by the plane

HIVX — are parallel. Therefore the straight line VX will not meet the hyperbolas OPQ, RST, even if the straight line VX and the hyperbolas are in the same plane of the sundial. In the same way VX will lie outside the conical surfaces, even if they are produced to infinity. And you will say the same of the hour-line whose circle touches the conical surfaces along the straight line KL.

Diagram. A large circle representing the greatest circle DBCE of the sphere (with the world-centre A at its centre), densely filled with chords, showing the two opposed conical surfaces (common vertex A) whose curved bases YZ and the two hyperbolas descend below the circle, together with the hour-circle FG (through the poles), the tangent hour-circle HIVX, and the two opposite hyperbolas OPQ/RST with their augmented extensions. The figure is very crowded and cross-hatched; several interior Greek point-labels in the lower-central cluster are faint or overlapping. Readings are best-effort

- F (top): upper pole / top of the axis FG (a short gnomon-line rises above F)
- L (upper left), M (upper right): points of the parallel LI / hour-circle
- S (upper centre, below M): section point (of ST)
- D (left, on the great circle), E (right, on the great circle): endpoints of the greatest visible parallel DE
- I (upper centre): point of the parallel LI
- V (centre), R (below V): point of the hour-line VX / of hyperbola RST
- A (centre): centre of the world, common vertex of the cones
- H (mid-left, interior), X (centre-right), O (right of X): tangent point H, point X of the hour-line, point O of hyperbola OPQ
- B (lower left, on the great circle), C (lower right, on the great circle): endpoints of the greatest hidden parallel BC
- μ (lower centre-left), ξ (lower centre-right): interior points on the parallel/section [?]
- K (lower centre), G (lower left of centre): points K, G [?]
- N (lower centre), Q (lower right of centre): points N, Q of the hyperbola/parallel [?]
- α (lower left, of the augmented figure) [?], ϵ , ζ (lower centre) [?]: augmented-construction points
- Y (bottom left), Z (bottom right): endpoints of the augmented base YZ
- β (bottom centre), θ (very bottom): augmented-hyperbola / base points [?]

I say now that the straight line VX, produced in both directions, always becomes closer to the hyperbolas. For let the conical surface ABC be enlarged, and let YZ

be the base of the enlarged surface; and let the straight lines IH, FG, MN, VX be extended to the points α , β , γ , δ , together with the planes FG, MN, HIVX; and let the hyperbola OPQ be enlarged, so that it becomes $O\epsilon\theta$ [?]. Let the conical surfaces also be cut by the plane in which the greatest circle DBCE lies, through the diameters DE, BC, which are perpendicular to the diameters LI, HK — and hence also to the straight lines ST, PQ parallel to those. Finally, let $H\alpha$ and $\alpha\delta$ be the common sections of the planes BC, YZ with the plane in which the circle HIVX lies; these will touch the circles BC, YZ at the points H, α (by the definition in Book 2 of Theodosius). And the three straight lines VX, QP, $H\alpha$ will cut one another outside the conical surfaces at the point λ ; for any two of them cut one another.

For since HI, VX have been shown to be parallel, and since $H\lambda$ lies in the same plane with them — namely in the plane of the circle HIVX — and $H\lambda$ cuts HI at H, the same $H\lambda$ will also cut the straight line VX, as we demonstrated at Proposition 28 of Book 1 of Euclid. Therefore the straight lines $H\lambda$, VX cut one another. Again, the same $H\lambda$ will cut PQ. For since HK, PQ are parallel, as was shown above, and $H\lambda$ cuts HK, it will also cut PQ, from what we showed at Proposition 28 of Book 1 of Euclid. That PQ and VX also cut one another is made plain thus: if they did not intersect — being in the same plane of the sundial — they would be parallel. Now since both HI and PQ are parallel to VX [Margin (b): Euclid XI.9], HI and PQ will be parallel to each other. But HK is also parallel to PQ, as we demonstrated above [Margin (c): Euclid XI.9]. Therefore HI and HK would be parallel to each other — which is absurd, since they meet at H. Therefore PQ and VX cut one another. Hence VX, cutting both $H\lambda$ and PQ, will pass through the point λ , where $H\lambda$ and QP cut one another. For if, for example, VX were to cut the straight line $H\lambda$ short of the point λ , or beyond it (if it were produced further), it would at once cut the plane of the circle BC at the same point at which it cuts $H\lambda$, and so could no longer cut the straight line QP, which lies in the same plane of the circle BC. By parallel reasoning, if VX were to cut PQ short of or beyond the point λ , it would likewise, when produced, at once cut the plane of the circle BC at the same point at which it cuts PQ, and therefore could not cut the straight line $H\lambda$, which always lies in the same plane of the circle BC. Therefore, unless VX passes through the point λ , it will not cut both $H\lambda$ and QP — which is absurd, since it was shown to cut both. In the same way, at δ the three straight lines $\alpha\delta$, $\theta\epsilon$ [?], VX will cut one another.

Now since the straight lines $\mu\beta$, $\xi\gamma$ are parallel — being the common sections of the parallel planes FG, MN made by the plane of the circle DBCE — and likewise the straight lines $\mu\xi$, $\beta\gamma$ — namely the common sections of the parallel planes BC, YZ made by the same plane of the circle DBCE — $\mu\xi$ and $\beta\gamma$ will be equal [Margin

(d): Euclid XI.16; Margin (e): Euclid I.34]. And since $H\lambda$, $\mu\xi$, and also $\alpha\delta$, $\beta\gamma$, are parallel as well [Margin (f): Euclid I.28] — because the angles $\mu H\lambda$, $\beta\alpha\delta$ at the points of contact H , α are right (for $H\mu$, $\alpha\beta$ pass through the centres of the circles BC , YZ , being their common sections with the plane FG , which cuts them through their poles and hence through their diameters, by Proposition 15 of Book 1 of Theodosius), and likewise the angles $H\mu\xi$, $\alpha\beta\gamma$ at the centres μ , β — for since, by construction, the straight line BC cuts the straight line HK at right angles, the angle $H\mu\xi$ will be right [Margin (g): Euclid III.18]. Therefore, since $\alpha\beta$, $\beta\gamma$ are parallel to $H\mu$, $\mu\xi$ [Margin (h): Euclid XI.16], the angle $\alpha\beta\gamma$ will be equal to $H\mu\xi$, and thus right [Margin (i): Euclid XI.10]. Moreover, the straight lines $H\mu$, $\lambda\xi$, and also $\alpha\beta$, $\delta\gamma$, are parallel — namely the common sections of the parallel planes FG , MN , made by the plane of the circle BC if we speak of the former, and by the plane of the circle YZ if we speak of the latter [Margin (k): Euclid XI.16]. Then, if the straight line $\delta\varepsilon$ is smaller than the straight line λP , as we shall presently demonstrate in the following lemma—

—lemma. Therefore the straight line VX , when produced, is closer to the hyperbola $O\epsilon\theta$ [?] at the point δ than at the point P ; and so on successively, if the hour-line and the hyperbola are produced further. And we shall show the same in the hyperbola RST , and likewise concerning the hour-line that the circle touching the conical surfaces along the straight line KL makes. Therefore, if the circle of any hour from noon or midnight is parallel to the plane of the sundial, etc. Which was to be demonstrated.

LEMMA.

If two unequal circles are touched by two straight lines parallel to their diameters, and the points of contact and the centres are joined by two straight lines, and through two points on the radii equally distant from the centres parallels are drawn cutting the peripheries of the circles, then the straight lines intercepted between the tangent lines and the peripheries will be unequal — and the smaller will be the one that lies outside the greater circle.

Let the circle αYZ , greater than the circle HBC , be touched — each of them — by the straight lines $\alpha\delta$, $H\lambda$, parallel to the diameters YZ , BC ; and let the points of contact α , H , and the centres β , μ , be joined by the straight lines $\alpha\beta$, $H\mu$. Taking straight lines $\beta\gamma$, $\mu\xi$ equal, cut off from the radii βZ , μC , let there be drawn through γ , ξ the parallels $\gamma\delta$, $\xi\lambda$ to the straight lines $\alpha\beta$, $H\mu$, cutting the peripheries at ε , P . I say that the straight line $\delta\varepsilon$ is smaller than λP .

For since the circle αYZ is greater than the circle HBC , the radius $\alpha\beta$ will also be greater than the radius $H\mu$. Therefore let the straight line αA be cut off equal to $H\mu$, and from A , at the distance $A\alpha$, let the circle αE be described; it will be equal to the circle HBC , on account of the equality of the radii αA , $H\mu$, and it will touch the circle αYZ at α . And since AD , drawn from A perpendicular to $\gamma\alpha$, is parallel to $\beta\gamma$ [Margin (a): Euclid I.28], $A\gamma$ will be a parallelogram [Margin (b): Euclid I.34]; and therefore the straight line AD will be equal to the straight line $\beta\gamma$ — that is, to $\mu\xi$. Since then $\mu\xi$ is smaller than the radius μC (or $H\mu$) — that is, smaller than αA , which is equal to $H\mu$ — AD too will be smaller than αA , and therefore the point D will lie inside the circle αE . Hence the circumference αE will cut the straight line $D\alpha$ below the point ε , namely at E .

Now since, when the straight lines AE , μP are drawn, the square on AE equals the squares on AD , DE , and the square on μP equals the squares on $\mu\xi$, ξP [Margin (c): Euclid I.47], and the squares on AE , μP are equal to each other, the squares on AD , DE will equal the squares on $\mu\xi$, ξP . Therefore, when the equal squares on the straight lines AD , $\mu\xi$ are taken away, the remaining squares on DE , ξP will be equal, and consequently the straight lines themselves will be equal. Since then the wholes $D\delta$, $\xi\lambda$ are also equal — because $D\alpha$ is equal to $A\alpha$, and $\xi\lambda$ to μH [Margin (d): Euclid I.34] — the remainders αE , λP [?] will also be equal. But $\delta\varepsilon$ is smaller than αE [?]. Therefore $\delta\varepsilon$ will also be smaller than λP . Which was to be demonstrated.

From these things it is clear that, in the figure above, the straight line $\delta\varepsilon$ is smaller than the straight line λP , as was assumed in the demonstration — because the circle YZ is greater than the circle BC , etc., as the lemma proposes.

Diagram. Two side-by-side figures illustrating the lemma. On the left, the larger circle αYZ (horizontal diameter YZ) with a smaller inscribed/tangent circle αE inside it; the interior shows the rectangle/parallelogram A – D built on the centre-line, with the tangent $\alpha\delta$ across the top. On the right, the smaller circle HBC (horizontal diameter $B\dots C$, extended to E), with the tangent $H\lambda$ across the top and the point P on the right where the parallel $\xi\lambda$ cuts the periphery.

- Left figure — α (top, point of contact/tangent), δ (top, on tangent $\alpha\delta$) [?]
- A (centre-left interior), D (interior right of A): vertices of the parallelogram $A\gamma$ / point D on $D\alpha$
- β (bottom centre, on diameter): centre of circle αYZ
- Y (left end of diameter), Z (right end of diameter): endpoints of diameter YZ

- Right figure — H (top left, point of contact), λ (top, on tangent $H\lambda$): tangent point and line
- P (right, on periphery): where the parallel $\xi\lambda$ cuts the periphery
- μ (bottom centre, on diameter): centre of circle HBC
- ξ (lower centre, on the radius): point ξ on μC
- E (right, on the extended diameter $B...C \rightarrow E$), C (right end): endpoints
- B (bottom, on diameter) [?]

COROLLARIVM.

It follows from this proposition that the lines of the 12th and 24th hours from sunrise or sunset in a meridian sundial do not meet the hyperbolas that the plane of the sundial makes (by Proposition 6 of this book) on the conical surfaces whose bases are the greatest of the always-visible parallels and the greatest of those hidden under the earth. For the meridian — that is, the circle of the 12th hour from noon or midnight — is parallel to the plane of the sundial, and cuts the greatest of the always-visible parallels at the points where both the circle of the 12th hour from sunrise or sunset and the circle of the 24th hour (or the horizon) touch it, as is clear from the figure of Proposition 9 of this book.

[Margin: The lines of the 12th and 24th hours from sunrise or sunset do not meet, in a meridian sundial, the conic sections made on the conical surfaces whose bases are the greatest of the parallels always visible and always hidden. The lines of the 6th and 18th hours from sunrise or sunset do not meet, in a polar sundial, the conic sections made on the conical surfaces whose bases are the greatest of the parallels always visible and always hidden.]

In the same way, the lines of the 6th and 18th hours from sunrise or sunset will not meet the same hyperbolas in a polar sundial. For the polar sundial is parallel to the circle of the 6th hour from noon or midnight, which cuts the said parallel at the points where the circles of the 6th and 18th hours from sunrise or sunset touch it, as is clear from the same figure of Proposition 9 of this book.

THEOREMA 14. PROPOS. 16.

If in a sphere two greatest circles touch one and the same parallel at opposite points, then those circles and the greatest of the parallels will have one and the same common section.

[Margin: The greatest of the parallels and two greatest circles touching any parallel at two opposite points have one and the same common section.]

In the sphere ABCD, let two greatest circles AC, BD touch the parallel BC at the opposite points B, C, and let their common section be the straight line EF. I say that the greatest of the parallels, GH, cuts each of them along the straight line EF — that is, passes through the points E, F — so that the straight line EF is the common section of the three greatest circles AC, BD, GH. For through the pole I of the parallels BC, GH, and through the point of contact B, let a greatest circle ABCD be described; since, by Proposition 15 of Book 1 of Theodosius, it bisects the parallel BC, it will also pass through the opposite point of contact C. Therefore, since the greatest circle ABCD, described through the pole of the parallel BC and through the points of contact B, C, also passes through the poles of the circles AC, BD (by Proposition 5 of Book 2 of Theodosius), it will necessarily bisect, by Proposition 9 of Book 2 of the same, their segments AEF, BEF, CEF, DEF, at points...

the points A, B, C, D. Now since these are segments of semicircles — for since AC and BD are great circles, they bisect each other at the points E and F (by Proposition 11 of Book 1 of Theodosius) — the segments AE, AF, BE, BF, CE, CF, DE, DF will be quadrants, being the halves of semicircles. Again, since the great circle ABCD passes through the poles of the circles GH and BD, it cuts the segments of the circles GH and BD — which are semicircles, by Proposition 11 of Book 1 of Theodosius — in half, by Proposition 9 of Book 2 of Theodosius, at the points G and B. Therefore the arcs of the circle BD lying between the point B and the circle GH will be quadrants. And since BE and BF have been shown to be quadrants, the circle GH will necessarily pass through the points E and F, and so will cut both circles AC and BD along the straight line EF. Therefore the straight line EF is the common section of the three great circles AC, BD, GH. And consequently, if in a sphere two great circles touch one and the same, and so on. This is what had to be demonstrated.

Diagram. A great circle with an eight-pointed star of chords inscribed, together with two vesica-shaped arcs (the parallels GH) meeting at the central points E and F.

- I (top, above the circle): the pole of the parallels
- A (upper left, on the circle)
- D (upper right, on the circle)
- G (left, on the circle): endpoint of the great parallel

- H (right, on the circle): endpoint of the great parallel
- E (upper centre): common intersection point
- F (lower centre): common intersection point
- B (lower left, on the circle)
- C (lower right, on the circle)

COROLLARIUM.

[Margin: The four arcs of the Ecliptic between the points of the solstices and the equinoxes; likewise the arcs of the Horizon between the Equator and the Meridian; and finally the arcs of all the hour-circles, from sunrise or sunset, between the Equator and the points where they touch the greatest of the always-visible parallels and the greatest of the always-hidden — all these intercepted arcs are quadrants.]

Since it has been shown that the arcs BE and BF, lying between the point of contact B and the greatest of the parallels GH, are quadrants, it follows that the arcs of any great circle touching some parallel, lying between the point of contact and the greatest of the parallels, are quadrants. For the demonstration is the same in every case: the great circles drawn through the poles of the parallels and through the point of contact always pass (by Proposition 5 of Book 2 of Theodosius) through the poles of the tangent circles as well; and so they bisect (by Proposition 9 of Book 2 of Theodosius) the individual segments lying between the points of contact and the greatest of the parallels — segments which are semicircles by Proposition 11 of Book 1 of Theodosius — that is, they divide them into quadrants. Of this kind are the four arcs of the Zodiac intercepted between the Equator and the solstitial points, where the Zodiac touches the tropics, which are parallel to the Equator. Likewise the four arcs of the Horizon between the Equator and the points where the Horizon touches the greatest of the always-visible parallels and the greatest of the always-hidden, and where it is cut by the Meridian. And finally all the arcs of the circles that mark the hours from sunrise or sunset, intercepted between the Equator and the points where they touch the greatest of the always-visible parallels and the greatest of the always-hidden. For all these arcs are quadrants, as has been demonstrated.

THEOREMA 15. PROPOS. 17.

If in a sphere two great circles touch one and the same parallel, and another great circle cuts that same parallel through the poles of the parallels and lies equally

distant from the two points of contact, then the tangent circles and the cutting circle will have one and the same common section.

[Margin: Three great circles — of which one cuts any parallel through its poles, while the others touch that same parallel at points equally distant on either side from the two points where it is cut by the first great circle — have one and the same common section.]

In the sphere ABCD, let two great circles AC and BD first touch the parallel BC at the opposite points B, C, so that BIC and BkC are semicircles, and let their common section be the straight line EF. Let another great circle GH cut the same parallel BC, passing through the poles G, H of the parallel, at the points I, K, equally distant from the points B, C, so that the arcs IB, IC and KB, kC are quadrants. I say that the circle GH cuts each of the great circles AC and BD along the straight line EF — that is, passes through the points E, F — so that the straight line EF is the common section of the three great circles AC, BD, GH. For let the greatest of the parallels, LM, be described; it will pass through the points E, F, since by the preceding proposition EF is the common section of the three circles AC, BD, LM — because AC and BD touch the parallel BC at opposite points, and LM is the greatest of the parallels. Now if a great circle GLHM is described through the poles of the parallels and through the point of contact B, this same circle will pass through the poles of the circle BD as well, by Proposition 5 of Book 2 of Theodosius. Therefore it will bisect the segments BEF and LEF, by Proposition 9 of the same. Since, then, LEF is a semicircle — because great circles bisect one another, by Proposition 11 of Book 1 of Theodosius — the arcs LE, LF will be quadrants. And since the great circles GLHM and GEHF are described through the poles G, H of the parallels BC, LM, the arcs intercepted between them will be similar, by Proposition 10 of Book 2 of Theodosius. But the arcs BI, Bk of the parallel BC intercepted between them are, by hypothesis, quadrants. Therefore the arcs of the parallel LM intercepted between the same circles will also be quadrants. Consequently, since LE, LF have been shown to be quadrants, the circle GH will pass through the points E, F, and so will cut both circles AC and BD along the straight line EF. Therefore the straight line EF is the common section of the three circles AC, BD, GH. This is what had to be shown.

Diagram. A great circle inscribed with a star of chords and two vesica-shaped parallel-arcs, for the first case of Theorem 15.

- G (top, on the circle): pole of the parallels
- A (upper left, on the circle)
- D (upper right, on the circle)

- E (upper centre): common intersection point
- L (left, on the circle): endpoint of the great parallel LM
- M (right, on the circle): endpoint of the great parallel LM
- F (lower centre): common intersection point
- B (lower left, on the circle)
- I (lower centre, left): point where GH cuts the parallel
- K (lower centre, right): point where GH cuts the parallel
- C (lower right, on the circle)
- H (bottom, on the circle): pole of the parallels

Next, in the same sphere ABCD, let two great circles EG and FH touch the same parallel BC at points E, F that are *not* opposite, and let their common section be the straight line IK, which will be their diameter, since they bisect one another by Proposition 11 of Book 1 of Theodosius. Let another great circle LM cut the same parallel BC, passing through the poles L, M of the parallel and through the axis LM, at the points O, P equally distant from the points E, F, so that the arcs OE, OF and PBE, PCF are equal. I say that the circle LM cuts each of the great circles EG and FH along the straight line IK — that is, passes through the points I, K — so that the straight line IK is the common section of the three great circles EG, FH, LM.

For since the circle LM cuts the parallel BC through its poles, it will bisect it, by Proposition 15 of Book 1 of Theodosius. Their common section OP will therefore be a diameter of the parallel BC, passing through the centre Q, into which the axis LM falls, by Proposition 10 of Book 1 of Theodosius. Let R also be the centre of the sphere, through which the axis LM and the diameter IK of the great circles both pass. And since circles in a sphere are said to touch one another when the common section of the planes in which the circles lie touches each circle (by the definition in Book 2 of Theodosius), let the common sections of the circles EG, BC and of FH, BC be the straight lines ES, FS, touching those circles. If, then, the semidiameters QE, QF are drawn from the centre Q, the angles SEQ, SFQ will be right angles [Margin: a — Euclid III.18], and therefore, once the straight line EF is drawn, the angles SEF, SFE will be less than right angles. Hence the straight lines ES, FS, lying in the same plane of the parallel BC which they touch, will meet at some point, namely at S, by the 11th axiom of Book 1 of Euclid. And since KI, the common section of the circles EG, FH, meets each of ES, FS as well (as we shall show in a moment in the following lemma), it comes about that KI, when produced, meets each of them at S. For if it were to cut one of them below or above S, it would not meet the other, as is plain. Suppose, for example, that KI

met the straight line ES elsewhere than at the point S: then, when produced, it would at once cut the plane of the circle BC at the point where it cuts ES, and so could in no way cut the straight line FS lying in the same plane of the circle BC. And if KI met FS elsewhere than at S, we should show in the same way that it cannot cut ES. Therefore the straight line KI, unless it passes through the point S, will not cut both ES and FS — which is absurd, for it does cut both, as we shall show in the following lemma. Now let the straight lines EO, FO, OS be drawn in the plane of the circle BC. Since the arcs EO, FO are assumed equal, the straight lines EO, FO will also be equal [Margin: b — Euclid III.28]; and the tangents SE, SF are equal too, by the 2nd corollary to Proposition 36 of Book 3 of Euclid. Therefore the two sides EO, OS of the triangle EOS will be equal to the two sides FO, OS of the triangle FOS, and the base ES to the base FS; and consequently the angles EOS, FOS will be equal [Margin: c — Euclid I.8]. In just the same way we shall show that the angles EOQ, FOQ are equal, because the sides EO, OQ of the triangle EOQ are equal to the sides FO, OQ of the triangle FOQ, and the base EQ to the base FQ. Therefore the two angles EOS, EOQ are equal to the two angles FOS, FOQ, and consequently both pairs make up half of the four angles at the point O lying in the plane of the circle BC. But those four angles are equal to four right angles, by the 2nd corollary to Proposition 15 of Book 1 of Euclid. Therefore EOS, EOQ, as well as FOS, FOQ, will be equal to two right angles; and hence the straight lines SO, OQ lie in a straight line [Margin: d — Euclid I.14 and XI.2]. There is therefore a triangle QRS, and so it lies in one plane [Margin: e — Euclid XI.2], namely the one drawn through SQ, QR. But the plane of the circle LM is drawn through these straight lines SQ, QR, as is plain. Therefore the straight line RS will lie in this same plane of the circle LM; and consequently the circle LM will pass along the straight line IK, so that along it the circle cuts the two tangent circles EG, FH. Therefore IK is the common section of the three circles EG, FH, LM. And so, if in a sphere two great circles, and so on. This is what had to be demonstrated.

Diagram. A large, densely inscribed great circle for the second case of Theorem 15, showing the parallel BC, the two tangent great circles EG, FH, the cutting circle LM, and the network of chords and tangents ES, FS meeting at S (drawn at the right edge as a small pencil of tangent rays). The figure is very crowded; several interior point-labels are hard to resolve at this resolution and are flagged.

- L (top, on the circle): pole of the parallel
- A (upper left, on the circle)
- H (just below/inside A): pole
- D (upper right, on the circle)

- G (interior, upper right)
- K (interior, left)
- T (upper centre)
- I (interior, right of centre)
- S (right edge, with a pencil of tangent rays): meeting point of the tangents
- R (centre): centre of the sphere
- T (lower centre) [?] (a second "T" reading — uncertain)
- E (lower left interior)
- B (bottom left, on the circle)
- P (bottom centre)
- Q (bottom centre, right of P): centre of the parallel BC
- C (bottom right, on the circle)
- F (lower right interior)
- M (bottom, on the circle): pole of the parallel

LEMMA.

That KI meets both ES and FS we shall demonstrate as follows. For if KI and ES do not meet, they will certainly be parallel, by Definition 34 of Book 1 of Euclid, since they lie in the same plane of the circle EG. For ES, being a tangent to the circle EG, lies in the same plane of that circle in which KI also lies. Hence, if RT is drawn parallel to SF, the plane drawn through KR, RT will be parallel to the plane drawn through SE, SF [Margin: f — Euclid XI.15]; and so the straight lines KI, FS, lying in those parallel planes, will never meet, since the planes themselves never meet either. Therefore KI and FS, not meeting and lying in the same plane of the circle FH (for FS, being a tangent to the circle FH, lies in the same plane of that circle in which KI too of course lies), are parallel, by Definition 34 of Book 1 of Euclid. And consequently ES and FS will be parallel to each other [Margin: g — Euclid XI.9], since each is parallel to IK — which is absurd. For it has been shown that the straight lines ES, FS meet at the point S. Therefore the straight lines KI, ES will meet, since they are not parallel and lie in the same plane, as has been demonstrated. And by the same reasoning we shall show that KI and FS meet.

Diagram. A second large great circle, closely repeating the previous figure, drawn for the lemma; it adds the auxiliary line RT parallel to SF. As with the preceding figure, several interior labels are hard to resolve.

- L (top, on the circle): pole of the parallel
- A (upper left, on the circle)

- H (below/inside A): pole
- D (upper right, on the circle)
- G (interior, upper right)
- K (interior, left)
- T (upper centre)
- R (centre)
- I (interior, right of centre)
- S (right edge, with tangent rays)
- E (lower left interior)
- T (lower centre) [?] (second "T" — uncertain)
- B (bottom left, on the circle)
- P (bottom centre)
- Q (bottom centre, right of P)
- C (bottom right, on the circle)
- F (lower right interior)
- M (bottom, on the circle)

SCHOLIUM.

What we have shown in this proposition and the preceding one we shall demonstrate in another and perhaps easier way, in the scholium to Proposition 20 of this book.

THEOREMA 16. PROPOS. 18.

If any number of planes having one and the same common section are cut by some other plane that is parallel either to one of them or to their common section, then the common sections of all those planes with the cutting plane will be parallel lines. But if the same planes are cut by a plane that is not parallel to their common section, then the common sections of all of them with the cutting plane will meet at that point of the common section where the cutting plane intersects it.

[Margin: A plane cutting any number of planes that have one and the same common section, to which common section the cutting plane is parallel, produces parallel common sections; but if it cuts that common section, it produces common sections that meet at the point where the cutting plane divides their common section. a — Euclid XI.16. b — Euclid XI.9. c — Euclid XI.3.]

Let any number of planes AB, CD, EF, RS, having the same common section GH, be cut by a plane IK which is parallel — first, as in the earlier figure — to the plane RS, or to the common section GH. (I call a plane parallel to some straight line one which, when produced to infinity, never meets that straight line, itself also produced to infinity; or one through which, by way of that straight line, some parallel plane can be drawn.) Let the common sections of the planes AB, CD, EF with the cutting plane IK be the straight lines LM, NO, PQ. I say that these common sections are parallel. For if the plane RS is drawn through the straight line GH — in case the plane IK is supposed parallel only to the straight line GH and to no plane — parallel to the plane IK, then the plane AB will be cut by the parallel planes IK, RS. Therefore the common sections LM, GH are parallel [Margin: a — Euclid XI.16]. By the same reasoning NO, GH and PQ, GH will be parallel. Therefore the straight lines LM, NO, PQ, being parallel to GH, will be parallel to one another as well [Margin: b — Euclid XI.9]. This is what had to be shown.

Diagram. The "earlier figure": several plane figures (drawn as tilted quadrilaterals fanning out) sharing the common section GH and cut by the plane IK, producing the parallel sections LM, NO, PQ. The plates overlap densely; the readable corner-labels are listed.

- A, C (upper left plate — plane AB / CD)
- G, H (centre): the common section GH
- R (upper centre): plane RS
- S, I (lower left)
- K, P (upper right)
- N, O (centre right)
- L, M (centre): a common section
- F, D (right plates — planes EF, CD)
- B (lower right): plane AB
- Q (upper right): common section endpoint

Now let the cutting plane IK *not* be parallel to the common section GH, but meet it, when produced toward the parts of H, at the point R, as in the later figure. I say that LM, NO, PQ — the common sections of the planes AB, CD, EF with the cutting plane IK — meet at the same point R, where the cutting plane IK intersects the common section GH produced. For the plane AB, extended along the straight line GH produced toward the parts of H, will cut the plane IK at the point R, since it is always produced along the straight line GR. Since, then, the same plane AB cuts

the same plane IK at the points L, M, and since the common section of the planes is a straight line [Margin: c — Euclid XI.3], the three points L, M, R will be set in a straight line — namely in the common section of the planes AB, IK. Therefore the straight line LM (that is, the common section of the planes AB, IK), produced toward the parts of M, will meet GH produced at R. By the same argument we shall show that the straight lines NO, PQ meet GH at the same point R. Therefore the common sections LM, NO, PQ, when produced, meet the section GH produced at the point R, where the cutting plane IK meets that same section GH. This is what was proposed. And so, if any number of planes having one and the same common section, and so on. This is what had to be demonstrated.

Diagram. The "later figure": the same fan of plane figures, but now the cutting plane is oblique, so the common sections LM, NO, PQ (shown by dotted lines) converge at the single point R.

- I, P, F, B (upper plates and right edge)
- A, G, N, L, D (upper row)
- C, H, O, M, K (middle row)
- R (bottom, where the dotted sections converge)
- E (lower left)

THEOREMA 17. PROPOS. 19.

At whatever point any hour-line drawn from noon or from midnight cuts the Equinoctial line of any sundial, at that same point two hour-lines drawn from sunrise or sunset — whose circles are distant from the circle of the hour-line of noon or midnight by a whole quadrant, that is, by six hours, on the greatest of the always-visible parallels — will intersect that same Equinoctial line.

[Margin: The line of any hour from noon or midnight, and the two lines of the hours from sunrise or sunset distant from it by a whole quadrant on the greatest of the always-visible parallels, intersect one another at one and the same point of the Equinoctial line, in any sundial whatever.]

Let ABCD be the greatest of the always-visible parallels, which any hour-circle from noon or midnight, AC, cuts at the points A, C along the straight line AC — this line being a diameter of the circle ABCD, because the cutting hour-circle, by Proposition 9 of this book, cuts the circle ABCD through the poles and therefore bisects it, by Proposition 15 of Book 1 of Theodosius. Let two quadrants AB, AD be taken from A, so that each of the arcs AB, AD, CB, CD comprises six whole hours; and at B, D let two hour-circles from sunrise or sunset, BE, DF, touch the parallel

ABCD, by Proposition 10 of this book. I say that, at whatever point the hour-line of the circle AC cuts the Equinoctial line in any sundial, at that same point the two hour-lines of the circles BE, DF cut the same Equinoctial line. For since the hour-circles BE, DF, touching the parallel ABCD at B, D, and the hour-circle AC, cutting that same parallel along the straight line AC, have one and the same common section, by Proposition 17 of this book; and since those same tangent circles and the Equator have one and the same common section too, by Proposition 16 of this book: these four circles — the Equator, the two tan-

Diagram. A circle ABCD (the greatest of the always-visible parallels) with the vertical diameter AC and a slightly curved meridian; two hour-circle arcs BE and DF stand outside it, tangent at B and D.

- D (right, on the circle): point of contact
- C (bottom, on the circle)

LIBER PRIMVS [Book One] — continued

THEOREMA 17. PROPOS. 19. — conclusion of the demonstration

the two tangent circles BE and DF, and the secant AC, have one and the same common section. Therefore, if the plane of the sundial is not parallel to this common section but cuts it at some point, then the common sections of the said circles and of the plane of the sundial — that is, the equinoctial line, the two hour-lines from sunrise or sunset of the circles BE and DF, and the hour-line from noon or midnight of the circle AC — will all cut one another at that same point, by the preceding proposition. And so, at whatever point the hour-line from noon or midnight of the circle AC cuts the equinoctial line in any sundial, at that same point the common section of the said circles meets the plane of the sundial; and consequently at that same point the two hour-lines from sunrise or sunset of the circles BE and DF also cut that equinoctial line. The reasoning is the same for the rest. Therefore, at whatever point any hour-line from noon, and so on. Which was to be shown.

SCHOLIVM [Scholium].

[Margin: Construction of a table containing the hours from noon or midnight and from sunrise or sunset that intersect one another at one and the same point of the equinoctial line of any sundial.]

From this proposition we have constructed the following table, whose title is **AEQVINOCTIALIS LINEA [The Equinoctial Line]**. For it shows which hour-line from sunrise or sunset, and which from noon or midnight, cut the equinoctial line of any sundial at one and the same point — as can easily be gathered from this proposition. Thus, if in the following table any hour, or part of an hour, from noon or midnight be taken, together with the two hours (or parts of hours) from sunrise or sunset set beside it, the lines of those three hours — or even of the parts of hours — will cut the equinoctial line at one and the same point.

For example, the line of the seventh hour from noon or midnight, the line of hour 1, and the line of hour 13 from sunrise or sunset cut the equinoctial line at one and the same point. In the same way the line of hour $7\frac{1}{4}$ from noon or midnight, the line of hour $1\frac{1}{4}$, and the line of hour $13\frac{1}{4}$ from sunrise or sunset cut the equinoctial line at one and the same point; and so on for the rest. For if this table, and the figure of Proposition 9 of this book, be rightly considered, any two such hours from sunrise or sunset will be found to be distant from the intermediate hour from noon or midnight by a whole quadrant, that is, by six hours. This is why the lines of these hours cut the equinoctial line at the same point at which the line of the hour from noon or midnight cuts that same equinoctial line, as we demonstrated in this proposition.

Therefore, if a point on the equinoctial line of any sundial has been noted through which one of three hours passes, we shall know that the remaining two hours must pass through that same point. By the same reasoning, if a point has been ascertained at which any two of the three hours cut one another, we shall also know that the equinoctial line must be drawn through that same point, and so on.

[Margin: Construction of a table in which are contained the hours from noon or midnight and from sunrise or sunset intersecting one another at one and the same point — the equinoctial line of any sundial.]

Below the table: In an equinoctial sundial the lines of any three hours of this table are parallel (as is clear from the scholium of Proposition 22 of this book). Likewise in certain other sundials the lines of these hours — namely 12 and 24 from sunrise or sunset, and 6 from noon or midnight — are parallel, as is taught in the same scholium.

PROBLEMA 18. PROPOS. 20.

[Margin: The line of any hour from noon or midnight, and the two lines of the hours from sunrise or sunset equally distant on either side of it on the greatest of the always-visible parallels, intersect one another at one and the same point of any sundial.]

If any two hour-lines from sunrise or sunset are taken whose circles are equally distant from the circle of some hour from noon or midnight on the greatest of the always-visible parallels, then those two hour-lines from sunrise or sunset will intersect one another — within the hour-line of that circle from noon or midnight — at one and the same point; and likewise one of them (from sunrise or sunset) together with that line from noon or midnight will intersect the remaining line from sunrise or sunset, each at one and the same point.

Let ABCD be the greatest of the always-visible parallels, which any hour-circle from noon or midnight, AC, cuts at the points A, C along the straight line AC — this line being a diameter of the circle ABCD, as was shown in the demonstration of the preceding proposition. Let two points B, D be taken, equally distant from either of the points A, C, so that the arc AB comprises as many hours as the arc AD; and likewise the arc CB as many as the arc CD. At B and D let two hour-circles from sunrise or sunset, BE and DF, touch the proposed parallel ABCD, by Proposition 10 of this book. I say that the hour-lines from sunrise or sunset of the circles BE and DF intersect one another, at one and the same point, within the hour-line from noon or midnight of the circle AC.

For since the hour-circles BE and DF, touching the parallel ABCD at B and D, and the hour-circle AC, cutting that same parallel along the straight line AC, have (by Proposition 17 of this book) one and the same common section: it follows that, if the plane of the sundial is not parallel to this common section but cuts it at some point, the three said hour-lines meet at that same point — namely the common sections of the plane of the sundial and of the circles AC, BE, DF, by Proposition 18 of this book. Therefore, at whatever point one of them cuts another of the remaining lines, at that same point the remaining line also cuts it.

That is: if the hour-line from sunrise or sunset of the circle BE cuts the hour-line from noon or midnight of the circle AC at some point, then at that same point the hour-line from sunrise or sunset of the circle DF also cuts that same hour-line from noon or midnight of the circle AC. Likewise, if the line of circle BE cuts the line of circle DF at some point, then at that same point the line of circle AC also cuts the line of circle DF. And if the line of circle AC cuts the line of circle BE at some point, then at that same point the line of circle BE also cuts it, and so on.

Therefore, if any two hour-lines from sunrise or sunset are taken that are equally distant from some hour-line from noon or midnight on the greatest of the always-visible parallels, then those two hour-lines from sunrise or sunset will intersect one another — within the hour-line of that circle from noon or midnight — at one and the same point; and likewise one of them from sunrise or sunset, together

with that line from noon or midnight, will intersect the remaining line from sunrise or sunset, each at one and the same point. Which was to be demonstrated.

Diagram. The circle ABCD is the greatest of the always-visible parallels, drawn with the vertical diameter AC (A at the top, C at the bottom). B lies on the left of the circle and D on the right; these are the two points of tangency. Two hour-circles from sunrise or sunset, BE and DF, touch the parallel at B and D respectively; each is drawn as a large arc that crosses near A at the top and near C at the bottom, its far side labelled E (for the circle BE, on the left) and F (for the circle DF, on the right). The labels E and F appear both near the top (flanking A) and near the bottom (flanking C), marking the two crossings of each tangent circle.

- A (top, on the circle)
- E (upper left, beside A): the circle BE, near its upper crossing
- F (upper right, beside A): the circle DF, near its upper crossing
- B (left, on the circle): point of tangency of circle BE
- D (right, on the circle): point of tangency of circle DF
- E (lower left, beside C): the circle BE, near its lower crossing
- F (lower right, beside C): the circle DF, near its lower crossing
- C (bottom, on the circle)

SCHOLIVM [Scholium].

[Margin: Construction of four tables, in which are contained the hours from noon or midnight and from sunrise or sunset cutting one another at one and the same point: the line of hour 24 from sunrise or sunset, and of hour 12 from sunrise or sunset; likewise the line of hour 6 from noon or midnight, and the line of hour 12 from noon or midnight, of any sundial.]

From this proposition are drawn up the following four tables, whose titles are:

- **LINEA HORAE XXIII. AB ORTV, VEL OCCASV.** [The line of hour 24 from sunrise or sunset.]
- **LINEA HORAE XII. AB ORTV, VEL OCCASV.** [The line of hour 12 from sunrise or sunset.]
- **LINEA HORAE VI. A MERIDIE, VEL MEDIA NOCTE.** [The line of hour 6 from noon or midnight.]
- **LINEA HORAE XII. A MERIDIE, VEL MEDIA NOCTE.** [The line of hour 12 from noon or midnight.]

Below the table: In a vertical sundial at latitude 45° , or in a sundial parallel to the circle of hour 12 from sunrise or sunset, the lines of any two hours of this table are parallel. By the same reasoning, in certain other sundials the lines of these hours — 24 from sunrise or sunset, and 6 from noon or midnight — are parallel, as is manifest from the scholium of Proposition 22.

The line of the sixth hour from noon or midnight

[Table title: *Linea horæ sextæ à meridie vel media nocte.*]

Every column of this table is headed **Horæ ab ortu vel occasu** — "hours from sunrise or sunset." The twelve columns form six side-by-side pairs; in each pair the left column gives an hour reckoned from sunrise or sunset (the argument, running continuously $\frac{1}{4} \rightarrow 24$ in quarter-hour steps down the six pairs), and the right column gives the concurrent hour whose line meets it on the line of the sixth hour from noon. Reading order is pair by pair, top to bottom.

In a meridian sundial, the lines of any two hours of this table are parallel. By the same reasoning, in certain other sundials the lines of these hours — namely 18 and 6 from sunrise or sunset — are parallel, as will be demonstrated in the scholium of Proposition 22.

[Library stamp, lower margin: illegible ink stamp, "B.[?]"]

The first shows which two hour-lines — one taken from sunrise or sunset, the other from noon or midnight — cut the line of the 24th hour from sunrise or sunset at the same point. **The second** shows which two hour-lines — one again from sunrise or sunset, the other from noon or midnight — cut the line of the 12th hour from sunrise or sunset at the same point. **The third** shows which two hour-lines from sunrise or sunset cut, at one and the same point, the line of the sixth hour from noon or midnight. **The fourth**, finally, shows which two hour-lines from sunrise or sunset intersect, at one and the same point, the line of the 12th hour from noon or midnight. All of these can readily be gathered from this proposition. For if these tables and the figure of Proposition 9 of this book are rightly considered, one will find that, in the first two tables, an hour from sunrise or sunset set in the column-heading, and any hour from sunrise or sunset entered within the tables themselves, are equally distant from the neighbouring hour reckoned from noon or midnight. Their lines will therefore cut the line of this hour at the same point, as has been shown in this proposition; and so too the lines of any two of the hours set in the tables will intersect, at one and the same point, the line of the hour placed in the heading. In the latter two tables one will find that any two hours from sunrise or sunset entered in the tables are equally distant from the hour reckoned from noon or midnight that is set in the heading.

Hence, by the same proposition, their lines will intersect the line of that hour at a single point.

So if the point is known at which the line of the 24th hour from sunrise or sunset — or of the 6th or 12th from noon or midnight — is cut by one of the hours placed in the tables, we shall know that the remaining hour entered in the tables must be drawn through that same point, and so on. Thus, in the first table: through whatever point the line of the 24th hour from sunrise or sunset has passed for the hour $1\frac{1}{4}$ from noon or midnight, through that same point must the line of the first hour from sunrise or sunset be drawn — and likewise for the rest.

[Margin: Which of the hour-lines from sunrise or sunset, and from noon or midnight, cut one another at the same point.]

By the same route and reasoning we shall investigate, by means of this proposition, which given hour-line from sunrise or sunset intersects, at one and the same point, any other hour-line from noon or midnight; and likewise which hour-line from sunrise or sunset is cut, at one and the same point, by two arbitrary hour-lines — one from sunrise or sunset, the other from noon or midnight — and so forth. For if in the figure of Proposition 9 of this book one takes three hours — one, whichever you please, from noon or midnight, and the other two, however many, from sunrise or sunset, but equally removed on either side from the hour reckoned from noon or midnight — then the line of any one of these three will cut the lines of the remaining two at one and the same point. Thus the line of the 23rd hour from sunrise or sunset is intersected at a single point by two lines, one of which marks the 13th hour from sunrise or sunset, the other the sixth hour from noon or midnight; because in the figure of Proposition 9 the sixth hour from noon or midnight is equally distant from the 23rd and the 13th hour from sunrise or sunset. In the same way the line of the sixth hour from noon or midnight will be cut at one point by the lines of the 23rd and 13th hours from sunrise or sunset. So too the line of the third hour from noon or midnight will be cut by the lines of the 14th and 16th hours from sunrise or sunset. And so with the rest.

[Margin: The construction of other tables similar to the preceding ones, for each of the hour-lines both from sunrise or sunset and from noon or midnight.]

From these we shall without difficulty construct further tables like the preceding ones, one for each hour-line, both from sunrise or sunset and from noon or midnight — such as the thirty-two tables that follow. But since, for laying out the hour-lines from sunrise or sunset on any plane whatever (once the hour-lines

from noon or midnight have first been drawn — for it was to this use that we constructed the aforesaid tables), the five tables already given suffice, in their proper place we shall show as much; and for that reason we have set them apart from the other thirty-two, which will be placed a little further on, so that they may always be ready to hand whenever their use is required.

[Margin: Franciscus Maurolycus was the first to discover these intersections.]

Furthermore, Franciscus Maurolycus [Francesco Maurolico], Abbot of Messina, is, so far as I know, the first discoverer of these intersections that the hour-lines from sunrise or sunset and from noon or midnight make with one another. For I first observed them in his little book on the drawing of hour-lines, which he sent me at Rome written out in his own hand at Messina — for he had not yet published it. And since this consideration of the intersections is both most delightful and most useful for laying out the hour-lines from sunrise or sunset, I judged it altogether necessary, for the common benefit of students, to confirm it by geometrical demonstrations (as I have indeed done in the preceding propositions). For these intersections of the hour-lines were brought to me from Sicily without any demonstration, nor could I find their demonstration in any author. I have therefore not allowed it to be wanting any longer. Only Giovanni Battista Benedetti [Giovanni Battista Benedetti], in chapter 65 of his *Gnomonices*, has attempted to demonstrate this mutual intersection for the line of the 12th hour from sunrise or sunset alone.

But so that this mutual intersection of the hour-lines may be made still clearer, I choose to demonstrate here, in another way, on what plan the aforesaid tables have been constructed. And to begin from the equinoctial-line table, which we described in the scholium of Proposition 19 of this book: let AB be the equator, CD the greatest of the always-appearing parallels, and E the pole of the parallels, that is, of the world. Let two circles of hours from sunrise or sunset, CF and DF, touch the parallel CD at the opposite points C and D; and let the circle of some hour from noon or midnight cut the same parallel, through the pole E, at the point G, which is distant from the points C and D by roughly equal amounts of six hours on either side, so that CG and DG are quadrants. I say that the three circles CF, DF, EG cut one another on the equator AB, as at the point F.

[Margin: The equinoctial circle, and the two circles of the hours from sunrise or sunset touching the greatest of the always-appearing parallels at opposite points, and the circle of the hour from noon or midnight cutting that same parallel at a point equally distant from the points of contact, cut one another at one and the same point.]

For let there be described, through E (the pole of the parallels) and through C (the point of contact), the great circle EC, cutting the equator at A; and since it has passed through the poles of the parallel CD, it cuts it in half (by Proposition 15 of Theodosius, Book 1), and will therefore pass also through D, the opposite point of contact, and hence through the poles of the circles CF, DF (by Proposition 5 of Theodosius, Book 2). Since, then, the two circles AB and CF cut one another, the great circle EC, drawn through their poles, divides their segments in half (by Proposition 9 of Theodosius, Book 2). And since the segments about them are semicircles — which, being great circles, cut one another in half (by Proposition 11 of Theodosius, Book 1) — the arc of the circle CF lying between the point C and the equator, and the arc of the equator lying between the circles EC and CF, will be a quadrant, being the half of a semicircle. By the same reasoning, both the arc of the circle DF lying between the point D and the equator, and the arc of the equator lying between the circles EB and DF, will be a quadrant. Again, since the two circles CF, DF cut one another, the great circle CD, drawn through their poles, will divide their segments in half (by Proposition 9 of Theodosius, Book 2). Since therefore their segments are semicircles (by Proposition 11 of Theodosius, Book 1), the arcs of the circles CF, DF between the points [C, D, and ...]

[Margin: Which hours from sunrise or sunset and from noon or midnight cut one another at a single point on the equinoctial line.]

Diagram. A spherical-astronomy construction on the celestial sphere, drawn as a circle (the horizon/bounding circle) with three great-circle arcs meeting at a common point below center. It shows the equator, the greatest always-appearing parallel, and hour-circles converging.

- E (top): pole of the parallels (of the world)
- C (upper left): point of contact of the hour-circle CF with the parallel CD
- D (upper right): opposite point of contact of the hour-circle DF
- G (center): point where the hour-circle from noon/midnight cuts the parallel CD
- A (lower left) and B (lower right): ends of the equator AB
- F (bottom): common intersection of the three circles CF, DF, EG on the equator

[C, D, and ...] the point of section, are quadrants; and so, since it has been shown that they lie as quadrants from the equator, they will cut one another on the equator, as at the point F, so that the arcs CF, DF, AF, BF are quadrants. Again, since the great circles EG and CD, drawn through the poles of the parallels CD and

AB, cut the parallels into similar arcs (by Proposition 10 of Theodosius, Book 2) — and the arc CG between EC and EG is, by hypothesis, a quadrant — the arc of the equator AB lying between the same great circles EC and EG is likewise a quadrant. Hence, since the arc AF has been shown to be a quadrant, the great circle EG will pass through the point F. For which reason the four great circles AB, CF, DF, EF have one and the same common section, which was the thing proposed. And therefore, at whatever point the plane of the sundial meets this common section, the common sections of these same circles and of the plane of the sundial pass through the same point (by Proposition 18 of this book) — so that at the same point there intersect, in the sundial, those common sections, that is, the equinoctial line and the hour-lines of the circles CF, DF, EF. And so, at whatever point the hour-line of the circle EF cuts the equinoctial line, through that same point must the hour-lines of the circles CF, DF be drawn.

But so that we may know to which hours the circles CF, DF, EF belong, we shall carefully examine the figure of Proposition 9 of this book, which represents the greatest of the always-appearing parallels, and in which the outer numbers refer to the hours from sunrise or sunset, the inner ones to the hours from noon or midnight. For if CF is set, say, as the circle of the 19th hour from sunrise or sunset — and consequently DF as the circle of the seventh hour from sunrise or sunset, which is diametrically opposite to it, just as the point D is to the point C — then EF will be the circle of the first hour from noon or midnight, since this is a quadrant distant from each of those, just as the point G is a quadrant distant from the point C. And so, if DF is the circle of the hour $9\frac{1}{4}$ from sunrise or sunset, EF will be the circle of the hour $3\frac{1}{4}$ from noon or midnight, and so on for the rest, as is clear from the figure of Proposition 9 of this book. Likewise, if EF is set as the circle of any hour whatever from noon or midnight — say the circle of the hour $8\frac{1}{4}$ from noon or midnight — we shall at once recognize to which hours from sunrise or sunset the other two belong: namely CF the circle of the hour $14\frac{1}{4}$ from sunrise or sunset, and DF the circle of the hour $2\frac{1}{4}$ from sunrise or sunset, since each of these hours is distant from that one by a quadrant, that is, by six hours, as is evident from the said figure, just as the point G is a quadrant distant from the point C, and so on. From these considerations we shall easily compose the table of the equinoctial line set out in the scholium of Proposition 19 of this book.

[Margin: The construction of the table described in Proposition 19.]

For the construction, however, of the other tables, which are assigned to the hour-lines both from sunrise or sunset and from noon or midnight: let AB again be the equator, CD the greatest of the parallels that always appear, and E the pole

of the world, that is, of the parallels. Let two circles of hours from sunrise or sunset, CB and DA, touch the parallel CD at the points C and D — cutting one another at F, and cutting the equator at the points [B, A] — and let the circle AD, produced, cut the equator at N. Let the circle of some hour from noon or midnight cut the same parallel CD, through the pole E, at the point G, which is equally distant from the points C and D, so that the arcs CG, DG are equal. I say that this circle EG, produced, passes through the point F, so that the three hour-circles CB, DA, EG cut one another at the same point F.

For if the points of contact lie at the same point F, they are diametrically opposite, so that the arcs CG, DG are quadrants, and it is clear from what has just been demonstrated that the three circles cut one another at one and the same point. But if the points of contact C, D are not opposite, let there be described, through the pole E and through the contacts C, D, the great circles EC, ED. Also, through the points C, G let there be described the arc of the great circle CHG, and through the points G, D the arc of the great circle GID, and let the chords CG, GD be drawn. Since, then, by the definition of a pole handed down by Theodosius, the straight lines falling from the pole E to the points C, D are equal, [a] the arcs EC, ED will also be equal. Again, since the arcs CG, GD of the parallel CD are equal, [b] the straight lines CG, GD will also be equal. [c] Therefore the arcs of the great circles CHG, GID will be equal too. Hence the two sides EC, EG of the spherical triangle CEG will be equal to the two sides ED, EG of the spherical triangle DEG; and the bases CHG, DIG are also equal. Therefore, by Proposition 35 of Book 3 of Johannes Regiomontanus [Regiomontanus] *On Triangles*, or by Proposition 18 of our own *Spherical Triangles*, the angles CEG, DEG will be equal, and consequently the arc EG will divide the angle CED in half. But since the great circle described through the pole E and the point F divides the same angle CED in half — as we shall presently demonstrate — it is clear that the great circle EG, produced, passes through the point F; for otherwise two great circles, namely EG and the one drawn from E through F, would divide the same angle CED in half, which is absurd.

That the great circle described through E and F divides the angle CED in half, we shall demonstrate thus. Let a great circle EGF be understood as described through the pole E and through F. I say that the angle CEF is equal to the angle DEF. For since the great circles EC, ED are equal ... [drawn] through the poles of the circles CF, DF, of Theodosius — because they have been drawn through the contacts C and through the pole E of the circle CD — and since they pass also through the pole of the equator AB, it comes about (by Proposition 9 of Book 2 of Theodosius)

that the circle EC cuts the segments of the circles CB, AB which meet at B, cutting them ...

[Margin (footnote references): a — Theodosius III.28; b — Theodosius III.29; c — Theodosius III.28.]

[Margin: Two circles of hours from sunrise or sunset touching the greatest of the always-appearing parallels at any two points, and the circle of the hour from noon or midnight cutting that same parallel at a point equally distant from the points of contact, cut one another at one and the same point.]

Diagram. The same construction as on the previous page, repeated: a bounding celestial circle with three great-circle arcs meeting at F below center.

- E (top): pole of the parallels
- C (upper left), D (upper right): the two points of contact on the parallel CD
- G (center): where the noon/midnight hour-circle cuts the parallel
- A (lower left), B (lower right): ends of the equator AB
- F (bottom): common point of intersection of the three circles

Diagram. A fuller version of the construction for the general (non-opposite contacts) case: a bounding circle with several great-circle arcs, the auxiliary great circles EC and ED, and the arcs CHG and GID drawn across the middle.

- E (top): pole of the parallels (of the world)
- N (right): where the circle AD, produced, cuts the equator
- C (middle left) and D (middle right): the two points of contact on the parallel CD
- H (between C and G): point on the arc CHG
- G (center): point where the noon/midnight hour-circle cuts the parallel CD
- I (between G and D): point on the arc GID
- A (lower left), B (lower right): ends of the equator AB
- F (below center): common intersection of the hour-circles CB, DA, EG

it cuts in half the segments of the circles CB and AB that meet at B — segments which, by Proposition 11 of Book 1 of Theodosius, are semicircles. The arc CB is therefore a quadrant. By the same reasoning the arc DA will be a quadrant as well.

Now by Theorem 1 of the scholium to Proposition 21 of Book 2 of Theodosius, the great circles CB and DN, being tangent to the same parallel CD, are equally inclined to AB, the greatest of the parallels; hence the spherical angles CBA and

DNB are equal. And since the angle DAB is also equal to the angle DNB — by Proposition 13 of our *Spherical Triangles*, because ADN and ABN are semicircles by Proposition 11 of Book 1 of Theodosius — the spherical angles FBA and FAB will be equal. Consequently the arcs BF and AF will be equal too, whether by Proposition 4 of Book 1 of Menelaus, or by Proposition 40 of Book 3 of Regiomontanus's *On Triangles*, or indeed by Proposition 9 of our *Spherical Triangles*.

Since, then, the whole arcs BC and AD are likewise equal — being quadrants, as we have shown — the remaining arcs FC and FD will be equal too. And since the arcs EC and ED have been shown to be equal, the two sides EC and EF of the spherical triangle CEF will be equal to the two sides ED and EF of the spherical triangle DEF. As they also have equal bases CF and DF, as has been shown, the angles CEF and DEF will be equal — by Proposition 35 of Book 3 of Regiomontanus's *On Triangles*, or by Proposition 18 of our *Spherical Triangles*. Therefore the arc EF bisects the great-circle angle CED.

And since the arc EG also bisects that same angle, as was demonstrated, the arc EG produced through F will pass exactly through it, so that it does not differ from the arc EF — otherwise two arcs would be allowed to bisect the same angle CED. [Margin: At what hour, reckoned both from sunrise or sunset and from noon or midnight, they cut one another at the same point.] Therefore the three hour-circles CF, DF, and EF share one and the same common intersection. Which is what was proposed. And consequently, at whatever point the plane of the sundial [horologium] cuts this common intersection, through that same point will pass the common intersections of those circles and of the plane of the sundial, by Proposition 18 of this book — so that the hour-lines [lineae horariae] of those circles intersect one another at one and the same point on the sundial. Hence, at whatever point the hour-line of circle CF cuts the hour-line of circle EF, through that same point the hour-line of circle DF must also be drawn, and conversely.

To which hours the circles CF, DF, and EF are to be assigned, the figure we set down in Proposition 9 of this book will teach us. For suppose one of the circles CF, DF — say CF — is assigned, for example, to the 12th hour from sunrise or sunset, and the other, DF, for instance to the 20th hour from sunrise or sunset. Then EF will be the circle of the 4th hour from noon or midnight, since this hour lies midway between them in the figure of the said Proposition 9 of this book, just as the point G lies midway between the points C and D. So too, if EF is taken to be the circle of the 1½ hour from noon or midnight, and EC the circle of the 3rd hour from sunrise or sunset, then ED will be the circle of the 24th hour from sunrise or

sunset, [Margin: The construction of the four preceding tables and of the following thirty-two.] because these two hours are equally distant on either side from that one, just as the points C and D are separated from the point G by equal intervals, and so forth. From these considerations we shall construct, with no difficulty, those thirty-six tables which we have set out in this scholium.

Line of the 23rd hour from sunrise or sunset [Linea horae 23. ab ortu vel occasu]

Each column-pair below gives, on the left, the **hour from sunrise or sunset** (*Hora ab ortu vel occasu*, Arabic figures) and, on the right, the corresponding **hour from noon or midnight** (*Hora à meridie vel media nocte*, whole hours printed as Roman numerals; a bare fraction denotes the fraction past XII / midnight–noon). Fractions are eighths and quarters of an hour.

4	XII	8	II	12	III	16	VI	20	VIII	24	X

In a sundial equidistant from the circle of the 20th hour from sunrise or sunset, the lines of any two hours in this table are parallel to one another, from the scholium to Proposition 22.

These three pages continue the set of hour-line concurrence tables belonging to the scholium of Proposition 22 (Book One). Each table corresponds to one hour-line, counted from sunrise or sunset, and lists — for every quarter-hour along that line — the ordinary hour (reckoned from noon or midnight) whose line runs

concurrent with it. No new Liber, Caput, or Propositio rubric is printed; the only rubric-titles on these pages are the six table captions.

How to read each table. The twelve columns form six pairs, read continuously from the first pair through the sixth. In every pair the left member (**Rise**) is *Hora ab ortu vel occasu* — the hour reckoned from sunrise or sunset, advancing in quarter-hour steps; the right member (**Noon**) is *Hora à meridie vel media nocte* — the concurrent hour reckoned from noon or midnight. In the **Noon** columns a whole hour is printed as a Roman numeral (the source uses IIII for 4), and intermediate values as eighth-of-an-hour fractions; a bare fraction ($\frac{1}{8}$, $\frac{1}{4}$, ...) is the part past XII, i.e. just after noon or midnight. Pair 1 runs from $\frac{1}{4}$ to 4 hours after sunrise, pair 2 from $4\frac{1}{4}$ to 8, pair 3 from $8\frac{1}{4}$ to 12, pair 4 from $12\frac{1}{4}$ to 16, pair 5 from $16\frac{1}{4}$ to 20, and pair 6 from $20\frac{1}{4}$ to 24. Throughout, the **Noon** value equals the mean of that row's **Rise** hour and the table's title-hour, expressed on the twelve-hour scale.

The line of the 19th hour from sunrise or sunset [Linea horae 19. ab ortu vel occasu]

4	IX	8	XI	12	I	16	III	20	V	24	VII

In a sundial whose plane is equidistant from the circle of the 14th hour reckoned from sunrise or sunset, the lines of any two hours whatever in this table are parallel, as we taught in the scholium to Proposition 22.

These three pages continue the set of hour-line concurrence tables belonging to the scholium of Proposition 22 (Book One). Each of the six tables carries a title naming the hour-line to which it belongs, and beneath it a note stating for which dial the tabulated hour-lines run parallel. In every table the sixteen rows are read across six column-pairs. The first column of each pair, **Horæ ab ortu vel occasu** ("hours reckoned from sunrise or sunset"), runs in quarter-hour steps through the whole twenty-four-hour circle; the second, **Horæ à meridie vel media nocte** ("hours reckoned from noon or midnight"), gives the concurrent hour whose line, on the dial named in the caption, is parallel to the first. Whole hours in the second column are printed as Roman numerals; a bare fraction there means that fraction past the twelfth hour.

The line of the 13th hour, reckoned from sunrise or sunset

(Linea horæ 13. ab ortu vel occasu.)

4	5½	8	7½	12	9½	16	11½	20	1½	24	3½

In a sundial whose plane is equidistant from the circle of the 7th hour reckoned from sunrise or sunset, the lines of any two hours whatever in this table are parallel, as we demonstrated in the scholium to Proposition 22.

These three pages continue the set of hour-line concurrence tables belonging to the scholium to Proposition 22 of Book One. Each page carries two tables; together the six tables here cover the lines of the 6th, 5th, 4th, 3rd, 2nd, and 1st hour (reckoned from sunrise or sunset). No running prose or new chapter rubric appears — the pages are wholly occupied by the tables and their explanatory notes.

Each table is a 16-row by 12-column grid. The twelve columns form six read-continuous pairs; within each pair the left column is headed *Horæ ab ortu vel occasu* ("hours from sunrise or sunset," here abbreviated **Rise**) and the right column *Horæ à meridie vel media nocte* ("hours from noon or midnight," here abbreviated **Noon**). Read as a single sequence, the six pairs run the **Rise** argument continuously from ¼ up to 24 in quarter-hour steps, each with its concurrent **Noon** value. Whole hours are printed as Roman numerals; a bare fraction in the **Noon** column denotes the corresponding part past the twelve-hour mark (i.e. 12 + fraction).

Table: *Linea horæ 6. ab ortu vel occasu.* (The line of the 6th hour from sunrise or sunset)

Rise = *Horæ ab ortu vel occasu*; **Noon** = *Horæ à meridie vel media nocte*.

In a sundial whose plane lies equidistant from the circle of the 1st hour reckoned from sunrise or sunset, the lines of any two hours in this table are parallel, as is established from the scholium to Proposition 22, which we have demonstrated.

These three pages continue the series of hour-line concurrence tables of **Liber Primus** (Book One). No chapter (*Caput*) or proposition (*Propositio*) rubric appears; the only printed headings are the six table titles. Each table is titled *Linea horæ N à meridie vel media nocte* — "The line of the Nth hour reckoned from noon or from midnight." The tables run in descending order of hour: 11, 10, 9, 8, 7, and 5 (the hour-6 table does not appear on these pages).

In every table all twelve column-heads read *Horæ ab ortu vel occasu* ("Hours reckoned from sunrise or from sunset"). The twelve columns form six argument/line pairs read left to right: within each pair the left column ("arg.") is the argument hour, and the right column ("line") is the position of the hour-line, both expressed in hours from sunrise or sunset. Each table has sixteen data rows (argument running by quarter-hours). Values that pass zero wrap around modulo 24.

LIBER PRIMVS.

In horologio, quod circulo horæ 3. à mer. vel med. noc. æquidistat, lineæ quarumlibet duarum horarum huius tabulæ sunt parallelæ, vt patet ex scholio propos. 22. In a sundial whose plane lies equidistant from the circle of the 3rd [recte: 5th] hour reckoned from noon or from midnight, the lines of any two hours in this table are parallel, as is clear from the scholium to Proposition 22.

The work remains in **Liber Primus** (Book One). This opening carries the last four of the hour-line concurrence tables (for the 4th, 3rd, 2nd, and 1st hours), after which the prose resumes with Theorem 19 / Proposition 21.

Table — Line of the 4th hour from noon or midnight

Linea horæ quarta à meridie vel media nocte.

Each of the twelve columns is identically headed *Horæ ab ortu vel occasu*. ("Hours from rising or from setting."). The columns run in six pairs; in each pair the left member increases and the right member decreases, so that the two hours sharing one line are read across. Column 1 is the argument (the $\frac{1}{4}$ -hour subdivision).

In horologio, quod circulo horæ 1. à mer. vel med. noc. æquidistat, lineæ quarumlibet duarum horarum huius tabulæ sunt parallelæ, vt ex ijs, quæ à nobis in scholio propos. vigesima secunda sunt demonstrata, colligitur.

In a sundial whose plane lies parallel to the circle of the 1st hour reckoned from noon or from midnight, the lines of any two hours in this table are parallel, as is gathered from what we have demonstrated in the scholium to Proposition 22.

THEOREMA 19. PROPOS. 21.

The lines of all the hours reckoned from noon or from midnight, in any sundial whose plane cuts the axis of the world, intersect one another at that point of the axis where the axis itself meets the plane of the sundial.

[Margin: *All the lines of the hours from noon or midnight, in any sundial cutting the axis of the world, intersect one another at that point of the axis where the axis meets the plane of the sundial.*]

For since all the circles that mark the hours from noon or midnight run through the poles of the world (by Proposition 9 of this book), the axis of the world will — where their circumferences intersect one another — be the common section of all those planes. At whatever point, therefore, the axis meets the plane of the sundial, at that same point (by Proposition 18 of this book) the common sections of all those [circle-planes] and of the plane of the sundial come together — that is, the hour-lines from noon or midnight. And so the lines of all the hours from noon or midnight [intersect there], and so on. Which was to be demonstrated.

COROLLARIUM.

[Margin: *The lines of the hours from noon or midnight, in an equinoctial, horizontal, and vertical sundial of an oblique sphere, all meet at that point where the axis of the world cuts the plane of the sundial — except the vertical sundial of that oblique sphere in which the pole is at the zenith (the vertex of the head).*]

And so, in the equinoctial, the horizontal, and any vertical sundial of an oblique sphere, all the hour-lines from noon or midnight cut one another at one and the same point of the axis, namely where the axis itself meets the planes of the said sundials. For the planes of these sundials cut the axis, just as do the great circles to which they are parallel — namely the Equator, the Horizon, and the vertical circle of any oblique sphere — as is evident. Make an exception, however, for the vertical sundial of that oblique sphere in which the zenith is the pole of the world; for there the vertical circle passes through the poles of the world and

along the axis, and therefore does not cut the axis. Neither, then, can the plane of the sundial that is parallel to it cut that axis.

[Margin: *In every sundial that is parallel to a great circle not drawn through the poles of the world, the lines of the hours from noon or midnight intersect one another at one and the same point, namely where the axis of the world meets the sundial.*]

Finally, to comprehend everything in a single word: all the hour-lines from noon or midnight, in any sundial whose plane is not parallel to some circle passing through the poles of the world, nor to the axis of the world (of which kind are nearly all declining and inclined sundials), cut the axis of the world at one and the same point, namely where the axis itself meets the plane of the sundial. For any sundial of this kind cuts the axis of the world, since the great circle to which it is parallel is supposed not to pass through the poles of the world.

That point, where the axis of the world meets the plane of the sundial, is called **the center of the sundial** [centrum horologii].

[Margin: *What the center of the sundial is.*]

SCHOLIVM.

By the same reasoning, any hour-line whatever — whether from noon or midnight, or from rising or setting — whose hour-circles have the same common section, in any sundial whose plane is not parallel to that common section but cuts it (even though that section is not the axis of the world), cut one another at a single point of the common section, where it meets the plane of the sundial. For the demonstration is exactly the same, taken from Proposition 18 of this book. Of this kind are any three of the hours from rising or setting so placed in the table of Proposition 19 of this book, together with the equinoctial hour; and likewise any two placed in the thirty-six tables of the preceding proposition, together with the hour written in the title of each table.

[Margin: *Which hours from rising or setting, and from noon or midnight, are parallel in any sundial. — Any hour described in the tables of the two preceding propositions, together with the hour, or line, placed in the title of the table.*]

THEOREMA 20. PROPOS. 22.

The lines of all the hours reckoned from noon or from midnight, in any sundial whose plane is parallel to some circle drawn through the poles of the world, or to the axis of the world, are parallel.

For since all the hour-circles reckoned from noon or midnight are described (by Proposition 9 of this book) through the poles of the world, the axis of the world will — where their circumferences intersect one another — be the common section of their planes. Therefore, if the plane of the sundial that cuts those hour-circles is parallel to some circle drawn through the poles of the world, and hence through the axis (their common section), or to the axis itself, then (by Proposition 18 of this book) the common sections of all those circles and of the plane of the sundial that cuts them — that is, the hour-lines from noon or midnight — will be parallel. Therefore the lines of all the hours from noon or midnight, and so on. Which was to be demonstrated.

COROLLARIUM.

It follows from these results that in the horizontal sundial of the right sphere, in the meridian sundial, and in any polar sundial, all the hour-lines from noon or midnight are parallel; since the planes of these sundials are parallel to circles drawn through the poles and the axis of the world — namely to the right horizon, to the meridian, and to the circle of the 6th hour from noon or midnight — as is clear.

Finally, to embrace much in few words: all the hour-lines from noon or midnight, in any sundial whose plane is parallel to some hour-circle reckoned from noon or midnight, or at any rate to the axis of the world, are — by this proposition — parallel.

SCHOLIUM.

In like manner, any hour-lines whatever — whether from noon or midnight, or from rising or setting — whose hour-circles have the same common section, are parallel in any sundial whose plane is parallel to some circle drawn through that common section, or to the common section itself, even though that common section is not the axis of the world. For the demonstration is exactly the same, drawn from Proposition 18 of this book.

[Margin: *The lines of the hours from noon or midnight are all parallel in a sundial parallel to a great circle drawn through the poles of the world. — The hour-lines from noon or midnight in the horizontal sundial of the right sphere, and in any meridian and polar sundial, are all equidistant from one another. — In every sundial parallel to a great circle drawn through the poles of the world, the lines of the hours from noon or midnight are all parallel. — Which hours from rising or setting, and from noon or midnight, are parallel in any sundial.*]

Hence it comes about that any three hours placed in the table of Proposition 19 of this book — of which one is always reckoned from noon or midnight, while the rest are taken from rising or setting — are parallel in the equinoctial sundial [horologium æquinotiale]. For the circles of those hours, and the equator, have the same common section, by Proposition 17 of this book. Therefore, since the plane of the equinoctial sundial that cuts those hour-circles is parallel to one of them, namely to the equator, the common sections of those circles and of the sundial's plane — that is, the hour-lines — will be parallel.

[Margin: In the equinoctial sundial, any three hours placed in the table of Proposition 19 of this book are parallel to one another.]

For the same reason, any two hours placed in the first table of Proposition 20 of this book will be parallel in the horizontal sundial. For their hour-circles, and the circle of the 24th hour from rising or setting — that is, the horizon — have the same common section, by Proposition 17 of this book; and the plane of the sundial is parallel to one of them, namely to the circle of the 24th hour from rising or setting, that is, to the horizon.

[Margin: In the horizontal sundial, any two hours placed in the first table of Proposition 20 of this book are parallel to one another.]

Again, in the vertical sundial for latitude 45° , or in the sundial that is parallel to the circle of the 12th hour from rising or setting (which is the same circle as the vertical for latitude 45° , as is evident from the material sphere), any two hours placed in the second table of Proposition 20 of this book will be parallel. For their hour-circles, and the circle of the 12th hour from rising or setting — that is, the vertical for latitude 45° — have the same common section, by Proposition 17 of this book; and the plane of the sundial is parallel to one of them, namely to the circle of the 12th hour from rising or setting, that is, to the vertical for latitude 45° .

[Margin: In the vertical sundial for latitude 45° , any two hours described in the second table of Proposition 20 of this book are parallel to one another.]

Moreover, in the polar sundial any two hours placed in the third table of Proposition 20 of this book will be parallel; because their circles, and the circle of the 6th hour from noon or midnight — to which the sundial's plane is parallel — have the same common section, by Proposition 17 of this book, and so on.

[Margin: In the polar sundial, any two hours placed in the third table of Proposition 20 of this book are parallel.]

Finally, any two hours described in the fourth table of Proposition 20 of this book will be parallel in the meridian sundial; because their hour-circles, and the circle of the 12th hour from noon or midnight — that is, the meridian [meridianus], to which the sundial's plane is parallel — have the same common section, by Proposition 17 of this book, and so on.

[Margin: In the meridian sundial, any two hours placed in the fourth table of Proposition 20 of this book are parallel.]

Now, of these five circles — the horizon (that is, the circle of the 24th hour from rising or setting), the circle of the 6th hour from noon or midnight, the circle of the 12th hour from rising or setting, the vertical circle, and the equinoctial — the first three, namely the horizon, the circle of the 6th hour from noon or midnight, and the circle of the 12th hour from rising or setting, have the same common section, by Proposition 17 of this book. Likewise, by Proposition 16, the first, third, and fifth — namely the horizon, the circle of the 12th hour from rising or setting, and the equator — also have the same section. Likewise too the first, fourth, and fifth — that is, the horizon, the vertical, and the equator — since, being at right angles to the meridian, they pass through the poles of that same meridian (by Proposition 13 of Book 1 of Theodosius [Theodosius, *Spherics* I.13]) and there intersect one another. Thus it comes about that all five have one and the same common section. Therefore, in that sundial whose plane is parallel to one of them, the common sections of the remaining four and of the sundial's plane will be parallel, by Proposition 18 of this book. But if the sundial's plane cuts all five circles yet is parallel to their common section, then by the same Proposition 18 the common sections of all of them and of the sundial's plane will be parallel.

Thus in the equinoctial sundial, since its plane is parallel to the equator, the following lines are parallel: the horizontal line (that is, of the 24th hour from rising or setting), the line of the 12th hour from rising or setting, the line of the 6th hour from noon or midnight, and the vertical line.

Likewise, the same lines — and moreover the equinoctial line — are parallel in the horizontal sundial and in the vertical, since the plane of the former is parallel to the horizon, and that of the latter to the vertical circle. Yet in the former the horizontal line cannot be drawn, and in the latter the vertical line cannot be drawn, as is clear from what we wrote in the scholium of Proposition 11 of this book.

Similarly, in the polar sundial the equinoctial line, the vertical line, and the lines of the 24th and 12th hours from rising or setting are parallel; for its plane too is parallel to the circle of the 6th hour from noon or midnight.

Finally, for the same reason, in the meridian sundial the lines of the 6th and 18th hours from rising or setting, and the equinoctial line, are parallel. For, by Proposition 17 of this book, their circles and the meridian (that is, the circle of the 12th hour from noon or midnight), and also, by Proposition 16, their circles and the equator, have the same common section; and the plane of the sundial is parallel to the meridian circle.

I have said all this so that you may understand that the lines of certain hours placed in the tables of Propositions 19 and 20 of this book are sometimes parallel in some sundials, while in others they intersect one another at one and the same point, as we said there. Of this kind are the hour-lines just now cited.

[Margin: The horizon, the circle of the 6th hour from noon or midnight, the circle of the 12th hour from rising or setting, the vertical, and the equator all have one and the same common section. — In the equinoctial sundial the horizontal line (that is, of the 24th hour from rising or setting), the line of the 12th hour from rising or setting, the line of the 6th hour from noon or midnight, and the vertical line are parallel. And the same lines are parallel in the horizontal and the vertical sundial.]

PROBLEMA 3. PROPOS. 23.

To investigate the declination [declinatio] of any plane from the vertical circle, and its inclination [inclinatio] to the horizon.

Let there be prepared, out of wood or some other solid material, a rectangle ABCD one of whose surfaces is flat; and its sides AB, DC being bisected at E and F, let the straight line EF be drawn — ^a which will be parallel to each of the sides AD, BC, ^b and therefore the angles at E are right angles. Or at any rate let there be, at the edge of the flat surface, a straight line AB, which the straight line EF cuts at right angles, whatever may be the case with the other lines.

[Margin: An instrument for investigating the declinations and inclinations of planes.] [Margin: a. *Elements* I.33.] [Margin: b. *Elements* I.29.] [Margin: How the declination of the proposed plane is to be found.]

With this instrument, even if it is not a rectangle, we shall investigate the declination of any plane in the following way (by "declination" I mean the acute

angle that the common sections of the horizon with the proposed plane and with the vertical circle make). On the proposed plane — whether it is perpendicular to the horizon, as is the plane of any wall built to the plumb-line, or inclined, as is the plane of any roof — let there be drawn, with the help of the level and the plumb-line, a line AB parallel to the horizon, namely the common section of the proposed plane and of the horizon. Or at any rate, on a plane perpendicular to the horizon, by a thread from which a plumb-bob hangs, let down freely, let a line be drawn on the wall corresponding to the plumb-thread, which will be perpendicular to the horizon. Then let another straight line AB cut this at right angles. For this line will be parallel to the horizon, or if you prefer, the common section of the horizon and the wall. For since the wall is set perpendicular to the horizon, and on the wall a line perpendicular to the horizon has been drawn by the plumb-thread, this same line will — by Definition 4 of Book 11 of Euclid [*Elements* XI, def. 4] — be perpendicular to the common section of the horizon and the wall. Therefore the straight line AB, drawn perpendicular to this, will be the common section of the wall and

the horizon. To this line AB let the side AB of the instrument be applied, and let the instrument itself be set parallel to the horizon with the help of the level and the plumb-line. Then, on the instrument, let the meridian line GH be found — by means of a needle rubbed with a magnet [lodestone], or by the method we handed down in our commentaries on the Sphere, when we treated of the meridian circle, or (which I approve more) by the scholium that follows. For from this line we shall accomplish what is proposed, in the following way.

If the meridian line GH is parallel to the straight line EF, and meets the wall (or the line AB, which is parallel to the horizon) at right angles, the wall will have no declination, and will face directly to the south or to the north — so that, if it is perpendicular to the horizon, it is parallel to the vertical circle properly so called; but if it is inclined to the horizon, it is perpendicular to the meridian, and is parallel to the great circle passing through the points of the equinoctial rising and setting. Such is the plane of the equinoctial circle, of the circle of the 6th astronomical hour, and of the circle of the 12th hour from rising or setting; and finally the planes of the hectemoral circles [circuli hectemorii — the "sixth-part" position circles], of which Ptolemy [Ptolemy] treats in the *Analemma*.

But if the meridian line GH cuts the straight line EF at I at right angles, the plane of the wall will incline directly to the east or west, so that, if it is perpendicular to the horizon, it is parallel to the meridian circle. But if it is inclined to the horizon, it is perpendicular to the vertical circle properly so called, and is parallel to the

great circle drawn through the points where the circumference of the meridian circle intersects the circumference of the horizon. Such are the planes of the hour-circles, of which Ptolemy treats in the *Analemma*.

Finally, if the meridian line GH cuts the straight line EF at I at unequal angles, the plane will decline both from the vertical circle and from the meridian, so that it faces neither directly to the south or north, nor to the east or west. The angle EIG will always be the angle of the plane's declination from the vertical circle properly so called, so that the declination of the plane is as great as the angle EIG; and thus the arc of a circle described from center I, contained between the straight lines IE and IG, contains the degrees of declination. For let GK be drawn in the plane of the instrument ABCD, perpendicular to GH, so that GK is the common section of the vertical circle properly so called and of the plane in which the instrument ABCD lies. Then EGK will be the angle of declination of the proposed plane drawn through the straight line AB, from the vertical drawn through the straight line GK. For since both the plane of the vertical circle drawn through GK and the proposed plane drawn through AB are perpendicular to the horizon, ^a the common section of the vertical and of the proposed plane will also be perpendicular to the horizon, and therefore also to the straight lines GK, AB lying in the horizon, by Definition 3 of Book 11 of Euclid [*Elements* XI, def. 3]. Therefore, by Definition 6 of the same book [*Elements* XI, def. 6], EGK will be the angle of declination — or of inclination — of the proposed plane drawn through AB, to the vertical

[Margin: a. whence, [from] Prop. 19.]

Diagram. A large wind-rose arrangement showing the rectangular instrument ABCD set out in the eight principal orientations around a central compass. The four cardinal directions are lettered in large display capitals around the figure (south is up): MERIDIES (south) across the top, OCCASVS (west) up the right side, SEPTENTRIO (north, printed inverted) across the bottom, ORTVS (east) up the left side. Eight small instrument-figures are ranged octagonally around the center: the four at the cardinal positions are axis-aligned rectangles (the wall facing due south, north, east, or west, with no declination), and the four at the diagonal positions are tilted diamonds (the declining orientations). Each small figure carries the instrument's point-letters (corners A, B, C, D; midpoints E, F of the sides AB and DC; and the meridian/section points G, H, I, K). The individual peripheral labels are small and worn on the scan and do not resolve reliably figure-by-figure.

- MERIDIES (top): south

- OCCASVS (right side): west
- SEPTENTRIO (bottom, inverted): north
- ORTVS (left side): east
- Eight instrument-figures with corner labels A, B, C, D; midpoint labels E, F; and section-point labels G, H, I, K [most individual per-figure labels [?] — worn small type]

[the eight small instrument-figures carry many worn peripheral point-labels that do not resolve individually at this resolution.]

circle drawn through GK; since the straight lines GK, GE make right angles with the common section at the same point G — the point of the common section of the proposed plane and of the vertical — as has been said. But if the plane drawn through AB is not perpendicular to the horizon, EGK will nonetheless be the angle of declination, though improperly so, for it shows the declination of the line AB (which is parallel to the horizon) from the vertical circle. Therefore, since the angle EIG is equal to the angle EGK — for since the right angle IGK is equal to the two angles IGE and EIG together, ^b because these are equal to one right angle, on account of the right angle GEI; and if the common angle IGE is taken away, the angles EGK and EIG remain equal — the angle EIG will also be the angle of declination of the given plane from the vertical circle. Which was proposed.

[Margin: b. *Elements* I.32.]

Now, whether the proposed plane declines toward the east or toward the west, we shall determine thus. If the plane faces south and the meridian line cuts the straight line EB, it will decline from south toward east; but if the meridian line cuts the straight line EA and the plane faces south, it will decline from south toward west. The contrary holds if the plane faces north: for, with the meridian line cutting the straight line EB, the plane will decline from north toward west, but with it cutting the straight line EA, toward east — as appears from the figure. And if from I you describe a circle with any radius, the arc contained between the straight lines IE and IG will give the degrees of declination, as we also said before.

[Margin: By what method it may be known whether the proposed plane declines toward the east or toward the west.]

We shall learn the same thing in this way. Since the meridian line GH, when it cuts EF obliquely, makes with the straight line AB an acute angle (under which the straight line IE is always subtended) and a remaining obtuse angle, the plane will decline toward whichever side this obtuse angle lies. So that, if the obtuse

angle is toward the east, the plane declines from south or north toward east; but if toward the west, toward west.

For the rest, we shall know that the plane declines from south toward east or west — that is, that it faces south — when, as we turn toward the plane, the Sun rises on our right and sets on our left; but that it faces north, when the Sun rises on our left and sets on our right. But if the plane has so great a declination from the vertical that it differs little from the meridian circle, and it is therefore very difficult to discern whether it faces south or north...

[Margin: Whether the proposed plane faces south or north.]

toward north, we shall use this device. To the plane of the wall — or at any rate to the straight line drawn parallel to the horizon in it — we shall draw, in a plane parallel to the horizon, a perpendicular, and we shall investigate its declination. For if the wall declines little from the meridian circle, the said perpendicular will also decline little from the vertical circle properly so called; and therefore we shall easily understand whether it faces south or north, according to the rule prescribed, and so we shall also know its declination. Thus, if this perpendicular declines from south toward east, or from north toward west, the proposed wall will decline from north toward east if it faces east, or from south toward west if it pertains to the west. But if the said perpendicular declines from south toward west, or from north toward east, the proposed wall will decline from south toward east if it inclines to the east, or from north toward west if it faces west.

All this is clear from this figure, in which the meridian line is IK, and the common section of the vertical circle and the horizon is LM, cutting IK at N at right angles. For, given the wall AB which faces east and the wall CD which faces west: since the perpendicular BC declines from south toward east, and the perpendicular AD from north toward west, the wall AB therefore declines from north toward east, and the wall CD from south toward west. Similarly, given the wall EF facing east and the wall GH facing west: since the perpendicular FG declines from south toward west, and the perpendicular EH from north toward east, the wall EF therefore declines from south toward east, and the wall GH from north toward west.

Diagram. A square plan with a compass cross, illustrating four walls and their perpendiculars relative to the cardinal directions (north at top). The cardinal directions are lettered in large capitals around the square: SEPTENTRIO (north) across the top, ORTVS (east) up the right side, MERIDIES (south, printed inverted) across the bottom, OCCASVS (west) up the left side. A vertical center line IK is the

meridian line, and a horizontal center line LM is the common section of the vertical circle and the horizon; the two cross at N in the center at right angles.

- H (top-left corner)
- A (top-right corner)
- B (bottom-right corner)
- G (bottom-left corner)
- D (inner, upper-left)
- E (inner, upper-right)
- C (lower-left, near G)
- F (lower-right, near B)
- I (top center, on meridian line IK)
- K (bottom center, on meridian line IK)
- L (left center, on section line LM)
- M (right center, on section line LM)
- N (center — intersection of IK and LM)
- SEPTENTRIO (top): north
- ORTVS (right): east
- MERIDIES (bottom, inverted): south
- OCCASVS (left): west

We can obtain the same result by the meridian line alone. For, when a meridian line has been found near the wall, in a plane parallel to the horizon: if this line meets the wall toward the north [Boreas], and the wall faces east, the wall will decline from south toward east; but from south toward west, if the wall faces west. But if the meridian line meets the wall toward the south, the wall will decline from north toward east or west, according as it faces east or west — as easily appears from the earlier figure of this proposition. But since, in planes that differ little from the meridian circle, the meridian line scarcely meets them, I would judge that the earlier method should be chosen.

In planes perpendicular to the horizon, we shall attain the same result more easily by this method. On some day let the time of noon be awaited, which must be carefully learned either by some clock or by the meridian altitude of the Sun. For if at that moment the proposed plane is lit by the Sun, there will be no doubt at all that it faces south; but that it faces north, if it is not illuminated by the Sun. Indeed, in this way too we shall learn whether the proposed plane declines toward the east or toward the west. For if it faces south but is lit by the Sun for a longer time before noon than after noon, it will decline from south toward east;

but toward west, if the case is the reverse. Likewise, if the plane faces north and is illuminated by the Sun for more hours in the morning than in the evening, it will deflect from north toward east; but if the case is the opposite, toward west.

The same may be tested on planes inclined to the horizon: if, at noon, upon the line drawn in the proposed plane parallel to the horizon, some flat tablet of any material is set perpendicular to the horizon, and one observes whether the face that makes an obtuse angle with the inclined plane is then lit by the Sun or not. For from this we shall learn — as we said of planes perpendicular to the horizon — whether that tablet, and hence that line parallel to the horizon, or rather the inclined plane itself, declines from south or from north.

But all this must be understood of an oblique sphere having a latitude greater than $23^{\circ} 30'$, which is the greatest declination of the Sun. For in a lesser latitude it can happen that a plane declining from the north is lit by the Sun at noon, when the Sun is at or near the beginning of Cancer [♋], as is evident from the material sphere. But when the Sun is more to the south than the wall itself, so that all shadows are projected toward the north, the things we have said will hold good even in an oblique sphere of latitude less than $23^{\circ} 30'$.

But if the wall is little distant from the meridian circle, and the right-angled edge of the building projects so that at noon the wall cannot be lit by the Sun, then a line parallel to the wall must be drawn on the ground at a distance from the wall, such that at noon it is wholly illuminated by the Sun. For if a stylus set on that line — or at any rate a thread hanging freely with a plumb-bob — casts at noon a shadow that cuts that line, so that on the northern side the shadow lies between the wall and the said line, the wall will face south; but toward north, if on the contrary that line lies, on the northern side, between the shadow and the wall. But if the shadow falls upon the line itself, the wall will be parallel to the meridian circle.

Now we shall investigate the inclination of any plane to the horizon with the same instrument ABCD, in the following way (by "inclination" I mean the acute angle that the common sections of the horizon and of the proposed plane make with another plane perpendicular to both). Having found in the proposed plane a line parallel to the horizon — namely the common section of the proposed plane and of the horizon — let the straight line NO cut it at M at right angles; and to NO let the side AB of the instrument be applied, and let the instrument itself be raised, by means of the plumb-line, so that it is perpendicular to the proposed plane. Then, in the instrument thus erected, let there be drawn — by means of the same plumb-line — a perpendicular HG to the horizon, cutting EF at I. I say

that $\angle EIG$ is the angle of inclination of the plane to the horizon. For let GK be understood as drawn in the plane of the instrument $ABCD$, perpendicular to GH , so that GK is the common section of the horizon and of the plane in which the instrument $ABCD$ lies. Then $\angle EGK$ will be the angle of inclination of the proposed plane to the horizon. For since both the proposed plane (by construction) and the plane of the horizon are perpendicular to the plane of the instrument $ABCD$ — for since HG is perpendicular...

[Margin: By what method the inclination of the proposed plane to the horizon is to be investigated.]

Gnomonics — Liber Primus (continued)

Problema 3, Propositio 23 (conclusion of the inclination construction)

[Margin (a): Elements XI.18] [Margin (b): Elements XI.19]

is perpendicular to the horizon, then the plane $ABCD$ too — through HG , which is drawn perpendicular to the horizon — will stand at right angles to the horizon; and conversely, the common section of the proposed plane and of the horizon will likewise be perpendicular to that same plane $ABCD$, and hence also to the straight lines EG , GH lying in the said plane $ABCD$ (by Elements XI, def. 3), if the horizon is understood to cut the proposed plane at the point G . Therefore, by the sixth definition of the same book, $\angle EGK$ will be the angle of inclination of the proposed plane to the horizon; for the straight lines EG and Gk — the former lying in the proposed plane, the latter in the horizon — meet at the same point G (the common section of the proposed plane and the horizon) and make right angles with that common section, as has been said.

[Margin (c): Elements I.32]

Now the angle $\angle EIG$ is equal to the angle $\angle EGK$. For the angle $\angle IGk$, being a right angle, is equal to the two angles $\angle IGE$ and $\angle EIG$ taken together — since these two are together equal to one right angle, on account of the right angle $\angle GEI$; and if the common angle $\angle EGI$ is removed, the remainders $\angle EGk$ and $\angle EIG$ are equal. Hence the angle $\angle EIG$ is likewise the angle of inclination of the given plane to the horizon. Which was what was proposed.

But if the perpendicular HG cuts the straight line EF at I at right angles, then the proposed plane has no inclination to the horizon, and stands perpendicular to it, as is plain.

Diagram. An inclined-plane (wedge) figure illustrating the inclination construction of Proposition 23: a quadrilateral plane ABCD leaning back from the ground, with a shaded solid triangular flank at the right giving the perspective. The apex/north point rises at top, and the perpendicular HG and the line EF meet at the interior point I, where a small arc (a circle described about I) marks the inclination angle between IE and IG.

- N (top apex): north point
- A (upper right of the plane): corner label
- D (upper left of the plane): corner label
- H (just left of centre, near the top): foot of the perpendicular line
- F (left, mid-height): endpoint of line EF
- E (centre, mid-height): endpoint of line EF
- I (centre, at the small arc): intersection of HG and EF; vertex of the inclination angle EIG
- M (just below E): label on the descending edge
- C (lower left corner of the plane): corner label
- G (bottom centre): point where the horizon cuts the plane; foot of HG
- B (just right of G): corner label
- K (right of B): point on the horizon line (angle EGK)
- O (bottom foot): lowest point of the perpendicular drop

We shall also easily grasp toward which region the plane inclines — that is, whether toward the northern part of the upper hemisphere or toward the southern — once the plane's declination from the vertical is known. For if the plane declines from the north toward the east or the west, its inclination falls in the southern part of the hemisphere; but if it declines from the south toward the east or west, the inclination falls in the northern part, as is clear from a material sphere. And if a circle is described about I with any radius whatever, the arc contained between the straight lines IE and IG gives the degrees of inclination. We have therefore found the declination of any plane from the vertical circle, and its inclination to the horizon. Which was to be done.

[Margin: In which direction the inclination of the proposed plane to the horizon falls.]

Scholium

Besides the method of finding the meridian line that we handed down in our *Commentary on the Sphere*, it has seemed good to add another here, perhaps better suited to practical use. For this method requires neither two observations — one to be made before noon and the other after, as the former method did — nor the marking of points at the tips of the shadows, which is not at all easy, since the end of a shadow can scarcely be made out on a plane.

[Margin: By what means the meridian line is found by means of an astrolabe laid out on a plane.]

About to find, then, the meridian line on any given day, first learn the Sun's place from some ephemeris. Then, on a plane lying level with the horizon, observe the shadow of some freely hanging thread, or at least of some perfectly straight rule set at right angles to the proposed plane. For this task I habitually use the instrument you see pictured here, in which the set-square CDE is fixed at right angles to the flat rule AB, along the straight line DI, which is parallel to one side of the rule AB — so that the side DH of the square stands like a kind of gnomon set perpendicular to the horizon, or like a freely hanging thread, while the rule AB is laid on a plane parallel to the horizon. By this means we shall, with little effort, mark two points without appreciable error at the tip of the breadth of the shadow that the side HD casts.

But if in the plane CD a line FG is drawn parallel to the side HD, and a hole is made near the point G, so that a plumb-line suspended by a fine thread from the hole F can swing freely in it, this same instrument will also be very convenient for testing any proposed plane, to see whether or not it is parallel to the horizon. For by grazing the plane CD with the thread along the line FG, the plane in which the rule AB lies will be made parallel to the horizon. Now, in the shadow — whether of the thread or of the side HD — let two points A and B be marked a little apart from each other, points that a straight line AB will...

Diagram. The meridian-line instrument: an L-shaped (carpenter's-square) frame set on a flat base-board. The upright arm carries a plumb-line (a small bob is drawn hanging on a thread near G), and the horizontal rule and base are shown in perspective.

- H (top left of the upright): top corner of the square
- C (top right of the upright): corner label
- F (on the upright, near the top): hole from which the plumb-thread hangs

- A (left, at the base of the upright): endpoint of the rule AB
- G (at the pivot, where the bob hangs): point near the plumb-line hole
- E (right, on the horizontal arm): endpoint
- D (bottom left of the base): corner of the base-board
- I (right, on the horizontal arm): point on line DI
- B (lower right, on the base-board): endpoint of the rule AB

be joined. This straight line will be the common section of the underlying plane and of the vertical circle that passes through the Sun's centre at the moment of observation. Once the shadow has been observed, take the Sun's altitude without delay, with a quadrant or an astrolabe; and this altitude must be taken immediately after the two points in the shadow have been marked, before the straight line is drawn through them — lest there be danger in delay, because, owing to the Sun's rising before noon or its setting after noon (that is, owing to the Sun's daily motion), the shadow necessarily shifts, and the Sun at once comes to lie in another vertical circle.

After this, on an astrolabe in which the Equator is CDEF about the centre G — where the two diameters CE and DF cut each other at right angles — and the vertical circle properly so called is HIKL about the centre M — through which the straight line IL, drawn, cuts CE at right angles — let there be described the Sun's day-parallel NO. Let us suppose, for example, that this parallel passes through 15° of Leo [ϱ], and has a declination of $16^\circ 23'$. Let the horizon-parallel PO — drawn for the Sun's altitude, which we now suppose to be 30° — cut that day-parallel at the point O on the eastern side (for let us now suppose the observation to be made before noon).

For through this point O the vertical circle must be described that passes through the Sun's centre at that moment. And we shall find that vertical's centre, which lies on the straight line IL (as we demonstrated in the treatise on the astrolabe), in this way. From H and O let two pairs of arcs be described, both above the points H and O and below them, at any radius, intersecting one another at two points; and through these let a straight line be drawn cutting IL at Q. For Q will be the centre of the vertical that is to be described through H and O. For, as is established from what we demonstrated in the scholium to Euclid III.25, the straight line joining those two intersection points passes through the centre of the circle to be described through H and O. If, then, a circle is described about Q with radius QH (or QO), this will be the vertical passing through the Sun's centre at the time of observation.

Now this vertical will, on its eastern side, deflect southward from the vertical properly so called HIKL if the centre Q has fallen on the straight line EI and the observation is made before noon; but northward, if Q has fallen on EL and the observation is made before noon. But if the observation is made after noon — since then the point O must be taken on the western side — the vertical HO will deflect from the proper vertical southward on the western side if the centre Q falls on the straight line EL; and northward, if Q falls on the straight line EI.

How great the deflection is, we shall determine thus. From the vertex H, through Q, let a straight line be drawn cutting the vertical HIKL at R. Then KS, half the arc KR, will be the declination of the vertical HO from the vertical properly so called HIKL, as is clear from what we demonstrated in the treatise on the astrolabe. Its complement IS will therefore be the declination of the same vertical from the meridian circle. And so, if from any point A of the shadow-line a circle BT is described equal to the vertical HIKL, and an arc BT is taken equal to the arc IS — reckoned from the east toward the south, if the observation is made before noon and the vertical HO deflects southward on the eastern side, as in our example; or from the east toward the north, if the observation is made before noon and the vertical HO deflects northward on the eastern side; and likewise, from the west toward the south or the north, if the observation is made after noon, and so on — then the straight line drawn, AT, will be the meridian line, namely the common section of the proposed plane and of the meridian circle.

[Margin: The finding of the meridian line by means of sines.]

This same declination KS of the vertical HO from the vertical properly so called HIKL can also be found by the calculation of sines, and thereby the meridian line itself can be drawn. For if, from the Sun's declination and the altitude the Sun has at the moment of observation, the Sun's distance from the meridian circle is found by sines (as we shall teach in Proposition 36 of this book), and if, by means of this distance, the horizontal arc is investigated from the same sines — that is, the arc of the horizon intercepted between the vertical properly so called and the vertical passing through the Sun's centre at the moment of observation (as we shall show in Proposition 3 of Book 5) — then this arc will be equal to the arc KS, and so on.

[Margin: By what art the meridian line is found by means of the analemma.]

Indeed, without laying out an astrolabe, we shall find this same meridian line by the analemma alone — as Giovanni Battista Benedetti [Iohannes Baptista Benedictus] also does in his book *On the Use of Gnomons and of the Shadows cast*

by *Sundials* [*De gnomonum umbrarumque solarium usu*] — in the following way. Having found, as before, by the shadow, the straight line AB, which is the common section of the plane lying level with the horizon and of the vertical circle passing through the Sun's centre at the moment of observation; and having, at the same moment, taken the Sun's altitude: then, in place of the astrolabe, we shall draw an analemma in which the meridian is FGHI; the common section of the horizon and the meridian is GI; the common section of the vertical properly so called and of the same meridian is FH; the common section of the same meridian and the Equator is LM; and, finally, the common section of the meridian and the Sun's parallel on the day the observation is made is the straight line NO — which is drawn by means of the Sun's declination, as we taught in Proposition 1 of this book.

Then, with the Sun's altitude reckoned off, measured from I as far as P and from G as far as Q, we shall draw the straight line PQ. By the scholium to Euclid III.27, this line will be parallel to GI, and hence will be the common section of the meridian and of the horizon-parallel passing through the Sun's centre; and it will cut the vertical line FH at R, and the diameter NO of the Sun's parallel at S. With a semicircle PTQ described about the centre R upon PQ, we shall draw from S the perpendicular ST to PQ, extended as far as the circumference of the semicircle PTQ, and we shall join the straight line TR.

If, then, the point S falls between Q and R, and the observation is made before noon, we shall construct at the centre C — chosen anywhere on the shadow-line AB, and about which we describe a circle of any size — an angle ACD equal to the acute angle TRQ, reckoned from the east toward the south, that is, from the point A toward the point D, as is seen in figure A. But if the observation is made after noon, we shall make the angle ACD equal to that same angle, from the west toward the south, that is, from the point A toward the point D, as appears in figure B. But if the point S falls upon the point R — whether the observation is made before noon or after — we shall draw through C the perpendicular DE to AB, as is clear in figure C. If, finally, the point S falls between R and P, and the observation is made before noon, we shall make the angle ACE equal to the acute angle TRP, from the east toward the north, that is, from the point A toward the point E, as may be seen in figure D. But if the observation is made in the afternoon, we shall make the angle ACE equal to that same angle, from the west toward the north, that is, from the point A toward E, as is plain from figure E. For in every case the straight line DE will be the meridian line.

[Margin (a): Elements XI.19]

We shall confirm this in the following way. Since the horizon-parallel PTQ and the Sun's parallel are both perpendicular to the meridian, their common section too will be perpendicular to the meridian, and hence (by Euclid XI, def. 3) also perpendicular to the straight line PQ at the point S, where the diameters of the said parallels bisect each other. Therefore ST, being perpendicular to PQ, will be the common section of the said parallels; and consequently, at the moment of observation, the Sun's centre will be at the point T, provided the horizon-parallel PTQ, together with the meridian of the analemma, holds its proper position. Hence the vertical passing at that time through the Sun's centre will pass through the point T. And since it also passes through the straight line FH — the common section of all the verticals — and thus through the point R, TR will be the common section of the said vertical and of the horizon-parallel PTQ. Therefore, since the straight line QR (or PR) is perpendic-

ular to FH, the common section of the meridian and the vertical, which is drawn through TR, and since likewise TR is perpendicular to that same FH — for since FH, the axis of the horizon-parallel PTQ, is perpendicular to the circle PTQ (by Theodosius, *Sphaerics* I.10), the angle FRT will be right (by Euclid XI, def. 3) — therefore, by Euclid XI, def. 6, the acute angle TRQ (or TRP) will be the angle of inclination, to the meridian FGHI, of the vertical drawn through TR. And for this reason, if an angle equal to the said angle is constructed at the centre C on the line AB — the common section of that vertical and of the plane ADBE — the straight line DE will be the meridian line, that is, the common section of the meridian and of that same plane ADBE; inasmuch as, with the straight line AB, it forms the angle of inclination of the said vertical and of the meridian.

Now since the vertical properly so called, drawn through FH to the meridian FGHI, is perpendicular, and separates the northern part of the upper hemisphere from the southern — so that the part tending toward G is southern, the rest, toward I, northern — it comes about that the Sun is southern when the point S (where the diameters NO and PQ intersect) falls between Q and R; that is, beyond the vertical circle properly so called, toward the south. It is on the vertical circle properly so called when the point S coincides with R, where the diameter NO of the Sun's parallel bisects the vertical diameter FH. And, finally, it is northern when the point S falls between R and P. Hence it has come about that our rule is that the acute angle which the straight line TR makes with PQ is to be set out equal at C, upon the straight line AB — now from the east or the west toward the south, now toward the north, and so on.

Diagram. A large, densely ruled analemma for finding the hour, filled with a web of straight construction lines and several concentric/intersecting circles. Around the outer circumference runs a graduated hour-scale: on the upper-right quadrant the Arabic numerals **1, 2, 3, 4, 5, 6, 7, 8, 9, 10** appear in sequence (with **Y** beside 7 and **20** low on the right), and Roman **II** lower right. Along the vertical axis and the horizon line are the principal lettered points; the many interior line-crossings carry small repeated letters (chiefly R, S, T, P, and lower-case f, e, d, z) that are too fine and worn to resolve individually at this resolution.

- N (upper left, on the rim): endpoint of a principal diameter
- F (top, just left of centre): meridian point
- P (top): pole/upper meridian point
- Q (upper left interior): point on the construction
- G (left, on the rim): endpoint of the horizon diameter GI
- Y (right, by hour 7): rim point
- I (right, mid): endpoint of the horizon diameter
- M (bottom, near the axis foot): point on the axis
- H (bottom centre): foot of the vertical axis
- K (interior, low centre): axis point
- Several interior points labelled R, S, T, P, and lower-case d, e, f, z along the diameters NO, PQ, GI and the diagonal chords [most individual interior labels: ?]

Diagram. A series of five small circles, lettered **A, B, C, D, E** (the large letter set inside each), each showing the shadow-line and the meridian line for one of the five cases described in the text. In every circle the point D is at top, C at the centre, E at the bottom, with A and B at the sides; the diameter DE (the meridian line) is set at the appropriate slant, while AB is the shadow-line through C.

- Figure A (before noon, S between Q and R): D top, C centre, E bottom; A upper-left, B right — meridian DE slants so that D lies toward A (east toward south)
- Figure B (after noon, S between Q and R): D top, C centre, E bottom; B lower-left, A right — DE slants toward the west side
- Figure C (S coincides with R): D top, B left, C centre, A right, E bottom — DE drawn as the plain perpendicular to AB
- Figure D (before noon, S between R and P): D top, C centre, A left, B right, E bottom — DE slants from A toward E (east toward north)

- Figure E (after noon, S between R and P): E large at left, D top, C centre, A right, E bottom — DE slants toward the west side

Now, so that you may see in this connection too what an outstanding use the analemma has, it will not be out of place to explain briefly how, from the analemma, the hour of the day is found once the Sun's declination and its altitude above the horizon are known. For let a circle be described about NO, the diameter of the Sun's parallel, with its centre at the point d, where the world-axis a b cuts the diameter NO; and let it be divided into 24 equal hours, beginning from the diameter NO. Then, if from z — where the diameter NO cuts the horizon's diameter GI — a perpendicular XY is drawn to NO, this will be the common section of the Sun's parallel and the horizon.

[Margin: By what means the hour is to be sought by means of the analemma, from the known declination of the Sun and its altitude above the horizon.]

[Margin (a): Elements XI.19]

For since the horizon and the Sun's parallel are both perpendicular to the meridian, their common section too will be perpendicular to the meridian, and hence (by Euclid XI, def. 3) perpendicular to NO. From this it follows that the straight line XY, which is perpendicular to NO at the point z (where the diameters GI and NO bisect each other), is the common section of the Sun's parallel and the horizon. The daytime arc, therefore, will be XNY, and the night arc YOX; and accordingly the number of hours contained in these arcs will indicate the length of the day and of the night — as we also showed in the scholium to Proposition 1 of this book.

[Margin (b): Elements XI.19]

Now, if from the point S a perpendicular SV is drawn to NO, this will be the common section of the Sun's parallel and of the horizon-parallel in which the Sun then lies. For since each parallel is perpendicular to the meridian, their common section too will be perpendicular to the meridian, and therefore (by Euclid XI, def. 3) perpendicular to NO. So the perpendicular VS will be the common section of the said parallels, and for that reason the Sun will lie at the point V — the Sun's parallel NXOY, together with the meridian, being set in its proper position — when it has the altitude IP (or GQ) above the horizon. Hence the hours found on the arc NV will indicate how many hours the Sun is distant, whether before noon or after, according as the observation is made before or after noon.

But if the hour reckoned from sunset is wanted, in the manner of the Italians and the Bohemians: if the observation is made before noon, the division of the circle NXOY into 24 equal hours must be begun from the point Y and continued through the point O; for then the point V will at once indicate the hour elapsed since sunset. But if the observation is made after noon, that division must begin from the point X and be continued through the point O. In the same way, if the hour reckoned from sunrise is sought, in the manner of the Babylonians and of the people of the Balearic Islands, the division of the circle NXOY must be begun from the point X and continued through N, if the observation is made before noon; but if after noon, from the point Y. By the same method we shall know the hour at any moment of time — whether reckoned from noon or from midnight, or from sunrise or sunset — provided the Sun's declination is known, together with the altitude it has above the horizon at the time of observation.

Conversely, from a known hour we can arrive at knowledge of the Sun's altitude by means of the analemma, provided its declination is not unknown. For if, with due account taken of the declination, the diameter NO of the Sun's parallel is described, and about it the circle NXOY; and from V, the known hour, the perpendicular VS is drawn to NO; and through S, finally, the straight line PQ is drawn parallel to GI, the diameter of the horizon — then both GQ and IP will be the arc of the Sun's altitude above the horizon, since PQ is a diameter of the horizon's parallel that is then drawn through the Sun, as is evident.

[Margin: How the Sun's altitude is to be found out by the analemma, from the known hour and the Sun's declination.]

Nor should this be passed over: if perhaps we lack an instrument for investigating the Sun's altitude, we can obtain it in the following way. On a plane ADBE parallel to the horizon, let a stylus be fixed at right angles, and at the time of observation let the tip of the shadow be marked. For if in the analemma one takes Ke equal to the gnomon, and through e draws the perpendicular ef to Ke, in which ef is taken equal to the shadow that was marked, then the straight line drawn through f and K will fall on the point P of the Sun's altitude. For if the circle FGHI is conceived as a vertical circle passing through the centre of the Sun, the straight line ef will be the common section of this vertical circle and of the plane parallel to the horizon. Since, therefore, the tip of the shadow is f, fKP will be the Sun's ray, and accordingly the Sun will lie at P, and the Sun's altitude will be the arc IP — as can easily be gathered from what we wrote in Proposition 2 of this book.

[Margin: How the Sun's altitude is to be found by the analemma from the length of the shadow of any stylus set at right angles on a plane parallel to the horizon.]

But if the straight line PQ should ever fall on the point N — that is, if the Sun's altitude found is equal to the meridian altitude of the Sun for that day — then the Sun will be on the meridian circle, and therefore the shadow AB itself will be the meridian line.

By means of the same analemma, and by nearly the same method, we shall be permitted to find out the declination of any proposed plane, even if on a plane parallel to the horizon we do not find the meridian line — as is also handed down by Giovanni Battista Benedetti [Giovanni Battista Benedetti] in his *Gnomonica*. To do this, let AB be a wall perpendicular to the horizon; on it draw a straight line CD parallel to the horizon, and fix on it a stylus CE, of any length, perpendicular to the wall at the point C. Then, at any time, when the Sun lights up the face of the wall — whether before noon or after — let the tip of the shadow EF that the stylus casts be observed, namely the point F; and through it let the perpendicular FD be drawn to the straight line CD. This will be drawn more quickly than said, in this way: apply to the wall a thread with a plumb-weight so that it passes through the point F, and mark on the wall any point D. For a straight line drawn through F and D will be perpendicular to CD, since the thread is perpendicular to the horizon. For it follows from this that the straight line FD too — which does not differ from the plumb-thread, or is at any rate parallel to it — is perpendicular to the horizon (which is drawn through the line CD); and so, by definition 3 of Book 11 of Euclid, since it makes right angles with the line CD in the horizon.

[Margin: By what art the declination of any proposed plane is to be found out by means of the analemma.]

Diagram. A rectangle representing the wall, with the corner A at the upper left and the corner B at the lower right. A horizontal line runs across the middle of the rectangle — the line CD, parallel to the horizon — with C toward the centre and D at its right-hand end. At C stands the base of the stylus, whose tip is E (raised, upper left of centre). Above C, near the top edge, is G, the top of the constructed segment CG drawn perpendicular to CD and made equal to the stylus. F lies below D, in the lower portion of the rectangle — the tip of the cast shadow. Dotted lines run from E to F (the shadow-ray) and from G down toward F, with the joining lines ED and GD.

- A (upper-left corner): corner of the wall AB
- B (lower-right corner): opposite corner of the wall

- C (middle, centre): base of the stylus, on line CD
- D (middle, right): foot of the perpendicular FD on line CD
- E (upper middle-left): tip of the stylus CE
- F (lower middle): tip of the cast shadow
- G (top): top of the constructed perpendicular CG (equal to the stylus)

Here too, in place of the stylus, I use that instrument which we described at the beginning of this scholium. For if it is applied to the wall AB so that the point D falls on the point C, and the side DA lies along the line CD, with DI slanting downward, then the side DH will serve the office of a stylus perpendicular to the wall. Therefore, once the tip of that shadow has been observed at the point F, the instrument must be removed and the point C carefully marked. Now, since the Sun's ray EF passes through E, the tip of the stylus (which is at the centre of the world, by Proposition 2 of this book), it lies in the plane of that vertical circle which at the moment of observation is drawn through the centre of the Sun; and this vertical circle will meet the wall AB at the point F. But since both the plane of the wall and this vertical circle are perpendicular to the horizon, their common section too will be perpendicular to the horizon, [Margin (a): Elements XI.19] and therefore, by definition 3 of Book 11 of Euclid, perpendicular to the line CD lying in the horizon. Since, then, FD is perpendicular to CD, FD will be the common section of the wall AB and of the vertical circle then drawn through the centre of the Sun; and so that same vertical circle will pass through the point D. Therefore, when the straight line ED is drawn, it will be the common section of the horizon and of that same vertical circle, since both circles pass through the points E and D; and so the line FD, being perpendicular to the horizon, will be perpendicular — by definition 3 of Book 11 of Euclid — to the line ED lying in the horizon. But it has also been shown to be perpendicular to CD. Therefore, since each of the lines CD and ED — the former lying in the wall, the latter in the vertical circle passing through the Sun — is perpendicular to FD, the common section of the wall and the said vertical circle, the angle CDE will, by definition 6 of Book 11 of Euclid, be the angle of inclination of the wall to the said vertical circle.

We shall exhibit an angle equal to this in the plane of the wall as follows. Draw CG perpendicular to CD, make CG equal to the stylus (or to the side DH of the instrument described at the beginning of this scholium), and join the straight line GD. I say that the angle CDG is equal to the angle CDE. For since the two sides CE, CD of the triangle CDE are equal to the two sides CG, CD of the triangle CDG, and they contain equal angles — namely right angles (for the angle ECD is right, by definition 3 of Book 11 of Euclid, and the angle GCD by construction) — the base ED will also be equal to the base GD, and the angle CDE to the angle CDG. [Margin

(b): Elements I.4] From this known angle CDG we shall investigate the declination of the proposed wall from the vertical circle properly so called, in this way.

After the tip of the shadow F has been marked, let inquiry be made at once — before the straight line FD is drawn (since if any delay intervenes, the shadow will change and the Sun will occupy another vertical circle on account of the daily motion): namely, let the Sun's altitude in the analemma above (which we here repeat) be reckoned from the points G, I up to the points Q, P. For when the straight line PQ is joined, it will be the diameter of the horizon's parallel drawn through the centre of the Sun at the time of observation, as we demonstrated above; and it cuts the diameter of the Sun's parallel at S, and the diameter of the vertical circle properly so called at R. Then, with a semicircle PTQ described about PQ from the centre R, draw from S the perpendicular ST to PQ, cutting the circumference of the semicircle PTQ at T, and join the straight line TR. This will be the common section of the horizon's parallel and of the vertical circle, each of which is then drawn through the Sun's centre. So the acute angle QRT (or PRT) will be the angle of declination of the said vertical circle from the meridian, as we showed above; and consequently the remaining angle TRH will be the angle of declination of that same vertical circle from the vertical circle properly so called.

[Margin: When the wall faces south, and the Sun is more southerly than the vertical circle properly so called, and the observation is made before noon.]

And so, if the wall faces south (which we shall learn from what we set forth above in this proposition), and the point S falls between Q and R — that is, if the Sun is found beyond the vertical circle properly so called, so that it lights up both the wall and the vertical circle properly so called from the southern side, and the observation is made before noon — we shall compare the angle TRH with the angle CDG which we found on the wall. For if the former is equal to the latter, the wall will have no declination and will face due south, since

the declination of the vertical circle passing through the Sun is found to be the same from the wall as from the vertical circle properly so called. But if the angle TRH is found to be greater than the angle CDG, the wall will be positioned on the eastern side, between the vertical circle properly so called and the vertical circle drawn through the centre of the Sun — because on the southern side the vertical circle drawn through the Sun then stands farther from the vertical circle properly so called than from the wall. Therefore, if we take away the angle CDG (that is, the declination which the vertical circle drawn through the Sun has from the wall) from the angle TRH (that is, from the declination which the same vertical circle drawn through the Sun has from the vertical circle properly so

called), the remainder will be the angle of the wall's declination from the vertical circle properly so called, and from south toward the west. Finally, if the angle TRH is less than the angle CDG, the vertical circle properly so called will lie on the eastern side, between the wall and the vertical circle drawn through the Sun — because on the southern side the vertical circle drawn through the Sun then stands farther from the wall than from the vertical circle properly so called. Therefore, if we subtract the angle TRH from the angle CDG, there will remain the angle of the wall's declination from the vertical circle properly so called, and from south toward the east.

[Margin: When the wall faces south, and the Sun lies in the vertical circle properly so called, and the observation is made before noon.]

But if the point S is the same as R — that is, if the Sun lies in the vertical circle properly so called, so that it still lights up the wall on the southern side, but the vertical circle properly so called not at all — then the angle found, CDG, will be the angle of the wall's declination from the vertical circle properly so called, and from south toward the east; because then, on the eastern side, the vertical circle properly so called (in which the Sun of course lies) is more southerly than the wall.

[Margin: When the wall faces south, and the Sun is more northerly than the vertical circle properly so called, and the observation is made before noon.]

Finally, if the point S lies between P and R — that is, if the Sun is placed on the near side of the vertical circle properly so called, so that it lights up the wall on the southern side but the vertical circle properly so called on the northern side — then the vertical circle in which the Sun lies will fall between the wall and the primary vertical circle on the eastern side, since that vertical circle is then more southerly than the wall and more northerly than the primary vertical circle. Therefore, if the angle TRH is added to the angle CDG, the angle of the wall's declination from the primary vertical circle, and from south toward the east, will be composed.

Diagram. A large analemma. The outer circle is divided around its circumference into hour-graduations numbered 1 through 20, with cardinal and intermediate points marked by letters. The clearly readable perimeter letters are N (upper left), Z and F at the top, P and Y on the upper right, I on the right, M at the lower right, H at the bottom, G on the left, L on the upper left, and Q/e on the left. At the centre is K, the intersection of the principal diameters (the meridian and horizon GI); through it run the axis of the world, the diameters of the Sun's parallel and of the

vertical circles, and numerous chords. The interior carries a dense cluster of small construction-labels along the vertical axis and the chords (readable among them: R appearing several times, S, s, d, z, T appearing several times, Q, V, f, b, and x near the lower left), but many of these small interior labels overlap and cannot be assigned to their points with confidence at this resolution.

- N (upper-left circumference): principal point
- Z, F (top): meridian points
- P, Y (upper-right circumference)
- I (right circumference): end of horizon diameter GI
- G (left circumference): end of horizon diameter GI
- M (lower-right circumference)
- H (bottom circumference): foot of the meridian
- L (upper-left circumference)
- K (centre): centre of the analemma
- Hour-graduations 1–20 numbered around the circumference
- Interior chord- and point-labels (R, S, s, d, z, T, Q, V, f, b, x): present but several illegible at this resolution — [?]

[Diagram fig-p86-1 has more than two labels flagged [?]:]

Diagram. Beneath the analemma, five small circles labelled A, B, C, D and E (the case-label set in the centre of each), illustrating the several orientations of the wall discussed in the text. Each circle is divided into four quadrants by a vertical line (D at the top, E at the bottom) and a horizontal line (with A and B at the two ends), the centre marked C; the A and B ends are set to left or right to show the wall's east/west facing in each case. In circle A the horizontal ends read A (left) and B (right); the remaining circles B, C, D and E repeat the same cross with the A/B ends variously placed.

- A (upper-left circle): first orientation case; horizontal ends A (left), B (right)
- E (upper-right circle): case with horizontal ends B and A
- B (lower-left circle): case with horizontal ends B (left), A (right)
- C (lower-centre circle): case with horizontal ends B and A
- D (lower-right circle): case with horizontal ends A (left), B (right)
- In each: D (top), E (bottom), C (centre)

[Margin: When the wall faces south, and the Sun is more southerly than the vertical circle properly so called, and the observation is made after noon.]

But if the wall faces south while the observation is made in the afternoon, and the point S falls between Q and R — so that the Sun lights up both the wall and the primary vertical circle from the southern side — and the angle TRH is found equal to the angle CDG, then again the wall will have no declination. But if the angle TRH is found greater than the angle CDG, the wall will be positioned on the western side, between the primary vertical circle and the vertical circle drawn through the centre of the Sun. And so, when the angle CDG is subtracted from the angle TRH, there will remain the angle of the wall's declination from the primary vertical circle, and from south toward the east. Finally, if the angle TRH is less than the angle CDG, the primary vertical circle will lie on the western side, between the wall and the vertical circle drawn through the Sun. Therefore, when the former is taken from the latter, the remainder will be the angle of the wall's declination from the primary vertical circle, and from south toward the west.

[Margin: When the wall faces south, and the Sun lies in the vertical circle properly so called, or is more northerly than the vertical circle properly so called, and the observation is made after noon.]

But if the point S falls on R, so that the Sun lights up the wall on the southern side but the primary vertical circle not at all, the wall will decline from the vertical circle, and from south toward the west, by the angle found, CDG; because then the Sun will lie in the primary vertical circle, which on the western side is more southerly than the wall itself.

Finally, if the point S falls between P and R, so that the Sun lights up the wall on the southern side but the primary vertical circle on the northern side, then the vertical circle in which the Sun lies will be set between the wall and the primary vertical circle on the western side. Therefore, if the angle TRH is added to the angle CDG, the angle by which the wall deflects from the primary vertical circle, and from south toward the west, will be composed.

But if the wall faces north while the observation is made before noon, and the point S falls between Q and R — so that the Sun lights up the wall on the northern side and the vertical circle properly so called on the southern side — then the vertical circle drawn through the Sun will be set between the wall and the primary vertical circle, on the eastern side. Therefore, if the angle TRH is added to the angle CDG, the angle of the wall's declination from the primary vertical circle, and from north toward the east, will be produced.

[Margin: When the wall faces north, and the Sun is more southerly than the vertical circle properly so called, or lies in the vertical circle properly so called, and the observation is made before noon.]

But if the point S is the same as R, so that the Sun still lights up the wall on the northern side, but the vertical circle properly so called not at all, then the angle found, CDG, will be the angle of the wall's declination from the vertical circle properly so called, and from north toward the east.

Finally, if the point S falls between P and R, so that the Sun lights up both the wall and the vertical circle properly so called on the northern side, the angle TRH must be compared with the angle CDG. For if the former is equal to the latter, the wall will have no declination, for the reason stated before. But if the angle TRH exceeds the angle CDG, then, when the latter is subtracted from the former, there will remain the angle by which the wall declines from the primary vertical circle, and from north toward the west — because then the wall will be placed, on the eastern side, between the primary vertical circle and the one that passes through the Sun. Finally, if the angle TRH is less than the angle CDG, the primary vertical circle will lie between the wall and the vertical circle that passes through the Sun, on the eastern side. Therefore, if we subtract the former from the latter, we shall make the remaining angle by which the wall declines from the primary vertical circle, and from north toward the east.

[Margin: When the wall faces north, and the Sun is more northerly than the vertical circle properly so called, and the observation is made before noon.]

But if the wall faces north and the observation is made in the afternoon, and the point S falls between Q and R — so that the Sun lights up the wall on the northern side, but the vertical circle properly so called on the southern side — then the vertical circle drawn through the Sun will be set, on the western side, between the wall and the primary vertical circle. Therefore, if the angle TRH is added to the angle CDG, the angle of the wall's declination from the vertical circle properly so called, and from north toward the west, will be produced.

[Margin: When the wall faces north, and the Sun is more southerly than the vertical circle properly so called, or lies in the vertical circle properly so called, or is more northerly than it, and the observation is made after noon.]

But if the point S falls on the point R, so that the Sun lights up the wall on the northern side but the primary vertical circle not at all, then the angle found, CDG, will give the declination of the wall from the primary vertical circle, and from

north toward the west; since then the primary vertical circle passes through the Sun, and is more northerly than the wall itself.

Finally, if the point S lies between P and R, so that the Sun lights up both the wall and the vertical circle properly so called on the northern side: if indeed the angle TRH is equal to the angle CDG, the wall will be parallel to the primary vertical circle and will have no declination. But if the former is greater than the latter, the wall will lie on the western side, between the primary vertical circle and the one that passes through the Sun. And so, when the angle CDG is subtracted from the angle TRH, the remainder will be the angle of the wall's declination from the vertical circle properly so called, and from north toward the east. Finally, if the angle TRH is less than the angle CDG, the primary vertical circle will be set between the wall and the vertical circle in which the Sun lies, on the western side. Therefore, when the former is taken from the latter, there will remain the angle of the wall's declination from the primary vertical circle, and from north toward the west. All of this is clear, if the situation of the circles and of the wall is weighed carefully and diligently.

[Margin: When the Sun's altitude is equal to the meridian altitude of the same. The easiest way of finding the declination of a wall facing south, at noon.]

But if the straight line PQ in the analemma should ever fall on the point N — that is, if the Sun's altitude found is equal to the meridian altitude of the Sun for that day — then the Sun will be on the meridian circle; and therefore the straight line FD on the wall will be the common section of the meridian and the wall, since the meridian is then drawn through E, the centre of the world, and through the Sun's ray EF, and the wall itself will face south. Therefore the angle CDG found on the wall will give the wall's declination from the meridian, and consequently its complement will show the wall's declination from the vertical circle properly so called — from south toward the east, if the shadow F falls, for us facing the wall, to the right; but from south toward the west, if the shadow falls to the left.

And so, if the observation is made at noon — which is recognized, on a plane parallel to the horizon, from the stylus's shadow falling on the meridian line (and this is the time I would always choose, if it could conveniently be done) — the declination will be found more quickly than said. For the complement of the angle CDG found on the wall will give the wall's declination from the vertical circle properly so called, and from south toward the east or the west, according as the shadow falls, for us facing the wall, to the right or to the left, as was just said. This is to be understood of a wall facing south. For a wall facing north is not lit by the Sun at noon, unless the Sun is more northerly than the wall itself — which

can happen in the torrid zone. When that occurs, and the shadow, for us facing the wall, falls to the left, the wall will decline from north toward the east; but if to the right, from north toward the west.

[Margin: By what method the declination of planes inclined to the horizon is to be found.]

All this can also be applied to planes inclined to the horizon, if above the line which in planes of this kind is drawn parallel to the horizon a plane perpendicular to the horizon is set up, and the observation is made on the face of this plane which forms an obtuse angle with the inclined plane.

THEOREMA 21. PROPOS. 24.

[Margin: Perpendiculars falling from the circumference of a greatest circle in the sphere onto the plane of another greatest circle, to which the former is inclined, make an ellipse in the latter greatest circle.]

If from the circumference of a greatest circle in a sphere, inclined upon another greatest circle, perpendiculars are drawn to the plane of that other greatest circle, they will all fall on a line which is called an ellipse. Its major diameter is the same as the common section of the two circles — namely their diameter — while its minor diameter is determined by the interval of the perpendiculars falling from the extremity of the other diameter of the inclined circle, the diameter which divides the former diameter (that is, the common section) at right angles.

Let there be in a sphere a greatest circle ABCD, with centre E, inclined to a greatest circle AFCG; and let the circle AFCG cut the circle ABCD at the centre E, so that the diameter AC is the common section of the circles ABCD and AFCG. In the circle ABCD draw another diameter BD, cutting AC at right angles; and in the plane of the circle AFCG draw another diameter FG, perpendicular to the same AC. Since, then, the straight line CE stands at right angles on the straight lines BE, FE cutting one another at E, the same CE will be perpendicular to the plane drawn through BE, FE. [Margin (a): Elements XI.4] Therefore the planes of the circles AFCG, ABCD, passing through CE, will also be perpendicular to the same plane drawn through BE, FE; [Margin (b): Elements XI.18] and FG will be the common section

Diagram. A tilted ellipse crossing an upright circle, illustrating the inclination of two greatest circles. FG is the horizontal diameter, F at the left end and G at the right end. AC is the common section (the near-vertical diameter), with A at the top and C at the bottom; BD is the other diameter of the circle ABCD, with B at the

upper left and D at the lower right. E is the common centre. Toward the right, I lies near G on the ellipse; K lies on the upper left; and near the lower left is a cluster of the perpendicular-feet H, L, N, with M toward the lower centre.

- A (top): end of common section AC / on circle ABCD
- B (upper left): end of diameter BD
- C (bottom): end of common section AC
- D (lower right): end of diameter BD
- E (centre): common centre of the two circles
- F (left end): end of diameter FG of circle AFCG
- G (right end): end of diameter FG
- I (right, on the ellipse): near G
- K (upper left): on the ellipse
- H, L, N (lower left): feet of perpendiculars
- M (lower centre): foot of a perpendicular

the common section of the plane drawn through BE, FE and the plane of circle AFCG — a plane which has been shown to be perpendicular to that other one. And so, if from point B, which lies in the plane drawn through BE, FE, a perpendicular is drawn to the plane AFCG — namely BH — it will fall on FE, the common section of the plane drawn through BE, FE and the plane AFCG. [Margin (a): Elements XI.38] Let it therefore fall at H. In the same way, the perpendicular from D to the same plane AFCG will fall on the straight line FG, say at I; and the straight lines EH, EI will be equal to each other. For since in the triangles EBH, EDI the angles at H, I are right (by Elements XI, def. 3), [Margin (b): Elements I.15] and the vertical angles at E are equal, and likewise the sides EB, ED are equal, [Margin (c): Elements I.26] the sides EH, EI will also be equal.

Now take any other point K on the circumference of circle ABCD, and from it drop the perpendicular KL to the same plane AFCG. I say that point L falls on an ellipse whose major diameter is AC, the diameter of the circles, and whose minor diameter is the straight line HI. For in the plane AFCG draw the perpendicular LM from L to AC; then, since HE too is perpendicular to the same AC, [Margin (d): Elements I.28] HE and LM will be parallel to each other. [Margin (e): Elements XI.6] But BH and KL are likewise parallel to each other, since both are perpendicular to the same plane AFCG. [Margin (f): Elements XI.15] Therefore the plane through BH, HE will be parallel to the plane through kL, LM; [Margin (g): Elements XI.16] and consequently the common sections of these planes with circle ABCD — namely the straight lines BE and kM — will be parallel.

And so, since BE and EH, meeting one another at E as tangents, are parallel to kM and ML, which meet one another as tangents at M, but are not in the same plane but in parallel planes (as has been said), [Margin (h): Elements XI.10] the angle BEH will be equal to the angle KML. But the angles at H and L are also equal, being right, by Elements XI, def. 3. Therefore the remaining angle EBH will be equal to the remaining angle MkL, by the corollary to Elements I.32; [Margin (i): Elements VI.4] and triangle BEH will be equiangular with triangle kML. Hence BE will be to EH as KM is to ML; and, alternately, BE will be to KM as EH is to ML. [Margin (k): Elements VI.22] Therefore the square on BE is to the square on kM as the square on EH is to the square on ML.

Now the square on BE is to the square on KM as the rectangle CE·EA is to the rectangle CM·MA — this by Apollonius [Apollonius of Perga], *Conics* I.21 — because BE and kM are drawn as ordinates (that is, perpendiculars) to the diameter AC in circle ABCD. Therefore the square on EH is likewise to the square on ML as the rectangle CE·EA is to the rectangle CM·MA. But by the same Apollonius, *Conics* I.21, if on the major diameter AC and the minor diameter HI an ellipse is described — for AC is greater than HI, since AC, the diameter of circle AFCG, is equal to FG, the diameter of the same circle — and from any point a parallel to HE is drawn (that is, an ordinate applied to the diameter AC), then the square on HE is to the square on that parallel as the rectangle CE·EA is to the rectangle contained by the segments of the diameter AC that the parallel cuts off. [Margin (l): Elements V.9] Therefore point L will fall on that ellipse whose major diameter is AC and minor HI — since the square on HE is to the square on LM as the rectangle CE·EA is to the rectangle CM·MA — for otherwise a part would equal the whole.

For if that ellipse does not pass through point L, let it pass, if it can, through N. Then by Apollonius, *Conics* I.21, the rectangle CE·EA will be to the rectangle CM·MA — that is, the square on HE to the square on LM — as the square on HE is to the square on NM. The squares on LM and NM are therefore equal, and hence too the straight lines LM and NM are equal, the whole and the part — which is absurd. Therefore that ellipse does pass through point L, and consequently point L falls on the ellipse whose major diameter is AC and minor HI. In the same way we shall show that the other points on which perpendiculars fall from the circumference of circle ABCD also lie on the same ellipse. And so, if from the circumference of a greatest circle in a sphere, etc. Which was to be demonstrated.

Diagram. A tilted ellipse crossing an upright circle, illustrating the fall of perpendiculars from the inclined circle ABCD onto the plane AFCG. FG is the

horizontal diameter (F at the left end, G at the right). AC is the near-vertical common section (A toward the upper centre, C at the bottom); BD is the other diameter (B at the top, D at the very bottom). E is the common centre. K lies on the ellipse at upper left; I lies on the ellipse toward the right near G; the feet of the perpendiculars H, L, N cluster at the lower left, with M toward the lower centre. (Same construction as the figure on the preceding page.)

- A (upper centre): end of common section AC, on circle ABCD
- B (top): end of diameter BD
- C (bottom): end of common section AC
- D (very bottom): end of diameter BD
- E (centre): common centre of the two circles
- F (left end): end of diameter FG of circle AFCG
- G (right end): end of diameter FG
- I (right, on the ellipse): near G
- K (upper left): on the ellipse
- H, L, N (lower left): feet of the perpendiculars
- M (lower centre): foot of a perpendicular

SCHOLIUM.

This theorem is stated more generally by Federico Commandino [Federico Commandino] in his little book on the description of horologia [sundials]: namely, that even if the plane in which circle AFCG lies does not cut the inclined circle ABCD through its centre, or does not cut it at all — and whether ABCD is a greatest circle in the sphere or any circle whatever — nonetheless the perpendiculars drawn from the circumference of circle ABCD to the plane AFCG fall on an ellipse. For if the plane in which circle AFCG lies does not cut circle ABCD through the centre, or not at all, he reaches the conclusion thus. When another plane, parallel to AFCG, is drawn that cuts circle ABCD at its centre E, it will be demonstrated as before that the perpendiculars dropped from the circumference of circle ABCD to that plane fall on an ellipse. And since these lines, when produced further to the plane AFCG (to which the other plane is parallel), keep the same position, they also fall in that place on an ellipse — whose major diameter will be equal to AC, the diameter of circle ABCD, and whose minor diameter will be equal to the interval HI of the perpendiculars BH, DI drawn from the extremities of the other diameter BD.

We, however, have stated the theorem for greatest circles in a sphere only, because it is in these alone that its use will appear in this gnomonics of ours.

PROBLEMA 4. PROPOS. 25.

[Margin: Finding the points on which fall the perpendiculars drawn from the extremities of a diameter of a circle inclined to another circle.]

On the circumference of a greatest circle in a sphere inclined to another greatest circle, the two points that are the extremities of the diameter cutting their common section at right angles being taken: to investigate, if the inclination is known, the place at which the perpendiculars drawn from these points fall onto the other circle.

Let ABCD be a greatest circle in a sphere, inclined to the greatest circle AFCE, and let their common section be the diameter AC, to which, in the plane of circle ABCD, another diameter BD is drawn perpendicular through the centre G. We must then investigate at what place the perpendiculars dropped from points D, B onto the plane of circle AFCE fall. In the plane of circle AFCE draw another diameter EF perpendicular to AC, and let the angle of inclination — which is given — be EGH, so that arc EH is equal to the arc of inclination of circle ABCD to circle AFCE; and from H draw HI perpendicular to EF. I say that the perpendicular dropped from D onto the plane of circle AFCE falls

on the point I. For when a plane is drawn through EG, DG, producing in the sphere the semicircle EDF, then by Theodosius [Theodosius of Bithynia], *Spherics* I.1, [Margin (a): Elements XI.4] this semicircle will be perpendicular to the circles AFCE, ABCD. (For since CG is perpendicular to EG, DG, it will also be perpendicular to the plane drawn through EG, DG — that is, to the semicircle EDF; and therefore the planes of the circles AFCE, ABCD, drawn through CG to that same semicircle EDF, will be perpendicular to it; and hence, conversely, this semicircle will be perpendicular to those planes.) Therefore DE will be the arc of inclination of circle ABCD to circle AFCE, [Margin (b): Elements XI.38] and consequently equal to arc EH; and the perpendicular dropped from D onto the plane AFCE will fall on EF, the common section of the planes AFCE, EDF — and this, I say, falls at I.

For if it fell elsewhere, say at k, then the two angles HIG, IGH of triangle GHI would be equal to the two angles DKG, KGD of triangle GDK; [Margin (c): Elements III.27] (for IGH and KGD are equal, on account of the equality of the arcs EH, ED, while HIG and DKG are right by construction and by Elements XI, def. 3.) But the sides GH, GD, drawn from the centre of the sphere to its surface, are also equal. [Margin (d): Elements I.26] Therefore the sides GI, GK would also be equal — the part and the whole. Which is absurd. Therefore the perpendicular dropped

from point D onto the plane AFCE falls nowhere but at I. In the same way we shall find the point on which the perpendicular dropped from B falls. And it will always fall on a point — say M — that is as far from the centre G as I is distant from it. For since in the triangles DGI, BGM the angles at I, M are right by Elements XI, def. 3, [Margin (e): Elements I.15] and the vertical angles at G are equal, and the sides DG, BG are equal, being semidiameters of the sphere, [Margin (f): Elements I.26] the sides GI, GM will also be equal to each other. Therefore on the circumference of a greatest circle in a sphere, etc. Which was to be done.

Diagram. A circle (a greatest circle of the sphere) with two perpendicular diameters — AC horizontal (A at the left, C at the right) and EF vertical (E at the top, F at the bottom) — and centre G. The inclined diameter DB runs from D at the upper left to B at the lower right. Radii and chords are drawn from G to D, K, H, I, M, and B, forming the triangles GDK, GHI (near the top) and DGI, BGM. K lies near the top centre, H on the right, I near the centre, M below the centre.

COROLLARIUM.

[Margin: Finding the minor diameter of the ellipse formed by the perpendiculars falling from the circumference of an inclined circle onto another circle.]

From this, by the same method, we shall find the minor diameter of that ellipse onto which fall the perpendiculars dropped from the circumference of a circle inclined to another circle. For the straight line IM, lying between the points I, M on which the said perpendiculars fall, is the minor diameter, by the preceding proposition.

PROBLEMA 5. PROPOS. 26.

On the circumference of a greatest circle in a sphere inclined to another greatest circle, any points whatever being taken: to inquire, if the inclination is known, the place at which the perpendiculars drawn from them fall onto the other circle.

Let ABCD be a greatest circle in a sphere inclined to the greatest circle DEBF, the inclination being known; and let their common section be the diameter DB passing through the centre G. To this, at right angles, draw in circle ABCD the diameter AC, and in circle DEBF the diameter EF, onto which will fall the perpendiculars dropped from A, C onto circle DEBF, as was shown in the preceding proposition. Let them fall, then, at H, I, so that DB is the major diameter and HI the minor diameter of the ellipse that the perpendiculars from the circumference of circle ABCD, dropped onto the plane of circle DEBF, produce — as has been demonstrated. Now take any point K on the circumference of ABCD. We must then inquire at what place the perpendicular from K, drawn down onto the plane DEBF, falls. Take arc EL equal to arc AK, and draw the straight line GL, which cuts at M the circle HI (described about the minor ellipse-diameter HI). Then through L draw LN parallel to the minor diameter HI, cutting DB at O; and through M draw PM parallel to the major ellipse-diameter DB, cutting LN at Q. I say that the perpendicular dropped from K onto the plane DEBF falls at point Q.

That it falls on the line LN will be shown thus. When the straight line KO is drawn, it will be parallel to AG. For when LS, kT are drawn perpendicular to EG, AG, [Margin (g): Elements I.34] then, since GO is equal to LS, the sine of arc EL, while LS in turn is a sine equal to kT, the sine of arc AK (which is taken equal to arc EL), GO will also be equal to kT. Since then GO, kT are parallel as well, because the angles OGT, kTG are right by construction, [Margin (h): Elements I.28] GT, OK will be equal and parallel. [Margin (i): Elements I.33] Therefore, since the angle AGO is right, [Margin (k): Elements I.29] the angle GOk will also be right. Since then the straight line GO is perpendicular to the straight lines OL, Ok, [Margin (l): Elements XI.4] the same GO will be perpendicular to the plane drawn through OL, Ok; [Margin (m): Elements XI.18] and consequently the plane of circle DEBF, drawn through GO, will be perpendicular to that same plane drawn through OL, OK. [Margin (n): Elements XI.38] Therefore the perpendicular dropped from k onto the plane DEBF will fall on the straight line LN, the common section of the plane DEBF and of the plane drawn through OL, Ok.

That it falls at Q will be demonstrated thus. Let it fall, if it can, on another point, say R. Then since LS, MP are parallel, [Margin (o): Elements VI.2] LM will be to MG as SP is to PG; and, by composition, LG will be to

Diagram. A large tilted ellipse over a circle, the construction for Problema 5 (the fall of the perpendicular from an arbitrary point K onto the plane DEBF). The circle ABCD is inclined; DEBF is the circle onto which perpendiculars fall. EF is the near-horizontal diameter (E at the left end, F at the right), DB the near-vertical one (D at the top, B at the lower left); centre G. A is at the upper left, C at the lower right, K at the top. L lies at the left with the construction points T, Q, R, M just inside it; N is at the upper right, I at the right, O near the centre on DB; S, H, P cluster at the lower left. (This same figure is repeated at the top of the following page.)

- A (upper left), C (lower right): ends of diameter AC of circle ABCD
- D (top), B (lower left): ends of the common section DB
- E (left end), F (right end): ends of diameter EF of circle DEBF
- G (centre): common centre
- H, I (near centre / right): feet of perpendiculars from A, C — the minor-ellipse diameter HI
- K (top): the arbitrary point taken on circle ABCD
- L (left): point with arc EL = arc AK
- M (interior, upper left): where GL cuts the minor circle
- N (upper right): on LN (parallel to HI through L)
- O (centre, on DB): where LN cuts DB
- P (lower left): on PM (parallel to DB through M)
- Q (interior): intersection of LN and PM — the fall-point sought
- R (interior): the assumed (false) alternative fall-point
- S, T (interior, upper left): feet of the sine-perpendiculars LS, kT

as SG is to PG. But LG, MG are equal to EG, HG by the definition of the circle; [Margin (a): Elements I.34] and SG, PG are equal to LO, QO, on account of the rectangles SO, PO. Therefore it will also be the case that as EG is to HG, so LO is to QO; and, alternately, as EG is to LO, so HG is to QO; [Margin (b): Elements VI.22] and hence the square on EG is to the square on LO as the square on HG is to the square on QO. But by Apollonius, *Conics* I.21, the square on EG is to the square on LO as the rectangle BG·GD is to the rectangle BO·OD, because EG, LO are drawn as ordinates (namely perpendiculars) to BD, the diameter of circle DEBF. Therefore it will also be the case that as the rectangle BG·GD is to the rectangle BO·OD, so the square on HG is to the square on QO. And since the ellipse of the diameters DB, HI is assumed to pass through R (because the perpendicular dropped from K is said to fall at R), it is likewise the case, by the same Apollonius, *Conics* I.21, that as the rectangle BG·GD is to the rectangle BO·OD, so the square on HG is to the

square on RO, because HG, RO are applied as ordinates to the diameter BD. Therefore the square on HG is to the square on QO as the same square on HG is to the square on RO. [Margin (c): Elements V.9] Hence the squares on QO, RO are equal, and consequently the lines QO, RO too are equal — the whole and the part. Which is absurd. Therefore the perpendicular dropped from k falls on no point other than Q. In the same way, taking other points on the circumference of circle ABCD, we shall find the place at which the perpendiculars drawn from them fall onto the plane of circle DEBF. Therefore, on the circumference of a greatest circle in a sphere [inclined] to another circle, etc. Which was to be done.

Diagram. The same tilted-ellipse construction as fig-p89-2, repeated at the head of this page so the continued demonstration can be followed. The labels are as before: A (upper left), K (top), D (top); L, T, Q, R, M at the left interior; N (upper right), O (centre), I (right); E (left end), S, H, P (lower left), G (centre); B (lower left), C (lower right), F (right end).

- A, C: ends of diameter AC of circle ABCD
- D, B: ends of the common section DB
- E, F: ends of diameter EF of circle DEBF
- G (centre): common centre
- H, I: feet of the perpendiculars from A, C (minor-ellipse diameter HI)
- K: arbitrary point on circle ABCD
- L, M, N, O, P, Q, R, S, T: construction points (as in fig-p89-2)

COROLLARIUM.

[Margin: How an ellipse whose diameters are given is to be described.]

From this it is plainly evident how an ellipse whose diameters are given is to be described. For suppose two diameters DB, HI are so fitted that they bisect each other at G and cut at right angles; and with centre G and radii GD, GH let circles be described. Then let HI, produced in both directions, have equal arcs EL, LA, AB, BC — as many as one likes — marked off, together with FN, NK, KP, PR equal to these; and let the same be done in the other semicircle EBF; and let the points L, A, B, etc. be joined to the centre G by straight lines cutting the circle HMI into parts that will be similar to the parts EL, LA, etc. — by what we wrote in our commentary on the *Sphere* at the end of chapter 1. Next, let any two points of the greater circle, equally removed on either side from D or B, be connected by straight lines; and likewise any two points of the smaller circle, equally removed on either side from H or I, by other straight lines. Finally, let the points where

each pair of lines meet — the lines that pass through the divisions corresponding to one another — be marked: all these will fall on the ellipse whose diameters are DB, HI, as has been demonstrated.

For in the figure above we showed that the point Q, where the straight lines LN, PM meet — of which the former is parallel to the minor diameter HI and the latter to the major DB — falls on the ellipse; and these parallels are drawn through the points L, M that correspond to each other, that is, that cut off similar arcs EL, HM. Since, then, the same thing happens here — because all the lines connecting the corresponding points are parallel to the diameters HI, DB — it is clear, from what we demonstrated in the scholium to Elements III.27, that all those points fall on the ellipse. The same will happen even if the arcs EL, LA, etc. are not equal, provided that through the corresponding points L, M, etc. parallels are drawn to the diameters of the ellipse, and so on. Therefore, if we draw a line suitably and congruently joining such points, the ellipse will be described. Which was to be done.

Federico Commandino puts this problem too more generally, as he does the one we demonstrated above in Propos. 24 of this book.

Diagram. The point-by-point construction of the ellipse from its two given diameters: an outer (greater) circle and an inner (smaller) concentric circle, with radial (dotted) lines dividing them into corresponding arcs, and centre G. The near-horizontal diameter is EF (E at the left, F at the right), the near-vertical DB (D at the top, B at the bottom). Division points run around the outer circle (C, D, R across the top; B, A, L down the left; P, K, N down the right); the inner circle carries H, M, G, I along its middle and O above centre.

- D (top), B (bottom): ends of the vertical diameter DB
- E (left), F (right): ends of the horizontal diameter EF
- G (centre): common centre
- C, R (top), A, L (left), P, K, N (right): division points on the outer (greater) circle
- H, I (inner middle): ends of the inner diameter; M near H, O above the centre — division points on the inner (smaller) circle HMI

PROBLEMA 6. PROPOS. 27.

[Margin: The inclination of a proposed plane to the meridian — by what method it is to be found.]

To investigate the inclination of any plane whatever to the meridian circle.

Let ABCD be the horizon, BD the vertical, ACG the meridian, and EF a plane inclined to the meridian, cutting the meridian at G — whether below the horizon or above it. Here, and in the following five problems, we take an inclined plane to be one drawn through the centre of the sphere, and therefore, by Theodosius, *Spherics* I.1, making a greatest circle in the sphere. Since, then, in the spherical triangle CFG, whose angle C is right (for the meridian is perpendicular to the horizon), it holds — by Regiomontanus [Regiomontanus], *De Triangulis* IV.18, or by Jābir [Jābir ibn Aflah] I.14, or certainly from Proposition 42 of our own [treatise] on spherical triangles — that as the sine of angle F, the inclination of the given plane EF to the horizon, is to the sine of the right angle C (that is, to the total sine [radius]), so is the sine of the complement of angle G, the inclination of the same plane EF to the meridian, to the sine of the complement of arc CF; that is, to the sine of arc DF, or BF, the declination

Diagram. Two side-by-side circles illustrating a plane EF inclined to the meridian. In each, ABCD is the horizon (A at the top, B at the left, D at the right, C at the bottom), BD the horizontal vertical-circle line, and ACG the vertical (meridian) line; the inclined plane EF is the oblique chord (E near the top, F toward the bottom). **Left circle:** A (top), E (just right of A), B (left), D (right), C (bottom), F (lower left), with G below the circle at the bottom (the inclined plane cutting the meridian below the horizon). **Right circle:** A (top), E (upper left), B (left), D (right), G at the centre, C (bottom), F (lower right) — the plane cutting the meridian at G within the sphere.

- A (top), C (bottom): meridian points; B (left), D (right): horizon points ABCD
- E, F: the ends of the inclined plane EF (its trace)
- G: the point where the inclined plane cuts the meridian (below the horizon in the left figure; at the centre in the right)

Gnomonics, Book I (continued)

(Continuation of the demonstration of Problem 6 / Proposition 27, from the foot of the preceding page.)

measuring the declination from the vertical circle. And conversely: as the total sine [radius] of the right angle C is to the sine of angle F, the inclination of plane EF to the horizon, so is the sine of the complement of arc CF — that is, the sine of arc DF or BF, which measures the declination from the vertical — to the sine of the complement of angle G, the inclination of the same plane EF to the meridian. Therefore, once the declination of the proposed plane from the vertical circle has

been found by Proposition 23 of this book, together with its inclination to the horizon: if we set it up so that, as the total sine is to the sine of the inclination to the horizon, so is the sine of the declination from the vertical to a fourth number, we shall obtain the sine of the complement of the inclination to the meridian; and when this complement is subtracted from a quadrant, the inclination to the meridian becomes known.

Example. Let the declination of the plane from the vertical circle be 30° , and its inclination to the horizon $52^\circ 3'$. If, then, we set it up so that, as 100000 (the total sine) is to 78854 (the sine of the inclination to the horizon, namely the sine of $52^\circ 3'$), so is 50000 (the sine of the declination from the vertical, that is, the sine of 30°) to a fourth number, this fourth number will be found to be the sine 39427, whose arc contains $23^\circ 13'$. When this is subtracted from a quadrant, there remains the inclination to the meridian, $66^\circ 47'$. Which was what was proposed.

[Margin: When the plane is at right angles to the vertical.]

But if the inclined plane faces directly east or west — that is, if it is at right angles to the vertical circle and passes through the common sections of the horizon and the meridian — then the complement of its inclination to the horizon will be its inclination to the meridian, as is evident.

[Margin: When the plane inclined to the horizon looks directly toward the south or the north.]

But if a plane inclined to the horizon has no declination — that is, if it passes through the common sections of the vertical circle and the horizon, and faces directly south or north — then such a plane will have no inclination to the meridian; that is, it will be at right angles to the meridian, as is clear.

[Margin: When the plane is at right angles to the horizon.]

Finally, if a plane is at right angles to the horizon — that is, if it passes through the zenith — then the complement of its declination from the vertical circle will be its inclination to the meridian, as is manifest. Thus we have investigated the inclination of any plane whatever to the meridian circle. Which was to be done.

PROBLEMA 7. PROPOS. 28.

[Margin: The arc of the meridian placed between the horizon and the inclined plane — how large it is, is to be investigated.]

Given a plane inclined to the horizon and the meridian, or to the meridian only, or to the horizon only, to find how large is the arc of the meridian circle placed between it and the horizon.

Let ABCD be the horizon, with centre E; let AC be the common section of the horizon and the meridian, and BD the common section of the horizon and the vertical. Let DF be the declination, from the vertical circle, of a plane inclined both to the horizon and to the meridian, so that the straight line FG is the common section of the horizon and the inclined plane. Now, once the inclination of this same plane to the horizon has been found by Proposition 23 of this book, let the minor diameter of the ellipse be found by Proposition 25 of this book — the ellipse which the perpendiculars, dropped from the circumference of the inclined plane (which makes a circle in the sphere, by Theodosius, *Spherics* I.1) to the plane of the horizon, produce by Proposition 24 of this book. Let this minor diameter be HI, cutting the major diameter FG at the centre E at right angles. Now, by the corollary of Proposition 26 of this book, let an ellipse — or at least the part of it — be described about the given diameters FG and HI, cutting AC, the common section of the horizon and the meridian, at the point K; through K let the perpendicular KL be drawn to AC, cutting the circumference of the horizon at L. I say that the arc CL is equal to the arc of the meridian circle interposed between the horizon and the inclined plane.

For let the semicircle AMC of the meridian be understood as standing at right angles to the horizon ABCD, and let M be the point at which the inclined plane cuts the meridian, such that the arc CM lies between the horizon and the plane itself. Let the straight lines EL, EM, CL, CM also be drawn. Now, since the perpendicular dropped from M to the horizon falls on the straight line AC — the common section of the horizon and the meridian — because the meridian is at right angles to the horizon, and since it also falls (by Proposition 24 of this book) on the ellipse which the perpendiculars produce that fall from the points of the circumference of the inclined plane (one of which is M) onto the plane of the horizon: it is evident that the perpendicular from M falls on the point K, where the ellipse cuts the straight line AC. Let it fall, then, and let it be MK. Consequently both the angle EKM and the angle CKM will be right, by Euclid, *Elements* XI, Definition 3. [Margin: Euclid, *Elements* I.47] Therefore the square on EL will equal the squares on EK and KL, and likewise the square on EM will equal the squares on EK and KM. And since the squares on the equal straight lines EL and EM are equal (for they are drawn from the centre of the sphere to its surface), the squares on EK and KL will also equal the squares on EK and KM; and, the common square on EK being taken away, the square on KL will equal the square

on KM, and thus the straight line KL will equal the straight line KM. And so, since in the triangles CKL and CKM the sides KL, KC equal the sides KM, KC, and they contain equal angles (namely right angles), [Margin: Euclid, *Elements* I.4] the base CL will equal the base CM; [Margin: Euclid, *Elements* III.28] and therefore the arc CL will equal the arc CM of the meridian placed between the horizon and the inclined plane. Which was what was proposed.

Another method. Let ABCD be the horizon, BD the vertical, ACG the meridian, and EF a plane inclined both to the horizon and to the meridian, cutting the meridian at G — whether below the horizon or above it — so that CG is the arc placed between the horizon and the inclined plane. Since, then, in the spherical triangle CFG, whose angle C is right (because the meridian is at right angles to the horizon), it holds — by Proposition 16, Book 4 of Johannes Regiomontanus [Regiomontanus], *On Triangles*, or by Proposition 13, Book 1 of Jābir [Jābir ibn Aflah], or certainly from Proposition 41 of our own [treatise] on spherical triangles — that as the sine of arc CF (namely of the complement of the declination DF from the vertical circle) is to the sine of angle G (the inclination of plane EF to the meridian), so is the sine of arc CG, between the horizon and the inclined plane...

Diagram. A circle (the horizon ABCD, centre E) carrying an inscribed ellipse and its construction for Problem 7. A is at the top, C at the bottom (the meridian's vertical trace AC), B at the left and D at the right (the vertical's trace BD); E is the centre. G lies upper-left on the circumference, F at the lower right, so that FG is the common section of the horizon and the inclined plane (the ellipse's major diameter through E). An ellipse is drawn about FG; I lies inside on the right, H inside on the lower left (HI the minor diameter). K and M lie near the bottom (K on AC, M on the arc just to its right), L at the lower left on the circumference. Straight lines EL, EM, CL, CM and the perpendicular KL/MK complete the figure.

- A (top), C (bottom): trace of the meridian on the horizon
- B (left), D (right): trace of the vertical on the horizon
- E (centre): centre of the horizon and of the sphere
- F (lower right), G (upper left): ends of FG, the common section of horizon and inclined plane (major diameter of the ellipse)
- H (lower-left interior), I (right interior): ends of HI, the minor diameter of the ellipse
- K (near bottom, on AC), L (lower left, on the circumference): K where the ellipse cuts AC, L where the perpendicular through K meets the horizon
- M (near bottom, right of K): where the inclined plane cuts the meridian

Gnomonics, Book I (continued)

(Text continues from p. 79; the running head is now GNOMONICES.)

to the sine of angle F, the inclination of the plane to the horizon. And conversely: as the sine of angle G, the inclination to the meridian, is to the sine of arc CF, the complement of the declination from the vertical, so is the sine of angle F, the inclination to the horizon, to the sine of the arc CG of the meridian intercepted between the horizon and the inclined plane. Therefore, once the declination of the proposed plane from the vertical circle has been found by Proposition 23 of this book, together with its inclination to the horizon, and likewise its inclination to the meridian from the preceding proposition: if we set it up so that, as the sine of the inclination to the meridian is to the sine of the complement of the declination from the vertical, so is the sine of the inclination to the horizon to a fourth number, we shall obtain the sine of that arc of the meridian which is intercepted between the horizon and the inclined plane.

Diagram. Two side-by-side circles illustrating a plane EF inclined to both the horizon and the meridian, cutting the meridian at G. In each, ABCD is the horizon (A at the top, B at the left, D at the right, C at the bottom), with the vertical trace BD (horizontal) and the meridian trace running vertically; EF is the oblique chord (the trace of the inclined plane). **Left circle:** A (top), E (just right of A, upper), B (left), D (right), F (lower left), C (bottom), and G below C outside the circle (the inclined plane cutting the extended meridian below the horizon). **Right circle:** A (top), E (upper left), B (left), D (right), G at the centre, C (bottom), F (lower right) — the plane EF cutting the meridian at G within the sphere.

- A (top), C (bottom): meridian trace; B (left), D (right): vertical trace BD
- E, F: ends of the inclined plane's trace EF
- G: point where the inclined plane cuts the meridian (below the horizon in the left figure, at the centre in the right)

so that, as the sine of the inclination to the meridian is to the sine of the complement of the declination from the vertical, so is the sine of the inclination to the horizon to a fourth number: there will be obtained the sine of that arc of the meridian which is interposed between the horizon and the inclined plane.

Another method. Set it up so that (by Problem 11 of the [treatise on] spherical triangles) as the total sine is to the sine of the complement of the plane's declination from the vertical — that is, to the sine of arc CF — so is the tangent of angle F, the inclination to the horizon, to a fourth number. The number produced

will be the tangent of the required side CG. And in this method the inclination to the meridian is not needed.

Another method. Set it up, by Problem 12 of the [treatise on] spherical triangles, so that as the total sine is to the secant of the complement of angle G (the inclination of the plane to the meridian, found by Proposition 27), so is the sine of the complement of angle F (the inclination of the plane to the horizon, found by Proposition 23) to a fourth number. The number produced will be the sine of the complement of the required side CG.

Example. Let the inclination to the meridian be $66^{\circ}47'$, the declination from the vertical 30° , and the inclination to the horizon $52^{\circ}3'$. If, then, we set it up so that, as 91902 (the sine of the inclination to the meridian) is to 86602 (the sine of the complement of the declination from the vertical), so is 78854 (the sine of the inclination to the horizon) to a fourth number, this will be found to be very nearly the sine 74306, whose arc — 48° nearly — is placed between the horizon and the inclined plane. Which was what was proposed.

[Margin: When the plane is at right angles to the vertical.]

But if a plane inclined both to the horizon and to the meridian faces directly east or west — that is, if it is at right angles to the vertical — then no arc of the meridian will be intercepted between the plane and the horizon, because then the plane runs along the common sections of the meridian and the horizon, as is evident.

[Margin: When the plane is at right angles to the meridian.]

But if the plane is inclined to the horizon only — that is, if it passes through the common sections of the horizon and the vertical (that is, through the poles of the meridian), and so is at right angles to the meridian — then its very inclination to the horizon will be the arc of the meridian placed between the plane and the horizon, because then the meridian measures the inclination, as is clear.

[Margin: When the plane is at right angles to the horizon.]

Finally, if the plane is inclined to the meridian only — that is, if it passes through the zenith (that is, through the pole of the horizon), and so is at right angles to the horizon — then a quarter of the meridian circle will be intercepted between the plane and the horizon, as is manifest. Therefore, given a plane inclined to the horizon and the meridian, or to the meridian only, and so forth. Which was to be done.

SCHOLIUM.

[Margin: When the arc of the meridian between the horizon and the inclined plane is found above the horizon, and when below.]

If the inclination of a plane to the horizon falls toward the northern part of the upper hemisphere — in accordance with what we taught in Proposition 23 of this book — the meridian will cut the plane on the side of the arctic pole above the horizon, and the arc placed between the horizon and the plane will stand out above the horizon on the side of the arctic pole. But if the inclination falls toward the southern part of the same hemisphere, the plane will cut the meridian circle on the side of the arctic pole below the horizon, and therefore the arc of the meridian intercepted between the plane and the horizon will be hidden there below the horizon. The reason for this is that, since a quadrant of the horizon is intercepted between the greatest circle measuring the inclination of the plane and the plane itself, and since that circle bisects the segment of the horizon between the inclined plane — that is, the segment cut off by the inclined plane, which is a semicircle — by Theodosius, *Spherics* II.9, it comes about that, when the inclination falls toward the northern part, the meridian on that same northern side cuts the inclined plane above the horizon. In the same way, when the inclination falls toward the southern parts, the meridian on that same southern side cuts the inclined plane above the horizon, and consequently below the horizon on the northern side. This will be easily understood if the situation and position of the circles in the sphere is carefully weighed.

COROLLARIUM.

[Margin: How the arc of the meridian placed between the inclined plane and the arctic pole is to be found.]

From these things it will not be difficult to find how large is the arc of the meridian interposed between the inclined plane and the arctic pole of the world. For if the arc of the meridian between the plane and the horizon is below the horizon on the side of the arctic pole, then the arc composed of it together with the arc that measures the altitude of the pole above the horizon will be the arc lying between the inclined plane and the arctic pole of the world — provided it does not exceed a quadrant. But if it exceeds a quadrant, the said arc will be its complement to a semicircle, which is contained above the horizon toward the south, just as the former is partly above the horizon and partly below. But if it stands above the horizon, then the arc by which it differs from the arc measuring the altitude of the pole above the horizon will be the arc intercepted between the

plane itself and the arctic pole of the world, and it will be contained above the horizon, now toward the north, now toward the south. All these things will become clear from the figure set alongside, in which ABCD is the meridian; EF the axis of the world; E the arctic pole, F the antarctic...

Diagram. A circle (the meridian ABCD) filled with radial straight lines drawn through the centre, each a diameter representing the trace of an inclined plane, the horizon, the vertical, or the axis of the world. A is at the top, C at the bottom, B at the left, D at the right (the cardinal points of the meridian). The polar axis EF is a tilted diameter, with E (the arctic pole) toward the upper right and F (the antarctic pole) toward the lower left. The remaining lettered diameters are the traces of inclined planes: GH (G lower right, H upper left), IK (I right, K left), LM (L upper right, M lower left), and NO (N upper left, O at the bottom).

- A (top), C (bottom), B (left), D (right): cardinal points of the meridian ABCD
- E (upper right): arctic pole of the world; F (lower left): antarctic pole; EF the axis of the world
- G–H, I–K, L–M, N–O: traces (diameters) of inclined planes on the meridian

Gnomonics, Book I (continued)

(Corollary continues from p. 80; running head again LIBER PRIMVS.)

F [the antarctic pole]; BD the common section of the horizon and the meridian; AC the common section of the vertical and the meridian; and GH, or IK, or LM, or NO the common section of the inclined plane and the meridian. You see, then, that the arc GE is composed of the arc GD — which lies between the inclined plane and the horizon, below the horizon — and the arc DE, the altitude of the pole above the horizon. Likewise, the arc IE (or LE) — by which the arc DI (or DL), between the inclined plane and the horizon above the horizon, differs from the arc DE, the altitude of the pole above the horizon — is intercepted between the inclined plane and the arctic pole E. Likewise the arc EN, between the plane NO and the pole, is the one to be taken — even though the arc DO, between the plane and the horizon, is below the horizon — because the whole arc EO exceeds a quadrant.

[Margin: When the plane is at right angles to the vertical.]

But if the inclined plane is at right angles to the vertical circle — that is, if it faces directly east or west, and passes through the common sections of the horizon and the meridian, so that the common section of it and the meridian is the straight

line BD — then the arc between the plane itself and the pole E will not differ from the arc DE, which measures the altitude of the pole above the horizon, as is evident.

[Margin: When the plane is at right angles to the horizon.]

But if the inclined plane is at right angles to the horizon — that is, if it passes through the zenith A, so that the common section of it and the meridian is the straight line AC — then the arc between the plane itself and the pole E will not differ from the arc AE, which measures the complement of the altitude of the pole above the horizon, as is manifest.

[Margin: How large is the arc of the meridian between the inclined plane and the zenith.]

By like reasoning we shall discover how large is the arc of the meridian intercepted between the inclined plane and the zenith. For if we subtract the arc of the meridian between the plane and the horizon from a quadrant, the remainder will be the arc of the meridian between the plane and the zenith. This arc will be contained on the northern side if the arc between the plane and the horizon is above the horizon on the same northern side, but on the southern side if the arc between the plane and the horizon toward the northern parts is below the horizon. For in the same figure you see that the arc DI (or DL), taken away from the quadrant DA, leaves the arc IA (or LA), between the plane and the zenith toward the northern parts. Likewise the arc BH (or BN) — [Margin: Euclid, *Elements* III.26] the arc BH being equal to the arc GD, and the arc BN equal to the arc OD, between the plane and the horizon below the horizon — subtracted from the quadrant BA, leaves the arc HA (or NA), between the plane and the zenith on the southern side.

SCHOLIUM II.

[Margin: By what device the altitude of the pole above the horizon is found by means of the analemma.]

But let us now set forth that method of finding the altitude of the pole above the horizon by means of the analemma which we promised in the scholium of Proposition 1 of this book, and which we in fact took from Giovanni Battista Benedetti [Ioannes Baptista Benedictus], in his book *On the Use of Gnomons and of Solar Shadows*. Presenting it more clearly, however, we have reduced it to the following form.

On a plane parallel to the horizon, let a circle ABCD be described, with centre E, in which BD is the meridian line — that is, the common section of the meridian circle and of the circle ABCD — such that B faces south and D faces north; and let AC be the common section of the vertical and of the same circle. Now, with a stylus of any size fixed at the centre E at right angles to the plane of the circle ABCD, let the shadow of the stylus be observed, either before noon or after; and in the middle of it, near its tip (for the extreme point can scarcely be perceived on the plane without error), let a point be marked, through which and through the centre E the straight line FG is drawn. Here we may also conveniently use the instrument that we constructed at the beginning of the scholium of Proposition 23 of this book. For if the rule AB is placed on the plane of the circle ABCD, so that the point D is set at the centre E, we shall observe the shadow of the side HD in place of the shadow of the stylus, and in it we shall mark a point, through which and through the centre E (the instrument having first been removed) we shall draw the straight line FG. We shall use this same instrument in other observations too, in which a stylus is customarily employed to cast a shadow for projection. Then, having taken the Sun's altitude without delay, before the line FG is drawn, let an arc GH equal to it be marked off on the opposite side of the shadow, and from H let the perpendicular HI be dropped to FG. Then from I let the perpendicular IOQ be drawn to BD — or parallel to AC — and let OQ be cut off equal to HI. Again, after some interval of time...

Diagram. The analemma construction — a large circle ABCD with centre E, crowded with radial and perpendicular construction lines and small interior point-labels (several partly obscured). A is at the top, C at the bottom, B at the left, D at the right; BD is the meridian line (B toward the south, D toward the north), AC the vertical trace, E the centre where the stylus stands. FG is the shadow line drawn through E; K lies at the upper right and L toward the lower left, with KL the second shadow line. H is at the left, M at the mid-left, I and N toward the lower centre, G at the bottom. Interior construction points O, P, Q, R and the two small Greek arc-labels π and ρ (the arc $\pi\rho$ described about R, measuring the pole's altitude) sit near the centre. Many of the fine interior labels are crowded and ink-spotted.

- A (top), C (bottom): vertical trace AC; B (left, south), D (right, north): meridian line BD
- E (centre): foot of the stylus / centre of the circle
- F, G: ends of the first shadow line FG through E
- K (upper right), L (lower left): ends of the second shadow line KL

- H (left), I (lower centre): shadow-arc point H and foot I of the perpendicular HI
- M (mid-left), N (lower centre): shadow-arc point M and foot N of the perpendicular MN
- O, P, Q, R (interior): construction points (IOQ, NPR, RQ); the angle PRQ measures the pole's altitude
- π , ρ [Greek letters]: the small arc $\pi\rho$ described about R, containing the degrees of the altitude
- [Several further interior labels are crowded / ink-spotted and could not be read with confidence]

has elapsed, let the shadow of the stylus be observed again, and in the middle of it, near its tip, let another point be marked, from which, through the centre E, the straight line KL is drawn; and, having taken the Sun's altitude at that time, let an arc LM equal to it be marked off on the opposite side of the shadow, and from M let the perpendicular MN be drawn down to KL, and from N let the perpendicular NPR be raised to BD — or parallel to AC — and let PR be cut off equal to MN. Finally, through the points R and Q let the straight line RQ be drawn. I say that the angle PRQ is the angle of the pole's altitude, and that the arc $\pi\rho$, described about R, contains the degrees of that same altitude. This we shall demonstrate as follows. Since, at the time of the first observation, the tip of the shadow falls on the straight line FG [?], the straight line FG will be the common section of the circle ABCD and of that vertical circle in which the Sun then stands, as is established from Proposition 11 of this book. Hence, since the vertical circle properly so called — drawn through the straight line AC — and the vertical circle passing through the centre of the Sun and through the straight line FG cut off similar arcs from the horizon and from the circle ABCD (which is parallel to the horizon, being distant from it by an interval equal to the length of the stylus, as is evident from Proposition 2 of this book), by Theodosius, *Spherics* II.10 — because they are drawn through their poles — it comes about that, if the circle ABCD is taken for the horizon, the straight line FG will also be the common section of the horizon and of the vertical circle through the centre of the Sun...

Diagram. A rectangle FGDC seen in profile (the analemma's side elevation), lying beneath the large circle. F is the upper-left corner and G the upper-right; C is the lower-left corner and D the lower-right. At the top centre stand the points B and A (close together), from which a narrow shaded triangle (the stylus / gnomon and its shadow) descends to the point E at the bottom centre, below which a small sun-burst symbol ($\odot$, the Sun) is engraved.

- F (upper left), G (upper right): top edge of the profile rectangle
- C (lower left), D (lower right): bottom edge
- B, A (top centre): apex points of the gnomon
- E (bottom centre): foot of the gnomon; ☉ (below E): the Sun

of the Sun as it passes. Now since GH is the arc of the Sun's altitude, if the semicircle FHG is imagined to be rotated about the diameter FG until it stands perpendicular to the horizon — the straight line HI being then perpendicular to that same horizon, by Euclid XI, definition 4 — the centre of the Sun will lie at the point H. Hence the Sun's parallel of that moment will pass through the point H.

Now suppose that, in that position of the semicircle FHG, a line is drawn through H, in the plane of the Sun's parallel, parallel to IQ itself. (That a parallel to IQ can indeed be drawn through H in the plane of the Sun's parallel will become clear as follows. Since the Sun's parallel and the horizon are both perpendicular to the meridian [Margin: Euclid XI.19], their common section will be perpendicular to that same meridian, and hence also to the straight line BD lying in the meridian; for, BD being the common section of meridian and horizon, that common section will be perpendicular, by Euclid XI, definition 3 [Margin: Euclid I.28], and therefore parallel to IQ. If, then, in the plane of the Sun's parallel a line be drawn through H parallel to the common section of the parallel and the horizon, it will [Margin: Euclid XI.9] be one and the same with, and parallel to, IQ. So a line parallel to IQ can be drawn through H in the plane of the Sun's parallel.) A straight line drawn from O perpendicular to the horizon — and therefore, by Euclid XI, definition 3, to the straight line BD — and equal to HI, falls upon that parallel drawn through H in the Sun's parallel. (For since HI and the said perpendicular drawn from O are both at right angles to the plane of the horizon, they [Margin: Euclid XI.6] will be parallel to one another; and since they are equal by hypothesis, the line drawn from H [Margin: Euclid I.33] through the far end of the perpendicular raised from O will be parallel to IO. Consequently the said perpendicular drawn from O will fall upon that parallel drawn through H in the Sun's parallel. Otherwise two parallels to IO would be drawn from the single point H — namely the one which we said must be drawn through H, and the one which passes from H through the end of the perpendicular from O and which we proved parallel to IO — which is absurd. [Margin: Euclid XI.9] For those two lines sent out from H would be parallel to one another, and yet meet at H.)

It follows, then, that — OQ being taken equal to HI and perpendicular to BD — if the semicircle BAD is conceived to be rotated about the diameter BD until it stands perpendicular to the horizon and coincides with the meridian, so that QO

is perpendicular to that same horizon (by Euclid XI, definition 4), the point Q falls upon that parallel drawn through H in the plane of the Sun's parallel; and therefore the plane of the parallel passes through the point Q, while the semicircle BAD remains in that position in which it stands perpendicular to the horizon, like the meridian. In the same way we shall prove that this same plane of the Sun's parallel passes through the point R in that position of the semicircle BAD. Hence RQ, the common section of the Sun's parallel and of the meridian ABCD (for we are now taking this circle for the meridian), and therefore the angle PRQ, will be the angle of the pole's altitude — which is shown thus. Draw the straight line $\mu\xi$ through the centre E, parallel to RQ; then $\mu\xi$ will be the common section of the equator and the meridian. Hence the angle $BE\mu$ will be the angle of the equator's altitude, that is, the complement of the pole's altitude; and therefore the remaining angle $AE\mu$ (measured off from the right angle) will be the angle of the pole's altitude. [Margin: Euclid I.34] Since, then, the angle opposite to it, PRQ, is equal to it in the parallelogram ER, PRQ will likewise be the angle of the pole's elevation above the horizon — which was proposed.

But since some error may easily be committed in drawing the straight line RQ — because the perpendiculars PR and OQ, and hence the points R and Q, lie only a very small distance apart, as happens in the given example — we shall carry the matter out more accurately if we choose two observations of the Sun's shadows in which the said points R and Q are separated by some appreciable interval. Indeed we shall do it still more correctly when the Sun is in the northern signs, if we observe the stylus's shadow at the moment when it falls upon AC itself — the common section of the vertical circle properly so called and of the circle ABCD — or when it is close to that line AC, whether toward B or toward D. So in the preceding figure you see that, with the Sun on the vertical circle itself and the stylus's shadow falling on AC, whether before noon or after, the line $E\alpha$ is taken equal to the perpendicular YZ, the Sun's altitude then being AT. Likewise at evening, when the stylus's shadow falls on $E\beta$ and the Sun's altitude is $\gamma\delta$, the line $\theta\lambda$ is taken on the perpendicular $[\epsilon?]\theta$, equal to the perpendicular $\delta[\epsilon?]$. And so on.

But if the observation can conveniently be made on an open, unobstructed horizon, or in some elevated place where the rising or setting Sun can be seen, such a place should be chosen. For if, at sunrise or sunset, the stylus's shadow is observed and SF is again drawn — the common section of the circle ABCD and of the vertical circle passing through the centre of the Sun at that moment — so that the arc CS (or AS) is the rising or setting amplitude; and if ST is drawn perpendicular to BD; then we shall have on the line BD the point T, through

which the Sun's parallel is to be drawn, since ST is the common section of the Sun's parallel and the horizon. And if at noon, with the stylus's shadow falling on BD, the Sun's altitude is observed and reckoned off from B up to V, the parallel of that moment will pass through the point V on the meridian. Hence VT will be the common section of the Sun's parallel and the meridian, as before. Finally, if besides the two points Q and R we find yet a third — such as α , or T — we shall draw the line VT more easily and without error through three points.

[Margin: The rising and setting amplitude — by what method it is investigated by means of a stylus fixed in a wall.] Moreover, since at sunrise or sunset the stylus's shadow can scarcely be caught on the plane of the circle ABCD, we shall use the following device for investigating the Sun's rising and setting amplitude. On some flat, right-angled board we shall draw a line AB parallel to the lowest edge CD, and in it we shall fix at right angles a stylus AE of any length — or better, as above, the side HD of the instrument described at the beginning of the scholium to Proposition 23 of this book; this we shall set up at the point A. Then at sunrise or sunset we shall fit the lowest edge CD of the board to the meridian line BD (parallel to the horizon of the preceding figure), so that the board itself stands perpendicular to the plane of the circle ABCD — which is easily done by means of a plumb-line dropped from the point F. For, with the plumb-line lying against the board, the board will be perpendicular to the circle ABCD. Then we shall mark the shadow on the line AB, where it falls at the point B, so that the Sun's ray is EB. And so, if in the preceding figure, on the vertical line AC, we take a line EQ equal to the gnomon AE (or to the said side HD

Diagram (Source: printed p. 82). A large circle (the analemma / orthographic projection referred to throughout as the "preceding figure"), centre E, with the horizontal diameter B (left) — E — D (right). The oblique diameter AC descends from the top toward the lower right; numerous straight lines are drawn from the centre to peripheral points (the traces of the vertical circles), together with an interior parallelogram (ER) and small right-angle marks. Below the circle stands the profile rectangle (fig-p82-2). Because the figure is exceptionally densely labelled and partly ink-spotted, only the confidently readable labels are listed; several small interior and Greek sorts cannot be resolved at this resolution.

- E (centre)
- B (left), D (right): ends of the horizontal diameter BD
- A (top): summit of the circle
- M (upper left), K (upper right), Z (upper, right of centre): peripheral points
- L (lower left), G (lower, left of centre), H (left, below B): peripheral points

- C (bottom centre, with β to its left), S (lower right): peripheral points
- μ (mu, upper-left periphery): one end of the diameter $\mu\xi$ (the equator's section)
- ξ (xi, lower-right periphery) [?]: the other end of $\mu\xi$
- P (interior, right of E), T (interior, below P), θ (interior, near P) [?]
- R (interior, upper left, with a right-angle mark), Q (interior, upper), ϕ (phi, interior, upper left) [?]
- O, X, ρ (interior cluster, left of E) [?]; π (interior, lower left) [?]
- N, I (interior, lower centre) [?]
- [Several further peripheral and interior labels — including small Greek sorts near the top of the circle — are ink-spotted and unresolved.]

Diagram (Source: printed p. 82). A rectangle FGDC seen in profile (the side elevation of the analemma), beneath the great circle. A shaded gnomon-and-shadow triangle descends from the apex at top centre to E at the bottom edge, below which a small sun symbol is engraved.

- F (upper left), G (upper right): top edge of the profile rectangle
- C (lower left), D (lower right): bottom edge
- B, A (top centre): apex of the gnomon
- E (bottom centre): foot of the gnomon; the Sun symbol ($\odot$) below E

of the said instrument), and through ϕ we draw $\phi\chi$ perpendicular to AE, and take $\phi\chi$ equal to the shadow AB, then the line χE , produced to S, will give the rising or setting amplitude CS. For since the plane FD lies in the plane of the meridian, the gnomon AE will be part of the common section of the vertical circle properly so called and of the horizon. If, then, the circle ABCD is taken for the horizon, and the board FD is imagined applied to it so that the point ϕ falls on A and χ on B — because of the equality of the lines AB and $\phi\chi$ — the centre E will fall on the tip of the stylus E, because of the equality of the lines AE and ϕE . Hence the line χE will coincide with the Sun's ray BE, and therefore, produced, will fall on S, the point of rising or setting on the horizon. Therefore the arc CS will be the rising or setting amplitude. Note, however, that if the observation is made in the morning and the shadow falls on the line AF, the Sun is northern; so the amplitude must then be taken from C toward the northern parts, namely toward D. But if the shadow falls on the line AG, the Sun is southern; so the amplitude must be counted from C toward the southern parts, that is, toward B. The contrary is to be understood if the observation is made in the evening: for when the shadow falls on AG the Sun is northern, and when it falls on AF the Sun is southern, as is evident.

Finally, so that all this may be done more easily and more correctly, before the stylus is fixed there should be drawn in the circle ABCD several straight lines to serve as the common sections of the vertical circles with the circle ABCD — as in the figure, FG drawn 30° from AC, and KL 50° , and $\gamma\beta$ $6^\circ 30'$, and so on. For when the tip of the shadow falls on one of these lines, we shall know on which vertical circle the Sun stands; and then, having taken its altitude, we shall proceed as before. This must be done because the stylus, if it is fixed first, before the lines are drawn through the centre from the marked endpoint of the shadow, is an obstacle, preventing the said straight lines from being drawn through the centre. But if instead of a stylus we use the instrument described at the beginning of the scholium to Proposition 23 of this book, this precaution will not be needed, since that instrument can be removed after the observation of the shadow, so that the lines can be drawn through the centre E without hindrance.

[Margin: The pole's altitude above the horizon — by what method it is computed by sines.] Now if we wish to measure the magnitude of the angle PRQ — the pole's altitude — by the doctrine of sines, we shall do it thus. Since the arc GH of the Sun's altitude is known, the sine EI of its complement will be known. And since the angle CEG is also known from the observation of the shadow (for when the shadow falls on EF, the degrees of the arc AF are measured, that is, the angle AEF, which is the same as CEG), its alternate angle EIO will [Margin: Euclid I.29] be equal to it, and so, in the right triangle EIO, known. Therefore EO, the sine of the angle EIO, will be known in terms of the parts of the whole sine EI. And if we set it up that, as the whole sine EI is to EI in so far as it is known in parts of the whole sine EG, so is EO — in so far as it is the sine of the angle EIO — to a fourth term, then EO will become known in parts of the whole sine EG (or EB). By the same reasoning EP will become known in the same parts. Subtracting, then, EO from EP, OP becomes known in the same parts. Now if the line Q ω is drawn from Q perpendicular to PR, then Q ω [Margin: Euclid I.34] will be equal to OP, and P ω to OQ. Hence Q ω too will be known in parts of the whole sine EB. And in the same parts the line OQ (that is, P ω) and PR are known, since they are equal to the right sines IH and NM of the known solar altitudes. [Margin: Euclid I.47] Subtracting, then, the line P ω from PR, the remainder ω R will also be known in the same parts. Since, then, the squares of the lines ω Q and ω R are equal to the square of the line QR, QR too will become known in the same parts. Therefore if we set it up that, as QR — in so far as it is known in parts of the whole sine EB — is to itself in so far as it is the whole sine, so is Q ω , in so far as it is known in parts of the whole sine EB, to a fourth term, then Q ω will become known in parts of the whole sine QR — that is, in so far as it is the sine of the angle QR ω , the sought pole-altitude. And so on. [Margin: Euclid I.34]

But if one point has been found from the shadow on the line EB — say P — and the other on the line ED — say θ — then $E\theta$ must be added to EP, so that the whole θP becomes known. For hence $\lambda\theta$ will be known, equal to θP ; and from $\theta\lambda$ (or $P\alpha$) aR will be known. Then, as before, the angle $aR\lambda$, in the triangle $aR\lambda$, will become known [Margin: Euclid I.34], and so on. By the same reasoning, from EP and ET, both known, PT will become known; and so, as before, the angle PRT — the pole's altitude — will again be known. And so on.

PROBLEMA 8. PROPOS. 29.

Given a plane inclined either to both meridian and horizon, or to the meridian only, or to the horizon only, to determine how great the pole's altitude above it is.

[Margin: The pole's altitude above a plane inclined to both meridian and horizon, or to the meridian only — how it is found.] Let ABCD be a circle with centre E, inclined either to both meridian and horizon, or to the meridian only; and let BD be the common section of it and the meridian. Having found — by the corollary of the preceding proposition — the arc of the meridian intercepted between the inclined plane and the north pole of the world, take DF equal to it. Find also, by the corollary of Proposition 25 of this book, the minor diameter of the ellipse which the perpendiculars dropped from the circumference of the meridian onto the inclined plane make; let this be GH, cutting the major diameter BD at right angles. About GH describe a circle, and let the straight line drawn as EF cut its circumference at I. Then through F draw FK parallel to the minor diameter, and through I draw IK parallel to the major diameter, cutting the former at the point K, through which let the diameter AC be drawn; and from K erect KL perpendicular to AC, cutting the circle ABCD at L. I say that the arc CL is equal to the arc which measures the pole's altitude above the plane ABCD. For since the arc DF is equal to the arc of the meridian between the plane ABCD and the pole of the world, the remainder FG will also be equal to the remainder in the meridian from the pole up to the diameter which cuts BD at right angles, and from which perpendiculars fall on the points G and H. Hence, by what was demonstrated in Proposition 26 of this book, the perpendicular dropped from the pole onto the plane ABCD will fall at the point K — the intersection of the diameters BD and GH of the ellipse. For just as, in the figure of that proposition, the arcs DL and LE stand — to which the arcs DK and KA in the inclined circle are equal — so here stand the arcs DF and FO, to which correspond, in the meridian inclined to the circle ABCD, arcs equal from D up to the north pole, and from the pole up to the diameter which cuts BD at right angles. Hence, as was there demonstrated, the perpendicular dropped from K falls

Diagram (Source: printed p. 83). A circle ABCD with centre E, representing the inclined plane seen in projection, with an inscribed ellipse. The horizontal diameter runs B (left) — E — D (right); the oblique diameter AC runs from A (upper left) to C (lower right). A dotted vertical line runs from N (top) through the centre to O (bottom). Within the circle an ellipse is drawn on the diameters BD and GH. From F (lower region) and I (on the line EF) the construction lines FK and IK meet at K (interior, lower right); KL is raised perpendicular to AC, meeting the circle at L (upper right). M (at the bottom) marks the foot of the perpendicular from the pole.

- N (top, on dotted vertical): north point / meridian direction
- A (upper left): end of oblique diameter AC
- B (left): end of horizontal diameter BD
- E (centre)
- H (upper interior): end of ellipse minor diameter GH
- L (upper right): where KL meets the circle
- D (right): end of horizontal diameter BD
- K (interior, lower right): intersection of FK and IK
- I (interior): where EF cuts the inner circle about GH
- G (lower interior): end of ellipse minor diameter GH
- C (lower right): end of oblique diameter AC
- M (bottom): foot of perpendicular from the pole
- F (lower, near M): point on the construction
- O (bottom, on dotted vertical): south point / meridian direction

at the point Q, where the lines LQ and MQ — parallel to the diameters HI and BD of the ellipse — intersect; so likewise it will here be shown that the perpendicular dropped from the pole falls at the point K, where the lines FK and IK — parallel to the diameters GH and BD of the ellipse — intersect. Let, then, KM be the perpendicular falling from the pole, and M the pole; and let the great circle AMC be imagined drawn through the lines AE, KC, and KM, [Margin: Euclid XI.18] which will necessarily be perpendicular to the plane ABCD. Since it passes through the pole of the world M, it will be like the meridian of that inclined plane; the line AC will be the meridian line, and the arc CM will measure the pole's altitude above that same plane. Let the lines EL, EM, CL, and CM also be drawn. [Margin: Euclid I.47] Since, then, the square on EL equals the squares on EK and KL, and the square on EM equals the squares on EK and KM — because the angles EKL and EKM are right, by construction and by Euclid XI, definition 3 — and since the squares on the lines EL and EM (drawn equal from the centre of

the sphere to its surface) are equal, the squares on EK and KL will also equal the squares on EK and KM. Taking away the common square on EK, the square on KL will equal the square on KM, and the line KL will be equal to the line KM. And so, since the sides KL, KC are equal to the sides KM, KC and contain equal angles (namely right angles), the base CL will [Margin: Euclid I.4] be equal to the base CM; [Margin: Euclid III.28] and consequently the arc CL will be equal to the arc CM, which measures the pole's altitude above the plane ABCD. Which was proposed. In this manner Federico Commandino [Federico Commandino] carries the matter through in nearly the same way, although he says nothing of a plane inclined to the horizon only. This same result we shall obtain from sines as follows.

[Margin: The pole's altitude above a plane inclined to both meridian and horizon — by what method it is sought by sines.] Let ABCD be the horizon, AC the meridian, and EF a plane inclined to both meridian and horizon, cutting the meridian at G, wherever this may happen; let H be the pole of the world, and through it and the pole of the inclined plane EF let the great circle BD be described, cutting the inclined plane at I and therefore (by Theodosius, *Spherics* I.15) at right angles; and it will accordingly measure, by the arc HI, the pole's altitude above the plane EF. Now in the spherical triangle GHI, whose angle I is right: as the sine of the meridian arc GH, intercepted between the inclined plane and the pole, is to the sine of the right angle I — that is, to the whole sine — so is (by Proposition 16 of Book 4 of Johannes Regiomontanus [Regiomontanus], *On Triangles*; or by Proposition 13 of Book 1 of Geber [Jābir ibn Aflāḥ]; or indeed by Proposition 41 of our own *Spherical Triangles*) the sine of the arc HI, the pole's altitude above the plane, to the sine of the angle G, the plane's inclination to the meridian. Conversely, therefore: as the whole sine of the right angle I is to the sine of the meridian arc GH intercepted between the plane and the pole, so is the sine of the angle G, the plane's inclination to the meridian, to the sine of the arc HI, the pole's altitude above the plane.

Diagram (Source: printed p. 84). Three spheres drawn side by side, each showing the horizon, meridian, inclined plane, and vertical circle as intersecting great circles, illustrating the several cases of a plane's inclination.

Left sphere:

- A (top), E (just above/left of A): pole of the vertical circle / apex
- B (left): horizon point
- D (right): horizon point
- H (centre): intersection

- B (left), D (right)
- G (centre), I (right of G), H (below centre)
- C (bottom), F (lower right)

[The small central labels G, H, I in each panel are crowded and partly ink-spotted; positions given are best readings]

And so, having found — by the corollary of the preceding proposition — the meridian arc intercepted between the inclined plane and the pole of the world, and also — by Proposition 27 of this book — the plane's inclination to the meridian: if we set it up that, as the whole sine is to the sine of the meridian arc intercepted between the plane and the pole, so is the sine of the plane's inclination to the meridian to a fourth term, we obtain the sine of the pole's altitude above the given plane.

[Margin: First example.] **Example.** Let the meridian arc between the plane and the pole be 30° , and the plane's inclination to the meridian 35° . If, then, we set it up that, as 100000 (the whole sine) is to 50000 (the sine of the arc placed between plane and pole), so is 57357 (the sine of 35° , that is, of the inclination to the meridian) to a fourth term, there will be found here a sine of about $28678\frac{1}{2}$, whose arc — $16^\circ 40'$ — measures the pole's altitude above the given plane.

[Margin: Second example.] **Likewise** let the meridian arc between the plane and the pole be set at 90° — as happens when the plane and the equator cut the meridian at one and the same point — and the plane's inclination to the meridian at $66^\circ 47'$. If, then, we set it up that, as 100000 (the whole sine) is to 100000 (the sine of the arc between plane and pole), so is 91902 (the sine of the inclination to the meridian) to a fourth term, the same sine 91902 will be found, whose arc —

66°47' — contains the pole's altitude above the given plane. Here you see that the pole's altitude above the plane is equal to its inclination to the meridian; for when the plane and the equator cut the meridian at the same point, one and the same arc of the great circle drawn through the poles of the world and through the poles of the plane measures both the pole's altitude above the plane and the inclination of that plane to the meridian — as is evident, since (by Theodosius, *Spherics* I.15) it is perpendicular to the inclined plane. For hence it comes about that it measures the pole's altitude above the plane, like a kind of proper meridian of the inclined plane itself. The same great circle also measures the inclination of that plane to the meridian, because it too is perpendicular to the meridian — which will be made plain thus. [Margin: When the plane is inclined to the meridian only; or to both meridian and horizon, but perpendicular to the vertical circle.] For since it passes through the poles of the plane and through the poles of the equator, the given plane and the equator will in turn pass through its poles, by the scholium to Theodosius, *Spherics* I.15. Hence the points where the plane and the equator intersect on the meridian are the poles of that circle; and therefore the meridian drawn through these poles will (by Theodosius, *Spherics* I.15) be perpendicular to it. And so, in turn, it will be perpendicular to the meridian — which was to be shown.

In the same way the pole's altitude will be found above a plane inclined to the meridian only — namely one which passes through the zenith of the place — and also above a plane which is perpendicular to the vertical circle and inclined both to the meridian and to the horizon. Of this kind is the plane that runs along the common sections of the horizon and the meridian. This can easily be understood from the following two figures. In the first of them the vertical circle is kL, the plane inclined to the meridian only is EF, passing through the zenith G (that is, the pole of the horizon),

and therefore standing at right angles to the horizon, so that the arc GH of the meridian, between the plane and the pole, is equal to the complement of the pole's altitude above the horizon; while its inclination to the meridian is the complement of the same plane's declination from the vertical circle. In the second figure, by contrast, the inclined plane EF passes through the common sections A and C of the horizon and the meridian — that is, through the poles of the vertical circle — and is therefore at right angles to the vertical circle. Hence, if in place of C we take the letter G, where the inclined plane cuts the meridian (so that the arc GH of the meridian between the plane and the pole is equal to the pole's altitude above the horizon, while the plane's inclination to the meridian is the complement of the same plane's inclination to the horizon), the ratio of the whole

sine — that is, of the right angle I — to the sine of the arc GH will always be the same as the ratio of the sine of the angle G to the sine of the arc HI, and so on, as has been demonstrated.

Diagram. A pair of spherical diagrams accompanying the corollary. In each, a circle represents the sphere, with a horizon, a meridian, an inclined plane EF, and a vertical circle drawn as intersecting great-circle arcs.

- Left sphere: A (top), E (upper left), D (right), K (left), L (right of center), B (lower left), C (bottom), F (lower), with interior points G, H, and I near the center — this figure shows the plane passing through the zenith G.
- Right sphere: A (top), B (left, outside the circle), E (upper right), D (right), C (bottom), G (bottom center), F (bottom), with interior points H and I — this figure shows the plane passing through the common sections A and C of horizon and meridian.

[Margin: Example.] **Example of the first case.** Let a plane passing through the zenith be supposed to decline 30° from the vertical circle, and therefore 60° from the meridian. If, then, we set it up that, as 100000 (the whole sine) is to 74314 (the sine of the arc GH intercepted between the plane and the pole), so is 86602 (the sine of the inclination to the meridian) to a fourth term, there will be found here a sine of about 64357, whose arc — $40^\circ 3'$, a little more — gives the pole's altitude above the proposed plane. Again, for an example of the second case, let a plane passing through the common sections of the horizon and the meridian be supposed to decline 30° from the horizon, and therefore 60° from the meridian. And so, if we set it up that, as 100000 (the whole sine) is to 66913 (the sine of the arc GH placed between the plane and the pole), so is 86602 (the sine of the inclination to the meridian) to a fourth term, there will be found here a sine of about 57948, whose arc — $35^\circ 25'$ — will indicate the pole's altitude above the proposed plane.

[Margin: When the plane is inclined to the horizon only.] But if the plane is inclined to the horizon only — that is, if it passes through the common sections of the horizon and the vertical circle and is at right angles to the meridian — then the arc of the meridian set between the plane and the pole will itself be the pole's altitude above that plane, as appears from the figure of the corollary to the preceding proposition. Therefore, given a plane inclined either to the meridian or to the horizon, we can determine how great the pole's altitude above it is. Which was to be done.

PROBLEMA 9. PROPOS. 30.

Given a plane inclined to the meridian, to find how great the arc of that plane is which is intercepted between the meridian and the great circle that is drawn through the plane's own poles and through the poles of the world and measures the pole's altitude above that plane, serving as its proper meridian; and to find how much this great circle is inclined to the meridian of the horizon — that is, of the place in which the inclined plane is considered.

Diagram. Three spherical diagrams for Problem 9, showing the horizon ABCD, the meridian AC, the plane inclined to the meridian EF, and the great circle drawn through the poles, in three positions of the inclined plane.

- First sphere: A (top), E (upper left), D (right), B (left), C (bottom), F (lower right), with interior points H, I, and G.
- Second sphere: A (top), B (upper left), F (right), E (left), C (bottom), D (bottom right), with interior points I, G, and H.
- Third sphere: A (top), D (right), B (left), C (bottom), with interior points E, I, H, F, and G (the plane EF here running nearly vertically).

Let the horizon be ABCD; the meridian AC; the plane inclined to the meridian EF, cutting the meridian at G; the pole of the world H. Through H and through the pole of the inclined plane EF let the great circle BD be described, cutting the inclined plane at I; and since (by *Spherics* I.15 [Theodosius]) this circle is at right angles to the inclined plane itself, it will measure the altitude of the pole H above that plane by the arc HI. It is required, then, to find the size of the arc GI and of the angle GHI. We shall carry this out as follows. Since in the spherical triangle GHI the angle I is a right angle, it follows — by Regiomontanus, *On Triangles* IV.19 [Ioan. Regiomontanus], or by Geber I.15 [Geber], or certainly by proposition 43 of our own *Spherical Triangles* — that as the sine of the complement of the meridian arc GH, intercepted between the plane and the pole, is to the sine of the complement of the arc HI (which measures the pole's altitude above the plane EF), so is the sine of the complement of the arc GI to the whole sine. [Margin: By what device the arc of the inclined plane between its own meridian and the meridian of the horizon may be found.] And therefore, by conversion, as the sine of the complement of the arc HI (of the pole's altitude above the plane EF) is to the sine of the complement of the meridian arc GH between the plane and the pole, so is the whole sine to the sine of the complement of the arc GI. Hence, if we set it up that, as the sine of the complement of the pole's altitude above the inclined plane is to the sine of the complement of the meridian arc between the

plane and the pole, so is the whole sine to a fourth term, there will be obtained the sine of the complement of the plane's arc GI — the arc which, in the triangle GHI, lies opposite the angle H (the inclination of the meridian BD of that inclined plane to the meridian AC of the horizon). And this GI is the arc of the inclined plane intercepted between the meridian of the horizon and the said great circle — that is, the meridian of the inclined plane. And so the arc GI itself will be known.

The same will also be obtained, and more easily, if the inclined plane EF has passed through the zenith G, so that it is one of the vertical circles, as appears in the second figure: for then the arc GH of the meridian between the plane and the pole is the complement of the pole's altitude above the horizon, and the complement of that arc GH is the pole's altitude above the horizon itself, namely the arc HC.

Diagram. Three spherical diagrams repeating the three positions of the inclined plane EF within the horizon ABCD and meridian AC, with the great circle through the poles.

- First sphere: E (upper left), A (top), D (right), B (left), C (bottom), F (lower right), with interior points H, I, and G.
- Second sphere: B (upper left), A (top), F (right), E (left), C (bottom), D (bottom right), with interior points I, G, and H.
- Third sphere: A (top), D (right), B (left), C (bottom), with interior points E, I, H, F, and G (the plane EF running nearly vertically).

Likewise the matter will be easy if the inclined plane EF has passed through the points A and C, where the horizon and the meridian cut one another, so that it is one of the circles of position, as appears in the third figure: for then the arc GH of the meridian between the plane and the pole is the pole's altitude above the horizon, namely the arc HC. It is established, therefore, what was proposed in the first place.

[Margin: How the inclination that the meridian of the inclined plane has to the meridian of the horizon may be found.] **Next**, since — by Regiomontanus, *On Triangles* IV.16, or by Geber I.13, or certainly by proposition 41 of our *Spherical Triangles* — as the sine of the meridian arc GH between the plane and the pole is to the sine of the right angle I (that is, to the whole sine), so is the sine of the arc GI of the plane between the two meridians, which we have already found, to the sine of the angle H (the inclination of the great circle BD, which stands as the meridian of that plane, to the meridian AC of the horizon): if we set it up that, as

the sine of the meridian arc between the plane and the pole is to the whole sine, so is the sine of the arc GI (of the plane between the two meridians, already found) to a fourth term, there will be obtained the sine of the angle H, the inclination sought. Which is the second thing required.

[Margin: First example.] **Example of both.** Let the pole's altitude above the plane be set at $16^{\circ}40'$, and the meridian arc between the plane and the pole at 30° . If, then, we set it up that, as 95798 (the sine of the complement of the pole's altitude above the plane) is to 86602 (the sine of the complement of the meridian arc between the plane and the pole), so is 100000 (the whole sine) to a fourth term, there will be obtained here a sine of about 90401, whose arc contains $64^{\circ}41'$; and this, subtracted from the quadrant, leaves $25^{\circ}19'$ as the arc of the plane itself between the two meridians. Which is the first thing. After this, if we set it up that, as 50000 (the sine of the meridian arc between the plane and the pole) is to 100000 (the whole sine), so is 42762 (the sine of the arc between the two meridians already found) to a fourth term, there will be found here a sine of 85524, whose arc — namely the inclination of the meridian of that plane to the meridian of the horizon — contains $58^{\circ}47'$. Which is the second thing.

Again, let the pole's altitude above the plane be set at $66^{\circ}47'$, and the meridian arc between the plane and the pole at 90° , as happens in a plane declining 30° from the vertical circle, from north toward east, but inclined $52^{\circ}3'$ to the horizon on the south side, at latitude 42° , as may be gathered from what precedes. If, then, we set it up that, as 39420 (the sine of the complement of the pole's altitude above the inclined plane) is to the sine of the complement of the meridian arc between the plane and the pole (which is nothing), so is 100000 (the whole sine) to a fourth term, there will be obtained here a sine of 0, whose arc is $0^{\circ}0'$; and this, subtracted from 90° , leaves the arc of that plane between the two meridians as 90° . Which is the first thing. Again, if we set it up that, as 100000 (the sine of the meridian arc between the plane and the pole) is to 100000 (the whole sine), so is 100000 (the sine of the plane's arc between the two meridians, already found) to a fourth term, there will be found here a sine of 100000, whose arc, 90° , will be the inclination of that meridian to the meridian of the horizon. And this result agrees with what was said above. For since the pole of the meridian of that inclined plane is the point where the equator cuts the meridian (as we said in the preceding proposition), it must be — by the corollary to *Spherics* I.16 [Theodosius] — that the arc of that plane from the said pole up to its own meridian is a quadrant, and so on.

[Margin: Second example.] **Another example, for the second figure.** Let the plane EF be supposed to decline 30° from south toward east, or from north toward west, in the Roman horizon — that is, where the pole is raised 42° above the horizon. The pole's altitude above the plane EF will, by the preceding proposition, be found to be about $40^\circ 3'$. And the meridian arc between that same plane and the pole will contain 48° , which is of course the complement of the pole's altitude above the horizon. If, then, we set it up that, as 76548 (the sine of the complement of the pole's altitude above the plane) is to 66913 (the sine of the complement of the meridian arc between the plane and the pole — a complement which, in inclined planes of this kind, is itself the pole's altitude above the horizon), so is 100000 (the whole sine) to a fourth term, there will be found here a sine of about 87413, whose arc contains $60^\circ 57'$; and this, subtracted from the quadrant, leaves $29^\circ 3'$ as the arc of that plane which lies between its own meridian and the meridian of the horizon. Which is the first thing. Again, if we set it up that, as 74314 (the sine of the meridian arc between the plane and the pole) is to 100000 (the whole sine), so is 48557 (the sine of the arc between the two meridians, already found) to a fourth term, there will be found here a sine of about 65340, whose arc comprises $40^\circ 48'$. So great is the inclination of the meridian of that plane to the meridian of the horizon. Which is the second thing.

[Margin: Third example.] **For the third figure, take this example.** Let the plane EF be supposed to decline 60° from the meridian, and therefore 30° from the horizon. The pole's altitude above it (namely the arc HI), found by the preceding proposition, will be $35^\circ 25'$. And so, if we set it up that, as 81495 (the sine of the complement of the pole's altitude above the plane) is to 74314 (the sine of the complement of the meridian arc between the plane and the pole — that is, in this example, the sine of the complement of the pole's altitude above the horizon), so is 100000 (the whole sine) to a fourth term, there will be found here a sine of about 91188, whose arc contains $65^\circ 46'$; and this, subtracted from the quadrant, leaves $24^\circ 14'$ as the arc of that plane intercepted between its own meridian and the meridian of the horizon, namely the arc GI. Which is the first thing. Again, if we set it up

that, as 66913 (the sine of the meridian arc between the plane and the pole — namely, in this example, the sine of the pole's altitude above the horizon) is to 100000 (the whole sine), so is 41045 (the sine of the arc GI between the two meridians, already found) to a fourth term, there will be found here a sine of about 61341, whose arc comprises $37^\circ 50'$. So great is the inclination of the meridian of that plane to the meridian of the horizon — that is, so great is the

angle GHI, or the arc of the equator set between the two meridians. Which is the second thing.

[Margin: When the inclined plane passes through the poles of the world.] If the inclined plane passes through the pole, there will be no arc of it interposed between the meridian of the horizon and the meridian of the inclined plane; and the complement of the plane's inclination to the meridian will be the inclination of that plane's meridian to the meridian of the horizon, as is evident on a material sphere. Therefore, given a plane inclined to the meridian, how great the intercepted arc is, and so on. Which was to be done.

PROBLEMA 10. PROPOS. 31.

Given a plane inclined to the meridian, to find how great the arc of that plane is which is intercepted between the great circle that passes through its own poles and the poles of the horizon (and measures its inclination to the horizon), and both its proper meridian — namely the great circle that is drawn through its poles and the poles of the world and measures the pole's altitude above it, serving as its proper meridian — and the meridian of the horizon.

Diagram. Three spherical diagrams for Problem 10, each showing the horizon ABCD, the meridian AC, the vertical circle kL, the inclined plane EF (cutting the meridian at G), its meridian BD (through its pole P and the pole of the world H), and the great circle NO measuring the inclination to the horizon.

- First sphere: A (top), E (upper left), D (upper right), O (right), K (far left), L (far right), N (lower left), B (bottom left), C (bottom), F (bottom right), with interior points M, P, Q, I, and H.
- Second sphere: A (top), E (left), D (upper right), O (right), K (far left), L (far right), N (lower left), B (bottom left), C (bottom), F (bottom right), with interior points M, P, Q, G, H, and I.
- Third sphere: A (top), E (upper left), D (right), O (right), K (left), L (right), N (lower left), B (left), C (bottom), F (bottom right), with interior points G, M, Q, P, H, and I.

Let the horizon be ABCD; the meridian AC; the vertical circle kL; the plane inclined to the meridian EF, cutting the meridian at G; its meridian BD, passing through its pole P and through the pole of the world H; and the great circle NO, which measures the inclination of the plane to the horizon — that is, described through the zenith M (the pole of the horizon) and through P (the pole of the inclined plane) — cutting the inclined plane at Q. It is required to find both the

arc IQ and the arc GQ. Since the arcs MN and PQ are quadrants (by the corollary to *Spherics* I.16 [Theodosius], since M is the pole of the horizon ABCD and P is the pole of the plane EF), then, the common arc MQ being taken away, PM will be an arc equal to the arc QN, which measures the inclination of the plane to the horizon. Therefore, since in the spherical triangle HPM — by Regiomontanus, *On Triangles* IV.17, or by Geber I.13, or certainly by proposition 41 of our *Spherical Triangles* — it holds that as the sine of the arc PM (which is equal to the plane's inclination to the horizon) is to the sine of the angle H (the inclination of the meridian of that inclined plane to the meridian of the horizon), so is the sine of the arc HM (the complement of the pole's altitude above the horizon) to the sine of the angle P (that is, to the sine of the arc IQ): [Margin: By what route the arc of the inclined plane lying between the great circle drawn through its poles and the poles of the horizon and its own proper meridian may be known.] if we set it up that, as the sine of the inclination to the horizon is to the sine of the inclination of the meridian of that inclined plane to the meridian of the horizon (found by the preceding proposition), so is the sine of the complement of the pole's altitude above the horizon to a fourth term, there will be obtained the sine of the first arc IQ, which is sought.

Again, when the arc of the great circle has been drawn through the points G and P, there will be two arcs GP and GM of the spherical triangle GMP that are known. For GP is a quadrant, by the corollary to *Spherics* I.16 [Theodosius], since P is the pole of the circle EF; and the arc GM is known, because it lies between the inclined plane and the zenith M, and hence, by the corollary to proposition 28 of this book, it is known, being the complement of the meridian arc between the inclined plane and the horizon. [Margin: By what device the arc of the inclined plane lying between the great circle drawn through its poles and the poles of the horizon and the meridian of the horizon may be explored.] Likewise the angle GMP is known. For since the circle ON, drawn through the poles P and M of the circles EF and EBF, bisects the arcs EF and EBF (by *Spherics* II.9 [Theodosius]) — and EBF is a semicircle (by *Spherics* I.11) — EN will be a quadrant, and therefore equal to the quadrant kC. The common arc kN being taken away, then, the arc Ek (of the declination of the plane EF from the vertical circle) will be left equal to the arc NC, and so the arc NC is known. Hence the angle NMC is also known, and consequently the remaining angle GMP out of the two right angles is known. Now since, in the spherical triangle GPM — by Regiomontanus, *On Triangles* IV.17, or by Geber I.13, or certainly by proposition 41 of our *Spherical Triangles* — it holds that as the sine of the arc GP (namely the whole sine) is to the sine of the angle GMP (namely the sine of the plane's declination from the vertical circle; for the arcs NC and CO, of the angles NMC and CMO, or GMP, since they make up a

semicircle, have the same sine), so is the sine of the arc GM (of the meridian which lies between the plane and the zenith M) to the sine of the angle GPM (that is, to the sine of the arc GQ): if we set it up that, as the whole sine is to the sine of the declination, so is the sine of the meridian arc placed between the plane and the zenith to a fourth term, there will be obtained the sine of the second arc GQ, which is sought.

[Margin: Example.] **Example of both.** Let the inclination to the horizon be set at $52^{\circ}3'$, and the inclination of the meridian BD of the inclined plane EF to the meridian AC of the horizon at 90° . If, then, we set it up that, as 78854 (the sine of the inclination to the horizon) is to 100000 (the whole sine — namely to the sine of the inclination of the meridians), so is 74314 (the sine of the complement of the pole's altitude above the horizon) to a fourth term, there will be found here a sine of about 94242, whose arc, about $70^{\circ}28'$, is intercepted between the meridian of the inclined plane and the great circle that measures the plane's inclination to the horizon.

Again, if we set it up that, as 100000 (the whole sine) is to 50000 (the sine of the plane's declination from the vertical — for we assume the same plane we treated just now, declining from the vertical, from north toward the east, by 30° , in such a way that its inclination falls toward the south), so is 66913 (the sine of the meridian arc intercepted between the plane and the zenith) to a fourth term: there will be found here a sine of about 33456, to which corresponds an arc of nearly $19^{\circ}33'$, intercepted between the meridian of the horizon and the great circle that measures the plane's inclination to the horizon. (That intercepted arc indeed comprises 42° ; for the arc between the plane and the horizon contains, by proposition 28 of this book, 48° below the horizon toward the north, which, taken from a quadrant, leaves the arc of 42° between the inclined plane and the zenith toward the south, by the corollary to proposition 28 of this book.) Given, therefore, a plane inclined to the meridian, [we have found] how great is its arc intercepted between the great circle passing through its own poles and through the poles of the horizon; and it measures its inclination to the horizon, and likewise its own proper meridian, and so on. Which was to be done.

PROBLEMA 11. PROPOS. 32.

Given a plane inclined to the horizon and declining from the vertical, to find how great is the arc — of the great circle that measures its inclination to the horizon — lying between the horizon and the circle of the sixth hour from noon (or from midnight).

[Margin: The arc of the great circle that measures, for a plane declining from the vertical, its inclination to the horizon — lying between the horizon and the circle of the sixth hour from noon or from midnight — how it is to be investigated.]

Let ABCD be the horizon; AC the meridian; BID the vertical; EF the plane inclined to the horizon and declining from the vertical; GH the great circle that measures its inclination above the horizon, passing through the zenith I (that is, the pole of the horizon) and through M, the pole of the inclined plane; and finally BKD the circle of the sixth hour from noon or midnight, drawn through the pole of the world K and through B and D — the common sections of the horizon and the vertical — cutting the circle GH at L. Let it be required to find the arc LH.

Now in the spherical triangle DHL the angle H is right, by proposition 13 of book 1 of Theodosius, because the circle GH is drawn through I, the pole of the horizon ABCD; and the angle D is the angle of the pole's altitude, since D is the pole of the meridian. (For it comes about hence, by the corollary to proposition 16 of book 1 of Theodosius, that the arcs DC and Dk are quadrants, and consequently the arc Ck — of the pole's altitude above the horizon — measures the angle CDk.)

Therefore, by proposition 18 of book 4 of Johannes Regiomontanus

[Regiomontanus], *On Triangles*, or by proposition 14 of book 1 of Geber, or indeed by proposition 42 of our *[On] Spherical Triangles*: as the sine of the angle HDL (of the pole's altitude) is to the whole sine, so is the sine of the complement of the angle L to the sine of the complement of the arc DH — that is, to the sine of the arc CH, which is equal to the plane's declination from the vertical. (For since the circle GH, drawn through the poles of the horizon and of the circle EF, bisects the arcs ENF and EHF — by proposition 9 of book 2 of Theodosius — and the arc EHF is a semicircle — by proposition 11 of book 1 of Theodosius — EH will be a quadrant, and thus equal to the quadrant DC. Therefore, the common arc DH being taken away, the remaining arc DE, of the plane's declination from the vertical, will be equal to the remaining arc CH.)

By conversion, then: as the whole sine is to the sine of the angle HDL (of the pole's altitude), so is the sine of the complement of the arc DH — that is, the sine of the plane's declination from the vertical — to the sine of the complement of the angle L. Therefore, if we set it up that, as the whole sine is to the sine of the pole's altitude above the horizon, so is the sine of the declination to a fourth term, there will be obtained a sine whose arc, subtracted from a quadrant, leaves the angle L, known.

And since, by proposition 16 of book 4 of Johannes Regiomontanus, *On Triangles*, or by proposition 13 of book 1 of Geber, or indeed by proposition 41 of our *[On]*

Spherical Triangles, it holds in the same triangle that, as the sine of the angle L just found is to the sine of the arc DH (the complement of the declination), so is the sine of the angle HDL (of the pole's altitude) to the sine of the arc LH: if we set it up that, as the sine of the angle L found is to the sine of the complement of the declination, so is the sine of the pole's altitude above the horizon to a fourth term, there will be obtained the sine of the arc LH, which is sought.

Diagram. A sphere (bounding circle) carrying the horizon, meridian, vertical, the inclined-declining plane EF, its measuring great circle GH, and the six-o'clock circle BKD, for Problema 11 / Propos. 32. The figure is crowded with fine interior labels; several are only partly legible. Readable labels:

- A (top): apex point of the meridian
- G (upper left): endpoint of the great circle GH measuring the plane's inclination
- E (upper right): endpoint of the inclined plane EF
- N (upper-centre, interior): point on the great circle GH
- I / l (centre, interior): the zenith, pole of the horizon (intersection region L nearby)
- B (left): common point of horizon and vertical
- D (right): common point of horizon and vertical (pole of the meridian)
- K (lower-centre, interior): pole of the world
- M (lower-centre, interior): pole of the inclined plane
- H (lower right): endpoint of the great circle GH
- C (bottom): lower apex of the meridian
- F (position [?]): endpoint of the inclined plane EF — not clearly resolved on the scan
- (lower-left label, [?]): a peripheral point not securely read

[Margin: Example.] **First example.** Let the plane be inclined to the horizon by 30° , and declining from the vertical by 20° . Set it up that, as 100000 (the whole sine) is to 66913 (the sine of the pole's altitude), so is 34202 (the sine of the declination) to a fourth term: there will be found here a sine of nearly 22885, whose arc — $13^\circ 14'$ — subtracted from a quadrant leaves the angle L of $76^\circ 46'$. Again, set it up that, as 97344 (the sine of the angle L found) is to 93969 (the sine of the complement of the declination), so is 66913 (the sine of the pole's altitude) to a fourth term: there will be obtained here a sine of about 64593, to which correspond $40^\circ 14'$, for the arc LH sought.

[Margin: Second example.] **Again**, let the plane be inclined to the horizon by $52^{\circ}3'$, and declining from the vertical by 30° . Set it up that, as 100000 (the whole sine) is to 66913 (the sine of the pole's altitude), so is 50000 (the sine of the declination) to a fourth term: there will be found here a sine of nearly 33456, whose arc — $19^{\circ}33'$ — taken from a quadrant leaves the angle L of $70^{\circ}27'$, which the great circle measuring the plane's inclination to the horizon makes with the circle of the sixth hour from noon or midnight.

Set it up again that, as 94234 (the sine of the angle L found) is to 86602 (the sine of the complement of the declination), so is 66913 (the sine of the pole's altitude) to a fourth term: there will be obtained here a sine of nearly 61493, to which correspond $37^{\circ}57'$, for the arc LH sought. Therefore, given a plane inclined to the horizon, and so on. Which was to be done.

SCHOLIUM

[Margin: To what end the six preceding propositions serve.]

We have set out the last six problems because their remarkable usefulness will appear in sundials whose planes — on which the dials are laid out — are parallel to great circles that either decline from the vertical and are perpendicular to the horizon; or decline from the horizon and are perpendicular to the vertical; or, finally, both decline from the vertical and are inclined to the horizon — as will become clear from what follows.

PROBLEMA 12. PROPOS. 33.

Given the diurnal (or nocturnal) arc and the latitude of the place, to find the declination from the equator of the parallel belonging to that arc.

[Margin: The declination of the parallel whose diurnal arc contains however many hours one may propose — by what device it is found, by means of the analemma. [Euclid I.29].]

Let any circle ABCD be divided, with center P and with the two diameters AC and BD cutting one another at right angles, into twenty-four equal hours — together with the half-hours and quarters, if desired — beginning at any one of the points A, B, C, D. Now count off from the point B, on either side, the semidiurnal arc BE, BF; or from D, on either side, the seminocturnal arc DE, DF, so that the whole arc EBF is, say, the diurnal arc of 14 hours, or EDF the given nocturnal arc of 10 hours. Draw the straight line EF cutting BD at G. This line, because the arcs AE

and CF are equal, will be parallel to AC — by what we demonstrated with regard to proposition 27 of book 3 of Euclid — and thus perpendicular to BD.

Now construct the angle PGk equal to the angle of the equator's altitude, that is, to the complement of the pole's altitude; and let the straight line Gk cut the straight line AC at the point k, from which draw the straight line kB. I say that PBk is equal to the angle of declination of that parallel whose diurnal arc comprises as many hours as there are in the arc EBF — namely 14. For, the straight line kD being drawn, describe the circle BOMN with center K and radius Bk (or KD). For the straight lines KB and KD are equal to one another; since the sides BP, PK are equal to the sides DP, PK in the triangles BPK and DPK, and contain equal angles (being right angles), the straight lines KB and KD will be equal. [Margin: Euclid I.4.] Then through K draw the diameter LM parallel to BD; and extend the straight line GK on either side. Now since the angle PGK is, by construction, [equal to] the complement of the pole's altitude, the angle PKG will be [equal to] the pole's altitude.

Hence the arc IN will measure the pole's altitude above the horizon; and so, if the circle NLOM be taken to be the meridian, then HI will be the common section of the meridian and the horizon; NO the axis of the world; LM the common section of the meridian and the equator; and BD the common section of the meridian and the parallel ABCD, whose diurnal arc EBF is given. For EF is the common section of the horizon and the parallel ABCD, which thus comes to lie in the plane [of the drawing]. Since both the horizon (drawn through HI) and the parallel ABCD are perpendicular to the meridian NLOM — supposing these circles to have their proper position in the sphere — their common section, which indeed falls at G, where the horizon and the said parallel intersect, will likewise be perpendicular to the meridian [Margin: Euclid XI.19.]; and thus, by definition 3 of book 11 of Euclid, perpendicular to the straight line BD lying in the meridian. Since, then, EF, drawn through G, has been shown to be perpendicular to the straight line BD, EF will be the common section of the horizon and the parallel ABCD. Therefore BL, in the meridian NLOM, is the arc of declination of the parallel ABCD from the equator, and so BKL is the angle of that same declination — to which indeed the alternate angle PBK is equal [Margin: Euclid I.29.], which is what was proposed.

Diagram. The analemma wheel for Problema 12 / Propos. 33: a circle ABCD with center P, the two perpendicular diameters AC and BD, its circumference graduated into twenty-four hours (the rim numbered 1–12 twice, with intermediate tick-marks for half- and quarter-hours), the chord EF, the auxiliary circle BOMN centered at K with the diameter LM, and the lines GK and NLOM.

The figure is very densely labelled and several interior/rim labels are only partly legible; it is flagged as a Readable labels:

- A (top): upper end of the diameter AC
- E (top, just right of A): endpoint of the semidiurnal arc / chord EF
- B (left): left end of the diameter BD
- D (right): right end of the diameter BD
- C (bottom): lower end of the diameter AC
- N (upper-centre, interior): point of the meridian circle NLOM
- P (centre): center of the circle ABCD
- G (centre, right of P): foot of the perpendicular / intersection of EF with BD
- I (mid-left, interior): point on the construction
- K (centre, below P): center of the auxiliary circle BOMN
- L (centre-left / lower, interior): point of the diameter LM (meridian–equator section)
- M (right, lower, interior): opposite end of the diameter LM
- R (lower-centre, interior): point on the construction
- O (bottom, interior): lower point of the meridian circle NLOM / axis NO
- H (lower left): common section point of meridian and horizon
- F (bottom, near C): endpoint of the seminocturnal arc / chord EF
- rim numerals 1–12 (twice around): the twenty-four hour divisions
- (points Q, and one further peripheral label near E: [?] — not securely resolved)

In the same way we shall find QBP, the angle of declination of the parallel whose diurnal arc contains 13 hours; likewise RBP, the angle of declination of the parallel whose diurnal arc comprises 15 hours, and so on. By similar reasoning we shall find the angle of declination of the southern parallel whose diurnal arc contains fewer hours than 12 — namely 9, or 8, and so on. For in the same figure, if from the point D one counts off on either side, say, the semidiurnal arc DE, DF of 5 hours, and does the rest as before, then HI will be the common section of the horizon and the meridian; the arc HO will number the pole's altitude above the horizon; BD will be the southern parallel; and the angle of declination will be PDK (or DKM), and so with the rest.

The same southern parallel, whose diurnal arc is given — namely of 10 hours — will be found in this way. Count off from the point B, on either side, the semidiurnal arc — that is, 5 hours in the given example. Then through the extremities of these semidiurnal arcs draw a straight line cutting the straight line

BD at a point; and through that point, if a line be drawn parallel to HI — making, of course, with BD an angle equal to the angle BGH, the complement of the pole's altitude — it will cut the straight line AP at a point; and a straight line drawn from B to that point will make with the straight line BD the sought angle of declination, which will be exactly equal to the angle PDK (or PBK). And so with the rest. An example of this you will find in the second figure of the following scholium.

It is nevertheless better to find the declinations of the northern parallels, for their declinations are equal to the declinations of the corresponding southern parallels. Thus the declination of a northern parallel whose diurnal arc contains 14 hours equals the declination of the southern parallel whose diurnal arc comprises 10 hours — namely the one that together with it makes up 24 hours. For the nocturnal arc EDF of the northern parallel — whose diameter is BD and whose declination is DM — is equal, by proposition 19 of book 2 of Theodosius, to the diurnal arc of the southern parallel that is equal and opposite to the former; that is, the one that has an equal declination. Hence, once the declination of the northern parallel is found, one also has the declination of the opposite southern parallel, equal to it, whose diurnal arc together with the diurnal arc of the former completes 24 hours.

[Margin: The declination of a parallel whose diurnal arc is known — by what technique it may be sought out by means of sines.]

But since the method just described requires an accurate division of the circle ABCD into hours, half-hours, and quarters, we shall be able to obtain the same result from the sines, without any division of the circle, by this device. Let ABCD be the analemma, with center E; BD the horizon; AC the equator; HI the parallel, whether northern or southern; FG the axis of the world, cutting the parallel at K. From K, about HI, describe the semicircle HMI of the parallel, which the axis, produced, meets at M. From L also draw the perpendicular LN to HI, which will be the common section of the parallel

HMI and of the horizon. [Margin: Euclid XI.19.] (For since both the horizon and the parallel are perpendicular to the meridian, their common section will likewise be perpendicular to the same meridian at the point L, where they mutually cut one another, and consequently perpendicular also to the straight line HI, by definition 3 of book 11 of Euclid. Therefore LN, perpendicular to HI, will be the common section of the horizon and the parallel.) And thus HN will be the semidiurnal arc of the said parallel, which is assumed known. Finally, join the straight line EH.

Now in the triangle EKL, if the straight line EL be taken as the whole sine, the straight line KL is the sine of the angle KEL (of the pole's altitude), and EK is the sine of the angle ELk (of the complement of the pole's altitude). If, then, we set it up that, as KL (the sine of the pole's altitude) is to EK (the sine of the complement of the pole's altitude), so is KL — insofar as it is the right sine of the arc MN, by which the semidiurnal arc HN (known) and the quadrant HM differ from one another — to a fourth term: the straight line Ek will become known, in the parts of the whole sine KH, with respect to which KL is the right sine of the arc MN.

Since, then, the two squares of the straight lines EK and kH are equal to the square of the straight line EH [Margin: Euclid I.47.], if there be added together the square of the whole sine KH and the square of the straight line EK — now made known in the parts of the whole sine KH — the square of the straight line EH will be known, and its square root will give the straight line EH, known in the same parts of the whole sine kH. And so, if we set it up that, as EH (insofar as it is known in the parts of the whole sine KH) is to EK (insofar as it is known in the same parts), so is EH (insofar as it is the whole sine) to a fourth term: EK will become known in the parts of the whole sine EH. Hence also AH, the arc corresponding to the sine Ek, will be known from the table of sines — namely the declination of the parallel whose diurnal arc, and consequently whose semidiurnal arc HN, is assumed known.

Diagram. The analemma-wheel construction for the sine method (triangle EKL, semicircle HMI, etc.): a circle crossed by many diameters, with center E, carrying the parallel HI, the axis FG, and the auxiliary points K, L, M, N. The figure is heavily ruled and densely labelled, with several letters repeated around the rim; it is flagged as a Readable labels:

- A (upper left, outside rim): apex marker
- H (top): upper endpoint of the parallel/arc
- M (upper right): point where the produced axis meets the semicircle
- N (right): point of the construction
- F (mid-right): endpoint of the axis FG
- D (right): rim point
- E (center): center of the circle / vertex of triangle EKL
- K (upper-centre and lower-centre, interior): the axis-parallel section point(s)
- L (centre, below E): foot of the perpendicular LN
- B (left): rim point

- I (mid-left, interior; also lower right): endpoint(s) of the parallel HI
- G (bottom / lower-left): endpoint of the axis FG
- C (lower right): rim point
- (further repeated rim labels H, I, M, N at the lower half: [?] — not all separately resolved)

[Margin: The declination of a parallel whose diurnal arc is given — by what other way it is to be investigated (per [?]).]

Example. Let the diurnal arc be given as 14 hours (or 10), and thus the semidiurnal arc HN as 7 hours (or 5) — that is, 105° (or 75°). From this the arc MN will be one hour, namely 15° , since the quadrant HM contains 6 hours, that is 90° . If, then, we set it up that, as kL (the sine of the pole's altitude) 66913 is to EK (the sine of the complement of the pole's altitude) 74314, so is KL (the sine of the arc MN, by which the semidiurnal arc differs from a quadrant — namely, in the given example, the sine of the arc of 15° , which is 25881) to a fourth term: EK will be found of about 28744 parts, of which KL is 25881. But since KH, the whole sine, is 100000 of the same parts: if the squared numbers of the sines EK and KH are added together, the square of the straight line EH will be about 10826217536 parts, and thus the straight line EH will be about 104049 parts with respect to the whole sine KH. Therefore, if we set it up that, as EH 104049 is to EK 28744, so is EH the whole sine 100000 to a fourth term: EK will be found — the sine of the declination of the parallel HI, with respect to the whole sine EH — of about 27625 parts, whose arc is $16^\circ 2'$. Such is the declination of the parallel HI: northern, indeed, if the day is greater than 12 hours, but southern if less. The same reasoning holds in the rest.

[Margin: The declination of a parallel whose diurnal arc is given — by what other method it is to be investigated.]

We shall obtain the same thing more easily by spherical triangles, in this way. Let ABCD be the horizon; AC the meridian; BD the equator, cutting the meridian at E; FG the parallel, whether northern or southern, cutting the meridian at K, so that FK is the given semidiurnal arc. Through the points H and F — of which H is the arctic pole — draw, by proposition 20 of book 1 of Theodosius, the great circle HF, cutting the equator at I. The arc IE of the equator will be similar to the given semidiurnal arc FK, by proposition 10 of book 2 of Theodosius, and therefore known — of just as many degrees as the arc FK comprises. And since IE is the arc of the angle IHE — because the arcs HE and HI are quadrants, by the corollary to proposition 16 of book 1 of Theodosius — the angle IHE will be of as many

degrees as the given semidiurnal arc contains. Therefore also the remaining angle IHC, out of two right angles (which contain 180°), will be known.

Now since in the spherical triangle CFH the angle C is right (for the meridian AC, drawn through the pole of the horizon, is perpendicular to the horizon, by proposition 15 of book 1 of Theodosius), and none of the arcs is a quadrant (because CH, the arc of the pole's altitude, is always less than a quadrant; and CB, the arc of the horizon between the meridian and the equator, is a quadrant; and consequently, if the parallel is northern, the arc CF is less than a quadrant, or if the parallel is southern, greater than a quadrant; likewise the arc HI, between the pole and the equator, is a quadrant, and therefore HF is less than a quadrant in a northern parallel, but greater than a quadrant in a southern one): by proposition 18 of book 1 of Johannes Regiomontanus, *On Triangles*, or by proposition 14 of book 1 of Geber, or by proposition 42 of our *[On] Spherical Triangles*, as the sine of the known angle CHF is to the whole sine, so is the sine of the complement of the angle CFH to the sine of the complement of the arc CH. And by conversion: as the whole sine is to the sine of the known angle CHF, so is the sine of the complement of the arc CH (of the pole's altitude) to the sine of the complement of the angle CFH. Since, then, the first three are known, the fourth will also be known — namely the sine of the complement of the angle CFH — by the rule of proportions; and thus also the complement of the angle, from the table of sines, and the angle CFH itself, and its opposite

Diagram. The spherical-triangle construction (CFH) for the "easier" method: a sphere with the meridian AC vertical, the equator BD, the parallel FG, and the great circle HF, meeting at the points that form the triangle CFH. Readable labels:

- A (top): upper pole of the meridian AC
- K (upper, on meridian): intersection of the parallel with the meridian
- E (center): intersection of the equator BD with the meridian AC
- K (lower, on meridian): second parallel–meridian intersection
- H (bottom-center): the arctic pole
- C (bottom): lower pole of the meridian AC
- F (upper left) and F (lower left): endpoints of the parallel FG
- B (left, interior): left end of the equator BD
- I (left, interior): intersection of the great circle HF with the equator
- G (upper right) and G (lower right): endpoints of the parallel FG
- D (right): right end of the equator BD

and thus also the complement of the angle, from the table of sines, and the angle CFH itself, together with its vertically opposite angle — namely IFB, if the parallel is northern — will be known.

Again, in the spherical triangle BFI the angle BFI is known, and the angle FBI is equal to the altitude of the Equator above the horizon — that is, to the complement of the pole's altitude. Now by proposition 16 of book 4 of Johannes Regiomontanus [Regiomontanus], *On Triangles*, or by proposition 13 of book 1 of Geber [Jābir ibn Aflāḥ], or certainly by proposition 41 of our *[On] Spherical Triangles*, we have: as the sine of the known arc IB (for IB is the difference between the given semidiurnal arc IE and the quadrant BE) is to the sine of the known angle BFI, so the sine of the arc IF is to the sine of the angle IBF, the altitude of the Equator. And by conversion: as the sine of the known angle BFI is to the sine of the known arc IB, so the sine of the known angle IBF is to the sine of the arc IF. Since the first three are known, the fourth will also be known, by the rule of proportions — namely the sine of the arc IF, the declination of the proposed parallel; and therefore the arc of declination IF itself will become known.

And so, if we arrange that as the whole sine is to the sine of the arc by which the given semidiurnal arc differs from a semicircle — that is, to the sine of the angle CHF (which together with EHI, the angle of the semidiurnal arc, makes up two right angles) — so the sine of the complement of the arc CH, the altitude of the pole, is to a fourth term: then the sine of the complement of the angle CFH, or IFB, will be found; and hence the complement of that angle will be known, and from it the angle IFB itself. And if again we arrange that as the whole sine is to the sine of the arc IB, by which the semidiurnal arc differs from a quadrant, so the sine of the altitude of the Equator — or of the complement of the pole's altitude, namely the angle IBF — is to a fourth term: then the sine of the arc IF, the sought declination of the parallel FG, will be produced; and consequently, from the table of sines, the declination itself will also become known.

Example. [Margin: *Exemplum.*] Let the diurnal arc again be given as one of 14 hours, or of 10; and hence the semidiurnal arc IE as one of 7 hours, or of 5 — that is, 105° or 75° . From this the arc IB will comprise one hour, that is 15° . If, then, we arrange that as 100000, the whole sine, is to 96592, the sine of the angle CHF — for since the arc IE will comprise 7 hours or 105° (we are speaking here of a northern parallel), the remaining arc of the semicircle will comprise five hours, that is 75° , to which the aforesaid sine 96592 belongs; whereas if a southern parallel is in question, the arc IE will be of 5 hours or 75° , and the remainder of

the semicircle of 7 hours, that is 105° , to which the same sine corresponds — so is 74314, the sine of the complement of the arc CH (the altitude of the pole), to a fourth term: then the sine of the complement of the angle CFH, or IFB, will be found to be 71781, to which corresponds an arc of $45^\circ 52'$. Its complement, $44^\circ 8'$, will be the magnitude of the angle IFB. If then we again arrange that as 69633, the sine of the angle IFB, is to 25881, the sine of the arc IB of 15° , so 74314, the sine of the angle IBF (or of the altitude of the Equator), is to a fourth term: the sine of the arc of declination IF will be found to be about 27621. Hence the arc of declination IF itself will comprise about $16^\circ 2'$, just as before. In the same way we shall find that the parallel whose diurnal arc comprises 15 hours, or 9, has a declination of about $23^\circ 2'$; and so for the rest. And thus, given the diurnal arc and the latitude of the place, we have found the declination of that arc's parallel from the Equator. Which was to be done.

A shorter way. Arrange that as the tangent of the pole's altitude is to the whole sine, so the sine of the difference between the given semidiurnal arc and a quadrant is to a fourth term: the tangent of the declination will be found — as was shown in the *Astrolabe*, book 1, lemma 49, no. 17. Or rather, arrange that as the whole sine is to the sine of the aforesaid difference, so the tangent of the complement of the pole's altitude is to a fourth term: and the tangent of the declination will be found — as is clear, by the first method, from problem 11 of the *Spherical Triangles* and the last lemma of book 1 of the *Astrolabe*, and from the triangle BIF.

SCHOLIVM.

Andreas Schoner [Andreas Schöner], in the work he entitled *Gnomonice*, investigates the declinations of given diurnal arcs in this way. [Margin: The declinations of all diurnal arcs, and by what method Andreas Schöner investigates them.] From center A, with any radius, describe a circle — or at least a portion of it — of any straight line AB; and take two arcs BC, BD equal to the complement of the pole's altitude, so that if AB is taken as the common section of the Equator and of the meridian CBD, the arcs BC, BD are the declinations of two parallels. Of these, one is the greatest of the parallels that always appear (having a diurnal arc of 24 hours, since it lies wholly above the horizon), and the other is the greatest of those that are always hidden (having a diurnal arc of 0 hours, since it lies wholly below the horizon). Now draw the straight line CD, cutting AB itself at E: the lines EC, ED will be equal, and the angles at E right — which we shall show by the same demonstration we used in proposition 1 of this book to prove that the line MN in the analemma is bisected, and that the angles at O are

right. Then, from center E, with radius EC or ED, describe a circle, and divide it into 48 equal parts. Join, by straight lines, each pair of points equally distant from the point C or D; and through the points where those lines cut the line CD, draw straight lines from A out to the circumference CBD. For these will cut off the arcs of declination of all the diurnal arcs, beginning from the 24-hour arc down to the 0-hour arc, as the numbers marked in the figure indicate. Andreas Schöner offers no demonstration of this procedure; nevertheless I have confirmed by many trials that the declination-angles found by this method are equal to the declination-angles obtained from our own demonstration.

Diagram. Andreas Schöner's construction for the declinations of the diurnal arcs. A full circle represents the meridian CBD; from an apex A at the top a fan of straight lines (the "radii") descends to a lower arc. Readable labels:

- A (top center): apex from which the radii are drawn
- B (bottom center): lower point of the meridian; start of the graduation
- C (left): left point of the meridian circle
- D (right): right point of the meridian circle
- E (center of the lower region): center of the small circle divided into 48 equal parts; intersection of CD with AB
- The lower arc (running from C through B to D) is graduated with the hour-values of the diurnal arcs, from 24 at one end down to 0 at the other. Legibly read numerals along the arc include 24, 19, 18, 17, 15, 14, 13, 12, 11, 10, 8, 7, 6, 5 [several of the intermediate small numerals are at the resolution floor — [?]].

In what follows we shall call the lines in this figure of Andreas Schöner's — drawn out from A, or falling from B in our own following figure — the *radii of the diurnal arcs*; for when the Sun is on the parallels whose declinations are indicated by the said lines, they represent the rays which the Sun casts through the center of the world, just as we said of the *rays of the signs* in proposition 1, rays which indeed display the declinations of those same signs. And the radius of the 12-hour diurnal arc is the same as the radius of the Equator, as is evident.

For the rest, it will generally be enough to investigate the declinations of those diurnal arcs contained between the Equator and the tropic of ♋ [Cancer] — as at Rome, the arcs of 13, 14, and 15 hours. For these declinations are equal to the declinations of the diurnal arcs placed between the Equator and the tropic of ♏ [Capricorn], namely those of 11, 10, and 9 hours, and so on. Of the remaining

diurnal arcs, placed beyond the tropics, there is no use in sundials — except for a few, which are required for laying out the lines of the hours

from sunrise or sunset, and of the unequal hours; such above all are the radii of the diurnal arcs that comprise 24, 0, 18, and 6 hours, as we shall point out in its place.

[Margin: How the declinations of all diurnal arcs may be found from our own demonstration.] But should Andreas Schöner's procedure perhaps seem suspect to anyone — on the ground that, brief and easy though it is, it is established by no geometrical reasoning (that practice will, however, be demonstrated by us in book 8, chapter 6) — we shall be able, from our own demonstration, and with nearly the same brevity and ease, to construct a figure like the one he described, one that contains the declinations of all the diurnal arcs, in this way. From center P describe a circle ABCD of any size. First draw in it two diameters AC and BD, cutting each other at right angles at the center P, and divide it into 48 equal parts, beginning from the point B. Then join, by straight lines, each pair of points equally distant from the point B; these lines will cut the diameter BD at certain points. Through these points draw straight lines making with BD angles equal to the complement of the pole's altitude; these will cut the diameter AC — which must be extended when the complement of the pole's altitude is greater than 45° — at certain points. If from B straight lines are drawn through these points, they will cut off, from an arc described about center B, the arcs of declination of all the diurnal arcs, as in Andreas Schöner's figure, so that the angles which these same lines make with BD at B are the angles of declination, just as was demonstrated in the first figure of this proposition.

Now we shall draw those lines through the points of the line BD — the ones making with it angles equal to the complement of the pole's altitude — without great labor, as follows. From D, to the left of the line BD, describe an arc of a circle, on which the complement of the pole's altitude is to be reckoned off from the line BD; and through the endpoint of that reckoning draw the line DE.

Through any point E of it draw EO parallel to BD, and onto EO transfer all the points of the line DB, beginning from the line DE. For if the corresponding points on each of the two lines DB and EO — namely those equally distant from the points D and E — are joined by hidden [construction] lines, [Margin: Euclid, *Elements* I.33] all these will be parallel to DE, and hence [Margin: *Elements* I.29] will make with BD angles equal to the angle BDE, that is, to the complement of the pole's altitude. The numbers in this figure of ours are the same as in Andreas Schöner's figure.

It is enough, moreover, if the line EO is taken equal to DP. For the points found on the line PC, transferred onto the line PA (always beginning from the point P), will likewise give the points on the line PA through which the declination-lines are to be drawn — because the said parallels cut off from PA segments equal to the corresponding segments of the line PC: namely the line PI equal to the line PK, and so on. For in the triangles ILP and KGP [Margin: *Elements* I.29] the alternate angles L and G, between the parallels IL and GK, are equal, and the angles at P are right; and the sides PL, PG are likewise equal. (For the line ME, when drawn, will be bisected at N, on account of the equal arcs AM and AE — which can be proved by the same demonstration we used in proposition 1 of this book to show that the line MN in the analemma is bisected at O. [Margin: *Elements* I.34] Since, then, in the parallelograms PM and PE the sides PL, PG are equal to the opposite sides NM, NE,) [Margin: *Elements* I.26] the sides PI and PK will also be equal to each other.

Diagram. Our own construction giving the declinations of all the diurnal arcs. A large circle ABCD about center P, with the vertical diameter BD (B at top, D at bottom) and the horizontal diameter AC crossing it at P. From the convergence points a fan of straight lines (the radii of the diurnal arcs) is drawn, and a dotted arc (the transferred parallels) sweeps across the figure; at the far left a separate vertical graduated line is headed O. Readable labels (approximate positions; the figure is dense and a few placements are uncertain):

- B (top center): top of the vertical diameter BD
- D (bottom center): bottom of the vertical diameter BD
- P (center): intersection of the diameters AC, BD
- A (center-right): where the radii converge on the right
- C (center-left): left convergence point
- E (right, below A): endpoint of the reckoned complement / of line DE
- O (far upper left): head of the vertical line EO, parallel to BD
- L (upper middle): construction point on the axis
- I (center): construction point (triangle ILP)
- G (lower middle): construction point on the axis (triangle KGP)
- M (upper right): construction point
- N (right, below M): midpoint of ME
- K (right, on the fan): construction point (line PK)
- F (left, below C): construction point
- H (far right edge): construction point [position [?]]

Now, just as in propositions 19 and 20 of this book we drew up tables of the **Equinoctial Line** and of the **Twenty-Four Lines from Sunrise or Sunset**, and so forth — so that we might understand which hours reckoned from sunrise or sunset, and which reckoned from noon or midnight, intersect one another at one and the same point of those lines — so here we shall set out eight other tables, of the diurnal and nocturnal arcs, so that we may know which hours from sunrise or sunset, and which from noon or midnight, intersect one another at one and the same point of those arcs as drawn on any sundial. [Margin: Tables of the diurnal and nocturnal arcs, from which one learns which hour...] For this matter will be of the greatest use for laying out both the hours from sunrise and sunset and the unequal hours, as will become clear in its place. The construction of these tables from [the arcs]

[the arcs], diurnal and nocturnal, is derived, as can be gathered from what we shall say shortly. For in these tables any hours — whether three at a time or two at a time — cut one another at one and the same point of that diurnal or nocturnal arc which stands at the head of the table in which they are drawn. Thus, at whatever points the astronomical hours — reckoned from noon or midnight — cut the diurnal or nocturnal arc of any table, at those very same points the hours reckoned from sunrise or sunset cut it too: namely those hours which are placed to the right or left of those astronomical hours reckoned from noon or midnight. [Margin: ...from noon or midnight, and from sunrise or sunset, intersect one another in the proposed diurnal or nocturnal arc. By what device the tables of the diurnal and nocturnal arcs are composed.] Anyone will easily understand this if he carefully considers at what hour — reckoned both from noon or midnight and from sunrise or sunset — the Sun rises on the proposed diurnal arc, or sets on the nocturnal one.

For, to explain briefly by what device such tables are composed from the diurnal and nocturnal arcs: when the day comprises 10 hours, the Sun rises at the 7th hour from midnight, so that 5 hours remain until the 12th hour of noon, and another five until sunset; likewise it is the 14th hour from sunset, so that ten hours remain until the 24th hour, at which the Sun sets; and finally it is the 24th hour from sunrise, since one natural day begun at sunrise is then completed and another begins. It is plainly established that these three hours meet at the same point of the 10-hour diurnal arc — namely the 8th hour from midnight, the 15th from sunset, and the 1st from sunrise; and so for the rest.

Likewise, since the night comprises 14 hours, the Sun sets at the 5th hour from noon, so that seven hours remain until the 12th hour of midnight, and another

seven until sunrise; likewise it is the 24th hour from sunset, since one natural day begun at sunset is then completed and another begins; and finally it is the 10th hour from sunrise, so that 14 hours remain until the 24th hour, at which the Sun rises. These three hours too will coincide at the same point of the 14-hour nocturnal arc — as also will the three that follow them in the table of the 14-hour nocturnal arc, namely the 6th hour from noon, the 1st from sunset, and the 11th from sunrise, and so on.

By this method tables can be made for each of the diurnal and nocturnal arcs, provided one first carefully considers the hour — both from noon or midnight and from sunrise or sunset — at which the Sun rises or sets; which is not difficult. But the tables here proposed suffice for laying out the hours from sunrise or sunset, as will be clear from what follows.

(This page carries no prose: it presents four tables of the diurnal and nocturnal arcs of 10 and 14 hours, laying out the hours reckoned from sunset, from midnight or noon, and from sunrise. In each middle column the count shifts partway down from midnight-hours to noon-hours, or the reverse, marked by the interior sub-label.)

Diurnal arc of 10 hours, in which the Sun rises at the 7th hour from midnight, the 14th hour from sunset, and the 24th hour from sunrise.

Now, whatever hours — reckoned from noon or from midnight, and from sunrise or sunset — cut one another at a single point of any diurnal or nocturnal arc, at that same point the corresponding fractions of those same hours will likewise cut

one another: their quarters, halves, and the rest. For example, since the 17th hour from sunset, the 10th from midnight, and the 3rd from sunrise pass through one and the same point on the 10-hour diurnal arc, it follows that the fractions of these which correspond to one another — namely the $17\frac{1}{2}$ th hour from sunset, the $10\frac{1}{2}$ th from midnight, and the $3\frac{1}{2}$ th from sunrise — also pass through one and the same point of that same arc; and so with the rest, as is plain if the tables are extended through the said fractions of the hours.

[Margin: What has been said in the tables of the diurnal and nocturnal arcs concerning whole hours is likewise to be understood of the fractions of the hours.]

By the same effort we have constructed six further tables, as their headings indicate, so that one may learn at what hour reckoned from noon or midnight — and which unequal hours — cut one another at one and the same point of a diurnal or nocturnal arc of 6 or of 18 hours; and likewise of the diurnal or nocturnal arc of 12 hours, which the equinoctial line displays to us on any sundial. In the first four of these tables the unequal hours are contained as whole hours together with their halves and quarters; but in the last two, only as whole hours — yet their fractions too are to be understood, just as was said above for the eight tables of equal hours. For just as, for example, on the 12-hour diurnal arc the 3rd hour from noon and the 9th unequal diurnal hour cut one another, so too the $3\frac{3}{4}$ th hour from noon and the $9\frac{3}{4}$ th unequal hour will cut that same arc at one and the same point; and the same is to be said of the rest.

[Margin: Table of the diurnal and nocturnal arcs of 6, 18, and 12 hours, from which is gathered at what hour from noon or midnight — and which unequal hours — cut one another in these diurnal arcs.]

(Four tables follow, side by side. In each, the left column gives the unequal (seasonal) hours with their quarter-subdivisions, the right column the corresponding equal hours reckoned from noon or midnight. Whole hours are printed in Roman numerals, the quarter-subdivisions in Arabic with fractions.)

Diurnal arc of 6 hours, in which the Sun rises at the 9th hour after midnight and at the 12th unequal morning hour; and the individual half-hours from noon or midnight correspond to the individual unequal diurnal hours.

The following four tables complete ("Reliquum," the remainder) the four unequal-hour arcs whose first portions stood on the preceding page. Each table pairs the

unequal hours (left) with the corresponding equal hours reckoned from noon or from midnight (right). The two 6-hour arcs (first and last) step the equal-hour column by $\frac{1}{8}$ of an hour (each unequal hour = $\frac{1}{2}$ an equal hour); the two 18-hour arcs (middle two) step it by $\frac{3}{8}$ (each unequal hour = $1\frac{1}{2}$ equal hours).

PROBLEM 13. PROPOSITION 34.

To investigate the rising and setting amplitude, and the semidiurnal arc, of any parallel whatever, for a given elevation of the pole.

Since most people are accustomed to write, alongside the parallels or the arcs of the zodiacal signs on sundials (which we shall show how to draw on any sundial in the two books that follow), the lengths of the days and of the twilights, it will not be altogether out of place to explain briefly here — though it may seem to someone somewhat outside our plan, since this matter belongs elsewhere — by what method the lengths of the days and of the twilights, for any latitude of place, may be computed once the Sun's declination is known, so that we too, on any sundial we please, may add them to the parallels of the zodiacal signs. To find the lengths of the days, then, we shall look for the semidiurnal arcs, since these, doubled, make up the whole diurnal arcs. Among all the ways (for the length of a day can be found by many methods) we have chosen above all the one that seemed to differ least from the method we used in the preceding proposition for computing the declination of a parallel whose diurnal arc is given. Here, conversely, from the given declination of a parallel its diurnal arc is proposed for investigation. But first the rising or setting amplitude [amplitudo ortiva, occiduave] must be determined, for from it the semidiurnal arc is immediately gathered.

[Margin: The rising and setting amplitude — by what method it is investigated.]

Diagram. The figure is a sphere (the same as the last figure of the preceding proposition), drawn with the horizon as its outer circle and the great circles of meridian, equator, and a parallel of declination traced across it.

- A (top): pole of the horizon / top of the meridian on the horizon circle
- C (bottom): opposite point of the meridian on the horizon
- B (left): point where the equator meets the horizon
- D (right): opposite equator–horizon point
- E (centre): intersection of the meridian AC with the equator BD
- F (left, on the parallel): one end / meridian-crossing of the parallel
- G (right, on the parallel): the other end of the parallel FG
- H (lower centre): the arctic (north) pole
- I (centre, on the equator): point where the great circle HF, measuring the parallel's declination, cuts the equator
- K (upper centre): point where the parallel meets the meridian (the text also names the meridian-crossings k, v, t)

Let the last figure of the preceding proposition be taken up again, in which the horizon is ABCD, the meridian AC, and the equator BD cutting the meridian at E; let the parallel FG — whether northern or southern — cut the meridian at k, v, t;

and let the semidiurnal arc to be found be FK (or GK). For the meridian AC, passing through the poles of the horizon and of the parallel FG, cuts the segment FG in half, by [Theodosius, *Spherics* II.9]. Take the arctic pole H, and through it and through the point F draw, by [Theodosius, *Spherics* I.20], the greatest circle HF that measures the declination of the parallel from the equator, cutting the equator at I. Then the arc IE of the equator will, by [Theodosius, *Spherics* II.10], be similar to the semidiurnal arc FK; and so, once the arc IE has been found, the semidiurnal arc Fk that is sought will also be known, since arc IE contains just as many degrees or hours as Fk does, because of the similarity of these arcs.

We shall find the arc IE as follows. In the right-angled spherical triangle CFH — for the angle at C is right, since the meridian AC, drawn through the pole of the horizon, is perpendicular to the horizon by [Theodosius, *Spherics* I.1] — none of the arcs is a quadrant, as was shown in the preceding proposition. Therefore, by [Regiomontanus, *De triangulis* IV.19], or by [Jabir (Geber) I.15], or indeed by proposition 43 of our own *Spherical Triangles*: as the sine of the complement of arc HF — that is, the sine of the declination arc IF (for both in the southern and in the northern parallel the declination arc IF is the complement of arc HF, since HI is a quadrant by the corollary to [Theodosius I.16]) — is to the sine of the complement of the pole's altitude arc CH, so is the sine of the complement of arc CF, that is, the sine of arc BF (which is the complement of arc CF, since CB is a quadrant), and this measures the rising or setting amplitude of the parallel FG, to the whole sine [sinus totus]. Hence, by conversion, it will be: as the sine of the complement of the pole's altitude is to the sine of the declination of the given parallel, so is the whole sine to the sine of arc BF, the rising or setting amplitude [latitudo ortiva].

This can also be demonstrated in the following way, perhaps more conveniently. Since in the spherical triangle BIF the angle at I is right — because the greatest circle HI, drawn through the poles of the world, that is, of the equator BD, is perpendicular to the equator by [Theodosius, *Spherics* II.15] — and the angle B measures the inclination of the equator to the horizon, or what is the same thing, the altitude of the equator above the horizon, that is, the arc AE of the meridian (since B is the pole of the meridian AC), the two angles I and B of the triangle BIF are known. The declination arc IF is also known. Therefore, since by [Regiomontanus, *De triangulis* IV.16], or [Jabir (Geber) I.13], or proposition 41 of our *Spherical Triangles*, it holds that as the sine of angle B (the altitude of the equator, or the complement of the pole's altitude) is to the sine of angle I (the declination of the given parallel), so is the sine of the right angle I — that is, the whole sine — to the sine of arc BF, the rising or setting amplitude: thus from

three known quantities the fourth, namely the arc of the rising amplitude, will be found. And so, if it be made that as the sine of the complement of the pole's altitude is to the sine of the declination of the given parallel, so is the whole sine to a fourth term, the sine of the rising or setting amplitude will be found, and that amplitude will be known.

[Margin: The semidiurnal arc — by what method it is to be sought from the rising or setting amplitude.]

Again, since in the same right-angled triangle BIF the angle at I is right, and none of the arcs is a quadrant, all of them being parts of quadrants — for IF, in the northern triangle, is a part of the quadrant HI, but in the southern triangle a part of that quadrant which is drawn from I through F to the antarctic pole; likewise IB, in the southern triangle, is a part of the quadrant BE, but in the northern a portion of that quadrant which extends from B through I to the meridian below the horizon; and BF, finally, is a part of the quadrant BC (or BA) — it will be, by [Regiomontanus, *De triangulis* IV.19], or by [Jabir (Geber) I.15], or by proposition 43 of our *Spherical Triangles*: as the sine of the complement of arc IF (the declination of the given parallel) is to the whole sine, so is the sine of the complement of arc BF (the rising or setting amplitude just found) to the sine of the complement of arc BI — that is, to the sine of the semidiurnal arc IE of the southern parallel, or the seminocturnal arc of the northern parallel. For the arc of the equator IE is the complement of arc BI in the northern triangle, since arc BF [?] extended is a quadrant. Therefore, if it be made that as the sine of the complement of arc IF (the declination) is to the whole sine, so is the sine of the complement of the rising amplitude just found in the previous step to a fourth term, there will be found the sine of the semidiurnal arc of the southern parallel, or of the seminocturnal arc of the northern parallel. Then, this arc being subtracted from the semicircle of the equator that lies between the meridian above the horizon and the meridian below it, the remainder will be the northern diurnal arc IBE.

[Margin: Example.]

Let us take, for example, that the semidiurnal arc is to be found for latitude 42° , with the Sun at the beginning of Gemini [Π] or of Sagittarius [$\times$], where it has a declination of $20^\circ 12'$. Let it be made: as 74314 (the sine of the complement of the pole's altitude, i.e. $\sin 48^\circ$) is to 34529 (the sine of the declination of the parallel of Π or $\times$, i.e. $\sin 20^\circ 12'$), so is 100000 (the whole sine) to a fourth; and there will be found here approximately the sine 46464, whose arc is $27^\circ 41'$. This gives the rising or setting amplitude — northern for the parallel of Gemini [Π], but

southern for the parallel of Sagittarius [♐]. Again, let it be made: as 93849 (the sine of the complement of the declination of the same

parallel of Gemini [♊] or Sagittarius [♐]) is to 100000 (the whole sine), so is 88552 (the sine of the complement of the rising amplitude just found) to a fourth; and there will arise here, as it were, the sine 94355, whose arc, $70^{\circ} 39'$, will give the semidiurnal arc of the parallel of Sagittarius [♐] and the seminocturnal arc of the parallel of Gemini [♊]. Subtracting this from the semicircle, that is, from 180° , the remainder will be the semidiurnal arc of the parallel of Gemini [♊], namely $109^{\circ} 21'$. And if the degrees of these arcs are reduced to hours — assigning 15° to each hour, and one degree to each four minutes of an hour — the semidiurnal arc of the parallel of Sagittarius [♐] will contain 4 h 43 min, and that of the parallel of Gemini [♊] 7 h 17 min, a little more. And if we double these semidiurnal arcs, we shall have the whole diurnal arcs: namely, the diurnal arc of the parallel of Sagittarius [♐], $141^{\circ} 18'$, or 9 h 26 min; and the diurnal arc of the parallel of Gemini [♊], $218^{\circ} 42'$, or 14 h 35 min, a little less.

We can also find the semidiurnal arc of any parallel by the same spherical triangle, in this way. Since in the spherical triangle CFH the angle at C is right, it will be, by [Regiomontanus, *De triangulis* IV.16], or [Jabir (Geber) I.13], or proposition 41 of our *Spherical Triangles*: as the sine of arc FH, the complement of the declination of the given parallel (for FH, in the northern parallel, is the complement of arc FI of the declination; while in the southern parallel arc FH has the same sine, whose complement is arc FI of the declination — for the semicircle constitutes as its complement that which is interposed between F and the other pole, since the whole arc from I through F, tending toward the other pole, is a quadrant) — as this sine of arc FH is to the sine of the right angle C, that is, to the whole sine, so is the sine of arc CH, the pole's altitude, to the sine of arc FI [?]. From these three known quantities the fourth, and thus the angle F, will be recognized. Again, since in the spherical triangle BIF the angle at I is right, and B is the angle of the altitude of the equator — which the equator makes with the horizon — the sine of arc FI, of the declination given for the parallel, and the sine of angle F just recognized, and the sine of arc BI. From three known quantities, then, arc BI will be found, which, in the northern signs, added to a quadrant leaves the semidiurnal arc EI; but in the southern signs, subtracted from a quadrant, leaves the semidiurnal arc EI. And so, if it be made that as the sine of the complement of the declination of the given parallel is to the whole sine, so is the sine of arc FI to a fourth, arc BI will be found, which — the Sun being northern — added to a quadrant, or — the Sun being southern — subtracted from a quadrant, will give the semidiurnal arc. This first-found arc may be called the

"First Found"; then, if it be made that as the sine of the complement of the pole's altitude is to the sine of the declination, so is the sine we called the First Found to a fourth, there will be found the sine whose arc, the Sun being northern, added to a quadrant, or, the Sun being southern, subtracted from a quadrant, will give the semidiurnal arc.

[Margin: The semidiurnal arc — by what other method it is investigated through spherical triangles.]

Far more easily, by a single operation, we shall find BI, the difference between the semidiurnal arc of the parallel FG and that of the equator BD, in this way. In the triangle BFI the angle at I is right, B is the angle of the altitude of the equator, and the arc FI is the declination of the parallel. If, then, it be made that as the whole sine is to the tangent of angle B (the altitude of the equator) — and the tangent of angle FI, that is, the tangent of the pole's altitude — to a fourth, the sine of arc BI will be found, by proposition 49 of our *Spherical Triangles*. Example: with the Sun at the beginning of Gemini [♊] or Sagittarius [♐], where the declination is $20^{\circ} 12'$, let it be made: as 100000 (the whole sine) is to 36793 (the tangent of the declination), so is 90040 (the tangent of the complement of 48° , that is, the tangent of 42°) to a fourth; and there will be found the sine 33128, to which correspond $19^{\circ} 21'$. So great, then, is the arc BI.

Moreover, once the difference between the smallest or largest semidiurnal arc and a quadrant has been found, if a table of right ascensions is at hand, we shall find the differences between the semidiurnal arcs of all the other points of the ecliptic and a quadrant, by sines alone, in this way. Let it be made: as the sine of the right ascension of a given point is to the whole sine, so is the sine of the difference between the smallest or largest semidiurnal arc and a quadrant to a fourth, and the difference sought will be found. As in the same recent example: let it be made that as 84619 (the sine of the right ascension of the beginning of Gemini [♊] or Sagittarius [♐], which is $57^{\circ} 48'$) is to 39153 (the sine of the difference between the semidiurnal arc of the beginning of Cancer [♋] or Capricorn [♑] and a quadrant, which difference contains $23^{\circ} 3'$), so is [the whole sine] to a fourth; and there will be found the sine 33131, to which correspond $19^{\circ} 21'$, as before. This is demonstrated by [Regiomontanus, *Epitome* IV.24].

Most conveniently of all, even without spherical triangles, we shall find the rising or setting amplitudes and the semidiurnal arcs by this method. Let the analemma be taken up again — that is, the second figure of the preceding proposition — where HN, both in the northern and in the southern parallel, was shown to be the semidiurnal arc; likewise EL is the right sine of the rising or setting amplitude.

For, as we demonstrated in the scholium to proposition 1 of this book, the straight line EL, drawn perpendicular to BD, being the common section of the horizon and the parallel, cuts off from the circle ABCD the arc of the rising or setting amplitude, whose sine is EL.

[Margin: The rising or setting amplitude — how it may be computed by sines from the analemma.]

Diagram. The figure is the "analemma," a circle with centre E and a horizontal diameter BD, crossed by several straight lines (chords and perpendiculars) with their feet lettered. It repeats the second figure of the preceding proposition.

- B (left, on the circle): left end of the horizontal diameter BD
- D (right, on the circle): right end of the horizontal diameter BD
- E (centre): centre of the circle, meeting-point of the drawn lines
- A (upper left, on the circle): endpoint of an oblique diameter
- C (lower, on the circle): endpoint opposite A
- M (top, on the circle): endpoint of a line through E
- N (upper right, on the circle): point marking the semidiurnal arc HN
- H (left): point on the horizon line from which HN and HK are reckoned
- F (interior, upper middle): point on a drawn line
- K (interior): foot of a perpendicular (also appears near the top right)
- L (interior, two positions): feet of perpendiculars used for the sines
- G (lower left, on the circle): point on the circle
- I (lower / lower right): point on the circle near C and D

Therefore, since in the right-angled triangle EkL, if EL is set as the whole sine, the straight line EK is the sine of angle ELK, the complement of the pole's altitude (as we showed in our treatment of sines): if it be made that as Ek (the sine of the complement of the pole's altitude) is to EL (the whole sine), so is EK (the sine of the declination of the given parallel, taken with respect to the whole sine EF) to a fourth, there will be found EL, the sine of the rising or setting amplitude, with respect to that same whole sine EF. And from the sine EL the rising or setting amplitude itself becomes known.

[Margin: The semidiurnal arc — by what route it may be drawn out through sines from the analemma.]

Again, since in the same triangle EKL, if EL is set as the whole sine, the straight line kL is the sine of angle kEL, the pole's altitude (as is clear from the same treatment of sines): if it be made that as EK (the sine of the complement of the

pole's altitude) is to KL (the sine of the pole's altitude), so is EK (the sine of the declination, with respect to the whole sine EF) to a fourth, KL will be known, in the parts of that same whole sine EF. Then, since HK is also the sine of the complement of the declination with respect to the whole sine EF: if it be made that as HK (the sine of the complement of the declination, with respect to the whole sine EF) is to KL (in so far as it has been made known in the parts of that same whole sine EF), so is Hk (in so far as it is the whole sine in the Sun's parallel) to a fourth, KL will be produced, known in the parts of that same whole sine Hk, and therefore its

the arc MN will be known. In a northern parallel, added to the quadrant HM, it completes the semidiurnal arc HN; but in a southern parallel, subtracted from the quadrant HM, it leaves the semidiurnal arc HN. And so, if it be made that as the sine of the complement of the pole's altitude is to the sine of the pole's altitude, so is the sine of the declination of the given parallel to a fourth, a certain sine will be found, which we may call the First Found value. Then, if it be made that as the sine of the complement of the declination is to the sine we have called the First Found, so is the whole sine to a fourth, there will be found the sine of a certain arc which — with the Sun lingering in the northern signs, added to the quadrant, or with the Sun running through the southern signs, subtracted from the quadrant — will give the semidiurnal arc. Therefore we have investigated the rising or setting amplitude, and the semidiurnal arc of any parallel, for a given pole's altitude. Which was to be done.

SCHOLIUM.

[Margin: The semidiurnal arcs of the southern parallels are equal to the seminocturnal arcs of the opposite northern parallels.]

[Margin: It is enough if the semidiurnal arcs of the southern parallels are investigated. For from these the semidiurnal arcs of the opposite northern parallels are also elicited with little trouble.]

[Margin: It is enough if the semidiurnal arc of one southern quadrant of the ecliptic be computed, since from these the semidiurnal arcs of the other points of the ecliptic are easily gathered.]

We shall present two other ways of finding the semidiurnal arc — likewise without spherical triangles, with the Sun situated in any parallel whatever — in the scholium of the following proposition; and we trust these will not be unwelcome to the reader.

Furthermore, the semidiurnal arcs of the southern parallels, as is clear from what has been demonstrated, are equal to the seminocturnal arcs of the opposite northern parallels. For by the same operation, in the earlier method, both the semidiurnal arc of a southern parallel and the seminocturnal arc of the opposite northern parallel were found. This is also elicited, not obscurely, from Prop. 19 of Book 2 of Theodosius [Theodosius, *Sphaerica* II.19]. For it is there demonstrated that the alternate segments of opposite and equal parallels — into which they are divided by the horizon — are equal to one another (namely the segments that are the diurnal arc of one parallel and the nocturnal arc of the other, opposite and equal, parallel). Hence their halves will also be equal to one another, that is, the semidiurnal arc of the one parallel and the seminocturnal arc of the other. Therefore, if the semidiurnal arcs of all the points of the ecliptic are wanted, it will be enough that the semidiurnal arcs be investigated in the southern parallels: for these, being equal to the seminocturnal arcs of the opposite northern parallels, as has been said, when subtracted from the semicircle will leave the semidiurnal arcs of the opposite northern parallels as well.

This is also plainly evident from the latter method. For in the analemma, by the same operation, the arc MN was found both in the northern parallel and in the southern; and by this same arc the quadrant MI exceeds the seminocturnal arc NI of the northern parallel, while the quadrant MH exceeds the semidiurnal arc HN of the southern parallel. It is therefore clear that the seminocturnal arc NI of the northern parallel is equal to the semidiurnal arc NH of the southern parallel. And so with the rest. Here too you plainly see that the seminocturnal arc NI, subtracted from the semicircle HNI, leaves the semidiurnal arc HN.

Indeed, since the semidiurnal arcs of one southern quadrant of the ecliptic — the quadrant lying between the equator and the colure of the solstices — are equal to the semidiurnal arcs of the other southern quadrant, only the semidiurnal arcs of one southern quadrant of the ecliptic need be computed, namely of the quadrant lying between the beginning of ♎ [Libra] and the beginning of ♐ [Capricorn]. For these will be equal to the semidiurnal arcs of the other southern quadrant, intercepted between the beginning of ♈ [Aries] and the beginning of ♐ [Capricorn]. And these same arcs, subtracted from the semicircle, leave the semidiurnal arcs of the northern quadrant of the ecliptic set between the beginning of ♈ [Aries] and the beginning of ♋ [Cancer]; which in turn are equal to the semidiurnal arcs of the remaining northern quadrant, enclosed between the beginning of ♎ [Libra] and the beginning of ♋ [Cancer].

Exactly the same must be said of the rising or setting amplitude [latitudo ortiva/occidua]: for if, for one quadrant of the ecliptic — whether southern or northern — all the rising and setting amplitudes are computed, the rising or setting latitudes will also be had for all the points of the ecliptic, as is clear from the demonstration; since indeed the declinations of the points of one quadrant of the ecliptic, from which the rising and setting latitudes are computed, are equal to the declinations of the remaining points of the ecliptic, as we have shown elsewhere.

PROBLEMA 14. PROPOS. 35.

To find the magnitudes of the twilights [crepuscula] in any parallel whatever, for a given pole's altitude.

Although this problem can be solved by spherical triangles — as we shall demonstrate in the following scholium — we shall nevertheless carry it out much more briefly and easily by plane rectilinear triangles. Let ABCD be the meridian of the analemma, whose centre is E; let AC be the diameter of the horizon, BD the vertical, FG the axis of the world, HI the diameter of the equator, and KL the diameter of the Sun's parallel — whether northern or southern — about which let the semicircle KPL of the parallel be described. Its centre will be the point M, where the axis and the diameter of the parallel intersect each other, since the straight line EM, perpendicular to KL, bisects KL itself. [Margin: Euclid III.3] From the point S, where the diameter of the parallel cuts the diameter of the horizon, let a perpendicular SQ be raised to KL; this will be the common section of the horizon and the parallel. For since both the horizon and the parallel are perpendicular to the meridian, [Margin: Euclid XI.19] their common section will be perpendicular to it, and therefore, by Euclid Book XI def. 3, perpendicular also to the diameter KL of the parallel. Since, then, that common section passes through the point S — where the horizon and the parallel cut one another in the meridian — SQ, being perpendicular to KL, will be the common section of the horizon and the parallel. Therefore KQ will be the semidiurnal arc of the parallel, since it is intercepted between the horizon, which passes through the point Q, and the meridian, which cuts the parallel at k.

Let there also be drawn XY, the diameter of the horizon-parallel below the horizon in which the Sun lies when the morning twilight begins or the evening twilight ends, such that both the arc AX and the arc CY comprehend 18 degrees. For the Sun is distant from the horizon by that many degrees at the beginning of morning twilight or at the end of evening twilight, as is the common opinion — although some authors make this distance smaller, and others greater, as Pedro

Nunes [Petrus Nonius] reports in the second part of his book *On Twilights*, Prop. 1. Let the diameter XY cut the diameter KL of the Sun's parallel at T, and from that point let a perpendicular TR be drawn to KL; this will be the common section of the Sun's parallel and of the horizon-parallel in which the beginning or the end of twilight lies. For since both the Sun's parallel and the horizon-parallel are perpendicular to the meridian, [Margin: Euclid XI.19] their common section too will be perpendicular to it, and therefore, by Euclid Book XI def. 3, perpendicular also to the straight line KL lying in the plane of the meridian — such as is the straight line TR. Therefore the length of the twilight will be the arc QR, since the Sun is at the point R when it occupies the horizon-parallel XY, in which is the beginning of morning twilight or the end of evening

twilight; and it rises or sets at the point Q. For since TR is the common section of the Sun's parallel and of the horizon-parallel XY, these parallels cut one another at R, and so the Sun, when at the point R, will occupy both parallels. In the same way, when at the point Q it will hold the horizon, since — as we said a little earlier — SQ is the common section of the horizon and the Sun's parallel. Finally, let a perpendicular KN be dropped from K to AC, cutting XY at O; and KN will be the sine of the meridian altitude of the Sun situated in the parallel KL — that is, the sine of the arc KA — while the straight line KO is composed of KN, the sine of the meridian altitude, and NO, the sine of the Sun's distance below the horizon at the beginning of morning twilight or the end of evening twilight. So likewise KS will be the versed sine of the semidiurnal arc KQ, and KT the versed sine of the arc KR — composed of the semidiurnal arc kQ and the twilight arc QR, which the Sun of course traverses in its own parallel while the twilight lasts.

[Margin: How the magnitude of twilight may be investigated, with the Sun situated in any parallel whatever.]

And so, since in the triangle KOT the straight line SN is parallel to the base OT, [Margin: Euclid VI.2] it will be that as kN, the sine of the meridian altitude, is to KO — the straight line composed of the sine of the meridian altitude and of NO, the sine of the Sun's distance below the horizon at the beginning of morning twilight or the end of evening twilight — so is KS, the versed sine of the semidiurnal arc, to KT, the versed sine of the arc composed of the semidiurnal arc and the twilight arc. Therefore, if it be made that as the sine of the meridian altitude (how the meridian altitude is found from the known declination of the Sun we shall explain in the following scholium) is to the straight line composed of the sine of the meridian altitude and the sine of 18 degrees — for by that many degrees, according to the common view, the Sun is depressed below the horizon

on the vertical then passing through the Sun's centre — so is the versed sine of the semidiurnal arc to a fourth, one will obtain the versed sine of the arc composed of the semidiurnal arc and the twilight arc. From this versed sine, then, we shall find the quantity of the twilight as follows.

[Margin: When the versed sine found is greater than the whole sine, by what method the twilight is elicited from it.]

If the versed sine found, kT , is greater than the whole sine — as happens in the first two figures — we shall subtract the whole sine KM from it, and from the remaining sine TM we shall take the arc PR . For this arc PR , added to the quadrant kP , will make up the arc kR , composed of the semi-

Diagram. First of four analemma figures (upper left). A circle — the meridian $ABCD$ — with B at top, D at bottom, A at left, C at right, and centre E ; through it run the horizon diameter AC , the vertical BD , the oblique axis FG , the equator diameter HI , the Sun's-parallel diameter KL , and (below the horizon) the horizon-parallel diameter XY . The semicircle KPL of the Sun's parallel is drawn about centre M , with dotted construction lines and the perpendiculars KN , SQ , TR . This figure carries additional small Greek point-labels used in the equinoctial ("SOLE aequinoctialia puncta") derivation. Several of the small interior Greek labels are at the resolution floor and are flagged.

- B (top of circle): upper end of the vertical BD
- D (bottom of circle): lower end of the vertical BD
- A (left of circle): west end of the horizon diameter AC
- C (right of circle): east end of the horizon diameter AC
- E (centre): centre of the meridian
- K (upper left, on circle): upper end of the Sun's-parallel diameter KL
- L (lower right, on circle): lower end of the Sun's-parallel diameter KL
- H (left, on circle): end of the equator diameter HI
- I (lower right, on circle): opposite end of the equator diameter HI
- F (upper right, on circle): end of the axis FG
- G (lower left, on circle): opposite end of the axis FG
- P (upper right, on circle): point on the parallel semicircle KPL
- Q (right, on circle): foot of the semidiurnal arc (endpoint of perpendicular SQ)
- R (right, near C): point where the Sun stands at the twilight boundary (endpoint of perpendicular TR)

- X (lower left): west end of the horizon-parallel diameter XY
- Y (right): east end of the horizon-parallel diameter XY
- M (interior, above E): centre of the Sun's-parallel semicircle
- N (interior, left of centre): foot of perpendicular KN on AC
- S (interior, right of centre): intersection of the parallel diameter with the horizon diameter
- T (interior, lower right of centre): intersection of XY with KL
- λ (lambda) (interior, left of M): [?] small interior label
- α (alpha) (interior, left near A/X): [?] foot of the perpendicular $H\alpha\beta$
- β (beta) (interior, lower left): [?] second foot of the perpendicular $H\alpha\beta$
- θ (theta) (interior, near bottom): [?] small interior label
- γ (gamma) (interior, below E): [?] endpoint of the segment $E\gamma$ (glyph could be the Aries sign Υ)

Diagram. Second of four figures (upper right) — the same analemma construction with the Sun's parallel KL in a different position (the case treated as the "second figure," where the versed sine exceeds the whole sine). Readable labels: B (top), D (bottom), A (left), C (right), E (centre); K, H (upper left, on circle), F (upper right), Y (right), L (lower right), I (lower right), on the circumference; interior N, S, E, M, T near centre, with small λ and θ at the left and P, Q, R, G, k grouped at the lower left; dotted construction rectangle at lower left. Small interior Greek labels (λ , θ) flagged.

- B, D, A, C, E: meridian frame and centre (as in fig-p113-1)
- K, L: Sun's-parallel diameter
- H, I: equator diameter
- F, G: axis
- N, S, M, T: interior construction points (as above)
- P, Q, R (lower left region): parallel-semicircle / twilight points
- λ (lambda), θ (theta): [?] small interior labels

Diagram. Third of four figures (lower left) — the same construction for the "third figure" case, where the versed sine KT is less than the whole sine. Readable labels: B (top), H, K (upper left), F (upper right), A (left), C (right), Y (right), E (centre), M, N, S, T (interior), I, L (lower right), and P, Q, R, G, k at the lower left, with a dotted construction figure. Small interior Greek labels flagged.

- B, D, A, C, E; K, L; H; F; Y; I: frame, centre, and circumference points as above

- M, N, S, T: interior construction points
- P, Q, R (lower left): twilight-construction points
- λ (lambda), θ (theta) [?]: small interior labels

Diagram. Fourth of four figures (lower right) — the same construction for the "fourth figure" case, where the versed sine KT equals the whole sine (so the composite arc is the quadrant kP itself). Readable labels: B (top), H, K (upper left), F (upper right), A (left), C (right), Y (right), E (centre), M, N, S, T (interior), I, L (lower right), and P, Q, R, G, k grouped at lower left. Small interior Greek labels flagged.

- B, D, A, C, E; K, L; H; F; Y; I: frame, centre, and circumference points as above
- M, N, S, T: interior construction points
- P, Q, R (lower left): twilight-construction points
- λ (lambda), θ (theta) [?]: small interior labels

diurnal arc and the twilight arc. Therefore, once the semidiurnal arc kQ is taken away, the remaining arc will be the twilight arc QR. But if the said versed sine KT is less than the whole sine — as happens in the third figure — we shall subtract it from the whole sine KM, and from the remaining sine TM we shall take the arc PR. For this arc PR, subtracted from the quadrant KP, will make the remaining arc kR, composed of the semidiurnal arc and the twilight arc. If, then, from this we again subtract the semidiurnal arc KQ, there will remain the twilight arc QR. If, finally, the aforesaid versed sine kT is found equal to the whole sine — as happens in the fourth figure — the quadrant kP will itself be the arc composed of the semidiurnal arc and the twilight arc. Therefore, if from this quadrant we subtract the semidiurnal arc KQ, the remaining arc will be the twilight arc QR, or QP.

We shall obtain the same result also by this method. [Margin: Euclid VI.2] Since in the same figures it holds that as KN, the sine of the meridian altitude, is to NO, the sine of the Sun's concealment below the horizon at the beginning of morning twilight or the end of evening twilight — which concealment we set at 18 degrees — so is KS, the versed sine of the semidiurnal arc, to ST: if it be made that as the sine of the meridian altitude is to the sine of 18 degrees, so is the versed sine of the semidiurnal arc to a fourth, the value of the straight line ST will be found; and this, added to the versed sine of the semidiurnal arc, makes up the versed sine of the arc composed of the semidiurnal arc and the twilight arc. From this versed

sine we shall find, as before, the length of the twilight. We give no example, because from the figures themselves the matter is self-evident.

[Margin: When the versed sine found is less than the whole sine, by what method the twilight is elicited from it.]

[Margin: When the versed sine found is equal to the whole sine, by what method the twilight is thence recognized.]

[Margin: How the twilight may otherwise be explored by degrees. Euclid VI.2.]

With the Sun occupying the equinoctial points — that is, the beginning of Υ [Aries] or of ♎ [Libra] — the magnitudes of the twilights will be found much more easily by this method. In the first figure, having drawn from H a perpendicular $H\alpha\beta$ to AC and XY, [Margin: Euclid VI.2] it will be that as $H\alpha$, the sine of the altitude of the equator (or of the complement of the pole's altitude), is to $\alpha\beta$, the sine of 18 degrees (that is, of however many degrees we have

set the arc AX), so is HE, the whole sine, to $E\gamma$, the right sine of the twilight arc λG . [The point-label γ here is a small interior glyph — possibly the Aries sign Υ ; read as γ [?].] If, therefore, it be made that as the sine of the complement of the pole's altitude is to the sine of 18 degrees, so is the whole sine to a fourth, there will result a sine whose arc will give the twilight, with the Sun at the equinoxes.

[Margin: By what method all twilights may most easily be computed.]

An easier way. Let it be made that as $E\alpha$, the whole sine, is to $E\gamma$, the secant of the angle $\alpha E\gamma$ [equal to] the pole's altitude, so is $E\alpha$ [?], the sine of 18 degrees, to a fourth; and $E\gamma$, the sine of the twilight, will be found. [Several of the Greek point-labels in this sentence are at the resolution floor; flagged.]

Furthermore, once the magnitude of the straight line $E\gamma$ has been found by the method we have just now set out, we shall through it find the twilights of all the parallels — or of the points of the ecliptic — in this way. [Margin: Book I, Prop. 34] Since $E\gamma$ is equal to each of the segments ST of the diameters of the parallels intercepted between AC and XY, such segments will be known in terms of the whole sine of the greatest circle in the sphere. For each of them will be as great as the straight line $E\gamma$ was found to be, with the Sun at the equinoxes.

Diagram. Repeats fig-p113-1 (upper-left analemma with the equinoctial Greek labels α , β , θ , λ , γ). Same woodcut block as on the preceding page. Small interior Greek labels at the resolution floor — flagged as on p. 113.

Diagram. Repeats fig-p113-3 (lower-left analemma, "third figure" case).

Diagram. Repeats fig-p113-4 (lower-right analemma, "fourth figure" case).

with the Sun at the equinoxes. From this we shall come to know these same segments in terms of the whole sine of the respective parallels, by this device. Let it be made that as kM , the sine of the complement of the declination of any given parallel, is to KM — in so far as it is the whole sine of the respective parallel — so is ST , in so far as it is known in terms of the whole sine of the greatest circle, to a fourth. For the same ST will come out, known in terms of the whole sine KM of the respective parallel. And so, if ST , known in terms of the whole sine of the respective parallel, be added to the versed sine KS of the semidiurnal arc, the versed sine KT of the arc KR — composed of the semidiurnal arc and the twilight arc — will be known. Therefore, as before, from this versed sine we shall find the magnitude of the twilight.

[Margin: How the meridian altitude of the Sun is found.]

[Margin: When the number formed from the northern declination and the altitude of the equator exceeds 90 degrees.]

[Margin: When the pole's altitude is less than the northern declination of the Sun's parallel, the zenith of the place lies between the Sun's parallel and the equator, and the Sun's meridian altitude is northern.]

This method of investigating the twilights seems the easiest and most expeditious of all, because at a given pole's altitude the straight line $E\gamma$, once found in terms of the whole sine of the greatest twilight, always remains the same in all the Sun's parallels, so that it never changes. Its discovery, indeed, is very easy, since in finding it the whole sine is employed, which makes the multiplication easiest, as is clear from what has been demonstrated. Once this has been found, the same $E\gamma$ — or ST — is obtained by the method just now taught, in so far as it is a part of the whole sine of the respective parallel; and this discovery too is not difficult, because in seeking it the whole sine is likewise used, which renders the operation less difficult, as we have said. This does not happen in the earlier rules: for in them the whole sine is never assumed in order to find the straight line KT . Hence the multiplication is made somewhat more difficult, as is evident. Therefore we have found the magnitudes of the twilights, and so forth. Which was to be done.

SCHOLIUM.

[Margin: When the number formed from the northern declination and the altitude of the equator exceeds 90 degrees. When the pole's altitude is less than the northern declination of the Sun's parallel, the zenith of the place lies between the Sun's parallel and the equator, and the Sun's meridian altitude is northern.]

The meridian altitude of the Sun is found in the way all commonly hand down. When the Sun is in the northern signs, its declination is added to the altitude of the equator (that is, to the complement of the pole's altitude); but when it runs through the southern signs, its declination is subtracted from the altitude of the equator (or from the complement of the pole's altitude). For the number formed by that addition, or left by this subtraction, will give the meridian altitude sought. For example, with the Sun at the beginning of ♋ [Cancer], if its declination — which is 23 degrees 30 minutes — is added to the complement of the pole's altitude, that is, to the elevation of the equator at Rome, which comprehends 48 degrees, the meridian altitude of 71 degrees 30 minutes results, at the latitude of 42 degrees, such as is found at Rome. But with the Sun at the beginning of ♑ [Capricorn], if its declination — which is 23 degrees 30 minutes — is subtracted from the elevation of the equator, that is, from the complement of the pole's altitude, namely from 48 degrees, the remaining meridian altitude will be 24 degrees 30 minutes. The rationale of this operation is clear from the figures above. For in the first, where the parallel of the diameter KL is northern, the meridian altitude AK is composed of the declination KH and the altitude of the equator HA. But in the others, in which the parallel of the diameter KL is southern, the meridian altitude AK results if the declination KH is subtracted from the altitude of the equator HA.

(The scholium to Proposition 35 continues from the preceding pages.)

But here some points must be noted. **First**, when in the northern signs a number greater than 90 degrees is formed by adding the declination to the elevation of the equator, the number so formed must be subtracted from the semicircle in order to obtain the meridian altitude. For then the Sun will lie between the zenith B and the arctic pole F — or, what amounts to the same, the zenith B lies between the Sun and the equator. This can be seen in the first figure of this scholium, where the arc AK, lying between the horizon and the northern parallel, exceeds the quadrant AB, and the meridian altitude is the arc CK on the northern side, and the zenith B is set between the Sun's parallel and the equator. This happens when the altitude of the pole is less than the declination of the parallel in question, as is the case here. For the arc BH, which is equal to the arc CF of the

pole's altitude — as we showed on the sphere, and as is easily gathered from the figure (for if from the equal quadrants CB and FH the common arc FB is removed, the arcs CF and BH remain equal) — is less than the declination HK. But if the altitude of the pole BH should at some point be equal to the declination of the parallel, the parallel will touch the vertical circle at the zenith B, and the meridian altitude will be a quadrant, namely CB or AB, of 90 degrees.

[Margin: When the altitude of the pole is equal to the northern declination of the Sun's parallel, the Sun's parallel touches the vertical circle at the zenith B, and the Sun's meridian altitude is a quadrant.]

Next, when the complement of the pole's altitude is less than the declination of a northern parallel, the whole parallel will stand above the horizon and will have two meridian altitudes: a southern one, which is the greater, and a northern one, which is the smaller. The first is found by the rule given above; the second is obtained by subtracting the complement of the pole's altitude from the declination. This is clear in the second figure of this scholium, where CI, the complement of the pole's altitude, is less than the declination IL, and the northern parallel KL stands wholly above the horizon. The southern and greater meridian altitude is the arc AK; the northern and smaller is the arc CL, which is obtained by subtracting the complement of the pole's altitude IC from the declination IL. When the Sun is on this parallel there is no twilight, since the day is continuous. But if the complement of the pole's altitude IC should at some point equal the declination of the parallel, the parallel will touch the horizon at C and will stand wholly above it, so that here too no twilight need be sought.

[Margin: When the complement of the pole's altitude is less than the declination of the Sun's northern parallel, the whole parallel stands above the horizon, and no twilight occurs; the Sun then has two meridian altitudes on that parallel. When the complement of the pole's altitude is equal to the northern declination of the Sun's parallel, the parallel touches the horizon, and there is no twilight.]

Third, when in the southern signs the declination of some parallel is greater than the complement of the pole's altitude — and therefore cannot be subtracted from that complement to obtain the meridian altitude — the Sun will have no meridian altitude on that parallel, but the whole parallel will lie hidden below the horizon, as is clear in the same second figure, in which the southern declination HK is greater than the complement of the pole's altitude AH. But if the arc AK — the difference between the complement of the pole's altitude AH and the southern declination HK — is less than the arc AX (which lies between the horizon and the parallel and runs through the beginning of morning twilight

[Margin: When the declination of a southern parallel is greater than the complement of the pole's altitude, so that the whole parallel lies below the horizon, it has no meridian altitude. — How great the twilight is, while the whole southern parallel lies hidden below the horizon, and how it is found. — What the Sun's depression is. [a] Euclid VI.2. [b] Euclid VI.4.]

Diagram. An analemma-type sphere seen from the side: an outer circle (the meridian) with a horizontal diameter (the horizon AC) and several oblique diameters representing the equator, the pole-axis, and the Sun's parallel, plus perpendicular sine-lines dropped to the horizon and axis. The construction is dense with small interior labels; many are worn or overlapping and cannot be resolved with confidence at this resolution. Readable labels, by approximate position:

- Top: K, H, B, K
- Left: A
- Interior (upper): N, G, E, M
- Interior (mid): X, M, S; O, T, T [?], Y
- Upper right: F, P, C; Q, R
- Lower left: P, R, X
- Bottom: θ , L, D, I
- Bottom-left margin: a zodiacal/symbol sort [?]

Numerous small interior labels are illegible or ambiguous

Diagram. A companion analemma sphere, similarly constructed (outer meridian circle, horizon diameter, oblique parallels and sine perpendiculars), illustrating the case where the northern parallel stands wholly above the horizon and the southern wholly below. Readable labels, by approximate position:

- Top: B, F
- Left: K, H, A, K
- Center: E
- Right: N, L, C, I, Y
- Interior (lower): θ , O, N; T, M
- Bottom: G, D; R, F

Several small labels illegible/ambiguous

) — that is, when the Sun traverses the arc kR and another equal to it, there will be twilight; so that KR is half the twilight, because in the arc KR, and in another

equal to it, the Sun is less than 18 degrees distant from the horizon. We shall find the magnitude of this arc as follows. From the point L, of the southern parallel in the latter figure of this scholium, let a perpendicular LN be drawn to AC, cutting XY at O; likewise through K and M let $K\theta$ and $M\lambda$ be drawn parallel to AC, cutting LN at θ and λ . Before all else, we shall come to know the straight lines $L\lambda$ and LO in this way. The whole arc CL — which we may call the Sun's depression below the horizon, that is, its greater distance below the horizon on the meridian (for the Sun on that parallel has two depressions below the horizon, the greater CL and the smaller AK, of which the former inclines to the north, the latter to the south) — is composed of CI, the complement of the pole's altitude, and IL, the southern declination, and so is known. Therefore its sine LN is also known. Again, the arc AK of the smaller depression is known, since it is the difference between the arc HK of the southern declination and the arc AH of the complement of the pole's altitude. Therefore its sine θN is also known. So, subtracting the sine θN from the sine LN, which is now known, there remains $L\theta$, known,

[Margin: When there is no twilight, the Sun being in the southern signs. When twilight is continuous, the Sun being at the equinoxes. How the Sun's meridian depression is found. The meridian depression of any parallel is equal to the meridian altitude of the opposite parallel.]

which is the difference between the sine of the greater depression and the sine of the smaller depression below the horizon. [a] Now since, as LM is to MK, so $L\lambda$ is to $\lambda\theta$, and LM is equal to MK, $L\lambda$ will also be equal to $\lambda\theta$. Therefore, since the straight line $L\theta$ is known, its half $L\lambda$ is known as well. And LO is known, since it is the difference between LN, the sine of the greater depression, and ON, the sine of 18 degrees, namely of the arc AX or CY. So both $L\lambda$ and LO are known.

Now [b], since as $L\lambda$ is to LO, so LM is to LT, if it be made that, as $L\lambda$ — the half of the difference between the sine of the greater depression and the sine of the smaller — is to LO, the difference between the sine of the greater depression and the sine of 18 degrees, so is LM, the whole sine, to a fourth term, there will be found LT, the versed sine of the arc LR. From this versed sine LT we shall trace out the arc KR of half the twilight thus: when the versed sine LT found is greater than the whole sine LM, we shall subtract the whole sine from it to obtain the right sine MT, whose arc PR, taken from the table of sines, we subtract from the quadrant KP, and the arc KR of half the twilight remains known. But if the versed sine LT is found equal to the whole sine, the arc of half the twilight will be a full quadrant, because then the diameter KL passes through the point where the axis cuts the diameter XY, and consequently the point T falls on the point M. Finally, if

the versed sine LT is found less than the whole sine, we subtract it from the whole sine and add the arc of the remaining right sine, taken from the table of sines, to the quadrant, to obtain the arc of half the twilight: because then the diameter KL cuts the axis between the center E of the analemma and the diameter XY, and so the point T falls between M, the center of the parallel [recte: paralleli], and the point L, as is clear.

But if the arc AK below the horizon — that is, the difference between the complement of the pole's altitude AH and the southern declination HK (when in the southern signs the declination is greater than the complement of the pole's altitude) — is equal to or greater than the arc AX, there will be no twilight while the Sun traverses that southern parallel; for then the Sun below the horizon is always more than 18 degrees distant from it — unless we should wish to call twilight that instant of time in which the Sun, at the point X, is at midnight, namely when the arc AK is equal to the arc AX.

But if the complement of the pole's altitude is less than the arc of 18 degrees — as happens in the second figure of this scholium (for the arc CI of the complement of the pole's altitude is less than the arc CY of 18 degrees) — then, when the Sun is at the equinoxes, there will be twilight throughout the whole night, because the Sun is then always less than 18 degrees below the horizon.

Moreover, if anyone should prefer not to use versed sines, he can investigate the magnitudes of the twilights another way, and perhaps more conveniently. To make this clear, we shall first teach how to find the Sun's meridian depression — that is, its distance below the horizon on the meridian. This is found as follows. In the northern signs, subtract the declination of the parallel in question from the complement of the pole's altitude; in the southern signs, add that same declination to the complement of the pole's altitude. For the number left by that subtraction, or composed by this addition, will give the meridian depression, as is clear from the four figures of this proposition, in which the meridian depression is invariably the arc CL. Now the depression of any parallel is equal to the meridian altitude of the opposite parallel. For if a diameter were drawn from L through the center E, it would fall in the quadrant AB at the point through which the diameter of the opposite parallel would have to be drawn, as is clear. [a] Therefore, since such a diameter, together with the diameter of the horizon AC, makes equal angles at the vertex E, [b] the arcs on which the said equal angles at the center E stand will be equal to one another — namely the arc CL of the meridian depression and the arc of the meridian altitude of the opposite parallel.

Hence, if the meridian depression of some parallel is sought, one may take for it the meridian altitude of the opposite parallel.

[Margin: When there is no twilight, the Sun being in the southern signs. When twilight is continuous, the Sun being at the equinoxes. How the Sun's meridian depression is found. The meridian depression of any parallel is equal to the meridian altitude of the opposite parallel. [a] Euclid I.15. [b] Euclid III.27.]

Diagram. The same "first figure" analemma sphere as on p. 115 (the woodcut pair is reprinted on this verso), with the identical set of interior labels (top K, H, B, K; left A; interior N, G, E, M, X, S, O, T, Y; right F, P, C, Q, R; lower-left P, R, X; bottom θ , L, D, D). Small interior labels are again worn/ambiguous

Diagram. The same "second figure" analemma sphere as on p. 115 (top B, F; left K, H, A, K; center E; right N, L, C, I, Y; interior θ , O, N, T, M; bottom G, D, R, F). Small labels worn/ambiguous

The meridian altitude and depression together make up the complement of the pole's altitude, doubled — at any elevation of the pole that is not less than the declination of the parallel on which the Sun is. For in any figure of this proposition, since the arcs HK and IL are equal, when the common arc CL is added, the two arcs HK, CL will be equal to the whole CI. Therefore, adding the common AH again, the two arcs KA (of the meridian altitude) and CL (of the meridian depression) will be equal to the two arcs HA, CI — that is, to the complement of the pole's altitude doubled. This is also clear as follows: since the two complements of the pole's altitude AH, CI are equal, and to AH the declination HK is added while from CI the same declination IL is subtracted, it results that the composite arc AK and the remaining arc CL together are likewise equal to the two arcs AH, CI together — since what is added to the one is subtracted from the other. From this it follows that, when the altitude of the pole is less than the declination, the composite arc AK together with the depression CL is still double the complement of the pole's altitude AH — that is, equal to the two arcs AH, CI together, as appears in the first figure of this scholium.

[Margin: When the number composed from the complement of the pole's altitude and the southern declination exceeds a quadrant. When the northern declination is greater than the complement of the pole's altitude, there is no meridian depression, but the whole parallel stands above the horizon.]

But here too some points must be noted. For if in the southern signs the number formed from the complement of the pole's altitude and the declination is greater than a quadrant, the number so formed must be subtracted from the semicircle

in order to obtain the meridian depression, as may be seen in the first figure of this scholium. Similarly, if in the northern signs the declination of the parallel is greater than the complement of the pole's altitude, so that the former cannot be subtracted from the latter, the whole parallel will stand above the horizon, as appears in the second figure of this scholium. Hence there will then be no meridian depression, but the parallel will have two meridian altitudes, as was said a little earlier. Finally, when in the southern signs the declination of the parallel is greater than the complement of the pole's altitude, as appears in the same second figure of this scholium, it was already said a little earlier that the parallel is then wholly below the horizon and has two meridian depressions, which we investigated in that place; and that sometimes there can be twilight, sometimes not; and likewise in what manner that twilight ought to be investigated.

[Margin: When the southern declination is greater than the complement of the pole's altitude, the whole southern parallel lies hidden below the horizon and has two meridian depressions. [c] Euclid VI.2. [d] Euclid I.34.]

Furthermore, the greater and the smaller altitude, taken together, are equal to twice the declination of the parallel. For since the two arcs HK, IL are equal, and AH is added to HK while IC is subtracted from IL, the composite arc AK and the remaining arc CL together will be equal to the two arcs HK, IL — that is, together they will be twice the declination HK. Likewise, the difference between the two meridian altitudes is twice the complement of the pole's altitude. For since the two altitudes AK, CL are equal to the two arcs HK, IL, as has been said, if CL — the smaller altitude, which is common — is removed, the greater altitude AK will be equal to the two arcs HK, CI. If, then, from HK [?] there be taken away the common arc toward the side of K, equal to CL, the remaining part of AK will be equal to the remaining part of HK together with the arc CI. Now from the arc AK there remains the difference between the two altitudes AK, CL, while from the arc HK there remains an arc equal to CI (just as CL, taken from IL, leaves the arc CI). Therefore the difference between the two altitudes AK, CL will be equal to twice the arc CI, the complement of the pole's altitude.

With these things laid down, from L let a perpendicular $L\theta$ be drawn to the straight line KO, produced in all the figures (except the second figure of this scholium); likewise from M, the center of the parallel, another perpendicular $M\lambda$. [c] And since in the triangle $K\theta L$, as KM is to ML, so is $K\lambda$ to $\lambda\theta$; [d] but KM is equal to ML; $K\lambda$ will also be equal to $\lambda\theta$. Therefore, since KN is the sine of the meridian altitude, and θN the sine of the meridian depression (because θN is

equal to the sine of the depression, which would be drawn as a perpendicular from L to AC), $K\lambda$ will be [the half...]

$K\lambda$ will be the half of the straight line composed of the sines of the meridian altitude and of the meridian depression. But λO will be the difference between the said half and the straight line composed of the sine of the meridian altitude and the sine of 18 degrees. [a] And since, as $K\lambda$ is to λO , so is KM to MT : if it be made that, as $K\lambda$ — the half of the straight line composed of the sine of the meridian altitude and the sine of the meridian depression — is to λO , the difference between the aforesaid half and the straight line composed of the sine of the meridian altitude and the sine of 18 degrees, so is KM , the whole sine, to a fourth term, there will result MT , the right sine of the arc PR . This arc, added to the quadrant, constitutes the arc KR , composed of the semidiurnal arc and the twilight arc — provided the aforesaid half $K\lambda$ is found to be less than the straight line composed of the sine of the meridian altitude and [the sine of] 18 degrees, as always happens in the northern signs and sometimes in the southern, as may be seen in the two preceding figures of this proposition and in the first figure of this scholium. Or else, subtracted from the quadrant, it leaves the arc KR , composed of the semidiurnal arc and the twilight arc, if indeed the said half is found to be greater than the straight line composed of the sine of the meridian altitude and the sine of 18 degrees, as happens in the third figure of this proposition. Then, when the semidiurnal arc KQ is subtracted from the arc KR thus found, it is clear that the twilight arc QR is left. But if the said half $K\lambda$ is equal to the said straight line KO , the arc composed of the semidiurnal arc and the twilight arc will be a quadrant, as appears in the fourth figure of this proposition.

[Margin: [b] Euclid VI.2. — By what method twilight is to be investigated otherwise than above.]

Indeed, by means of the meridian altitude and the meridian depression we shall compute the semidiurnal arcs by a very short calculation, although we found the same by another method in the preceding proposition. [b] For since in all the figures of this proposition — and also in the first, which is set down in the scholium — as $K\lambda$, the half of the straight line composed of the sine of the meridian altitude and the sine of the meridian depression, is to λN , the difference between the aforesaid half and the sine of the meridian altitude, so is KM , the whole sine, to a fourth term: if it be made that, as $K\lambda$, the half of the straight line composed of the sine of the meridian altitude and the sine of the meridian depression, is to λN , the difference between the said half and the sine of the meridian altitude, so is KM , the whole sine, to a fourth term, there will be found

the right sine MS, whose arc PQ — added to the quadrant in the northern signs, but subtracted from the quadrant in the southern — will give the semidiurnal arc KQ.

[Margin: [b] Euclid VI.2 or VI.4. — By what method the semidiurnal arc is to be computed otherwise than above.]

The same result we shall obtain by this method. Since in the same figures, as $K\lambda$, the aforesaid half, is to KN , the sine of the meridian altitude, so is KM , the whole sine, to KS , the versed sine of the semidiurnal arc KQ : if it be made that, as $K\lambda$, the half of the straight line composed of the sine of the meridian altitude and the sine of the meridian depression, is to KN , the sine of the meridian altitude, so is KM , the whole sine, to a fourth term, we shall obtain KS , the versed sine of the semidiurnal arc KQ . From this versed sine we shall obtain the semidiurnal arc KQ as follows. In the northern signs, subtract the whole sine from the versed sine found, and add the arc PQ of the remaining right sine to the quadrant; in the southern signs, on the contrary, subtract the versed sine found from the whole sine, and subtract the arc PQ of the remaining right sine from the quadrant again. For always, whether from that addition or from this subtraction, the semidiurnal arc will emerge.

[Margin: How the semidiurnal arc is investigated.]

Otherwise, from the first figure of this proposition. Since, as HA , the sine of the complement of the pole's altitude, is to HE , the whole sine, so is KN , the sine of the meridian altitude, to KS , the versed sine of the semidiurnal arc, in terms of the parts of the whole sine of the greatest circle: if it be made that, as the sine of the complement of the pole's altitude is to the whole sine, so is the sine of the meridian altitude to a fourth term, there will be found the straight line KS in terms of the parts of the whole sine HE . And if again it be made that, as KM [?], the sine of the complement of the declination, is to KM [?], the whole sine, so is KS (as found) to a fourth term, KS will be found as the versed sine of the semidiurnal arc in terms of the parts of the whole sine of the parallel. And the same reasoning holds in the southern parallel, as is clear in the third figure, if one draws from H the sine of the complement of the pole's altitude.

All this, however, must be understood for the case when the complement of the pole's altitude is greater than the declination of that parallel whose semidiurnal arc is being investigated. For when that complement is not greater, either the parallel touches the horizon — and so its diurnal arc, if it is northern, will contain 24 hours, or, if southern, 0 hours 0 minutes — or else the whole northern parallel

stands above the horizon and the southern one below it, so that there will be no diurnal arc at all, but there will be continuous day on the northern parallel and continuous night on the southern. All of this appears in the second figure of the scholium to this proposition, where the complement of the pole's altitude CI is less than the declination IL of the northern parallel, and again the same complement AH is less than the declination HK of the southern parallel. But if that complement were equal to the declination, the northern parallel would touch the horizon at C, and the southern at A, as is evident.

[Margin: How the diurnal arc behaves when the complement of the pole's altitude is not greater than the declination of the parallel in question.]

But so that the demonstration of this proposition may be complete in all its numbers, we shall also give the finding of the twilights in the right sphere, where they are found much more easily. Let ABCD be the meridian of the analemma; AC the diameter of the right horizon, passing through the poles A, C; FG the diameter of the parallel of the horizon on which the beginning or end of twilight is placed; BD the diameter of the equator, cutting FG at H; IK the diameter of the parallel of the Sun (whichever it may be), cutting AC and FG at L and M. From L, the center of the parallel, let the semicircle INK of that parallel be described, and let AC and FG be extended as far as N and O.

Diagram. A small analemma of the right sphere. An outer circle is the meridian ABCD, with B at top, D at bottom, A at the left and C at the right; AC is the horizontal diameter of the right horizon, passing through the poles A and C. A vertical diameter BD is the equator, its center at E. A pair of parallel chords (FG and IK) crosses the circle: FG is the diameter of the horizon-parallel and BD cuts it at H; IK is the diameter of the Sun's parallel, cutting AC and FG at L and M. On L a semicircle INK of the parallel is drawn, and AC, FG are produced to N and O. Readable labels, by approximate position:

- Top: I, B, I
- Left to right across the middle: A, L, E, C, N
- Lower band: F, M, H, M, O
- Bottom: K, D, K
- Left/right extensions: N (left), O

Several small labels (the repeated I, L, M and the extension points N, O) are worn or ambiguous

Therefore AF, or CG, will be the arc of twilight when the Sun is on the equator; its sine is the straight line EH, corresponding to the arc of 18 degrees. Therefore, if the arc of 18 degrees is taken, the arc of twilight in the right sphere will be obtained, the Sun being at the equinoxes.

But when the Sun is on any parallel, say the parallel INK, the arc ON will be the length of twilight. If, then, it be made that, as IL — in so far as it is a part of the whole sine BE of the greatest circle, that is, in so far as it is the sine of the complement of the declination (for the arc IC, or IA, is the complement of the declination) — is to LM, the sine of 18 degrees of the same greatest circle, so is IL, in so far as it is the whole sine in the parallel INK, to a fourth term, then LM will be known in terms of the parts of the whole sine IL; and thus its arc NO, which measures the twilight, will be known. And this is true whether IK is the diameter of a southern parallel or of a northern, as is evident from the figure.

It should not be passed over that we can investigate the twilights of two opposite parallels with almost a single labor, if we use the first method. For since the semidiurnal arc of any parallel is equal to the seminocturnal arc of the opposite parallel — as we showed in the scholium of the preceding proposition — the versed sine KS of the semidiurnal arc of the southern parallel will be equal to the versed sine LS of the seminocturnal arc of the opposite northern parallel, as appears in the following first figure. [c] Moreover, the portion ST of the diameter of the southern parallel is equal to the portion ST of the diameter of the northern parallel. Therefore, if it be made that, as KN, the sine of the meridian altitude of the southern parallel, is to NO, the sine of 18 degrees, so is KS, the versed sine of the semidiurnal arc of the southern parallel, to a fourth term, the straight line ST will be known; [d] since KN has the same ratio to NO as KS has to ST. And with this ST known (which perhaps you will find more easily by the method prescribed at the end of this proposition), if it is added to the versed sine KS of the semidiurnal arc of the southern parallel, there will be produced KT, the sine...

[Margin: By what method the twilights of two opposite parallels are found with a single labor. [c] Euclid I.34. [d] Euclid VI.2.]

versed sine of the arc KR, which is compounded of the semidiurnal arc KQ and the twilight arc QR. Therefore, once the semidiurnal arc KQ has been taken away, the twilight arc QR will remain, which is what marks the twilight. Now this same ST, subtracted from LS — the versed sine of the seminocturnal arc of the opposite northern parallel, which is equal to the versed sine KS of the semidiurnal arc in the southern parallel, as we said — will leave TL, the versed sine of the arc LR. And this TL, subtracted from the seminocturnal arc LQ of the northern parallel

(which we established to be equal to the semidiurnal arc kQ of the southern parallel), leaves the twilight arc QR . So, as you see, by a single multiplication and division the line ST is found in either parallel, and by its help each twilight is drawn out, as we have explained.

We prefer, however, to find the said line ST in the southern parallel rather than in the northern; for the sine kN of the meridian altitude of the southern parallel is smaller than the sine of the meridian altitude of the northern parallel, and the versed sine KS of the semidiurnal arc of the southern parallel is smaller than the versed sine of the semidiurnal arc of the northern parallel. Working in the southern parallel therefore makes the multiplication and division easier, since they are carried out with smaller numbers.

[Margin: When twilight is continuous in the northern parallel.]

One thing must be noted here. When the line ST found in the southern parallel turns out to be greater than the versed sine KS of the semidiurnal arc — which does in fact happen when the sine kN of the meridian altitude is smaller than the sine of 18 degrees, as occurs in the second figure — then twilight is perpetual in the opposite northern parallel. For in that case the line ST cannot be subtracted, in the northern parallel, from LS , the versed sine of the seminocturnal arc; because LS is equal to the versed sine KS of the seminocturnal arc [?] of the southern parallel, and so is itself even smaller than the line ST . Hence on that night the Sun will never reach the parallel of the horizon whose diameter is XT , and so on.

Diagram. A horizontal band of three spherical projections (meridian-plane / solstitial-culure diagrams) belonging to the twilight discussion. Each is a great circle carrying the horizon, meridian, equator, a vertical circle, an oblique parallel of the Sun, and — set below the horizon — a further "parallel of the horizon" used to measure the depression at the start and end of twilight. The construction letters named in the surrounding text are: the main circle A (west), B (top), C (east), D (bottom); centre E ; equator through F ; the Sun's parallel through G, I, H ; the horizon-parallel through K, P ; with auxiliary points L, M, N, O, Q, R, S, T and Greek point-letters (ξ, θ) in the dense central cluster. The three figures differ in the obliquity of the drawn parallel (the rightmost is the most oblique/armillary-like). The outer cardinal letters ($A, B, C, D, H, K, P, G, I, L, O, Q$) are legible; the numerous small interior labels ($E, M, N, O, R, S, T, \xi, \theta$ and repeated $K/L/M$) are worn and cannot be individually resolved at this resolution.

- Outer ring (confirmed): $A, B, C, D, H, K, P, G, I, L, O, Q$

- Interior cluster (present but individually worn — [?]): E, M, N, O, R, S, T, ξ, θ

[— many interior point-labels worn.]

[Margin: How the twilights are to be computed by spherical triangles.]

Finally, so as to leave out nothing that bears on our subject, I should like also to prescribe a method by which the twilights can be computed by spherical triangles. Let it be, then, as in the third figure, that ABCD is the horizon, BD the meridian, AFC the equator, AEC the circle properly called the vertical, and GIH a parallel, whether northern or southern. Let KP be the parallel of the horizon below the horizon in which the Sun stands at the beginning of morning twilight or the end of evening twilight, so that it is 18 degrees distant from the horizon (on the more accepted opinion); and let it cut the Sun's parallel at the point K. Then KG will be the twilight arc, the one the Sun runs through in its own parallel from the beginning of twilight to its end, and GI will be the semidiurnal arc. From M, the arctic pole, draw through G and K two great circles MG, MK, cutting the equator at O and at N. And since, by *Sphaerica* II.10 of Theodosius, the arc FO is similar to the arc IG, and the arc ON similar to the arc GK, FO will be the semidiurnal arc of the parallel GH, and ON the twilight arc — which we shall determine as follows. Through the vertex E and through K, the Sun's place at the beginning of morning or the end of evening twilight, draw the great circle EK, and let it cut the horizon at L; the arc KL will be 18 degrees. Now in the spherical triangle EKM all the sides are known: for EM is the arc of the complement of the pole's altitude; the arc EK is compounded of the quadrant EL and the arc Lk of 18 degrees, so that the whole arc EK contains 108 degrees; and the arc MK, in a northern parallel, is the complement of the declination of the given parallel, while in a southern parallel it is compounded of the quadrant MN and the arc Nk of the declination. Therefore the angle EMK will be known — by the last proposition of Book 4 of Regiomontanus's *De triangulis*, or by proposition 63 of our own *Spherical Triangles* — and hence its arc FN will also be known. If from this the semidiurnal arc FO be subtracted, the remainder will be the twilight arc NO. Which is what was proposed.

PROBLEMA 15. PROPOS. 36.

From the known hour of the day to find the Sun's altitude above the horizon; and, conversely, from the Sun's known altitude to find the hour of the day.

Since in the following books we are going to describe sundials [horologia] by which we recognize the hours of the day, I think many readers will welcome it if

in this last proposition of the present book I show a method by which, without any sundial, we can find those same hours from the Sun's altitude alone, and conversely find the Sun's altitude from the known hour. I do this above all because the matter is of great use both for laying out sundials and, especially, for constructing quadrants, cylinder-dials [Cylindros horarios], and other instruments of that kind on which the hours are depicted — as I shall explain in the proper places.

Let the figures, then, be the same as in the preceding proposition. Place the Sun at the point O in its own parallel, and from O draw OR perpendicular to KL, the diameter of the parallel; through R draw a line parallel to AC, the diameter of the horizon, cutting KN, the sine of the meridian altitude, at T. Then OR will be the common section of the Sun's parallel and of the parallel of the horizon in which the Sun stands at the time of observation. For since each parallel is at right angles to the meridian, [a] their common section will also be at right angles to it, and therefore, by definition 3 of Euclid Book 11, perpendicular to the line KL. Since, then, the Sun at that moment lies in that common section, and is placed at the point O, OR — drawn perpendicular to KL — will be the common section of the said parallels. Hence the parallel of the horizon drawn through the Sun's centre at that time will cut the meridian at R, and consequently the parallel RT will be the common section of the meridian and of the parallel of the horizon. [b] For the meridian, lying in the horizon, makes with any parallel of the horizon two parallel sections. Therefore TN will be the right sine of the Sun's altitude — that is, of the arc lying between AC and the parallel RT in the vertical circle drawn through the Sun's centre, for which the meridian ABCD may be taken. For if it be carried around BD, the axis of the horizon, it will serve the office of all the verticals, as is plain.

[Margin: [a] Euclid XI.19. [b] Euclid XI.16.]

[Margin: How the Sun's distance from the meridian, in degrees, is recognized from a given hour.]

Before all else, then, we must work out the Sun's distance from the meridian in degrees, which any given hour will reveal in the following way. If we are speaking of astronomical hours, the 1st hour from noon — or the 11th from midnight — will be, above the horizon, 15 degrees distant from the meridian, that is, from noon; the 2nd hour from noon, or the 10th from midnight, will be 30 degrees, and so on, since each hour spans 15 degrees. But if the talk is of Italian or Babylonian hours, we must first find the time of noon on the proposed day, as we

taught in chapter 3 of the *Sphaera*, when we were dealing with the semidiurnal arcs.

Diagram. The six figures of Problema 15 / Propos. 36, printed in two rows of three (the "same figures" referred to in the text). Each is a meridian-plane projection of the sphere carrying horizon, meridian, equator, vertical circle, the Sun's oblique parallel, and the parallel of the horizon, with the sine-lines of the construction (KN the sine of the meridian altitude, TN the sine of the Sun's altitude, OR, RT, etc.). The recurring construction letters, taken from the text, are: main circle A (west, left), B (top), C (east, right), D (bottom); centre E; F on the equator; H, K on the upper left; G at lower left; I at lower right; L, O, P, Q on the right; and the interior sine-cluster M, N, R, S, T with Greek point-letters (α , β , γ , δ , ζ , ξ , θ). The six figures show successive cases (Sun's distance from meridian less than / equal to / greater than a quadrant, southern signs, equinox, and the vertical-circle case). Legible outer letters are listed below; the crowded interior labels are worn and cannot be individually confirmed cell-by-cell.

- Row 1, figures 1–3 — outer letters (confirmed): H, K, B, P, O, Q, A, C, E, G, I, L, D
- Row 2, figures 4–6 — outer letters (confirmed): V, B, H, K, F, A, C, O, G, D, plus (fig. 6, an 8-spoke circle) B, O, H, F, A, C, T, R, N, E, G, D
- Interior sine-cluster and Greek point-letters (present but individually worn — [?]): M, N, R, S, T, ξ , θ , α , β , γ , δ , ζ

[— dense interior point-labels and Greek minuscule letters worn.]

we were dealing. Once this is known, it will not be hard to understand how great the given hour's distance from the noon moment is. For example, when noon falls at 17½ hours from sunset and 6½ from sunrise — which happens when the day contains 13 hours — it is clear that the 20th hour (or the 15th) from sunset, and the 4th (or the 9th) from sunrise, is 2½ hours distant from noon, that is 37 degrees 30 minutes, and so on. And finally, if the old, or unequal, hours are proposed, we must divide the diurnal arc by 12 so as to know the length of one unequal hour. From this we shall easily recognize the Sun's distance from the meridian from a given unequal hour. For instance, at the beginning of ♋ [Cancer] the diurnal arc for latitude 42 degrees contains 15 hours 4 minutes [?]; dividing this by 12, we find that one unequal hour comprises 1 hour 15 minutes 10 seconds of equal time. Hence the 4th unequal hour (for example), or the 8th, will be 2 hours 30 minutes 40 seconds distant from noon, that is from the 6th unequal hour; while the 3rd unequal hour, or the 9th, will be 3 hours 46 minutes away from noon, and so with the rest. From these equal hours we shall find the Sun's distance from the

meridian in degrees, as before. Moreover, once the Sun's distance from the meridian is known, its complement will also be known, namely the difference between the quadrant and the said distance.

In another way too we shall find the distances of the hours from rising and setting to the meridian. Since the semidiurnal arc indicates the distance of the 24th hour from the meridian, if we take 15 degrees from it, the distance of the 23rd hour from sunset — and the 1st from sunrise — will remain; if from this we again subtract 15 degrees, we shall have the distance of the 22nd hour from sunset and the 2nd from sunrise; and so on, until the subtraction can no longer be made. For then the last distance found, once 15 degrees have been subtracted, leaves the distance of the following hour on the other side of the meridian circle; and if 15 degrees be added to it, the distance of the next hour is produced, and so on, until the number grows greater than the semidiurnal arc — which then indicates the distance of an hour below the horizon, and so can be of no use. You see an example in the adjoined table, with the Sun at the beginning of ♋ [Cancer], where the semidiurnal arc for an elevation of 42 degrees contains 109 degrees 21 minutes, that is, 7 hours and 17 minutes. So, if you reduce an hour's distance from the 24th hour to degrees and minutes, and subtract that from the semidiurnal arc, its distance after noon will remain; but if you cannot subtract it, take the semidiurnal arc away from it, and its distance before noon will remain. This you should understand of the hours from sunset; for the hours from sunrise the reverse is to be understood. For example, the 19th hour from sunset is distant from the 24th hour by 5 hours, which make 75 degrees; these subtracted from the semidiurnal arc of 109 degrees 21 minutes leave 34 degrees 21 minutes, the distance of the 19th hour after noon. Likewise the 15th hour is 9 hours away from the 24th, that is 135 degrees; if from these you take the semidiurnal arc of 109 degrees 21 minutes, there will remain a distance before noon of 25 degrees 39 minutes. So too, because the 3rd hour from sunrise is 3 hours from the 24th, that is 45 degrees, these subtracted from the semidiurnal arc of 109 degrees 21 minutes leave a distance from the meridian, before noon, of 64 degrees 21 minutes. But the 13th hour from sunrise is distant from the 24th by 13 hours, that is 195 degrees; from these the semidiurnal arc of 109 degrees 21 minutes being subtracted leaves a distance from the meridian, after noon, of 85 degrees 39 minutes.

Table — full-width numeric table.

The four inner columns are, left to right: hours from setting; G. (degrees); M. (minutes); hours from rising. The outer vertical brackets label the groups: on the

left, the upper block (rows 24–17) is "Hours after noon" and the lower block (rows 16–7) is "Hours before noon"; on the right, the upper block is "Hours before noon" and the lower block is "Hours after noon"; the foot of both brackets is marked "below the horizon" (sub horiz.).

Hours from setting	G. (deg.)	M. (min.)	Hours from rising
24	109	21	24
23	94	21	1
22	79	21	2
21	64	21	3
20	49	21	4
19	34	21	5
18	19	21	6
17	4	21	7
16	10	39	8
15	25	39	9
14	40	39	10
13	55	39	11
12	70	39	12
11	85	39	13
10	100	39	14
9	115	39	15
8	130	39	16
7	145	39	17

[Margin: How the Sun's altitude above the horizon is computed from a known hour. — When the Sun's distance from the meridian in a northern parallel is less than a quadrant.]

Since, then, it holds that as kM , the whole sine, is to MR , the sine of the complement of the Sun's distance from the meridian, so $k\lambda$, half the line compounded of the sine of the meridian altitude and the sine of the meridian depression, is to the line λT : if it be arranged that, as the whole sine is to the sine of the complement of the Sun's distance from the meridian, so $k\lambda$ (half the line compounded of the sine of the meridian altitude and the sine of the meridian depression) is to a fourth term, the line λT will be found — namely the difference

between TN, the sine of the Sun's altitude at the time of observation, and the line λN . This difference is the one between the aforesaid half-line $k\lambda$ and KN, the sine of the meridian altitude. From this line λT we shall find TN, the sine of the Sun's altitude, and hence the Sun's altitude itself, in the following way. In the northern parallels, when the Sun's distance from the meridian is less than a quadrant, that is less than six hours, add the line λT (once found) to λN , the difference between the said half-line and the sine of the meridian altitude. For in this way the sine TN of the Sun's altitude will be compounded, as appears in the first figure and the third.

Diagram. The same six figures as on the facing page (see fig-p107-1), again printed in two rows of three: meridian-plane projections of the sphere for the successive cases of Problema 15 / Propos. 36. Construction letters as before — main circle A, B, C, D; centre E; equator through F; H, K upper left; G lower left; I lower right; L, O, P, Q on the right; interior sine-cluster M, N, R, S, T with Greek point-letters (α , β , γ , δ , ζ , ξ , θ). The first and third figures illustrate the "less than a quadrant" case; the second, the "greater than a quadrant"; the fourth shows the vertical-circle construction (with the northern parallel's diameter VX, points Y, Z); the sixth is the equinoctial case (8-spoke circle, letters H, E, R, N, T). Legible outer letters are confirmed below; the crowded interior labels are worn.

- Outer letters (confirmed): A, B, C, D, H, K, P, O, Q, G, I, L, V, F
- Interior sine-cluster and Greek point-letters (present but individually worn — [?]): M, N, R, S, T, ξ , θ , α , β , γ , δ , ζ , and (fig. 4) X, Y, Z

[— dense interior point-labels and Greek minuscule letters worn.]

[Margin: When the Sun's distance from the meridian in a northern parallel equals a quadrant. [a] Euclid VI.4. [b] Euclid I.34.]

But if the Sun's distance from the meridian contains a quadrant, that is six hours, then the difference between the said half-line and the sine of the meridian altitude — namely the line λN — is itself the sine of the Sun's altitude, as is clear from the same figures. For then the Sun stands at the point P of its parallel, and so the line λM will be a portion of the diameter of the parallel of the horizon, and so on. Hence, if the aforesaid half be subtracted from the sine of the meridian altitude, the sine of the Sun's altitude will remain.

We shall also find the Sun's altitude in another way when it is six hours from the meridian. In the first figure draw from M and F two perpendiculars $M\alpha$, $F\beta$ to AC. [a] Since it holds that, as EF, the whole sine, is to $F\beta$, the sine of the pole's altitude, so EM, the sine of the declination, is to $M\alpha$, the sine of the Sun's altitude [b] (for

Mα is equal to the sine λN of the Sun's altitude) — if it be arranged that, as the whole sine is to the sine of the pole's altitude, so the sine of the declination is to a fourth term, the sine of the Sun's altitude will be found.

[Margin: When the Sun's distance from the meridian in a northern parallel is greater than a quadrant. — When the Sun is in a southern parallel.]

But if the Sun's distance from the meridian exceeds a quadrant, that is six hours, as is seen in the second figure, then the line λT (once found) must be subtracted from λN, the difference between the said half-line and the sine of the meridian altitude, so that TN, the sine of the Sun's altitude, may be obtained.

In the southern signs, finally, the difference between the said half-line and the sine of the meridian altitude — that is, the line λN — must always be subtracted from the line λT once found, so that TN, the sine of the Sun's altitude, may remain, as is clear from the fourth figure and the fifth.

[Margin: How the Sun's altitude above the horizon at the equinoxes is to be reckoned from a given hour. [c] Euclid VI.2 or VI.4.]

Furthermore, when the Sun is at the equinoxes, we shall obtain its altitude much more briefly from a given hour. [c] For since, in the sixth figure, it holds that as HE, the whole sine, is to RE, the sine of the complement of the Sun's distance from the meridian, so HN, the sine of the complement of the pole's altitude, is to TN, the sine of the Sun's altitude — if it be arranged that, as the whole sine is to the sine of the complement of the Sun's distance from the meridian, so the sine of the complement of the pole's altitude is to a fourth term, the sine of the Sun's altitude at the time of observation will be obtained.

[Margin: How the Sun's altitude in the vertical circle is found from a given hour, even if the hour is unknown. [d] Euclid VI.2.]

Likewise, we shall find without much labor the Sun's altitude when it stands in the vertical circle properly so called, even if we do not know the hour. In the fourth figure draw the diameter VX of the northern parallel — for only in northern parallels can the Sun stand above the horizon in the vertical — cutting the axis at Y and the vertical's diameter at the point Z, and through Z draw the diameter of the parallel of the horizon, so that ZE is the sine of the Sun's altitude when it is in the vertical. Then, having drawn Dγ perpendicular to HE, cutting VX at δ, [d] since it holds that, as Dγ, the sine of the pole's altitude, is to γδ, the sine of the declination of the proposed parallel, so DE, the whole sine, is to EZ, the sine of the Sun's altitude — if it be arranged that, as the sine of the pole's altitude is to

the sine of the declination, so the whole sine is to a fourth term, we shall find the sine of the Sun's altitude in the vertical. Let this be an example of the matter. With the Sun at the beginning of ♊ [Capricorn; sign-glyph worn — pinned by the in-text declination of $23^{\circ}30'$; note that the vertical-circle case requires a northern parallel, so this may instead be ♋ Cancer], in the Roman horizon, or at latitude 42 degrees: let it be arranged that, as 66913, the sine of the pole's altitude, is to 39874, the sine of the declination — which contains 23 degrees...

30 minutes, so 100000, the whole sine, is to a fourth term; and we shall find about 59591, the sine of the altitude sought, to which corresponds an arc of 36 degrees 35 minutes, for the Sun's altitude in the vertical circle at the given latitude.

But if the declination of the northern parallel equals the pole's altitude — that is, the arc BH — then the parallel will touch the vertical circle at B, the Zenith, as is plain. Hence the Sun's altitude in the vertical will then amount to 90 degrees. But if the declination is greater than the pole's altitude, the parallel will not cut the vertical circle, as is clear from the third figure. Therefore the Sun will then never reach the vertical. And this is enough about the first part of this problem. But before we proceed to the second part, let us illustrate the whole matter with a few examples.

[Margin: First example.]

Suppose, then, that the Sun is at the beginning of Gemini [♊] or Leo [♌], when of course the meridian altitude is 68 degrees 12 minutes and the meridian depression 27 degrees 48 minutes, while the day contains about 14 hours 35 minutes — so that noon falls at hour 16 minutes 43 by the Italian reckoning, and at hour 7 minutes 17 by the Babylonian. And suppose we seek, in the Roman horizon (that is, at latitude 42 degrees), the Sun's altitude at hour 20 from sunset, or at hour 4 from sunrise, each of which is distant from the meridian by 3 hours 17 minutes, that is, by 49 degrees 15 minutes. Let it be arranged that, as 100000, the whole sine, is to 65275, the sine of the complement of the Sun's distance from the meridian, so 69743, the half of the sum compounded of the sine of the meridian altitude and the sine of the meridian depression, is to a fourth; and this number will be found to be about 45524. Added to 23105 — the difference between the said half of the compounded sum and the sine of the meridian altitude — because the Sun is placed on a northern parallel and its distance from the meridian is less than 6 hours, it makes 68629. The arc of this, 43 degrees 20 minutes, will give the Sun's altitude at the proposed hour.

[Margin: Second example.]

Again, with the Sun on the same parallel, suppose we seek its altitude at hour 6 from the meridian, that is, at midnight. The difference between 69743 — the half of the sum compounded of the sine of the meridian altitude and the sine of the meridian depression — and 92848, the sine of the meridian altitude, namely 23105, will be the sine of the Sun's altitude sought; for the Sun is then northern and has a distance from the meridian equal to a quadrant, or 6 hours. Therefore the Sun's altitude will then be about 13 degrees 22 minutes. This too can be found in the following way, as we showed before. Let it be arranged that, as 100000, the whole sine, is to 66913, the sine of the pole's altitude, so 34529, the sine of the declination, is to a fourth; and this sine of the Sun's altitude will be found to be about 23104, as above.

[Margin: Third example.]

Moreover, with the Sun tracing the same parallel, suppose we seek its altitude at hour 23 minutes 30 from sunset, or at hour 0 minutes 30 from sunrise, so that its distance from the meridian is 6 hours 47 minutes, that is, 101 degrees 45 minutes. Let it be arranged that, as 100000, the whole sine, is to 20364, the sine of the complement of the Sun's distance from the meridian, so 69743, the half of the sum compounded of the sine of the meridian altitude and the sine of the meridian depression, is to a fourth; and this number will be found to be about 14202. Subtracted from 23105 — the difference between the aforesaid half and the sine of the meridian altitude — because the Sun, being on a northern parallel, is here supposed to have a distance from the meridian greater than 6 hours, it leaves 8903, the sine of the Sun's altitude at that hour; and so the Sun's altitude will amount to 5 degrees 7 minutes.

[Margin: Fourth example.]

Finally, suppose the Sun's altitude is to be found at hour 3 after noon, or at hour 9 after midnight, the Sun being at the beginning of Sagittarius [♐]; the sign-sort is worn — pinned by the in-text values: the meridian altitude here is 27°48' (sine 46638) giving declination $\square$ -20°12', the southern counterpart of Gemini/Leo] or Aquarius [♒]. Let it be arranged that, as 100000, the whole sine, is to 70710, the sine of the complement of the Sun's distance from the meridian, so 69743, the half of the sum compounded of the sine of the meridian altitude and the sine of the meridian depression — this being the same as before, since Sagittarius [♐] and Aquarius [♒] are signs opposite to the signs Gemini [♊] and Leo [♌]; for it is established from what has been said that the meridian altitude of one sign is the meridian depression of the other, and conversely — is to a fourth; and this number will be found to be very nearly 49315. If from it 23105 be taken — the

difference between the aforesaid half and the sine of the meridian altitude, because the Sun is placed on a southern parallel — there will remain 26210, the sine of the Sun's altitude; and the arc of this, 15 degrees 12 minutes, will give the Sun's altitude at that time. And so the method by which we can pass from a known hour to knowledge of the Sun's altitude is plainly evident. Let us now explain the other part of the proposition: namely, by what method we may determine the hour from the Sun's known altitude. This we shall carry out as follows.

[Margin: [a] Euclid VI.2.] [Margin: By what method the hour is found from the Sun's altitude above the horizon once known.]

[a] Since, in the same figures, it holds that, as $K\lambda$ — the half of the sum compounded of the sine of the meridian altitude and the sine of the meridian depression — is to λT , the difference between TN (the sine of the Sun's altitude) and λN (the difference between the aforesaid half and the sine of the meridian altitude), so KM , the whole sine, is to MR , the sine of the complement of the Sun's distance from the meridian: if it be arranged that, as the half of the sum compounded of the sine of the meridian altitude and the sine of the meridian depression is to the difference which the sine of the Sun's altitude and the difference between the said half and the sine of the meridian altitude have between themselves, so the whole sine is to a fourth, we shall obtain the sine of the complement of the Sun's distance from the meridian. And so the complement of the Sun's distance from the meridian will itself be known, by means of which we shall determine the Sun's distance from the meridian, and hence also the hour at the time of observation, in this way. When the Sun is northern and the sine of the Sun's altitude exceeds the difference between the said half and the sine of the meridian altitude — as appears in the first and third figures — let the complement of the Sun's distance from the meridian, once found, be subtracted from the quadrant, and there will remain the Sun's distance from the meridian in degrees.

But if, with the Sun northern, the sine of the Sun's altitude turns out equal to the difference between the aforesaid half and the sine of the meridian altitude, the Sun will be distant a whole quadrant, or six hours, from the meridian, as can be made clear from the three earlier figures. For if λN — the difference between KN , the sine of the meridian altitude, and $K\lambda$, the aforesaid half — be set as the sine of the Sun's altitude, so that λM is the portion of the diameter of the horizon's parallel passing through the Sun, the quadrant KP will give the Sun's distance from the meridian.

But if, with the Sun northern, the sine of the Sun's altitude comes out less than the difference between the aforesaid half and the sine of the meridian altitude — as happens in the second figure — let the complement of the Sun's distance from the meridian, once found, be added to the quadrant, and the Sun's distance from the meridian in degrees will be made up.

Finally, with the Sun southern, the complement of the Sun's distance from the meridian, once found, must always be deducted from the quadrant, so that the Sun's distance from the meridian in degrees may remain, as is evident from the fourth and fifth figures. For if from the quadrant KP the complement OP of the Sun's distance from the meridian be subtracted, there will remain KO, the Sun's distance from the meridian.

[Margin: [b] Euclid VI.2 or VI.4.] [Margin: By what method, at the equinoctial time, the hour is discovered from the Sun's altitude above the horizon once known.]

This distance of the Sun from the meridian we shall discover more easily from the Sun's known altitude when the Sun is crossing the Equator. For, as is clear from the sixth figure, [b] it holds that, as HN, the sine of the complement of the pole's altitude, is to TN, the sine of the Sun's altitude at the time of observation, so HE, the whole sine, is to RE, the sine of the complement of the Sun's distance from the meridian. Therefore, if it be arranged that, as the sine of the complement of the pole's altitude is to the sine of the Sun's altitude at the time of observation, so the whole sine is to a fourth, the sine of the complement of the Sun's distance from the meridian will be found, and thus the distance itself will not be able to lie hidden.

[Margin: Example.]

Let us explain the matter by one example. Suppose the Sun is at the beginning of Gemini [♊] or Leo [♌], and that we have found the Sun's altitude before noon to be 43 degrees 20 minutes, from which the hour at the time of that observation is to be explored. Let it be arranged that, as 69743 — the half of the sum compounded of the sine of the meridian altitude and the sine of the meridian depression — is to 45519, the difference between the sine of the Sun's altitude and the difference between the aforesaid half and the sine of the meridian altitude, so 100000, the whole sine, is to a fourth. For there will come out about 65267, the sine of the complement of the Sun's distance from the meridian, whose arc, 40 degrees 45 minutes, subtracted from the quadrant — because the Sun is northern and the sine of the Sun's altitude, namely 68624, exceeds the difference (namely

23105) which is found between the often-mentioned half and the sine of the meridian altitude — will leave 49 degrees 15 minutes for the Sun's distance from the meridian, which comprises 3 hours 17 minutes. Since, then, the observation is made before noon, it will then be hour 8 minutes 43 after midnight, in the manner of the astronomers. And if the observation had been made after noon, it would be hour 3 minutes 17 from the meridian. But according to the Italians it will be hour 13 minutes 26 from sunset, because on that day noon falls at hour 16 minutes 43; and if from that noon the Sun's distance from the meridian just found, namely 3 hours 17 minutes, be taken away, there will remain 13 hours 26 minutes. But if the observation were made after noon, this distance would have to be added, so that the hour from sunset might come out known; and the hour would then be found to be 20 from sunset. Finally, according to the Babylonians it will be hour 4 minutes 0 from sunrise. For since on that day noon falls, according to these hours, at hour 7 minutes 17, if from this meridian time the Sun's distance from the meridian found, namely 3 hours 17 minutes, be subtracted, there remains hour 4. But if the observation were made after noon, this distance would have to be added, and thus the hour would be found to be 10 minutes 43 from sunrise. From this example the rest will be understood without effort.

[Margin: How great the hour is when the Sun is in the vertical circle, and by what method to determine it.] [Margin: [a] Euclid XI.19.]

With the Sun in the vertical circle, we shall likewise, over and above the method so far handed down, arrive at the hour from its altitude. In the fourth figure, from the point Z — where the parallel of the Sun intersects the vertical — draw $Z\beta$ perpendicular to VX , as far as the circumference of the parallel of the Sun described about the diameter VX from the center Y ; then $Z\beta$ will be the common section of the parallel of the Sun and the parallel of the horizon, whose semidiameter is μZ — which will become clear as follows. Since each parallel is perpendicular to the meridian, [a] their common section will also be perpendicular to the same, and hence, by definition 3 of Euclid's Book XI, perpendicular to VX at the point Z , where the said parallels cut one another in the meridian. Therefore $Z\beta$, being perpendicular to VX at Z , will be the common section of those parallels. From which it follows that, since Z is the center of the parallel of the horizon, whose semidiameter is μZ , the line $Z\beta$ is equal to the semidiameter μZ — inasmuch as all lines drawn from Z to the circumference of the parallel whose semidiameter is μZ (such as is also $Z\beta$, its common section with the parallel of the Sun, as was shown) are equal to the semidiameter μZ . Now since μZ is the sine of the complement of the Sun's altitude when it is in the vertical circle — namely the sine of the arc $B\mu$ — it will hold that, as VY , the sine

of the complement of the declination of the parallel VX (insofar as VY is a part of the whole sine AE of the greatest circle), is to VY insofar as it is the whole sine in its own parallel, so βZ , insofar as it is a part of the same whole sine AE of the greatest circle (and this is indeed equal to the sine μZ , the complement of the Sun's altitude in the vertical, as we have demonstrated), is to βZ insofar as it is a part of the whole sine VY. Therefore, if it be arranged that, as the sine of the complement of the declination of the proposed parallel is to the whole sine, so the sine of the complement of the Sun's altitude when it is in the vertical is to a fourth, $Z\beta$ will become known — namely the sine of the Sun's distance from the meridian. By this method, with the Sun tracing the parallel of Cancer [♋], we find hour 4 minutes 4, a little more, before and after noon, while it is in the vertical circle, at latitude 42 degrees.

[Margin: How to tell whether the Sun, being in the northern signs, has reached the vertical circle or not.]

From these hours you will easily infer at what hour after midnight, or from sunset or sunrise, it is when the Sun holds the vertical, provided the time of noon be known beforehand in the manner of the Italians and Babylonians. Again, from a known hour before or after noon on any day, with the Sun in the northern signs, you will gather whether the Sun has reached the vertical circle, or has not yet come to it, or indeed has already passed it. For when, in the forenoon, the known hour indicates a greater distance from the meridian than was found at the vertical circle (as, in our example, if it should indicate more than 4 hours 4 minutes), it is evident that the Sun has not yet come to the vertical by the motion of the prime mover; when it shows an equal distance, that the Sun is in the vertical; and when, finally, it shows a smaller distance, that the Sun has already passed the vertical and is placed between the vertical and the meridian on the southern side. In the afternoon you are to understand the contrary.

[Margin: How the Sun's altitude above the horizon is investigated from a known hour by a method other than the one above.] [Margin: [b] Euclid VI.2 or VI.4.]

We can carry out this whole problem in the following way as well. [b] Since, in the same figures, all set out above, it holds that, as KS, the versed sine of the semidiurnal arc, is to RS, the difference between the versed sine of the semidiurnal arc and the versed sine of the Sun's distance from the meridian, so KN, the sine of the meridian altitude, is to TN, the sine of the Sun's altitude: if it be arranged that, as the versed sine of the semidiurnal arc is to the difference between the versed sine of the semidiurnal arc and the versed sine of the Sun's distance from the meridian, so the sine of the meridian altitude is to a fourth, the

sine of the Sun's altitude sought will be found, and thus the altitude itself will be manifest.

[Margin: How the Sun's altitude at the equinoxes is known from a given hour.]

At the Equator, moreover — as appears from the sixth figure — the versed sine of the semidiurnal arc is the whole sine HE, and the difference between it and the versed sine of the Sun's distance from the meridian is RE, the sine of the complement of the Sun's distance from the meridian; and the sine of the meridian altitude is the sine of the complement of the pole's altitude. Hence, if it then be arranged that, as the whole sine is to the sine of the complement of the Sun's distance from the meridian, so the sine of the complement of the pole's altitude is to a fourth, the sine of the Sun's altitude at the time of observation will be obtained, as was also demonstrated above.

[Margin: By what method the hour is investigated from the Sun's altitude above the horizon once known.] [Margin: [c] Euclid VI.2 or VI.4.]

Again, [c] since it holds that, as kN, the sine of the meridian altitude, is to TN, the sine of the Sun's altitude, so KS, the versed sine of the semidiurnal arc, is to RS, the difference between the versed sine of the semidiurnal arc and the versed sine of the Sun's distance from the meridian: if it be arranged that, as the sine of the meridian altitude is to the sine of the Sun's altitude found at the time of observation, so the versed sine of the semidiurnal arc is to a fourth, a number will be found which, subtracted from the versed sine of the semidiurnal arc, leaves the versed sine of the Sun's distance from the meridian. From this versed sine we shall then find the Sun's distance from the meridian, and thence the hour, by this method. When the versed sine of the Sun's distance from the meridian, once found, is less than the whole sine — as always happens in the southern signs, and in the northern signs too whenever the Sun's distance from the meridian is less than a quadrant — we shall subtract it from the whole sine, and shall subtract from the quadrant the arc of the right sine of the remainder, and the Sun's distance from the meridian will remain. But if the said versed sine turns out equal to the whole sine — which can happen only twice in any diurnal arc of the northern parallels — the Sun's distance from the meridian will be a quadrant, comprising six hours. If, finally, the versed sine found turns out greater than the whole sine, we shall subtract...

from it the whole sine, and we shall add to the quadrant the arc of the right sine of the remainder, and so complete the Sun's distance from the meridian.

With the Sun at the equinoxes — as is manifest from the sixth figure — the sine of the meridian altitude is the sine of the complement of the pole's altitude, the versed sine of the semidiurnal arc is the whole sine HE, and the difference between the versed sine of the semidiurnal arc and the versed sine of the Sun's distance from the meridian is the sine of the complement of the Sun's distance from the meridian. Therefore, if it then be arranged that, as the sine of the complement of the pole's altitude is to the sine of the Sun's altitude at the time of observation, so the whole sine is to a fourth, the sine of the complement of the Sun's distance from the meridian will be obtained. And this too was demonstrated above.

[Margin: Which hour it is: how this is to be known at the equinoxes from a given altitude of the Sun. Example.]

EXAMPLE. Let us suppose the Sun on the parallel of Sagittarius [$\times$]; worn sign-sort — pinned by the meridian-altitude value $27^{\circ}48'$ (sine 46638) $\rightarrow$ declination $\approx -20^{\circ}12'$ or Aquarius [$\approx$], having after noon an altitude above the horizon of 6 degrees 45 minutes. Let it be arranged that, as 46638, the sine of the meridian altitude, is to 11753, the sine of the Sun's altitude found, so 66867, the versed sine of the semidiurnal arc, is to a fourth; and there will come out this number, nearly 16851, which, subtracted from 66867, the versed sine of the semidiurnal arc, leaves 50016, the versed sine of the Sun's distance from the meridian. Since this is less than the whole sine, we shall subtract it from 100000, the whole sine, and from the quadrant we shall take away the arc, 29 degrees 59 minutes, of the right sine 49984 of the remainder; and we shall have the Sun's distance from the meridian as 60 degrees 1 minute, that is, 4 hours 0 minutes after noon, because the observation is supposed to have been made after noon. Before noon it would be hour 8 after midnight. And once the hour of noon is known, in the manner of the Italians and Babylonians, from the length of the day, we shall easily discover what hour from sunset or from sunrise corresponds to the fourth hour from the meridian, or the eighth after midnight — that is, the fourth before noon — and so on.

[Margin: How the Sun's altitude in the right sphere is elicited at the equinoxes from a given hour.]

For the rest, in the right sphere this whole problem will be very easy. For let the Meridian be ABCD, its center E; the diameter of the right horizon AC, passing through the poles A, C; the diameter of the Equator BD; the diameter of any parallel of the Sun FG, cutting the diameter of the horizon at H; the diameter of the parallel of the horizon Ik, cutting BD and FG at L and M — this parallel

passing at the time of observation through the center of the Sun. And finally, from H, the center of the parallel of the Sun, let a semicircle FNOG be described, which IK and AC, produced, cut at N and O.

Diagram. A circle representing the Meridian ABCD, with center E, drawn symmetrically (mirror-imaged left and right, so most construction letters appear twice). Its horizontal diameter is the diameter of the right horizon AC (through the poles A on the left, C on the right); its vertical diameter is the diameter of the Equator, B at the top and D at the bottom. A chord parallel to AC, above center, is the diameter of the parallel of the horizon; a second chord parallel to AC, at center level, is the diameter of the parallel of the Sun. The upper chord is drawn as a semicircle band (FNOG) above the horizon diameter. Cross-hatching of horizontal/vertical rule-lines divides the interior into the construction cells.

- B (top center): top of the Equator diameter
- F, F (upper, flanking B): endpoints of the Sun's-parallel semicircle, on the circumference near the top
- N, N (upper band, near the ends): where IK and AC produced cut the semicircle
- I (upper band, left) / K (upper band, right): endpoints of the parallel-of-horizon diameter Ik
- M, M (upper band, inner, on the Sun's-parallel line): where Ik cuts FG
- L (upper band, center, on BD): where Ik cuts the Equator diameter BD
- O, O (horizon line, outer ends): where IK and AC produced cut the semicircle
- A (horizon line, left) / C (horizon line, right): the poles, ends of the horizon diameter
- H, H (horizon line, inner): where the Sun's parallel FG cuts the horizon diameter AC
- E (center): center of the Meridian
- G, G (bottom, flanking D): lower endpoints of the Sun's-parallel construction, on the circumference near the bottom
- D (bottom center): bottom of the Equator diameter

[Margin: The hour of the day which [?] at the equinoctial time is to be investigated in the right sphere from the Sun's known altitude.]

Therefore the arc AI, or CK, will be the altitude of the Sun when it is at the Equator and on the parallel of the horizon whose diameter is IK — that is, at the point I or k — as is evident, if the Meridian ABCD be turned about the axis of the

horizon BD, so that it is joined with the Equator of the right sphere and with the vertical. For the Equator, in the right sphere, is then also a vertical circle, measuring the Sun's altitudes at the equinoxes. Wherefore, since BI, or BK, is the Sun's distance from the meridian, the arc IA, or kC — that is, the complement of the Sun's distance from the meridian — will be the Sun's altitude. Hence, if the Sun's altitude be sought from a known hour in the right sphere, the Sun being at the equinoxes, we must take the complement of the Sun's distance from the meridian for the Sun's altitude.

[Margin: How the Sun's altitude, when it is on any parallel, is found in the right sphere from a given hour.]

But with the Sun placed on the parallel FNOG, and on the parallel of the horizon whose diameter is IK — that is, at the point N — in the same right sphere, the arc FN will be the Sun's distance from the meridian, and HM will be equal to the sine of the arc AI, or Ck, which measures the Sun's altitude at the time of observation, as is established if the Meridian ABCD be revolved about the axis of the horizon BD, so as to take the place of all the verticals in turn. If, then, it be arranged that, as FH, the whole sine of the Sun's parallel, is to MH, the sine of the complement of the Sun's distance from the meridian, so FH, insofar as it is a part of the whole sine BE in the greatest circle — that is, insofar as it is the sine of the complement of the declination of the Sun's parallel — is to a fourth, HM will be found in the parts of the same whole sine BE, and thus insofar as it is the sine of the Sun's altitude AI, or CK. The Sun's altitude AI, or CK, will therefore come out known. And so the first part of the problem has been explained.

[Margin: The hour of the day, at the equinoctial time, is to be investigated in the right sphere from the Sun's known altitude.]

Now from the Sun's known altitude we shall obtain the hour, in the same right sphere, in this way. With the Sun at the equinoxes, we shall take the complement of the Sun's altitude for its distance from the meridian, and so on, as is clear from the figure. For BI, or BK, the Sun's distance from the meridian, is the complement of the Sun's altitude AI, or CK.

[Margin: By what method the hour of the day, outside the equinoctial time, is to be inquired in the right sphere from the Sun's known altitude.]

But with the Sun placed outside the Equator, on any parallel FNOG: let it be arranged that, as FH, the sine of the complement of the declination, is to HM, the sine of the Sun's altitude, so FH, insofar as it is the whole sine in the parallel of the Sun, is to a fourth; and MH will be obtained in the parts of the same whole

sine — insofar, that is, as it is the sine of the complement of the Sun's distance from the meridian; and thus the complement of this distance, NO, will be known. Therefore, with this complement NO taken away from the quadrant, the remainder will be the Sun's distance from the meridian, FN.

[Margin: How the Sun's altitude is elicited from the hour by yet another method in the oblique sphere. [a] Euclid I.29.]

But by this method too, if you please, we shall carry out the whole problem in the oblique sphere. In the first figure of this proposition, from the point R — where the parallel of the Sun and the parallel of the horizon intersect one another — draw a perpendicular $R\Diamond[?]$ to the diameter of the horizon AC. Then, in the triangle $RS\Diamond[?]$, the line $R\Diamond[?]$ will be the sine of the complement of the pole's altitude — namely of the angle $RS\Diamond[?]$, [a] which is equal to the angle AEH — if RS be set as the whole sine. We shall therefore first find the line RS in the parts of the whole sine of the greatest circle in the sphere, in this way. Let it be arranged that, as KM, the whole sine in the parallel of the Sun, is to KM insofar as it is the sine of the complement of the declination of the parallel KL, so RS — the difference between KS, the versed sine of the semidiurnal arc, and KR, the versed sine of the Sun's distance from the meridian — is to a fourth. For by this method RS will be found, known in the parts of the whole sine of the greatest circle. Then let it be arranged that, as RS, the whole sine, is to $R\Diamond[?]$, the sine of the complement of the pole's altitude, so RS, insofar as it has been made known in the parts of the whole sine of the greatest circle, is to a fourth; and $R\Diamond[?]$ will be found, known in the parts of the same whole sine of the greatest circle. Since, therefore, $R\Diamond[?]$ is the sine of the Sun's altitude, the Sun's altitude itself will be known.

Besides this: let it be arranged that, as $R\Diamond[?]$, the sine of the complement of the pole's altitude, is to RS, the whole sine, so $R\Diamond[?]$, insofar as it is the sine of the Sun's known altitude, is to a fourth; and RS will be found, known in the parts of the whole sine of the greatest circle. Hence we shall find the same also in the parts of the whole sine KM, in the proposed parallel of the Sun — insofar, that is, as RS is the difference between KS, the versed sine of the semidiurnal arc, and KR, the versed sine of the Sun's distance from the meridian — in this way. Let it be arranged that, as KM, the sine of the complement of the declination of the parallel kL, is to KM, the whole sine in the parallel, so RS, insofar as it has been made known in the parts of the whole sine of the greatest circle, is to a fourth; and RS will be found, known, insofar as it is the difference between the versed sine...

the versed sine of the semidiurnal arc, and the versed sine of the Sun's distance from the meridian. And therefore the versed sine of the Sun's distance from the

meridian will also become known — namely if RS, found by this method, is subtracted from KS, the versed sine of the semidiurnal arc — and by this means the Sun's distance from the meridian itself will be known.

[Margin: How the hour is found from the Sun's known altitude.]

But of all the methods this one will perhaps be the most convenient. [Margin: a — Euclid VI.2 or VI.4.] Since at the outset of this proposition it was laid down, among the first five figures, that as KM (the whole sine in the Sun's parallel) is to KR, so is Kλ (half of the line compounded of the sine of the meridian altitude and the sine of the meridian depression) to KT; [Margin: b — Euclid VI.2.] and that as kR is to RS — the difference between KS, the versed sine of the semidiurnal arc, and KR, the versed sine of the Sun's distance from the meridian — so is KT to TN, the right sine of the Sun's altitude: then *ex aequo* it will follow that as KM (the whole sine in the Sun's parallel) is to RS — the difference between the versed sine of the semidiurnal arc and the versed sine of the Sun's distance from the meridian — so is Kλ (half of the line compounded of the sine of the meridian altitude and the sine of the meridian depression) to TN, the right sine of the Sun's altitude.

Therefore, if we set it up so that as the whole sine is to that difference between the versed sine of the semidiurnal arc and the versed sine of the Sun's distance from the meridian, so is that half-line compounded of the sine of the meridian altitude and the sine of the meridian depression to a fourth term, the fourth term found will be the right sine of the Sun's altitude that is sought; and so the altitude itself becomes known.

[Margin: How the altitude of the Sun may otherwise be found from the hour.]

Conversely, if it is set up so that as Kλ (the aforesaid half-line) is to TN (the sine of the Sun's altitude), so is KM (the whole sine) to a fourth term, then RS will be found — the difference between the versed sine of the semidiurnal arc and the versed sine of the Sun's distance from the meridian. When this difference is subtracted from the versed sine of the semidiurnal arc, the remainder will be kR, the versed sine of the Sun's distance from the meridian, and so on.

[Margin: How the hour is to be reckoned from the altitude of the Sun otherwise than was taught above.]

Or else we shall accomplish the same task in this way (which I myself find more satisfactory). [Margin: c — Euclid VI.2 or VI.4.] Since as KM (the whole sine in the Sun's parallel) is to KR (the versed sine of the Sun's distance from the meridian), so is Kλ (half of the line compounded of the sine of the meridian altitude and the sine of the meridian depression) to KT — the difference between kN, the sine of

the meridian altitude, and TN, the sine of the Sun's altitude at the time of observation: then, if it is set up so that as the whole sine is to the versed sine of the Sun's distance from the meridian, so is that half-line compounded of the sine of the meridian altitude and the sine of the meridian depression to a fourth term, the value of the line kT will be found, which, subtracted from the sine of the meridian altitude, will leave the sine of the Sun's altitude.

[Margin: By what method the altitude of the Sun may otherwise be found from the hour.]

Likewise, if conversely it is set up so that as $k\lambda$ (the aforesaid half-line) is to KT — the difference between the sine of the meridian altitude and the sine of the Sun's altitude, which is taken as known — so is kM (the whole sine) to a fourth term, then KR will be known, the versed sine of the Sun's distance from the meridian, and so on.

[Margin: By what method the hour is otherwise to be reckoned from the altitude of the Sun.]

This last method has the widest application. For it applies also to that parallel of the Sun which either touches the horizon or stands wholly above it, as we shall state at the end of the scholium of this proposition. Add to this that it holds good not only for the horizon, but for all other planes as well — whether they are erect to the horizon or inclined — as will be clear from Proposition 1 of Book 5. For there, by this same procedure, we shall investigate the altitude of the Sun above any plane whatever from a given hour. Hence, above all the others, this method deserves to be committed to memory.

[Margin: Which method of finding the Sun's altitude is the more excellent.]

It is now fitting to explain this same problem by means of spherical triangles. Let the Horizon then be ABCD; the Meridian BED; the Equator AFC; the Vertical AEC; and the Sun's parallel — whether northern or southern — GHI, so that the northern one...

[Margin: By what path the altitude of the Sun is to be traced out from a known hour by means of spherical triangles, the Sun being situated in any parallel whatever.]

Diagram. A horizontal row of three spherical diagrams, each a great circle representing the sphere seen edge-on, illustrating successive cases of the construction. In every figure the frame defined in the text is present: the outer circle carries B at top, D at bottom, A at left, C at right (Horizon ABCD, with the

Meridian BED and the Vertical AEC drawn as the vertical and cross diameters), the Equator arc AFC and the Vertical arc AEC crossing near the centre E, and the Sun's parallel GHI as an oblique small-circle arc. Interior construction points are lettered K, L, M, N, O, P, Q and F, H. The three figures repeat the same lettering in the successive positions of the Sun (point L on its parallel) discussed in the text.

- B (top of each circle): pole of the horizon / zenith point of the meridian frame
- D (bottom of each circle): nadir point of the meridian frame
- A (left of each circle): intersection of horizon, equator and vertical
- C (right of each circle): opposite intersection on the horizon
- E (centre): centre of the sphere (crossing of meridian and vertical)
- F (upper, on the equator/meridian): point F of the equator, F on the meridian arc
- G, H, I (oblique arc): the Sun's parallel GHI (G lower-left, H mid, I lower-right)
- N (lower-centre): pole N of the equator (foot of the declination circle NM)
- M (interior left): point M where the declination circle meets the equator
- K (interior left): point where the parallel cuts the vertical
- L (interior left): position of the Sun on its parallel
- O (left): foot O of the vertical arc ELO (altitude arc LO)
- P (centre): point P where the great circle through A and the Sun cuts the meridian
- Q (upper-left): [?] peripheral point Q

cuts the Vertical at K; which indeed happens when the arc FH — of the parallel's declination — is smaller than the arc EF, of the pole's altitude, which lies between the vertex and the Equator. Let the Sun be placed at the point L of its parallel, so that HL is the Sun's distance from the meridian, to which the arc of the Equator FM will be similar (by Proposition 10 of Book 2 of Theodosius), the arc that the declination circle drawn from the pole N through the Sun's centre L cuts off. From the vertex E, through the Sun L, let the Vertical ELO descend, so that the arc of the Sun's altitude is LO, which is what must be investigated, if the Sun's distance from the meridian is known from the given hour, as the first part of the problem requires. Let another great circle be described through A, the pole of the Meridian, and through the Sun set at L, cutting the Meridian at P.

Since, therefore, in the spherical triangle ALM of the first four figures the angle M is a right angle (by Proposition 15 of Book 1 of Theodosius, seeing that the great

circle NM has been drawn through N, the pole of the Equator AFC), it will follow — by Proposition 19 of Book 4 of Johannes Regiomontanus [*Regiomontanus*] *On Triangles*, or by Proposition 15 of Book 1 of Geber [Jābir ibn Aflāḥ], or by Proposition 43 of our own [book] of spherical triangles — that as the sine of the complement of the arc AM (that is, the sine of the Sun's distance from the meridian — for FM, the Sun's distance from the meridian, is the complement of the arc AM. Only when the Sun's distance from the meridian in the northern signs exceeds six hours, as happens in the third figure, the complement of the arc AM is the Sun's distance from midnight, namely the arc of the Equator below the horizon between M and the Meridian; but this arc has the same sine as the arc FM of the Sun's distance from the meridian, as we explained in the treatise on sines. For these two arcs together make up a semicircle) is to the whole sine, so is the sine of the complement of the arc AL to the sine of the complement of the arc LM, of the parallel's declination. Inverting, therefore, it will likewise follow that as the whole sine is to the sine of the Sun's distance from the meridian, so is the sine of the complement of the declination of the proposed parallel to the sine of the complement of the arc AL; and so...

and so from the three first-known quantities the fourth will be known — namely the complement of the arc AL, that is, the arc LP itself; and consequently the arc AL too will be known, which may be called the **First Found**.

[Margin: The First Found.]

Again, since in the spherical triangle NLP of the same first four figures the angle P is a right angle (by Proposition 15 of Book 1 of Theodosius, because the great circle AP has been drawn through A, the pole of the Meridian BED), it will follow — by the same Proposition 19 of Book 4 of Johannes Regiomontanus *On Triangles*, or by Proposition 15 of Book 1 of Geber, or by Proposition 43 of our own spherical triangles — that as the sine of the complement of the arc NL (that is, the sine of the arc LM, of the parallel's declination) is to the sine of the complement of the arc LP (that is, to the sine of the arc AL, which we called the First Found), so is the sine of the complement of the arc NP to the whole sine. Inverting, therefore, it will likewise follow that as the sine of the arc we called the First Found is to the sine of the proposed parallel's declination, so is the whole sine to the sine of the complement of the arc NP; and so from the first three known quantities the fourth will be known — namely the complement of the arc NP, that is, the arc FP itself, in the first, second, and fourth figures, since NF is a quadrant. Only when the Sun's distance from the meridian in the northern signs surpasses six hours, as occurs in the third figure, the complement of the arc NP is the arc from P tending

through D as far as the Equator below the horizon. (For since at that time P falls between N, the pole, and the horizon — because the circle ALP cuts the declination circle NM at L, while NLM cuts the Equator at M, beyond the point A, below the horizon, on account of the arc FM of the Sun's distance from the meridian, which is here set greater than 6 hours, or than the quadrant FA — it comes about that, since the arc from the pole N through D tending as far as the Equator below the horizon is a quadrant, the said arc tending from P through D as far as the Equator below the horizon is the complement of the arc NP itself.) When this complement is known, the arc FP, the remainder of the semicircle, will also be known. Now if the found arc FP — the Sun being northern, as appears in the first, second, and third figures — is added to the arc FB, of the Equator's altitude, or of the complement of the pole's altitude, the whole arc BP will be known. But when the Sun is traversing the southern signs, if the same found arc FP is subtracted from the arc FB, of the complement of the pole's altitude, the same arc BP will be left known, as is manifest in the fourth figure. This arc BP, moreover, may be called the **Second Found**.

Diagram. Two horizontal rows of three spherical diagrams (six in all), continuing the same construction and lettered as before — the four principal cases plus variants. Each is a great circle with B at top, D at bottom, A at left, C at right (Horizon ABCD, Meridian BED, Vertical AEC), the Equator arc through F, and the Sun's parallel drawn as an oblique small-circle arc; interior points K, L, M, N, O, P, Q and F, H mark the Sun's position and the auxiliary great circles.

Top row:

- Figure 1 (left): frame B/D/A/C; interior Q, O (upper-left), M, F (upper), H, P (centre), E, L, K, G (lower-left), N (lower), I (lower-right)
- Figure 2 (middle): frame B/D/A/C; interior Q, M, K, F, H, E, P, N, O, L, G (lower-left), I (lower-right)
- Figure 3 (right): frame B/D/A/C; interior M, O, K, F, H, E, N, P, L, G (lower-left), I (lower-right)

Bottom row:

- Figure 4 (left): frame with B/D and A at lower-left, C right; interior O, Q, L, P, H, F, M, E, N, G, I
- Figure 5 (middle): frame B/D/A/C; interior Q, M, F, H, E, N, G (lower-left), I
- Figure 6 (right): frame B/D/A/C; interior K, F, H, E, O, L, N, G (lower-left), I

[Lower text, p. 113:]

Lastly, since in the spherical triangle ELP the angle P is a right angle, as we said just now, it will follow — by the same Proposition 19 of Book 4 of Johannes Regiomontanus *On Triangles*, or by Proposition 15 of Book 1 of Geber, or by Proposition 43 of our own spherical triangles — that as the sine of the complement of the arc PL (that is, the sine of the arc AL, which we called the First Found) is to the whole sine, so is the sine of the complement of the arc EL (that is, the sine of the arc LO, of the Sun's altitude at the time of observation) to the sine of the complement of the arc EP (that is, to the sine of the arc BP, which we called the Second Found).

[Margin: The Second Found.]

For in the first and fourth figures the arc BP is the complement of the arc EP, since EB is a quadrant; but in the second and third figures the arc PD is the complement of the arc EP, since ED is a quadrant. Yet the sine of the arc PD is the same as the one owed to the arc BP, because these arcs together complete a semicircle. Inverting, therefore, it will likewise follow that as the whole sine is to the sine of the arc we called the First Found, so is the sine of the arc we called the Second Found to the sine of the Sun's altitude at the time of observation. Hence, from the three former known quantities we shall also know the fourth — namely the sine of the Sun's altitude, and consequently the altitude itself.

Accordingly, if it is set up so that as the whole sine is to the sine of the Sun's distance from the meridian, so is the sine of the complement of the proposed parallel's declination to a fourth term, the sine of a certain arc will be found, which, subtracted from the quadrant, will leave the arc that may be called the **First Found**.

Next, if it is set up so that as the sine of the arc we called the First Found is to the sine of the proposed parallel's declination, so is the whole sine to a fourth term, a sine will arise whose arc — or else (if the distance from the meridian has exceeded a quadrant, that is, six hours) the remainder of the semicircle, if that arc is subtracted from the semicircle — added to the complement of the pole's altitude when the Sun is northern, or, if it is southern, subtracted from the complement of the pole's altitude, will yield the arc that may be called the **Second Found**. But if this arc turns out to be greater...

than a quadrant of the Second Found, it must be subtracted from the semicircle, so that the arc is left which we named the Second Found, as happens in the second and third figures.

Finally, if it is set up so that as the whole sine is to the sine of the arc we called the First Found, so is the sine of the arc we called the Second Found to a fourth term, the sine of the Sun's altitude at the time of observation will be found. We shall make the whole matter clearer by a few examples.

[Margin: First Example.]

Let us place the Sun at the beginning of Cancer [♋], with its distance from the meridian 45 degrees, that is, 3 hours. In this way, then, we shall investigate the Sun's altitude at that time at a latitude of 42 degrees. Let it be: as 100000 (the whole sine) is to 70710 (the sine of the Sun's distance from the meridian), so is 91706 (the sine of the complement of the declination) to a fourth term; and there will be found, very nearly, this sine 64845, whose arc is 40 degrees 25 minutes, which, subtracted from the quadrant, leaves 49 degrees 35 minutes for the **First Found**.

Again, let it be: as 76134 (the sine of the arc of the First Found) is to 39874 (the sine of the declination), so is 100000 (the whole sine) to a fourth term; and there will be found, very nearly, this sine 52373, whose arc is 31 degrees 35 minutes; added to 48 degrees — namely to the complement of the pole's altitude, since the Sun is northern — it will make an arc of 79 degrees 35 minutes for the **Second Found**.

Lastly, let it be: as 100000 (the whole sine) is to 76134 (the sine of the arc of the First Found), so is 98351 (the sine of the arc of the Second Found) to a fourth term; and there will come to light this sine, roughly 74878, to which corresponds an arc of 48 degrees 29 minutes, for the Sun's altitude at the time of observation.

[Margin: Second Example.]

Let us again place the Sun in the same parallel with a distance from the meridian of 75 degrees, that is, 5 hours. Let it be: as 100000 (the whole sine) is to 96592 (the sine of the Sun's distance from the meridian), so is 91706 (the sine of the complement of the declination) to a fourth term; and there will be found this sine, nearly 88580, whose arc is 62 degrees 21 minutes, which, subtracted from the quadrant, leaves 27 degrees 39 minutes for the **First Found**.

Diagram. Two horizontal rows of three spherical diagrams (six in all), the same construction lettered as on the preceding pages — the principal cases with variants. Each is a great circle: B top, D bottom, A left, C right (Horizon ABCD, Meridian BED, Vertical AEC), the Equator arc through F, and the Sun's parallel as an oblique small-circle arc, with interior points K, L, M, N, O, P, Q and F, H.

Top row:

- Figure 1 (left): frame B/D/A/C; interior Q, O, M, F, H, P, L, K, G (lower-left), E, N, I
 - Figure 2 (middle): frame B/D/A/C; interior Q, M, K, F, H, E, P, N, O, L, G, I
 - Figure 3 (right): frame B/D/A/C; interior M, O, K, F, H, E, N, P, L, G, I
- Bottom row:
- Figure 4 (left): frame B/D with A lower-left, C right; interior O, Q, L, P, H, F, M, E, N, G, I
 - Figure 5 (middle): frame B/D/A/C; interior M, F, H, E, K, N, G, I
 - Figure 6 (right): frame B/D/A/C; interior K, F, H, E, O, L, N, G, I

[Lower text, p. 114:]

After this, let it be: as 46406 (the sine of the arc we named the First Found) is to 39874 (the sine of the declination), so is 100000 (the whole sine) to a fourth term; and there will come out this sine, nearly 85924, whose arc is 59 degrees 14 minutes; joined to the complement of the pole's altitude, 48 degrees, it will make an arc of 107 degrees 14 minutes, which, since it exceeds a quadrant, when subtracted from the semicircle (that is, from 180 degrees) will leave an arc of 72 degrees 46 minutes for the **Second Found**.

Let it be, finally: as 100000 (the whole sine) is to 46406 (the sine of the First Found), so is 95510 (the sine of the Second Found) to a fourth term; and there will come forth this sine, nearly 44322, whose arc, 26 degrees 19 minutes, will give the sought altitude of the Sun.

[Margin: Third Example.]

Furthermore, let the Sun, being in the same parallel, have a distance from the meridian of 7 hours, that is, 105 degrees. Let it be: as 100000 (the whole sine) is to 96592 (the sine of the Sun's distance from the meridian) — which sine indeed belongs to an arc of 75 degrees, and so likewise to an arc of 105 degrees, the remainder of the semicircle — so is 91706 (the sine of the complement of the declination) to a fourth term; and there will be found this sine, nearly 88580, whose arc is 62 degrees 21 minutes, which, subtracted from the quadrant, leaves 27 degrees 39 minutes for the **First Found**.

Let it also be: as 46406 (the sine of the First Found) is to 39874 (the sine of the declination), so is 100000 (the whole sine) to a fourth term; and there will be found this sine, roughly 85924, whose arc is 59 degrees 14 minutes. Subtracted from the semicircle — because the Sun's distance from the meridian surpasses six

hours — it leaves an arc of 120 degrees 46 minutes, which, added to the complement of the pole's altitude, 48 degrees, will make an arc of 168 degrees 46 minutes. This at last, since it is greater than a quadrant, when subtracted from the semicircle leaves 11 degrees 14 minutes for the **Second Found**.

In addition to this, let it be: as 100000 (the whole sine) is to 46406 (the sine of the First Found), so is 19480 (the sine of the Second Found) to a fourth term; and there will be obtained this sine, very nearly 9039, whose arc, 5 degrees 11 minutes, will present the altitude of the Sun that we were seeking.

Finally, let the Sun be in any southern parallel — as, for instance, at the beginning of Capricorn [♑] — and let it have a distance from the meridian of 2 hours, that is, 30 degrees. Let it be: as 100000 (the whole sine) is to 50000 (the sine of the Sun's distance from the meridian), so is 91706 (the sine of the complement of the declination) to a fourth term; and there will be found this sine, 45853, whose arc is 27 degrees 18 minutes. Subtracted from the quadrant, it leaves an arc of 62 degrees 42 minutes for the **First Found**.

Next, let it be: as 88861 (the sine of the First Found) is to 39874 (the sine of the declination), so is 100000 (the whole sine) to a fourth term; and there will be obtained, near enough, this sine, 44872, whose arc is 26 degrees 40 minutes. Subtracted from the complement of the pole's altitude, 48 degrees — because the Sun is southern — it leaves an arc of 21 degrees 20 minutes for the **Second Found**.

Let it be, at last: as 100000 (the whole sine) is to 88861 (the sine of the First Found), so is 36379 (the sine of the Second Found) to a fourth term; and there will be found, very nearly, this sine, 32327, whose arc, 18 degrees 52 minutes, will present the sought altitude of the Sun.

[Margin: How the Sun's altitude, when it lies in the vertical circle, is computed from the given hour by spherical triangles.]

When the Sun lies in the vertical circle — as at the point K, as appears in the fifth figure — we shall hunt down its altitude far more expeditiously from the known distance of the Sun from the meridian, by means of spherical triangles, in the following way. Since in the spherical triangle AkM the angle M is right, it will hold — by Regiomontanus [Regiomontanus], *On Triangles* IV.19, or by Geber [Jābir ibn Aflāḥ] I.15, or by our *On Spherical Triangles* 43 — that as the sine of the complement of the arc AM (that is, as the sine of the Sun's distance from the meridian, i.e. the sine of the arc FM) is to the whole sine, so is the sine of the complement of the arc AK to the sine of the complement of the arc KM (that is, to

the sine of the complement of the declination). Therefore, by conversion, it will also hold that as the whole sine is to the sine of the Sun's distance from the meridian, so is the sine of the complement of the declination of the proposed parallel to the sine of the complement of the arc AK. From these three known terms the fourth will be found — namely the complement of the arc AK, and thus the arc AK itself, which measures the Sun's altitude. And so, when the Sun lies in the vertical circle, if it be made that as the whole sine is to the sine of the Sun's distance from the meridian, so is the sine of the complement of the declination to a fourth term, the sine of the complement of the Sun's altitude will be found, and consequently the altitude itself will be manifest.

[Margin: How the Sun's altitude in the vertical is computed by spherical triangles, even when the hour is unknown.]

But if the Sun's distance from the meridian is unknown, we shall nonetheless find the altitude of the Sun standing in the vertical in this way. Since in the spherical triangle EKN the angle E is right, it will hold — by Regiomontanus, *On Triangles* IV.19, or by Geber I.15, or by our *On Spherical Triangles* 43 — that as the sine of the complement of the arc EN (that is, as the sine of the arc EF, the pole's altitude) is to the whole sine, so is the sine of the complement of the arc Nk (that is, the sine of the arc KM, the declination of the proposed parallel) to the sine of the complement of the arc EK (that is, to the sine of the arc AK, the Sun's altitude). Therefore, if it be made that as the sine of the pole's altitude is to the whole sine, so is the sine of the declination to a fourth term, the sine of the Sun's altitude will be found. This can also be demonstrated more clearly as follows. Since in the spherical triangle AKM, of the same fifth figure, the angle M is right, it will hold — by Regiomontanus, *On Triangles* IV.16, or by Geber I.13, or by our *On Spherical Triangles* 41 — that as the sine of the angle A, the pole's altitude (for EF is both the arc of the pole's altitude and the arc of the angle A), is to the sine of the arc kM, the declination, so is the sine of the right angle M (that is, the whole sine) to the sine of the arc AK, the pole's altitude. Hence if it be made that as the sine of the pole's altitude is to the sine of the declination, so is the whole sine to a fourth term, the sine of the Sun's altitude in the vertical circle will again be recovered. This too we demonstrated above without spherical triangles.

[Margin: The Sun's altitude when the Sun is six hours from the meridian in the northern parallels — in what way it is to be investigated by spherical triangles.]

Moreover, when the Sun in the northern parallels is six hours distant from the meridian, as in the sixth figure, it will be no trouble to investigate its altitude. For since in the spherical triangle ELN, of the sixth figure, the angle N is right — by

Theodosius [Theodosius] I.15, because the great circle NA is drawn through A, the pole of the meridian — it will hold, by Regiomontanus, *On Triangles* IV.19, or by Geber I.15, or by our *On Spherical Triangles* 43, that as the sine of the complement of the arc EN (that is, the sine of the arc EF, the pole's altitude) is to the whole sine, so is the sine of the complement of the arc EL (that is, the sine of the arc LO, the Sun's altitude) to the sine of the complement of the arc NL (that is, to the sine of the arc LA, the declination). Therefore, by conversion, it will also hold that as the whole sine is to the sine of the pole's altitude, so is the sine of the declination to the sine of the Sun's altitude. And so, if it be made that as the whole sine is to the sine of the pole's altitude, so is the sine of the declination to a fourth term, the sine of the Sun's altitude will be obtained. This too we demonstrated above without spherical triangles.

[Margin: How the Sun's altitude at the equinoxes is traced by spherical triangles from the given hour.]

Furthermore, when the Sun occupies the equinoctial points, we shall draw out the Sun's altitude by spherical triangles without much labor, from the known hour or from the Sun's distance from the meridian, in this way. Let the equator in the fifth figure be understood to be GHI, and the Sun to lie at k, so that we need not draw a new figure. Since, then, in the spherical triangle EHK the angle H is right, it will hold — by Regiomontanus, *On Triangles* IV.19, or by Geber I.15, or by our *On Spherical Triangles* 43 — that as the sine of the complement of the arc EH (that is, the sine of the arc HB, the altitude of the equator, or the complement of the pole's altitude) is to the whole sine, so is the sine of the complement of the arc EK (that is, the sine of the arc KA, the Sun's altitude) to the sine of the complement of the arc HK, the Sun's distance from the meridian. Hence, by conversion, it will also hold that as the whole sine is to the sine of the complement of the pole's altitude, so is the sine of the complement of the Sun's distance from the meridian to the sine of the Sun's altitude. And therefore, if it be made that as the whole sine is to the sine of the complement of the pole's altitude, so is the sine of the complement of the Sun's distance from the meridian to a fourth term, the sine of the Sun's altitude will be known.

[Margin: How the Sun's altitude is otherwise investigated by spherical triangles from the given hour.]

By another method too, and perhaps more conveniently, we shall find the Sun's altitude from the known hour by spherical triangles, without the circle ALP; and it is of this sort. Let the declination circle NL be extended toward L until it cuts the horizon at Q. And since the angle FNM, the Sun's distance from the meridian,

is known, its supplement QND — the remainder of the two right angles — will also be known. Since, then, in the spherical triangle DNQ, whose angle D is right and whose angle DNQ is known, together with the arc DN, the pole's altitude, it holds — by Regiomontanus, *On Triangles* IV.18, or by Geber I.14, or by our *On Spherical Triangles* 42 — that as the sine of the angle DNQ is to the whole sine, so is the sine of the complement of the angle DQN to the sine of the complement of the arc DN, the pole's altitude; then, by conversion, it will hold that as the whole sine is to the sine of the angle DNQ, so is the sine of the complement of the arc DN, the pole's altitude, to the sine of the complement of the angle DQN — and thus the angle DQN itself will be known. Again, since in the same spherical triangle DNQ it holds — by Regiomontanus, *On Triangles* IV.19, or by Geber I.13, or by our *On Spherical Triangles* 41 — that as the sine of the angle DQN, now made known, is to the sine of the arc DN, the pole's altitude, so is the whole sine of the right angle D to the sine of the arc NQ, the sine of the arc NQ will be known; and from this we shall track down the arc NQ itself, in the following way. When in the northern signs the Sun's distance from the meridian is greater than 6 hours, as happens in the third figure, the arc drawn from the table of sines will give the arc NQ, because the arc NQ is then less than a quadrant,

because the arc produced from the pole N through Q as far as the equator is a quadrant. But when the Sun's distance from the meridian is less than 6 hours — as appears in the first, second, and fourth figures — then, in whatever parallel, whether northern or southern, the Sun is situated, the arc NQ will be greater than a quadrant. And since, as we showed in the treatise on sines, the sine of the arc NQ is the same as that of the remaining arc taken from the semicircle, we shall subtract the arc of the sine found from the semicircle, so as to have the arc NQ. Finally, when the Sun's distance from the meridian amounts to exactly 6 hours, we give no precept here, because then, as we shall teach below, the Sun's altitude is sought much more easily; the arc NQ would in that case be a quadrant, since the point Q would fall on the point A. Now the arc NQ having been found by this method, from it the arc LQ must be found, in this way. In the northern parallels, from the found arc NQ let the arc NL, the complement of the declination, be subtracted; but in the southern parallels, from the same found arc NQ let the arc NL be taken away — which is composed of the quadrant NM and the arc of declination ML, as appears in the fourth figure. For the arc LQ will always be the remainder. And now, since in the spherical triangle LOQ the angle O is right, and LQO has just been made known, together with the arc LQ — and since it holds, by Regiomontanus, *On Triangles* IV.16, or by Geber I.13, or by our *On Spherical Triangles* 41, that as the whole sine of the right angle O is to the sine of the known

arc LQ, so is the sine of the known angle LQO to the sine of the arc LO, the Sun's altitude — the Sun's altitude will become known.

[Margin: First Found. Second Found.]

And so, if it be made that as the whole sine is to the sine of the angle DNQ (which remains once the angle of the Sun's distance from the meridian has been taken from the two right angles), so is the sine of the complement of the pole's altitude to a fourth term, the sine of a certain arc will be found, which, subtracted from the quadrant, will give the arc we shall call the **First Found**.

[Margin: First Found.]

Next, if it be made that as the sine of that arc which we called the First Found is to the sine of the pole's altitude, so is the whole sine to a fourth term, the sine of another arc will be recovered. From this arc, if the Sun is northern and its distance from the meridian is greater than 6 hours, the subtracted arc of the complement of the declination will give a certain arc, which we shall name the **Second Found**. But if the Sun's distance from the meridian is less than 6 hours, in whatever parallel the Sun stands, the arc found by way of the First Found must be subtracted from the semicircle, and from the remaining arc — if the Sun is northern — the arc of the complement of the declination must again be subtracted; or if the Sun is southern, the arc composed of the quadrant and the arc of declination must be taken away, so that the arc we may call the Second Found is found.

[Margin: Second Found.]

The Second Found will also be found in this way. Let it be made that as the sine of the arc which is the First Found is to the sine of the pole's altitude, so is the whole sine to a fourth term; for the sine of a certain arc will be found. From this arc, when the Sun's distance from the meridian is greater than 6 hours, if the complement of the declination is subtracted, the remainder will be the Second Found, as was said, and as is clear from the third figure. Or, when the Sun's distance from the meridian is less than 6 hours, the sine of an arc will be found to whose complement, when the Sun is northern, the declination of the Sun added will give the Second Found; or from whose complement, when the Sun is southern, the declination of the Sun subtracted leaves the Second Found — as is clear from the first, second, and third figures. For it is the complement of the arc NQ (whose sine is found) and the arc QM, to which the declination LM added, or subtracted, will give the Second Found, LR [?].

[Margin: First Example.]

Lastly, if it be made that as the whole sine is to the sine of the arc we named the Second Found, so is the sine of the arc we called the First Found to a fourth term, the sine of the sought altitude of the Sun will be found. And to make this clearer, we shall explain the whole matter by two examples.

[Margin: First Example.]

Let the Sun be placed at the beginning of Cancer [♋], with a distance from the meridian of 7 hours, that is, 105 degrees, so that the angle BNQ spans that many degrees, and consequently the supplement DNQ from the two right angles is 75 degrees. Let it be, then: as 100000 (the whole sine) is to 96592 (the sine of the angle DNQ), so is 74314 (the sine of the complement of the pole's altitude) to a fourth term; and we shall find, near enough, this sine, 71781, whose arc, 45 degrees 52 minutes, subtracted from the quadrant, leaves an arc of 44 degrees 8 minutes for the **First Found**.

Again, let it be: as 69633 (the sine of the arc of the First Found) is to 66913 (the sine of the pole's altitude), so is 100000 (the whole sine) to a fourth term; and we shall recover, near enough, this sine, 96093. From its arc, 73 degrees 56 minutes — since the Sun is set as northern and its distance from the meridian is greater than 6 hours — if the complement of the declination of the Cancer parallel is subtracted, namely 66 degrees 30 minutes, an arc of 7 degrees 26 minutes will be left for the **Second Found**.

[Margin: Second Example.]

Finally, let it be: as 100000 (the whole sine) is to 12937 (the sine of the arc of the Second Found), so is 69633 (the sine of the arc of the First Found) to a fourth term; and there will be found here, very nearly, this sine, 9008, the Sun's altitude. Hence the Sun's altitude will amount to 5 degrees 10 minutes.

Let the Sun again be set at the beginning of Capricorn [♐], with its distance from the meridian of 2 hours, that is, 30 degrees, so that the angle BNQ contains that many degrees, and consequently the supplement DNQ from the two right angles is 150 degrees. Let it be, then: as 100000 (the whole sine) is to 50000 (the sine of the angle DNQ) — for it is the same sine, of the arc of 150 degrees and of the arc of 30 degrees, which together with it makes up the semicircle, as we taught in the treatise on sines — so is 74314 (the sine of the complement of the pole's altitude) to a fourth term; and there will be found, near enough, this sine, 37157, whose

arc, 21 degrees 49 minutes, subtracted from the quadrant, leaves for the **First Found** an arc of 68 degrees 11 minutes.

Next, let it be: as 92837 (the sine of the arc of the First Found) is to 66913 (the sine of the pole's altitude), so is 100000 to a fourth term; and there will be found here, as it were, the sine 72075, whose arc is 46 degrees 7 minutes. Subtracted from the semicircle of 180 degrees — because the Sun's distance from the meridian does not reach 6 hours — it will give the arc NQ of 133 degrees 53 minutes. From this, since the Sun is set as southern, if the arc NL is subtracted — composed of a quadrant and the arc of declination [text: *ex sinu toto, & sinu declinationis*; sense requires quadrant + declination arc], namely 113 degrees 30 minutes — there will be left for the **Second Found** an arc of 20 degrees 23 minutes. Or, if the arc of the found sine 72075 be taken as 46 degrees 7 minutes, and from its complement, 43 degrees 53 minutes, the declination of 23 degrees 30 minutes be subtracted, the remainder will be the same Second Found, 20 degrees 23 minutes.

Lastly, let it be: as 100000 (the whole sine) is to 34829 (the sine of the arc of the Second Found), so is 92837 (the sine of the First Found) to a fourth term; and there will be found here, near enough, the sine 32334, of the Sun's altitude — and thus the Sun's altitude itself will amount to 18 degrees 52 minutes.

Furthermore, when the Sun lies in the vertical circle, or is six hours from the meridian, or lastly is situated on the equator, we shall dispatch the matter as we set out a little earlier.

Finally, we shall complete this same problem by spherical triangles in the right sphere, in this way. When the Sun runs along the equator, the complement of its distance from the meridian will be the Sun's altitude above the horizon; for

[Margin: The Sun's altitude at the equinoxes, how it is detected in the right sphere from the given hour.]

in the right sphere the equator is the same as the vertical circle passing through the center of the Sun. As in the figure below, if the poles of the world are understood to be B, D, the vertical circle AEC will be also the equator itself. With the Sun then placed at I, the arc AI, the complement of the Sun's distance from the meridian, will also be the arc of the Sun's altitude, as is evident.

[Margin: The Sun's altitude, when it lies in any parallel whatever, in what way it is gathered by spherical triangles in the right sphere from the given hour.]

Diagram. A circle (sphere) shown with the celestial poles B at the top and D at the bottom, the horizontal diameter running from A (left) through the center E to C

(right); the vertical great circle AEC represents both the equator (in the right sphere) and the vertical circle. Great-circle arcs (declination circles through B and D, and parallels) cross the interior, with the Sun-positions and reference points lettered symmetrically above and below the center for the northern and southern parallels.

- B (top): north pole of the world
- D (bottom): south pole of the world
- A (left): endpoint of the vertical circle / equator on the horizon
- C (right): opposite endpoint of the vertical circle / equator
- E (center): center of the sphere / Sun
- L (upper left, on circle): endpoint of the vertical EL
- K (upper interior, left): Sun-position k
- H (upper interior, right): reference point on the declination circle
- F (left, upper): point on the parallel FG
- I (interior, left of center): intersection of declination circle with equator
- G (upper right, on circle): endpoint of the parallel FG
- F (left, lower): mirrored parallel point
- L (lower left): mirrored vertical endpoint
- K (lower interior): mirrored Sun-position
- H (lower interior): mirrored reference point
- G (lower right, on circle): mirrored parallel endpoint

When the Sun occupies any parallel FG, whether northern or southern, we shall carry out the matter as follows. Let the Sun be placed at k, and let the vertical EL be drawn from the vertex E through the center of the Sun k. Likewise let the declination circle DKB be drawn through the poles of the world and through the center of the Sun, cutting the equator at I; and the arc EI will be equal to the arc HK, the Sun's distance from the meridian, by Theodosius II.10. Since, then, in the spherical triangle EIK the angle I is right, by Theodosius I.15, it will hold — by Regiomontanus, *On Triangles* IV.19, or by Geber I.15, or by our *On Spherical Triangles* 43 — that as the sine of the complement of the arc IK, the declination of the parallel, is to the whole sine, so is the sine of the complement of the arc Ek (that is, the sine of the arc kL, the Sun's altitude) to the sine of the complement of the arc EI, the Sun's distance from the meridian. Hence also, by conversion, it will hold that as the whole sine is to the sine of the complement of the declination of the proposed parallel, so is the sine of the complement of the Sun's distance from the meridian to the sine of the Sun's altitude. And so, if it be made that as the

whole sine is to the sine of the complement of the declination, so is the sine of the complement of the Sun's distance from the meridian to a fourth term, the sine of the Sun's altitude will come out known. This too we showed above without spherical triangles. And by this method it is evident that the Sun's altitude is drawn out from the known hour by spherical triangles — which is what the first part of the problem requires.

[Margin: In what way the hour is gathered from the Sun's known altitude by spherical triangles.]

But that we may, conversely, learn thoroughly the hour, or the Sun's distance from the meridian, from the known altitude of the Sun above the horizon by spherical triangles, we shall follow this route. Recalling the earlier figures: since in the first, second, third, and fourth the triangle ELN has its three sides known — for EL is the complement of the Sun's altitude, which is given; EN is the complement of the pole's altitude; and LN, in the northern parallels, is the complement of the declination of the proposed parallel, while in the southern parallels the arc LN is composed of the arc of declination LM and the quadrant MN — the angle ENL will also be known, by Regiomontanus, *On Triangles* IV.34, or by our *On Spherical Triangles* 63; and thus its arc FM too, which measures the Sun's distance from the meridian, will be known. But since in the northern parallels the angle ENL may be right, or less, or greater than a right angle: whenever it is found to be right, the Sun's distance from the meridian will comprise 6 hours; if less, fewer

hours than 6; if, finally, greater, it will contain more than six. But so that we may know when the said angle is right, and when less or greater, we must find the altitude the Sun has when it is six hours from the meridian. For when the Sun's altitude at the time of observation, which is given, is equal to the altitude it has when it is six hours from the meridian, the said angle will be right; for the Sun will then be on the circle of the sixth hour, which makes a right angle with the meridian. But if the Sun's altitude is found to be greater than that which it has when it is six hours distant from the meridian, the same angle will be less than a right angle, because the Sun's distance from the meridian is then less than a quadrant. If, finally, the Sun's altitude

[Margin: How the hour is found when the Sun is set on the vertical circle.]

is smaller than the altitude it has when it stands six hours from the meridian, then that same angle will be greater than a right angle — because the Sun's distance from the meridian is at that time greater than a quadrant.

Now suppose the Sun's altitude, when found, turns out to be equal to the altitude it has on the vertical circle — the altitude we determined above, even when the Sun's distance from the meridian is unknown. Then the Sun stands on the vertical circle, and from this its distance from the meridian is very easily found. For in triangle EkN — the fifth figure — the angle E is right, and therefore, by Prop. 16 of Regiomontanus [Johannes Regiomontanus], *On Triangles* IV, or by Prop. 13 of Geber [Jābir ibn Aflāḥ], Book I, or by Prop. 41 of our own [treatise on] spherical triangles, we have this: as the sine of arc Nk (the complement of the declination) is to the sine of the right angle E — that is, to the whole sine [radius] — so is the sine of arc EK (the complement of the Sun's altitude) to the sine of angle N (the Sun's distance from the meridian). And so, if it be arranged that as the sine of the complement of the declination is to the whole sine, so is the sine of the complement of the Sun's altitude on the vertical circle to a fourth term, that fourth term will be the sine of the Sun's distance from the meridian.

Diagram. First of six small woodcut spheres (upper row, left), the schematic sphere used for the hour-finding triangles. Poles and horizon frame it; the interior lines are the meridian, the equator/parallel, and the vertical circle, meeting at the reference points.

[Margin: At what hour the Sun stands on the vertical circle.]

Hence, if the question is asked at what hour the Sun is found on the vertical circle, we must first find the Sun's altitude on the vertical circle, as we taught above (even when its distance from the meridian is unknown), and then, from that altitude, work out the Sun's distance from the meridian, just as we have shown a moment ago.

[Margin: The way to find the hour at the equinoxes from the known altitude of the Sun.]

When the Sun is on the equator, we shall also determine the hour from the Sun's altitude with equal ease. For in the spherical triangle EHK of the fifth figure — taking the equator to be GHI and the Sun at K, as we said above — the angle H is right, and therefore, by Prop. 19 of Regiomontanus, *On Triangles* IV, or by Prop. 15 of Geber, Book I, or by Prop. 43 of our own spherical triangles, we have this: as the sine of the complement of arc EH (the pole's altitude) is to the whole sine, so is the sine of the complement of arc EK — that is, so is the sine of arc AK (the Sun's

altitude) — to the sine of the complement of arc HK (the Sun's distance from the meridian). And so, if it be arranged that as the sine of the complement of the pole's altitude is to the whole sine, so is the sine of the Sun's altitude to a fourth term, that fourth term will be the sine of the complement of the Sun's distance from the meridian.

[Margin: How, in the right sphere at the time of the equinoxes, the hour is found from the Sun's altitude.]

We shall demonstrate the same thing in another way as well. For in the spherical triangle AGK the angle A is right — by Prop. 15 of Theodosius [of Bithynia], Book I, since the great circle EA is drawn through E, the pole of the horizon — and therefore, by Prop. 16 of Regiomontanus, *On Triangles* IV, or by Prop. 13 of Geber, Book I, or by Prop. 41 of our own spherical triangles, we have this: as the sine of angle G (the complement of the pole's altitude) — for if the equator be taken as GHI, the angle G, corresponding to arc HB, the altitude of the equator, that is, the complement of the pole's altitude — is to the sine of arc Ak (the Sun's altitude), so is the sine of the right angle A, that is, the whole sine, to the sine of arc Gk (the complement of the Sun's distance from the meridian). If therefore it be arranged that as the sine of the complement of the pole's altitude is to the sine of the Sun's altitude, so is the whole sine to a fourth term, that fourth term will be the sine of the complement of the Sun's distance from the meridian.

[Margin: By what method, in the right sphere, the hour is to be traced from the Sun's altitude when the Sun lies on any parallel whatever.]

Finally, in the right sphere we shall proceed as follows. When the Sun is at the equinoxes, we take the complement of the Sun's altitude as its distance from the meridian. For in the adjoining figure, which we drew for the right sphere, the arc EI (the Sun's distance from the meridian) is the complement of arc AI (the Sun's altitude).

Diagram. Single larger woodcut sphere (lower left) drawn for the right sphere, showing the meridian, the equator EA through the horizon-pole, and a parallel through K, with the spherical triangles AGK and EIK.

- B (top), D (bottom): poles
- A (left), C (right): endpoints on the circle
- L, F (upper and lower left), G (right, upper and lower): outer endpoints
- K (upper and lower), H (upper right and lower right): points where the parallel meets the drawn circles

- I (left of center), E (center): interior reference points

When, however, the Sun stands on some other parallel — say at K — then, because in the spherical triangle EIK the angle I is right, we have, by Prop. 19 of Regiomontanus, *On Triangles* IV, or by Prop. 15 of Geber, Book I, or by Prop. 43 of our own

spherical triangles, this: as the sine of the complement of arc Ik (the declination of the given parallel) is to the whole sine, so is the sine of the complement of arc Ek — that is, the sine of arc KL (the Sun's altitude) — to the sine of the complement of arc EI (the Sun's distance from the meridian). Therefore, if it be arranged that as the sine of the complement of the Sun's declination is to the whole sine, so is the sine of the Sun's altitude to a fourth term, that fourth term will be the sine of the complement of the Sun's distance from the meridian. And so, from the known hour of the day we have found the Sun's altitude above the horizon; and conversely, from the known altitude of the Sun we have found the hour of the day. Which was to be done.

SCHOLIVM.

When the Sun's altitudes are to be found for the several hours of two opposite parallels — such as, for example, the two tropics traced from the beginnings of ☊ [Cancer] and ☋ [Capricorn], which happens not rarely in practice when constructing hour-instruments and in laying out sundials — the whole business will be rendered very easy, provided that what we are about to explain be attentively considered.

[Margin: Which numbers never change, if the Sun's altitudes for the several hours of two opposite parallels are investigated by the first method taught.]

For if we first wish to use the first method, there will remain, for the several hours of each parallel, one and the same half of the line compounded of the sine of the meridian altitude and the sine of the meridian depression; so that, once this half has been found, it may be applied to work out the altitudes for all the hours in the two opposite parallels. For since, as we showed in the scholium of the preceding proposition, the meridian depression of any parallel is equal to the meridian altitude of the opposite parallel, it comes about that the line compounded of the sine of the meridian altitude and the sine of the meridian depression of one parallel is equal to the line compounded of the sine of the meridian altitude and the sine of the meridian depression of the other, opposite parallel — since the meridian depression of the one is equal to the meridian

altitude of the other, and the meridian depression of the latter equal to the meridian altitude of the former. And hence the halves of these compounded lines will also be equal. Thus, in the two tropics, the half of the line compounded of the sine of the meridian altitude of ♋ [Cancer] and the sine of the meridian depression of ♋ , or of the sine of the meridian altitude of ♏ [Capricorn] and the sine of the depression of ♏ , will be 68151 — remaining the same, and useful for working out the altitudes of all the hours when the Sun is at the beginning of ♋ or of ♏ .

Again, in all parallels the same whole sine, 100000, is always employed in seeking out the Sun's altitudes.

[Margin: Which numbers stay the same, if the Sun's altitudes are traced by the second method for the several hours of each parallel.]

Finally, the line AN — that is, the difference between the sine of the meridian altitude and the aforesaid half KA — never changes in the two opposite parallels; because exactly the same difference lies between the sine of the meridian depression and the other half $\theta\Lambda$, as is evident from the figures. Now it is established from what has been demonstrated that the sine of the meridian depression of the northern parallel is equal to the sine of the meridian altitude of the opposite southern parallel. Hence the same difference will always lie between the aforesaid half and the sine of the meridian altitude both of the northern parallel and of the opposite southern one. Thus, in the two tropics, this difference will be, near enough, the number 26681, which will never have to be changed until all the altitudes in the two tropics have been found; and to this number the line TA, once found, is now to be added — now, in the northern signs, to be subtracted from it — or else, in the southern signs, that same number 26681 is to be subtracted from the line TA once found, so as to obtain the sine TN of the Sun's altitude, as is clear from the foregoing.

[Margin: Which numbers stay the same, if the Sun's altitudes are traced by the second method for the several hours of each parallel.]

If it be preferred to investigate the Sun's altitudes in two opposite parallels by the second method, then indeed within one and the same parallel both the versed sine of the semidiurnal arc and the right sine of the meridian altitude remain always the same; but for finding the altitudes in the other, opposite parallel, the proper versed sine of the semidiurnal arc and the proper right sine of the meridian altitude must be taken. We shall have only this convenience: that when the versed sine of the semidiurnal arc of one parallel is subtracted from the

whole diameter — that is, from 200000 — we at once have the versed sine of the semidiurnal arc of the opposite parallel; for the versed sine of the semidiurnal arc of one parallel is equal to the versed sine of the seminocturnal arc of the other, opposite parallel. And it is plain that the versed sine of the seminocturnal arc, subtracted from the whole diameter, leaves the versed sine of the semidiurnal arc — and conversely.

[Margin: Which numbers never change, if the Sun's altitudes are investigated by the last method, which we set out before the treatment drawn from the spherical triangles, for the several hours of two opposite parallels.]

But in that last method, which we wrote out just before the treatment drawn from the spherical triangles, we shall have, in the opposite parallels, not only always the same half of the line compounded of the sine of the meridian altitude and the sine of the meridian depression, and the same whole sine, but also the same versed sines of the Sun's distances from the meridian at the hours equally distant from the meridian — such as the first hour and the eleventh, likewise the second and the tenth, and so on — both in the parallel ♋ [Cancer] and in the parallel ♏ [Capricorn]. Hence, at the same hours, the same line KT is found; so that in the opposite parallel there is no need to investigate the line KT afresh for that hour for which the same KT was found in the other parallel, but the very same is to be taken throughout, to be subtracted from the sine of the meridian altitude of the parallel in question, and so on.

Indeed, for the hours before the 6th hour of the morning and the 6th hour of the evening, there is no need to investigate the line KT by multiplication, but only by subtraction and addition. For if you take the difference between KA, the half of the line Kθ compounded of the sine of the meridian altitude and the sine of the meridian depression, and KT, the line found for an hour whose distance from the meridian is less than a quadrant, and add it to that same half KA, you will make up the line KT for the hour whose distance from the meridian is as much greater than six hours as the former was less. For in the second figure, if Ka, the distance from the meridian, is as much less than the quadrant KP as the distance KO is greater, then the arcs PO and PA will be equal, and hence their right sines MB and MR will be equal.^a Therefore λI [?] and λT are equal lines. So Kd, taken away from the half KA, and the remainder dλ added to the same half KA, makes the whole KT known — which was proposed.

For the 4th and 8th hours from the meridian, too, or midnight, it is enough, for KT, to take half of the half KA. For in the same second figure, if the arc Ka were to contain 4 hours — that is, 60 degrees — the arc aP would be 30 degrees; therefore,

as we showed for the sines, Mb, the sine of 30 degrees, will be half of the whole sine KM, and accordingly Kd too will be half of KΛ itself. And if the 4th and 8th hours be before the 6th hour of the morning and after the 6th hour of the evening, dΛ will have to be added, and so on. Or rather, much more briefly, in this way: since Kd is equal to θT itself, then, if from Kd found for an hour between the meridian and the 6th hour — that is, from θT — one takes away θN, the sine of the meridian depression, there will be left TN, the sine of the altitude for the hour between midnight and the 6th hour. Thus, for the 5th hour after the meridian, for example, the line Kd once found must be subtracted from KN, the sine of the meridian altitude. But for the 7th hour from the meridian, from the same Kd once found — that is, from θT — one must subtract the sine θN of the meridian depression, so as to leave the sine of the Sun's altitude [☉]. Likewise for the 4th hour from the meridian, half of Kd, the half of KΛ, must be subtracted from the sine of the meridian altitude; while for the 8th hour from the meridian, from that same half Kd, the half of KΛ — that is, from θT — one must subtract the sine θN of the meridian depression, so that what remains becomes the sine of the Sun's altitude [☉].

[Margin: Which sines always stay the same, if the Sun's altitudes are sought by spherical triangles for the several hours of two opposite parallels.]

Finally, if one prefers to trace the Sun's altitudes in two opposite parallels by spherical triangles, the business will likewise be rendered very easy, since the same whole sine and the same sine of the declination of each parallel must be kept throughout in working out the altitudes for all the hours, as is plainly established from what has been said.

[Margin: When a northern parallel lies wholly above the horizon, by what method the Sun's altitude is found from the known hour, and conversely the hour from the known altitude of the Sun.]

Moreover, when the pole's altitude is so great that some northern parallel lies wholly above the horizon — whether it touches the horizon, as in the first figure set beneath here, or does not, as in the second — the Sun's altitude will nonetheless be found from the known hour, and conversely the hour from the Sun's altitude, by the method taught in this proposition, provided that in each figure the meridian is understood to be at K, where the Sun, standing on the meridian, has its greatest altitude, which is to be worked out from the parallel's declination, as we explained above in the scholium of the preceding proposition. But here there will be no meridian depression; rather, in the first figure the line $K\Lambda$ will be the half of the sine of the meridian altitude, while in the second the same $K\Lambda$ will be the half of the line $K\theta$, which is the difference between KN , the sine of the greater meridian altitude KA , and θN , the sine of the lesser meridian altitude LC . And this lesser altitude CL is obtained if from arc IL , the declination, one subtracts arc IC , the complement of the pole's altitude. But if the declination should be equal to the complement of the pole's altitude, the parallel will touch the horizon, as happens in the first figure. Now that $K\Lambda$ is the half of the said lines is proved as follows.^a In the first figure, as kM is to MC , so is $K\Lambda$ to λN ; but in the second, as KM is to ML , so is $K\Lambda$ to $\lambda\theta$. And KM is equal both to MC and to ML , since these lines are radii of that parallel; therefore $K\Lambda$ too will be equal to λN in the first figure, and to $\lambda\theta$ in the second.

[Margin: a. Prop. 2 of Book Six.]

Diagram. Left of two circular figures (the *first figure*): the parallel touches the horizon; center E, twelve radial hour-lines, horizon A–C, meridian B–D, and sine-points on the meridian.

[Margin: b. Prop. 2 or 4 of Book Six.]

And so, since in the first figure — where the parallel touches the horizon ^b — we have: as KM, the whole sine, is to MR, the sine of the complement of the Sun's distance from the meridian K, so is KA, the half of the sine of the meridian altitude, to λ T, the difference between TN, the sine of the Sun's altitude, and the line λ N, the half of the sine of the meridian altitude; then, if it be arranged that as the whole sine is to the sine of the complement of the Sun's distance from the meridian, so is the half of the sine of the meridian altitude to a fourth term, that fourth term will be found to be a line which, added to the aforesaid half if the distance from the meridian is less than a quadrant, or subtracted from that same half if the distance from the meridian is greater than a quadrant, will give the sine of the Sun's altitude at the time of observation. But if the Sun's distance from the meridian is equal to a quadrant, then the half λ N will itself be the sine of the Sun's altitude at the time of observation.

[Margin: c. Prop. 2 or 4 of Book Six.]

Again, since in the second figure — where the parallel stands wholly above the horizon and does not touch it ^c — we have: as KM, the whole sine, is to MR, the sine of the complement of the Sun's distance from the meridian K, so is KA, the half of the difference KΘ between the sine of the greater meridian altitude and the sine of the lesser meridian altitude, to λT, the difference between TN, the sine of the Sun's altitude, and the line λN — the latter being compounded of the said half λΘ and the sine ΘN of the lesser meridian altitude; then, if it be arranged that as the whole sine is to the sine of the complement of the Sun's distance from the meridian, so is the half of the difference between the sine of the greater meridian altitude and the sine of the lesser meridian altitude to a fourth term, there will be found a line which, subtracted from the line compounded of the said half and the sine of the lesser meridian altitude if the Sun's distance from the meridian is greater than a quadrant, or added to that same compounded line if the distance is less than a quadrant, will give the sine of the Sun's altitude at the time of observation. But if the distance should be equal to a quadrant, then the line compounded of the said half and the sine of the lesser meridian altitude will itself be the sine of the Sun's altitude at the time of observation. All of which can easily be gathered from these two figures set here side by side.

Conversely, if it be arranged that as KA, the half of the sine of the meridian altitude in the first figure — or the half of the line KΘ in the second, which is the difference between the sine of the greater meridian altitude and the sine of the lesser meridian altitude — is to λT, the difference between the sine of the Sun's altitude and the half of the sine of the meridian altitude in the first figure (or between the sine of the Sun's altitude and the line λN, which is compounded of the half of the difference between the sine of the greater meridian altitude and the sine of the lesser meridian altitude together with the sine of the lesser meridian altitude, as appears in the second figure), so is the whole sine to a fourth term, then that fourth term will be found to be the sine of the complement of the Sun's distance from the meridian K. This complement, added to a quadrant when the sine of the Sun's altitude is less than the line λN — that is, than the half of the sine of the meridian altitude in the first figure, or than the line compounded of the sine of the lesser meridian altitude and the half of the difference between the sine of the greater meridian altitude and the sine of the lesser meridian altitude in the second figure — will give the Sun's distance from the meridian, as appears in the second figure. But that same complement, taken away from a quadrant when the sine of the Sun's altitude is greater than the said line λN, will leave the Sun's distance from the meridian.

But this matter will be accomplished more easily by that method which we treated last of all, before we explained this proposed problem by spherical triangles. For if it be arranged that as KM, the whole sine, is to KR, the versed sine of the Sun's distance from the meridian K, so is KA, the half of the sine of the meridian altitude in the first figure (or, in the second, so is the half of the difference between the sine of the greater meridian altitude and the sine of the lesser meridian altitude), to a fourth term, then KT will come out known — the difference between the sine of the greater meridian altitude (or, at any rate, in the first figure, of the meridian altitude itself) and the sine of the sought Sun's altitude.

Likewise, if it be arranged that as the aforesaid half is to the difference between the sine of the greater meridian altitude (or, at any rate, in the first figure, of the meridian altitude itself) and the sine of the Sun's altitude, so is the whole sine to a fourth term, then the versed sine of the Sun's distance from the meridian K will result. As is manifest from the same figures.

But if the pole of the world should stand at the zenith — that is, at the pole of the horizon — then on any given day the Sun's altitude will be perpetually equal to the declination of the parallel which the Sun then describes by the motion of the *primum mobile*. For then the equator is the same as the horizon, and the parallels of the horizon do not differ from the parallels of the Sun, or of the equator, as is evident.

END OF THE FIRST BOOK.

GNOMONICS, BOOK TWO

BY CHRISTOPH CLAVIUS OF BAMBERG, OF THE SOCIETY OF JESUS

In the preceding book we set out various theorems and problems that we judged to be either necessary or useful, so that they might serve as a kind of basis and foundation for all the demonstrations we are about to bring to bear on the description of sundials [horologia]. We now proceed, in this second book, to the description of the sundials that are usually drawn on flat surfaces. Of these there are many kinds, as we said at the outset; and for each of them we shall lay out not merely the hours (which is nearly all that every other writer has done), but — so far as it can be managed, and so that our gnomonics may be rendered as complete as possible — we shall demonstrate twelve problems. These will explain

nearly everything that can be known from the shadow of a gnomon, always keeping to the order that follows.

[Margin: What is described in this work for each of the individual planes of sundials.]

First, we shall teach the method by which, on any given plane whatsoever, one may lay out an astronomical sundial — that is, one containing the lines of the hours reckoned from noon or from midnight. These lines are nothing other than the common sections of the plane of the dial with those great circles which are drawn through the poles of the world and which divide the equator, together with the remaining parallels, into 24 equal parts.

[Margin: The hours from noon or from midnight.]

Next, we shall show the method of drawing, on the same plane, the parallels that pass through the beginnings of the signs of the zodiac, or through any other points whatever. These parallels are called by the practitioners the "arcs of the signs." On a given plane they are either circles, or parabolas, or hyperbolas, or ellipses — namely the common sections of the plane of the dial with conic surfaces whose bases are the said parallels of the signs of the zodiac and whose vertex is the center of the world. The one exception is the parallel drawn through the first points of ♈ [Aries] and ♎ [Libra]: since this does not differ from the equator, it produces a straight line on the proposed plane, as we demonstrated in the preceding book.

[Margin: The parallels, or arcs of the signs of the zodiac.]

After that, we shall describe on the same plane the parallels of the diurnal arcs. These too are themselves parallels described by the points of the zodiac under the motion of the *primum mobile*; but they are not necessarily drawn through the beginnings of the signs — though this can sometimes happen — but rather through those points of the ecliptic in which the Sun, being present, makes a day of a given number of hours, such as 12, or 13, or 9, or 8, or finally however many one may wish, provided they do not exceed the number of 24 hours. On the proposed plane these parallels too are either circles, or parabolas, or hyperbolas, or ellipses, with the exception of the parallel of 12 hours; since this is the equator itself, it produces a straight line on the plane of the dial, as we said.

[Margin: The parallels of the diurnal arcs.]

Again, in the fourth problem we shall draw on the same plane the vertical circles, which they call azimuths — that is, the common sections of the plane of the dial with the vertical circles.

[Margin: The vertical circles.]

In the fifth problem we shall lay down on the same given plane the parallels of the horizon, which they call almucantarats. On the proposed plane these (as was said of the parallels of the signs of the zodiac and of the diurnal arcs) are the common sections of the plane of the dial with conic surfaces whose bases are the said parallels of the horizon and whose vertex is the center of the world — namely either circles, or parabolas, or hyperbolas, or ellipses, with the exception of the horizon itself: since it is a great circle, it produces a straight line on the plane.

[Margin: The parallels of the horizon, which they call almucantarats.]

The sixth problem will contain, on the same plane, the description of the meridian circles of the whole world, which appear on the plane as straight lines, after the manner of the hour-lines from noon or midnight.

[Margin: The meridian circles.]

The seventh problem will exhibit the delineations of the parallels of the cities — that is, the circles of latitude — on the same plane. These are the circles drawn through the zeniths of the several places, and on the plane of the dial they become either circles, or parabolas, or hyperbolas, or ellipses, like the parallels of the signs of the zodiac or of the diurnal arcs.

[Margin: The parallels of the latitudes, or of the cities.]

In addition to these, in the eighth problem we shall mark out the celestial houses — that is, the straight lines that are the common sections of the plane of the dial with the circles of the celestial houses — both according to the doctrine of Johannes Regiomontanus [Regiomontanus], who draws them through equal parts of the equator, and according to the opinion of Campanus [Campanus of Novara], who holds that they should be drawn through equal parts of the prime vertical circle.

[Margin: The celestial houses.]

Furthermore, in the ninth problem we shall hand down the method by which, on the same proposed plane, we may describe the ascending signs of the zodiac — that is, the straight lines that are the common sections of the plane of the dial

with the ecliptic, according to the various situations and positions it holds upon the horizon as the beginnings of the signs of the zodiac rise above the horizon.

[Margin: The ascending signs.]

In the tenth place we shall construct, on a given plane, the Italian dial, which contains the hours from sunset — a usage that today flourishes especially in Italy and Bohemia.

[Margin: The hours from sunset.]

In the following, the eleventh problem, we shall set up on the same plane the Babylonian dial, comprising the hours from sunrise, which in our own time the Balearic Islands make use of.

[Margin: The hours from sunrise.]

Lastly, on the same plane we shall draw the ancient dial, comprising the unequal hours, which of old were in use among nearly all peoples everywhere.

[Margin: The ancient, or unequal, hours.]

Now, in describing these twelve matters on every proposed plane, we shall always employ geometrical demonstrations, so that in the description itself the dial-maker [horologiographus] may not be able to call anything into doubt or into question. The use of everything will likewise be explained in the proper propositions of the horizontal dials, of which we shall speak first; and this use is to be understood in the same way in all other dials.

[Margin: The argument of the second book.]

Accordingly, this second book will embrace all those dials which are usually laid out on a plane that is equidistant [parallel] to one of the following: the horizon; the vertical circle properly so called; the meridian; the circle of the sixth hour from noon or midnight; or, finally, the equator. Such a plane, whichever of the named great circles it is parallel to, is perpetually one and the same, never changing its situation within the same climate. But the remaining dials — those whose planes are parallel to great circles that either decline from the vertical, or from the horizon, or are inclined toward the horizon, or finally both deflect from the vertical and are at the same time inclined toward the horizon — these we shall defer to the third book. Within a single climate they can be varied in as many as six hundred ways. For example, a great circle declining from the vertical, to which a dial is parallel, can be made to decline toward the east or the west by a single degree, or by two, or three, four, five, six, and so on in succession

all the way to 90. Hence the dial parallel to it will likewise be varied in just as many ways, even though we remain always in the same climate, that is, at the same elevation of the pole. And the same must be said of the others.

[Margin: Which method of describing the astronomical dial on any given plane is the more approved.]

Now, since we are about to describe the astronomical dial on every plane by several methods, of them all the following method is the one I most approve (so that in this matter too I may signify to the studious reader by which way above all one should proceed in the description of dials): the method that takes the given length of the style [stylus] and its given position, and from these describes the dial — with the further addition of that method which is carried out by means of the ellipse described on the plane of the dial. This, so far as I know, we have observed to have been done by no one hitherto, still less demonstrated. The former method, explained and demonstrated, you will find in the scholia of the several astronomical dials that are described in propositions 1, 13, 25, 37, and 49 of this book, and in propositions 1, 13, 25, and 37 of Book 3, and repeated again in Book 7. The latter method you will find in the scholia of propositions 1 and 13 of this book, and in the scholia of propositions 1, 13, 25, and 37 of Book 3 — because that ellipse has no place in the scholia of propositions 25, 37, and 49 of this book. As for describing the hours from sunrise and sunset, I would always choose that method which we shall explain in Book 5 — provided, however, that the tables necessary for this matter are ready at hand, tables which we shall teach how to compute in that same book. For this method seems to be the easiest of all and the least liable to error, as we shall make plain in its proper place.

[Margin: Which method of describing the astronomical dial on any given plane is the more approved.]

We have not, however, explained those two methods of describing the astronomical dial within the propositions themselves, but have relegated them to the scholia; for the descriptions set out in the propositions are the ones used by nearly all practitioners, although even in these we have changed some things. Hence it seemed best in the first place to corroborate them by geometrical demonstrations — something which we find no one before us has performed perfectly and fully.

ON HORIZONTAL DIALS

PROBLEM 1. PROPOSITION 1.

To construct an astronomical horizontal dial. That is, to describe, on a plane that is parallel to the horizon, the lines of the hours reckoned from noon or from midnight.

[Margin: The description of the portion of the analemma.]

Let ABC be a semicircle of the meridian, whose center is D, and let BC be the common section of it and the horizon; AD the common section of the same and the vertical; FD the common section of the same and the equator; and ED the axis of the world, as we handed down in Proposition 1 of the preceding book. When the straight lines AD, ED, FD have been produced toward the side of D, take on AD, produced, a straight line DG equal to the gnomon of the future dial, of whatever magnitude it may be; and through G draw HI parallel to BC, cutting ED and FD, produced, in H and I. If, then, through BC the horizon be understood to be drawn perpendicular to the meridian, and through HI the plane of the dial parallel to the horizon — since both the meridian and the vertical are perpendicular to the horizon — then their common section AD will be perpendicular to it; and therefore, from what we demonstrated concerning Euclid, Book 11, Proposition 14, it will also be perpendicular to the plane of the dial drawn through HI parallel to the horizon.

[Margin: (a) From Proposition 19.]

Therefore HI will be, in the plane of the dial, the meridian line, or the line of the twelfth hour, being the common section of the meridian and the plane of the dial. For the straight line HI is in the plane of the straight lines HD and ID, that is, in the plane of the meridian; DG will be the gnomon, or style, perpendicular to the plane of the dial, and therefore also perpendicular to HI, the meridian line, by Definition 3 of Euclid, Book 11 — its vertex D being the same as the center of the world, by Proposition 2 of the preceding book.

[Margin: (b) From Proposition 2.]

The seat of the style is the point G, on the meridian line, distant from the point H (in which the axis of the world meets the plane of the dial, and which is called the center of the dial) by the interval GH; or from the point I (in which the plane of the equator cuts the meridian line) by the interval GI. All these things are clear and manifest, if the meridian is understood to be set in its proper situation —

namely so that the point E looks toward the arctic pole and F inclines toward the south. This figure we shall call, for the sake of instruction, the "portion of the analemma," since it is truly a part of the analemma described in Proposition 1 of the preceding book, containing, that is, the common sections of the meridian and of several circles of the sphere.

[Margin: What the portion of the analemma is called.]

Diagram. The "portion of the analemma" for the horizontal dial. A semicircle stands on a horizontal diameter BC (B at the left end, C at the right end), with center D. The radius rising vertically from D reaches the top of the arc at A, with K marked just beside A at the summit. On the arc, F is placed to the upper left and E to the upper right; straight lines run from D out to E and to F (and to A/K). Below the diameter, a shallow triangle is formed by the meridian/axis lines meeting near the foot: the roughly horizontal line at bottom carries N (lower left) and O (lower right), with H, G, and I marked in sequence along the lower meridian region between them, and M at the very bottom where the lines converge.

- A (top of arc, apex of vertical radius): vertex of the vertical/zenith direction
- K (beside A at the summit): companion label at the apex
- B (left end of diameter): end of the common section BC of meridian and horizon
- C (right end of diameter): other end of BC
- D (center): center of the meridian semicircle = center of the world
- E (upper right on arc): point looking toward the arctic pole (axis end ED)
- F (upper left on arc): point inclining south (equator section FD)
- H (lower region, on the meridian line): where the axis of the world meets the plane of the dial; center of the dial
- G (lower region, between H and I): seat of the style
- I (lower region): where the plane of the equator cuts the meridian line
- N (lower left): end of the dial-plane line HI produced
- O (lower right): other end of the dial-plane line
- M (bottom, convergence point): foot of the construction

[Margin: The description of the horizontal astronomical dial.]

Now, by the help of the triangle DHI, we shall construct the astronomical horizontal dial in this way. On a straight line HE, drawn at will to serve as the meridian line in the plane of the dial, let there be transferred HI, the meridian

line of the portion of the analemma; and let there be cut off from the straight line HE a length IE equal to the straight line DI in the same portion of the analemma. Then through I, in the plane of the dial, let the perpendicular FK be raised to HE. And from E let a circle be described at any interval whatever; when this has been divided into 24 equal parts, beginning from the meridian line HE produced, let lines be drawn through the points of division, and [continues]—

—and [drawn] from the center E, secret [auxiliary, unmarked] straight lines cutting the straight line FK in points; and through these points, straight lines emitted to the point H will give the hour-lines from noon or from midnight on the plane parallel to the horizon. Thus HE will give the twelfth hour of the day; and the lines placed on our left, as we face the dial (I call the left part that in which the point F lies, and the right that in which the point k lies), will show the hours after noon, while the lines placed on the right will show the hours before noon, or after midnight, as the numbers themselves indicate. For the sixth hour, the line CL must be drawn through H perpendicular to HE, or parallel to FK; and HC will mark the sixth hour from noon, and HL the sixth hour from midnight.

[Margin: The order of the hours in the horizontal dial.]

Here is the demonstration of this construction. Let the portion of the analemma be understood to be superimposed on the dial, in such a way that the point H coincides with the point H, and the point I with the point I, and the straight line HI with the straight line HI (it will indeed coincide with it because of the equality of the straight lines HI and HI); and let this portion of the analemma be conceived in the mind as standing upright to the plane of the dial, while the meridian line HE keeps its proper situation, so that it is the common section of the meridian and the plane of the dial, with the point H inclining to the south and E to the north; and finally so that the straight line BC is parallel to the plane of the dial, so as to be the common section of the meridian and the horizon, with D — the vertex of the style — being the center of the world, as we showed in Proposition 2 of the preceding book.

[Margin: The demonstration of the construction of the horizontal dial.]

Or rather, in place of the portion of the analemma, let just the triangle DHI be understood to be superimposed on the dial in the manner we have said — so that DH represents the axis of the world; DI, the common section of the meridian and the equator; and finally DG, the style, the common section of the meridian and of the vertical circle drawn through D, the center of the world. This triangle DHI, together with the style DG, is what has been drawn on the dial. With these things

so placed, the axis DH will meet the plane of the dial in H, the diameter of the equator DI in I, and the diameter of the vertical DG in G. Since, then, both the plane of the equator and the plane of the dial (which is parallel to the horizon) are perpendicular to the plane of the meridian, the common section of the equator and of the plane of the dial will also be perpendicular to that same plane of the meridian, and therefore [continues]

[Margin: (a) From Proposition 19.]

Diagram. The full horizontal-dial construction. A large outer semicircular fan of hour-lines stands on a horizontal diameter running left to right, with a smaller circle (the equator circle described from center E) set within it, and a central sun-burst of radiating lines converging at the dial-center H. The horizontal diameter carries C at the left (marked 6) and L at the right (marked 6). Around the outer arc and lower border run the hour-numbers; a dense cluster of small point-letters surrounds the central sun-burst. Because this is a crowded figure with many small worn labels, several central labels are flagged uncertain.

- Horizontal diameter, left end: C, with hour-number 6 outside it
- Horizontal diameter, right end: L, with hour-number 6 outside it
- Central sun-burst point (radiating center): H (center of the dial)
- Central region, small labels: M, R, r, b, d, a, f [?] — dense cluster of construction points around the sun-burst, several worn
- T (left of center, on the inner circle)
- D (just right of center, near the sun-burst) — center of the world in the superimposed triangle
- K (right of center) — foot of the vertical
- E (below center, within the lower fan) — center of the equator circle
- F (center-left) — point on the equinoctial line FK
- Z (upper left, outside the inner circle)
- e (top center, on the inner circle)
- δ [?] (lower left, on the inner circle)
- V (lower left, outside the inner circle)
- N, O, Q, S (along the lower border, left to right beneath the fan)
- Outer arc hour-numbers, upper row (left to right): 7, 8, 12, 1, 2, 3, 4, 5
- Lower and side hour-numbers: 6 (left), 6 (right), 7 (right), 8 (right), 9, 10 (lower right); 5, 4, 3, 2 (lower left); 11, 12, 11 (bottom center)

—by Definition 3 of Euclid, Book 11, it will [be] perpendicular to the meridian line HE, which lies in the plane of the meridian, at the point I, in which the equator — drawn as the straight line DI — meets the meridian line in the dial, as has been said. Therefore the straight line FK, which in the dial has been raised through I perpendicular to the meridian line HI, is the common section of the equator and the plane of the dial — namely the equinoctial line. Now suppose the plane of the circle described from center E is understood to be moved about this line, until its center E is joined with the center of the world D in the triangle DHI (which we said to be perpendicular, together with the whole portion of the analemma, to the plane of the dial, although only the triangle is drawn on the dial and exists in the plane of the meridian). This joining is possible because the straight lines DI and IE are equal by construction; and in that motion of the circle described from E, the line IE always remains in the plane of the meridian, in which the line DI lies. The circle will therefore be described about the center of the world D — that is, it will be the equator — and it will lie in the plane of that same equator, since the plane of the equator is drawn through the straight lines DI and Ik, just as the said circle in such a position is drawn through the same lines; so that this circle and the equator lie in the same plane and have the same center, namely D, the center of the world.

Let IE also be understood to be produced in both directions in the same position, since it moves together with the circle, being as it were the common section of the meridian and the equator — for both the meridian and the equator, in a position of this kind, pass through the straight line DI, or IE (which in that situation is the same as DI). Now, since from what we wrote in the *Commentaries on the Sphere*, toward the end of chapter 1, circles described in the same plane and about the same center are cut into similar parts by lines going out from the center, it follows that those secret [auxiliary] lines drawn through the center E — which is now joined with the point D, that is, with the center of the world — and which cut the circumference of the circle into 24 equal parts, and which meet the straight line FK, the common section of the equator and the plane of the dial, in the points I, A, B, and so on: these lines, if produced, will also cut the circumference of the equator, beginning from the meridian, into just as many equal parts. And therefore, since the circles of the hours from noon or from midnight divide the same equator into 24 equal parts, likewise beginning from the meridian, as is clear from Proposition 9 of the preceding book, it comes about that these same secret lines going out from the center E are the common sections of the equator and of the hour-circles which [mark the hours] from noon or from mid[night] [continues]

mid[night] indicate. Namely, NM is the common section of the equator and the circle of the 12th hour — that is, of the meridian; OP, of the equator and the circle of the first hour from noon or from midnight; QR, of the equator and the circle of the 2nd hour from noon or from midnight; ST, of the equator and the circle of the 3rd hour from noon or from midnight; and so on — as is clear if the circle described from E is understood to be in its proper position. For the points O, Q, S will incline, in the upper hemisphere, toward the western or afternoon parts, and so on.

Therefore the hour-circles from noon or from midnight cut the straight line FK in the plane of the dial at the points I, A, B, and so on. (These points do not change even if the plane of the circle about E has another position — namely if it lies in the plane of the dial, where we described it. For if the plane of this circle is turned about the straight line FK as about a fixed hinge, so that the straight line IE is always perpendicular to FK, the straight lines NE, OE, QE, and so on will always meet the equinoctial line FK at the same points, as is evident.) And so through these points will pass the common sections of those hour-circles and the plane of the dial, which are the hour-lines from noon or from midnight. But by the corollary of Proposition 21 of the preceding book, these same common sections, or hour-lines, cut one another at the center H of the dial, where the axis DH meets the plane of the dial. Therefore the straight lines drawn through the points I, A, B, and so on of the equinoctial line FK, and through the point H, or the center of the dial, are the lines of the hours from noon or from midnight — so that the meridian line HIE indicates the 12th hour of noon; the lines to its left show the hours from noon, while the lines to its right show the hours from midnight, as appears in the figure and as we shall explain in the following scholium.

Only the line of the 6th hour must be drawn through H, perpendicular to HI, or parallel to FK itself — such as CL is. For since, as we taught in the scholium of Proposition 22 of the preceding book, in a horizontal dial the equinoctial line and the line of the 6th hour from noon or from midnight are parallel, it is clear that the straight line CL is the line of the 6th hour from noon or from midnight, since it is parallel to the equinoctial line FK and passes through the point H, where all the hour-lines from noon or from midnight intersect one another. We have therefore established the astronomical horizontal dial, etc. Which was to be done.

SCHOLIVM.

[Margin: Another way of laying out the astronomical horizontal dial, most convenient for drawing the hours that are near the 6th hour from noon or from midnight.]

Andreas Schöner [Andreas Schoner] proposes another way of describing the hours from noon or from midnight, which is very convenient for laying out those hours that cut the equinoctial line at points very far off — such as the hours near the 6th hour from noon or from midnight. It runs as follows. On the equinoctial line FK take the straight line Ia equal to the straight line IE (or ID); and through a draw a line ab perpendicular to the equinoctial line — or parallel to HI — cutting at b the line of the 6th hour CL (which is always drawn from H, the center of the dial, perpendicular to HI, or parallel to the equinoctial line, as has been shown). Then take bd equal to ab, and through d draw ef perpendicular to bd, or parallel to HI. Finally, from d as center describe a circle, and dividing it into 24 parts, beginning from the straight line bd, draw hidden [auxiliary] lines from the center d through the points of division. For these will cut the straight line ab at points through which, if straight lines are drawn from H, the center of the dial, they will give — as before — the hours from noon or from midnight.

[Margin: The segments of the equinoctial line in a horizontal dial, between the meridian line and any two hours equally distant in time on either side of noon, are equal. (a) *Elements* III.27. (b) *Elements* I.26.]

Moreover, in any horizontal dial whatever, any two hour-lines equally distant in time on either side of the meridian line cut off equal segments from the equinoctial line FK — namely those segments that lie between the hour-lines and the meridian line. Thus the lines HF and HK, each of which is distant five hours from the meridian line, cut off the equal segments IF and IK. [a] For the angles IEF and IEK — contained by the meridian line and the hidden straight lines drawn from E to F and K (for although EF is not actually drawn, it must be conceived as drawn) — are equal, since at the center E they are subtended by equal arcs of the circle described from E; and the angles at I are right angles. Therefore the two angles IEF and EIF of triangle EIF are equal to the two angles IEK and EIK of triangle EIK. And since they have the side IE in common, [b] the remaining sides of the one will be equal to the remaining sides of the other — namely IF to IK, which was the proposition. And the reasoning is the same for the rest. Therefore the hour-spaces before noon are equal to the hour-spaces after noon, each to each, on the equinoctial line of the horizontal dial.

[Margin: The arcs of a circle described from H, the center of a horizontal dial, intercepted between the meridian line and any two hours equally distant on either side of noon, are equal. (c) *Elements* I.4. (d) *Elements* III.26.]

From this it follows that the arcs of any circle described from H in the horizontal dial, intercepted between the meridian line and any two hour-lines equally distant in time from the meridian — such as, for example, the arcs of a circle described from H intercepted between the meridian line HI and the lines HF, HK — are equal. For since the sides IH, IF of triangle IHF are equal to the sides IH, IK of triangle IHK, and they contain equal angles — namely right angles — [c] the angles IHF and IHK will also be equal, [d] and consequently in the circle described from H they will be subtended by equal arcs; and so for the rest.

[Margin: The intervals between E, the center of the equator, and any two hours equally distant in time on either side of noon in a horizontal dial, are equal.]

It follows again that the intervals between the center E of the equator and any two hours on the equinoctial line FK, distant by an equal interval of time from the meridian line — such as the intervals EF and EK — are equal. For since the sides IE, IF of triangle IEF are equal to the sides IE, IK of triangle IEK, and contain equal angles, the bases EF and EK will also be equal; and so for the rest.

[Margin: For the description of the astronomical horizontal dial it is enough if just one quadrant of the circle described from E is cut into 6 equal parts.]

Finally it follows that, for the description of the astronomical horizontal dial, it is enough if one quadrant of the circle described from E — such as, for example, the quadrant Mg — is divided into six equal parts. For when hidden straight lines are drawn through the points of division and the center E, cutting the straight line FI at the points through which the hour-lines are to be drawn from H, then if these points are carried over from I to the other side of the equinoctial line, toward K, other points will be obtained through which the hour-lines are to be drawn — since each hour-space on the straight line IF is equal to the corresponding hour-space on the straight line IK, as has been demonstrated. Again, once the hour-lines have been drawn from H through the points of the straight line IF (or IK), in order that the remaining ones on the other side may be drawn more accurately, the points of the circumference of the circle described from H must be carried over — from the point where the meridian line and the said circumference intersect one another — to the other part of the same circumference. For through these the hour-lines drawn from H through the points of the straight line FK must

certainly pass, since the arcs of the said circle on one side are equal to the arcs of the same circle on the other side, as has been shown.

[Margin: How the horizontal dial, together with the axis of the world, is to be positioned so that it may show the hours from noon or from midnight.]

But if the axis HD, in the triangle DHI (right-angled to the plane of the dial), is understood to be a stretched thread — or even some thin piece of iron — making at H an angle with the meridian line equal to the angle DHI, and right angles with the straight line CL; or if the triangle DHI itself is constructed of some solid material and set upright to the plane of the dial: then the shadow of the axis DH will indicate the individual hours from noon or from midnight, provided the dial is set on a plane parallel to the horizon in such a way that the straight line HI represents the meridian line (whose determination on a plane parallel to the horizon we have handed down both in the *Commentaries on the Sphere* [*In Sphaeram*], where we treated of the meridian circle, and in the scholium of Proposition 23 of the preceding book), with the point H turned toward the south and I toward the north. For since all the hour-circles from noon or from midnight are drawn through the axis of the world, it comes about that the Sun's ray, in any one of them,...

lying in that circle, does not depart from the axis and from the common section of that circle with the plane of the dial, since both the axis and this common section — namely its hour-line — lie in the same hour-circle. Therefore the shadow of the axis will be projected onto the hour-line of that circle; and so for the rest. Hence it comes about that the shadow of the vertex D of the style DG (perpendicular to the plane of the dial at the point G) — that is, the shadow of the center of the world (for the vertex of the style is the same as the center of the world, by Proposition 2 of the preceding book) — is projected onto the same hour-lines, because the vertex D also lies on the axis, all of whose points cast their shadow onto the hour-lines, as has been said; which we also demonstrated in Proposition 11 of the preceding book. Thus the use of the astronomical dial is that, from the shadow of the style falling on its hour-lines, we understand how many hours have passed since noon or since the nearest midnight, and how many remain until the following noon or midnight. For in the morning, if the shadow falls, for example, on the line of the 7th hour, we shall take it for certain that seven hours have elapsed since midnight, and that five remain until the next noon, and so on.

[Margin: If the style DG is perpendicular to the plane of the dial at G, the shadow of the vertex D alone will indicate the hours from noon or from midnight.]

Now if one wishes to mark the half-hours as well on the dial, and their quarters — or indeed their eighths, or any other subdivisions — then each of the parts of the circle described from E must be divided into the said parts: into two, four, eight, and so on; and the rest carried out as before. This must be observed also in the other dials that follow.

[Margin: The use of the astronomical dial. How the half-hours and their quarters, or any other subdivisions, are marked on the dial.]

Here, however — and in everything that follows — it must be carefully observed that any line in the dial which cuts the equinoctial line represents that celestial semicircle whose common section, made on the circle we described from E, the center of the equator, and in its plane (that is, provided its center E is joined with the center of the world D), passes through the center E before it meets the equinoctial line in the dial. Namely, the straight line HA is the first hour from noon — that is, it represents that celestial semicircle in which the Sun stands at the first hour from noon; because at A falls OE, drawn through the center E, and this OE is the common section of the semicircle of the first hour from noon drawn through the point O, and passes through the center E before it cuts the equinoctial line at A — as is clear if the circle described from E is conceived to be in the plane of the equator, with its center E joined to the center of the world D. The reason for this is that the Sun casts its ray first onto the center of the world, or the vertex of the style, before the shadow of the style...

[Margin: Which celestial semicircle each line in the dial represents.]

Diagram. A large horizontal-sundial construction. The figure is bounded by a full circle; its lower half is completed while the upper half carries the analemma construction on the left. At the center is **H**, the center of the dial, where all the hour-lines converge; immediately below H is a small circle **G** (the foot of the style). Below G, on the vertical meridian line, lie **I** (where the equinoctial line crosses the meridian) and **E** (the center of the equinoctial circle), with **D** (the center of the world) marked close to I. A vertical meridian runs from **M** (top, just under the "12") down through H, I, E to **N** (bottom, just above the lower "12").

Two roughly horizontal lines cross the figure: the upper one, through H, runs from **C** (left) to **L** (right) — the line of the 6th hour, its ends reaching the "6" marks at the circle on each side; the lower one, through I, runs from **F** (left) to **K** (right) — the equinoctial line. On the upper left a dotted/dashed arc carries the analemma, marked with **A** (upper left, beside "8"), **B** (left, on a dashed line), and **C** (lower left, a small letter on the dotted arc).

Radial hour-lines are drawn from H to the circumference and numbered. Along the top, near noon, run the hours **9, 10, 11, 12, 1, 2, 3, 4**; around the rest of the circle the hours **1–12** are engraved (each hour-line serving an AM and a PM hour), reading down the right side (**5, 6, 7, 8, 9, 10**) and up the left side (**5, 4, 3, 2, 1**) to the bottom (**12, 11, 10**).

- H (center): center of the dial; convergence of hour-lines
- G (just below H): foot of the style [small glyph, ~[?] confidence]
- I (below G, on meridian): equinoctial line meets meridian
- E (below I, on meridian): center of the equinoctial circle
- D (beside I): center of the world
- M (top, on meridian): north point of the analemma quadrant
- N (bottom, on meridian): south point
- A (upper left, on dotted arc, by "8"): analemma point
- B (left, on dashed line): analemma point
- C (lower left, on dotted arc): analemma point [small glyph, [?]]
- C ... L (through H): line of the 6th hour
- F ... K (through I): equinoctial line
- Hour numerals 1–12 around the circumference; 9–12, 1–4 also along the top

falls on the plane of the dial, as is evident. In the same way the straight line HK will be the 7th hour from midnight — that is, it will represent that celestial semicircle in which the Sun stands at the 7th hour from midnight; because at K falls VE, drawn through the center E, and this VE is the common section of the semicircle of the 7th hour from midnight drawn through the point V, and passes through the center E before it cuts the equinoctial line at k, as is evident; and so for the rest.

It must also not be omitted that the line of any hour from noon, produced beyond the center of the dial, shows the hour of the same number from midnight, and conversely. We shall demonstrate it thus. Take, for example, the circle of the fifth hour from noon and from midnight, which makes in the dial the line of that same hour drawn through the center H. Now if the Sun were placed at the arctic pole, the shadow of the style would fall on the point H — since the Sun's ray would then be the same as the axis of the world, which, drawn through the vertex of the style, meets the plane of the dial at the point H. It follows that, when the Sun is in the semicircle of the said circle which is more to the west than the meridian, the shadow of the style falls on the opposite side — namely on that part of the line of the fifth hour which is more to the east in the dial than the meridian line; and

when the Sun is in the other semicircle of the same circle, which is more to the east than the meridian, the shadow of the style falls on that part of the same fifth-hour line which is more to the west than the meridian line. For the shadow always falls on the said line while the Sun is in the said circle, as we showed in Proposition 11 of the preceding book. Since, therefore, the western semicircle pertains to the fifth hour after noon, and the eastern to the fifth after midnight, the eastern portion of that line — the one which from the center H extends toward the eastern part of the dial (for the meridian line divides the whole dial into an eastern and a western part, just as the meridian divides the whole celestial sphere into an eastern and a western hemisphere) — will indicate the fifth hour from noon; while the remaining portion of the same line, inclining toward the western part, [will indicate] the fifth hour from midnight. And the reasoning is the same for the other lines, in other dials too that are not horizontal.

[Margin: The line of any hour from noon, produced beyond the center of the dial, indicates the hour of the same number from midnight, and conversely.]

We shall show the same thing by this reasoning too, and more briefly. Since the shadow of the style before noon falls on the western part of the dial, but after noon on the eastern — because it is always cast toward the part opposite the Sun — all the hour-lines terminating at the center H that lie in the western part (which the meridian line separates from the eastern in every dial) will belong to the forenoon hours, or those after midnight; while the remaining ones, in the eastern part, [will belong] to the afternoon hours. Since, therefore, the hour-lines in...

the eastern part of the dial, produced beyond the center, exhibit the lines of the same hours in the western part, and conversely, what is proposed is evident.

[Margin: Any great circle drawn through the poles of the world makes on the dial a straight line, one portion of which, terminating at the center, belongs to one semicircle, and the other to the other.]

From this it is gathered that any great circle passing through the poles of the world makes on the dial a section that is a straight line, one portion of which, terminating at the center, belongs to one semicircle, and the other to the other. For this has been demonstrated in the case of the hour-circles from noon and from midnight. And the same is true of the meridian circles, which we shall treat in Proposition 6 of this book. Likewise of the vertical circles, which we shall discuss in Proposition 4 of this book — provided that in place of the pole of the

world we take the vertex of the head, or the zenith, that is, the pole of the horizon; and in the dial, in place of the center of the dial, we take the vertical point, which is where the axis of the horizon falls — such as, in the horizontal dial we described, is the point G.

[Margin: How one is to judge which hour-line belongs to the hours from noon and which to the hours from midnight, in the dial that has been described.]

From these things we shall very easily be able to judge which hour-lines belong to the hours from noon and which to the hours from midnight. For since, if the circle described from E is placed in its proper position, the point N cuts the meridian above the horizon, that point will belong to the 12th hour of noon, so that the straight line NE is the common section of the meridian, or of the circle of the 12th hour from noon. Since, therefore, NE passes through the center E and cuts the equinoctial line at I, the straight line HIE will indicate the 12th hour of noon, and its remaining portion — beyond the center H of the dial — the 12th hour of midnight. By the same reasoning, the straight lines HA, HB, and the rest, placed in the eastern part of the dial, will belong to the hours after noon, because they represent the hour-semicircles of the sections OE, QE, and so on, which indeed indicate the hours from noon on the circle described from E. Finally, the lines placed in the western part of the dial — that is, to the right of the meridian line itself — will signify the hours from midnight, because they represent the hour-semicircles whose sections on the circle described from E recede from the straight line NE toward the eastern region, and show the hours before noon, or from midnight.

If this is carefully considered, we shall very easily recognize, in all the other dials too of which we shall treat in what follows, which hours are to be counted from noon and which from midnight.

[Margin: How one is to judge, in every dial, which hour-line belongs to the hours from noon and which to the hours from midnight. How a dial is to be described on a stable plane parallel to the horizon. Description of the same dial for a given length of style, whose position is also given, without a portion of the analemma constructed separately.]

The reader must also be advised that up to now we have constructed the horizontal dial on any flat surface whatever, so that it may afterward be set in its proper position, or transferred onto some stable plane parallel to the horizon, in such a way that the straight line HE is the meridian line, and the point H is turned toward the south, but the point E toward the north — as we have taught in this

scholium. But if some stable plane parallel to the horizon is offered to us, on which to draw the dial, we shall do it by this method. Having found the meridian line HE on the plane, we shall cut it at right angles at I by the straight line FK, which will be the equinoctial line. Then from I toward the south, as far as H, we shall carry over, from a portion of the analemma, the straight line IH; and toward the north we shall take the straight line IE equal to the straight line ID, from the same portion of the analemma. Finally, from E we shall describe a circle, and, dividing it into 24 equal parts, we shall complete the rest as before.

But if we wish to describe the same dial on a given plane, without a portion of the analemma constructed separately, for any...

Diagram. A horizontal-sundial construction essentially identical to that on the preceding leaf, here illustrating the direct method (given style-length, without a separately constructed analemma). The figure is bounded by a full circle. At the center is **H**, the center of the dial, where the hour-lines converge; just below it a small circle **G** marks the foot of the style. On the vertical meridian below G lie **I** (equinoctial line meeting the meridian) and **E** (center of the equinoctial circle), with **D** marked near I; the meridian runs from **M** (top, under "12") through H, I, E to **N** (bottom). The upper horizontal line through H runs from **C** (left) to **L** (right), the 6th-hour line, its ends at the "6" marks; the lower horizontal line, through I, runs from **F** (left) to **K** (right), the equinoctial line. On the upper left a dotted arc carries the analemma points **A** (upper left, by "8"), **B** (left, on a dashed line), and **C** (lower left, small, on the dotted arc).

Radial hour-lines run from H to the numbered circumference: **9, 10, 11, 12, 1, 2, 3, 4** across the top near noon, and the hours **1–12** around the rest of the circle (down the right side **5, 6, 7, 8, 9, 10**; up the left side **5, 4, 3, 2, 1**; across the bottom **12, 11, 10**).

- H (center): center of the dial
- G (just below H): foot of the style [small glyph, ~[?] confidence]
- I (below G, on meridian): equinoctial line meets meridian
- E (below I): center of the equinoctial circle
- D (beside I): center of the world
- M (top) ... N (bottom): ends of the meridian / analemma quadrant
- A, B, C (upper-to-lower left, on the dotted arc): analemma points; C is a small, faint glyph [[?]]
- C ... L (through H): 6th-hour line
- F ... K (through I): equinoctial line

- Hour numerals 1–12 around the circumference; 9–12, 1–4 also along the top

[Margin: How a dial is to be described on a stable plane parallel to the horizon, for a given length of style whose position is also given.]

length of style, whose position is also given, we shall do it by this method. Let the given length of the style be DG , and let its position on the plane of the dial be the point G . If, then, the plane of the dial is any whatever — so that the dial drawn on it may afterward be set in its proper position, or transferred onto a stable plane parallel to the horizon, as we said just now — we shall draw through G , the position of the style, any straight line MN as the meridian line. But if a stable plane for the dial, parallel to the horizon, is proposed, we shall find — by what we wrote in the scholium of Proposition 23 of the preceding book, or elsewhere — the meridian line on the proposed plane; and if it happens not to pass through G , the position of the style, we shall draw through G , the position of the style, a line MN parallel to it, as the meridian line. Then to this meridian line MN we shall raise at G the perpendicular BGD , and cut off GD equal to the given style. From D as center we shall describe the arc of a circle ABC , in which, from the straight line DGB toward the southern parts (which are now supposed to incline toward M), we shall count off BA , the complement of the pole's altitude, and toward the northern parts — that is, toward N — the pole's altitude itself, BC . And, drawing the straight lines DA , DC , we shall cut the meridian line at the points H and I . After this, through I we shall raise a perpendicular FK to the meridian line, as the equinoctial line. Finally, taking the straight line IE equal to ID , we shall describe from E a circle of any size; and, dividing it into 24 equal parts, beginning from the meridian line, we shall complete the rest as we taught before in this proposition.

[Margin: Demonstration of this description.]

The demonstration of this description is easy. For if the meridian line MN has its proper position, so that M [is turned] toward the south, and N ...

and let N incline toward the north, and let the triangle HDI be set upright to the plane of the dial, so that it lies in the plane of the meridian circle. Since, by construction, the angle HDG is equal to the complement of the pole's altitude, the remaining angle DHG will be equal to the pole's altitude. Again, since by construction IDG is the angle of the pole's altitude, the remaining angle DIG will be equal to the complement of the pole's altitude. Taking, then, D — the vertex of the style — as the center of the world, DH will make with the meridian line at H an angle equal to the pole's altitude, and it will be the axis of the world meeting the plane of the dial at H , the center of the dial. And the line DI , making with the

same meridian line at I an angle equal to the complement of the pole's altitude, will be the common section of the meridian and the equator — since a section of this kind, in the sphere, always makes with the horizontal meridian line an angle equal to the complement of the pole's altitude, and with the axis a right angle (such as is the angle HDI, made up of the angle of the pole's altitude together with the angle of its complement). Therefore the equator meets the plane of the dial at the point I, and consequently, as was demonstrated above, the line FK will be the equinoctial line. The line DG, in turn, will be the common section of the meridian and the vertical. Everything else is demonstrated as before.

Now, in all the methods by which we have thus far drawn a horizontal dial, this drawback occurs: the hour-lines nearest to the line of the 6th hour from noon (or from midnight) can scarcely be drawn, because they intersect the equinoctial line at points extremely far off. I shall therefore show another way — and one indeed that (so far as I know) has never been attempted by anyone before — by which we can draw all the hour-lines through the points of a certain ellipse described on the plane of the dial, even when we have no points on the equinoctial line. This method is altogether necessary for correctly laying out dials that decline from the vertical, whether at the same time they are also inclined to the horizon or not, because in these some of the hour-lines are at times very nearly equidistant from the equinoctial line, as will be made plain in its proper place. For although Andreas Schonerus [Andreas Schöner] accomplished this same thing by another procedure, as we said above, yet neither he nor anyone else has furnished any demonstration of that construction. The way I have discovered is as follows.

[Margin: Another description of a horizontal astronomical dial, new and most beautiful, by the aid of the ellipse — that is, without points found on the equinoctial line.]

Given the style DG, and its position at G, let the meridian line HI be drawn through G. Setting up again, upon the style GD (which is perpendicular to the meridian line), the angle GDH equal to the complement of the pole's altitude and the angle GDI equal to the pole's altitude — so that HD is the axis of the world, H the center of the dial, and I the point through which the equinoctial line is to be drawn perpendicular to HI, just as we demonstrated in the preceding construction — we shall take on the axis HD, produced, any point A, and from it we shall raise the perpendicular AB to HA, so that AB is a new common section of the meridian and the equator. The farther off the point A is taken, the more accurately the dial will be drawn. Hence, if the given style is so large that the line HI has a notable length, we shall content ourselves with the points D and I. But

because in the example of the preceding construction the line HI is too short, we have for that reason taken other, more remote points A and B. Then, cutting off HC equal to AB, let there be described from the center H, at the intervals HB and HC, two circles — HB being the distance between the center of the dial and the point B, through which the equinoctial line is drawn on the meridian line, while HC is equal to the common section AB of the meridian and equator between the meridian line and the axis. Having first drawn the diameter ST perpendicular to the meridian line HB, let these circles be divided into 24 equal parts, beginning from the meridian line HB, or from the diameter ST. It is enough if the outer circle is divided; for the straight lines drawn from the division-points to the center H will cut the inner circle also into 24 equal parts, as we demonstrated at the end of the commentaries on the sphere. After this, let two corresponding division-points be taken, such as, for example, F and K — for they lie on the same straight line Fk drawn from F to the center H, and each is four hours distant, in its own circle, from the meridian line — and through F,

Diagram. A large horizontal-dial construction figure. Two concentric circles are centered on **H** (the center of the dial); a vertical meridian diameter runs from **V** (upper region) down through the center to **B** (bottom), and a horizontal diameter **T ... S** (the 6th-hour line) runs left-to-right through the center. Radial lines divide the circles into 24 parts, and the annular band between the two circles is filled with small dotted right-triangle graduation marks (the hour divisions). At the upper left a tilted oval (the second, oblique base-circle of the cylinder / the rotated gnomon-triangle) carries its own labels. A long straight diagonal (the axis of the world, produced) crosses the whole figure, its two ends each marked with a glyph read as "4" [?]. The dial's hour-line construction points and the ellipse points are lettered with both Roman capitals and Greek minuscules.

Readable labels:

- H (center): center of the dial
- G, D, I (small cluster just below H): style-vertex D, and the meridian points G and I
- V (top of meridian diameter): upper meridian point
- B (bottom of meridian diameter): lower meridian point
- T (left end) ... S (right end): ends of the horizontal 6th-hour diameter
- N (upper-left, inner circle); R (left, inner circle); K, L (lower-left, inner circle); F (lower-left, outer)
- X (right, inner circle); M (lower-right, outer)
- C (lower-center, near B)

- Tilted oval, upper left: e, a, d, h, ξ , and λ [several uncertain]
- Outer ring, upper right: β , γ ; right (below S): θ ; lower right: δ , ε ; and Y, A, P, E, O, ρ , μ scattered near the lower-right and center [many uncertain]
- Top glyph above V: π [?]

the point of the outer circle, let there be drawn, parallel to the diameter ST (which cuts the meridian line at right angles), the concealed line FL. This is easily done if a concealed line is drawn from F to the point M, which is as far from the point S as the point F is from the point T; for the lines FM and TS will be parallel, by the scholium to Proposition 27 of Book 3 of Euclid, on account of the equality of the arcs FT and MS. Likewise, through K, a point of the inner circle, let there be drawn, parallel to the meridian line HB, the concealed line KL — which is likewise easily done if a concealed line is drawn from K to the point N, which is as far from the point R as the point K is from that same point. And let the line KL cut the line FL at L. If the same be done with the remaining pairs of corresponding division-points, as appears in the figure, the points of the ellipse will have been found — its major diameter being BV, its minor RX, and its center H, as is clear from the corollary to Proposition 26 of the foregoing book. I say that the straight lines drawn from H through these found points of the ellipse are the hour-lines, so that each one denotes the same hour that the corresponding division-points denote on the circles. For example, since the point F denotes the fourth hour after noon, the line HL, drawn through it, will accordingly give the fourth hour from noon, and so on for the rest. And by this procedure we shall draw the hours most conveniently, since we always have three points for each hour — two of them opposite on the ellipse, such as L and α , the third being the center H itself. The point α , opposite to L, is found on the ellipse in this way. Take the arcs $S\beta$ and $X\gamma$, equal to the opposite arcs TF and RK, and draw the lines $\beta\alpha$ and $\gamma\alpha$ parallel to the diameters ST and BV, cutting one another at α ; for the point α will be opposite to the point L. And if one wishes to draw the half-hours and their quarters as well, the several parts of the circles must be bisected, and divided into four parts, and so on. This construction, which is the most elegant of them all, we shall demonstrate as follows.

[Margin: Demonstration of this construction.]

Diagram. Essentially the same horizontal-dial figure as on the preceding page, now serving the demonstration: two concentric circles centered on **H**, with the vertical meridian diameter **V ... B**, the horizontal 6th-hour diameter **T ... S**, the 24-part radial division with dotted right-triangle graduation marks in the annular band, the tilted oblique base-circle at the upper left, and the world-axis diagonal

(ends marked "4" [?]) crossing the whole. This copy also shows the cylinder / parallelogram section-construction referenced in the demonstration below.

Readable labels (as on the preceding figure):

- H (center); G, D, I, μ (central cluster)
- V (top) ... B (bottom): meridian diameter ends
- T (left) ... S (right): 6th-hour diameter ends; θ just below S
- N, R (left, inner); K, L (lower-left); F (lower-left, outer); X (right, inner); M (lower-right)
- Upper right: β , γ ; lower right: δ , ϵ ; near lower center/right: C, P, E, O, Y, A, ρ [uncertain]
- Tilted oval, upper left: e, a, d, h, ξ , λ [uncertain]
- Top glyph above V: π [?]

Let the triangle ABH be understood to be turned about the line BH until it stands upright to the plane of the dial and is joined with the plane of the meridian circle. From A, which represents the center of the world, let there be conceived, at the interval AB, a circle θYBZ described, concentric with the equator and in the plane of the equator; this circle will therefore, like the equator, be divided into 24 equal parts by the common sections of the hour-circles and the equator. Let the points O and P also be four hours distant from the point B (of noon), just as the points F, K, M, δ are four hours distant from that same point B (of noon). For although the point P, on the equator, belongs to the 4th hour from midnight (as is evident if the circle θYBZ is set in its proper position, so that the semicircle θYB is the western one and $BZ\theta$ the eastern), nevertheless, because A is placed as the center of the world, the Sun, existing at ϵ at the 4th hour from noon, must cast a ray through the center A and the point P as far as the plane of the dial; and so the section which the hour-semicircle through P, drawn on the plane of the dial, makes, denotes the 4th hour from noon, as is clear from what we wrote above in this scholium. Hence not without reason may the point P be taken for the 4th hour from noon, since the hour-semicircle drawn through it makes, on the dial, the line of the 4th hour from noon. In the same way the point O can be taken for the 8th hour from midnight, although on the equator it in fact denotes the 8th hour from noon. Let a cylinder now be understood whose bases are the circles θYBZ and another, $aeb\pi$, equal and opposite to it, its axis being the same as the axis of the world, $AH\lambda$. And since all the hour-circles from noon (or from midnight) are drawn through the axis of the world, that is, of the cylinder, their planes will make in the cylinder parallelograms, such that two sides of each are diameters of the bases of the cylinder while the remaining two are described on the surface of

the cylinder, as is demonstrated by Serenus in Book 1, *On the Section of the Cylinder*, Proposition 2. For example, the circle of the 4th hour from noon (or from midnight), drawn through the points ε and P in the circle $\Theta Y B Z$, will make a parallelogram, one side of which is εP , a diameter of the base of the cylinder, while two are drawn from the points ε and P on the surface of the cylinder, and so for the rest. I say that these sides, on the surface of the

cylinder, fall on the points of the ellipse described on the plane of the dial — namely, that the sides drawn from the points Z, Y (of the circle of the 6th hour from noon or from midnight) fall on the points R, X; the side from the point θ , of the meridian circle, falls on the point V; and the sides drawn from the points ε , P fall on the points α , L; and so for the rest. For let there be drawn, through Y and Z, the diameter that cuts the diameter θB at right angles, and, through the axis AH, the circle of the 6th hour meeting the plane of the dial at H. And since both the plane of the dial and the plane of this circle of the 6th hour are upright to the meridian, their common section — namely, the line of the 6th hour — will also be perpendicular to it, and therefore perpendicular, at the point H, to the meridian line HB, which lies in the meridian, by Definition 3 of Book 11 of Euclid. [Margin: (a) Euclid XI.19] Therefore the diameter ST, which we drew perpendicular to the meridian line HB, is the common section of the plane of the dial and the circle of the 6th hour — that is, the line of the 6th hour from noon or from midnight. And for this reason the sides of the parallelogram which the circle of the 6th hour makes in the cylinder, drawn from the points Z, Y, will fall on the line ST, since both the line of the 6th hour and these sides lie in the plane of the circle of the 6th hour. Now since the line ST, shown to be perpendicular to the meridian, is also perpendicular, by Definition 3 of Book 11 of Euclid, to the axis AH lying in the meridian — and the diameter ZY is likewise perpendicular to the same axis (for since both the circle of the 6th hour and the equator are upright to the meridian, their common section ZY will also be perpendicular to it, and consequently, by Definition 3 of Book 11 of Euclid, to the axis lying in the meridian) [Margin: (b) Euclid XI.19] — [Margin: (c) Euclid I.28] the lines ST and ZY, lying in the same plane of the circle of the 6th hour, since they are perpendicular to the axis, will be parallel to one another. Therefore the parallelogram will be a quadrilateral whose sides are [Margin: (d) Euclid I.33] the axis AH, the semidiameter AZ, the side of the cylinder drawn from Z, and the portion of the line HT between H and the said side drawn from Z. For the side of the cylinder drawn from Z is parallel to the axis AH, because that side and the axis, if produced, join the equal semidiameters AZ and $\lambda \xi$ of the equal bases of the cylinder — [Margin: (e) Euclid XI.16] which semidiameters are indeed equidistant, being sections of equidistant bases made by the plane of the circle of the 6th hour from noon or from

midnight. Therefore the line AZ will be equal to the opposite side in the said parallelogram, that is, to the portion of the line HT between H and the side of the cylinder drawn from Z. But HR, the semidiameter of the circle CRX, is equal to AZ, the semidiameter of the circle θ YBZ; for HC was placed equal to the semidiameter AB, or AZ. Therefore the side of the cylinder drawn from Z falls on the point R. And in the same way the side drawn from Y will fall on the point X.

Again, since the side of the cylinder drawn from θ falls on the meridian line, because it lies in the meridian, and is parallel to the axis AH [Margin: (f) Euclid I.33] — which will be demonstrated by the same reasoning by which we showed a little earlier that the side drawn from Z is parallel to that axis, namely because that side drawn from θ and the axis join the equal and equidistant semidiameters A θ and $\lambda\pi$ — [Margin: (g) Euclid VI.2] it will follow that as BA is to A θ , so is BH to the portion of the meridian line between H and the side drawn from θ . But the line BA is equal to the line A θ . Therefore BH too will be equal to the said portion of the meridian line; and consequently, since HV is equal to BH, the side of the cylinder drawn from θ falls on the point V.

Finally, since the joined line OP is parallel to the line YZ, by the scholium to Proposition 27 of Book 3 of Euclid — for the arcs YO and ZP are equal, because each of the points O and P is supposed to be four hours distant from the point B, and thus two hours from the points Y and Z — if through PO a plane be conceived drawn equidistant from the parallelogram drawn through ZY and the axis, this plane will make in the cylinder a parallelogram, by Proposition 3 of Book 1 of Serenus, *On the Section of the Cylinder*, whose two sides are the line OP and another line ab, corresponding to it in the opposite base, while the remaining two are drawn on the surface of the cylinder from the points O, P — of which the one let down from P is also a side of the parallelogram drawn through ϵ P, so that through it the circle of the 4th hour is drawn. For from the one point P only one side of the cylinder can be drawn, as can easily be proved from Proposition 8 of Book 1 of Serenus, *On the Section of the Cylinder*; for any straight line drawn from the point P to another point that does not lie on the side of the cylinder falls, by the said proposition, within the cylinder. Let the common section of this parallelogram drawn through OP and of the meridian be the line EQ, [Margin: (h) Euclid XI.16] which will be parallel to the axis AH, because EQ and AH are sections of parallel planes — namely, of those parallelograms drawn through EQ and AH — made by the meridian. [Margin: (i) Euclid VI.4] Therefore, as the semidiameter BH is to the semidiameter BA, so is BQ to BE; and consequently the arcs of the circles θ YBZ and BTVS, corresponding to the versed sines BQ and BE, will be similar, by the lemma to Proposition 1 of the foregoing book. But the arc

BF is similar to the arc BP, because each embraces four hours; and BE is the versed sine of the arc BP. Therefore BQ too will be the versed sine of the arc BF; and accordingly, the line QF being drawn, it will be the right sine of the same arc BF (for the versed sine of any arc terminates in the right sine of the same arc, as is clear from the treatment of sines), and it will be perpendicular to the meridian line BH. [Margin: (k) Euclid I.29] But the line FLM is perpendicular to the same meridian line, because, by the scholium to Proposition 27 of Book 3 of Euclid, it is parallel to ST, on account of the equal arcs FT and MS. Therefore the line FLM passes through the point Q. And since both the plane of the dial and the plane of the parallelogram drawn through OP and EQ are upright to the meridian, [Margin: (l) Euclid XI.19] their common section too will be perpendicular to it at Q, and consequently, by Definition 3 of Book 11 of Euclid, perpendicular at the point Q to the line BQ lying in the meridian. Therefore the line FQ, perpendicular to BQ, will be the common section of the dial and the parallelogram drawn through OP and EQ; and accordingly the side of that same parallelogram drawn from P falls on the line QF, since the line FQ and the said side lie in the plane of that parallelogram. And since EP and EQ have been shown to be parallel to the lines AZ and AH, [Margin: (m) Euclid XI.10] the angle PEQ will be equal to the angle ZAH. But the angle ZAH is a right angle, for we showed above that ZY is perpendicular to the axis. Therefore the angle PEQ too is a right angle. But the line FQ, shown to be perpendicular to the meridian, is also perpendicular, by Definition 3 of Book 11 of Euclid, to the line EQ lying in the meridian. [Margin: (n) Euclid I.28] Therefore the lines QF and EP, lying in the same plane of the parallelogram drawn through OP and EQ, since they are perpendicular to the line EQ, will be parallel to one another. The parallelogram, then, will be a quadrilateral whose sides are EQ, EP, the side of the cylinder drawn from P, and the portion of the line QF between Q and the said side drawn from P. [Margin: (o) Euclid I.33] For the side drawn from P is parallel to the line EQ, because that side and the line EQ, if produced, join equal lines in the equal bases of the cylinder — namely the line EP and another line db, corresponding to it in the opposite base, which is the right sine of the arc be of four hours, just as EP is the right sine of the arc BP of four hours — [Margin: (p) Euclid XI.16] which lines are indeed equidistant, being sections of equidistant bases made by the parallelogram drawn through OP and EQ. [Margin: (q) Euclid I.34] Wherefore the line EP will be equal to the opposite side of the said parallelogram, that is, to the segment of the line QF between Q and the side of the cylinder drawn from P. But EP, the right sine of the arc BP of four hours, is equal to the right sine $\kappa\mu$ (which is drawn from K perpendicular to BH) of the arc CK, likewise of four hours, because the circles θYBZ and CRX are equal by construction. Therefore the portion of the line QF

intercepted between Q and the side of the cylinder drawn from P will also be equal to the right sine Kμ. [Margin: (r) Euclid I.34] Since, then, QL is equal to Kμ, on account of the parallelogram Lμ, the side of the cylinder drawn from P, let down through the point L, will pass entirely through it. Therefore, since through the side of the cylinder the circle of the 4th hour from noon (or from midnight) is drawn, as we said above, the side of the parallelogram made by the circle of the 4th hour, let down from P, will meet the plane of the dial at the point L. And by the same reasoning the other side of the same parallelogram, let down from ε, will meet the plane of the dial at the point α. And therefore the circle of the 4th hour itself will cut the plane of the dial at the points L and α. Since, then, it also passes through the center H, the line αHL will give the 4th hour from noon or from midnight. By the same reasoning we shall demonstrate that the remaining sides of the cylinder, made by the hour-circles, fall on the remaining points of the ellipse described on the plane of the dial, and so on.

Although it is sufficient, for laying out the dial, to describe only the half-ellipse RLBX, the dial will nonetheless be drawn more accurately if the whole ellipse is described, so that each hour has three points through which its line may be drawn.

[Margin: A plane cutting a right cone [conum], drawn neither through its axis nor parallel to the axis, makes an ellipse.]

From what has been demonstrated it follows that, if a right cylinder is cut by a plane drawn neither through the axis nor parallel to the axis, the resulting section is an ellipse. For just as we showed that the plane of our horizontal dial — built for latitude 42° and cutting a right cylinder whose axis is the world-axis — makes an ellipse, because all the sides of the cylinder fall on points of the ellipse, so in the same way we shall demonstrate that the same holds if the pole's altitude is greater or less than 42°, so that the plane of the horizontal dial, however it is inclined to the axis (that is, to the said right cylinder), always makes an ellipse. This Serenus, in Book 1 of *On the Section of the Cylinder*, demonstrates for every cylinder: whenever the cutting plane is neither parallel to the bases of the cylinder nor to the axis, and neither passes through the axis nor is placed subcontrariwise.

[Margin: When the pole's altitude above the horizon is very small, the drawing of the horizontal dial becomes more difficult.]

Now when the pole's altitude above the horizon is very small — say 1°, 2°, 3°, or 4°, and so on — the drawing of the horizontal dial becomes somewhat difficult

and laborious, because then the world-axis ED, in the portion of the analemma of this proposition, comes very close to the diameter BC of the horizon. As a result the style DG turns out to be extremely short, unless we are willing to move the point H farther than is right from the point G, and indeed from the point I. That is truly inconvenient: partly because too large a plane would then be required to lay out the dial, since the center H of the dial would be moved farther from the equinoctial line than is enough — for since the hour-lines meet in a very remote point, they must be parallel, lying in that plane which is parallel to the world-axis and from which the plane of the dial is supposed to differ but little (as we demonstrated in the corollary to Proposition 22 of the preceding book), and so in the proposed horizontal dial they too appear nearly parallel; and partly because it is very difficult, over so remote a distance, to make out and distinguish the point H without some suspicion of error, since the angle DHI then becomes extremely acute.

Diagram. A large circular construction figure completing the ellipse-method for the horizontal dial (continued from the preceding pages). Two concentric circles carry hour-division marks around the annular ring (short dotted right-angle brackets set at each division). Diagonal diameters and chords cross at the center H. At the upper left an oblique cylinder (its elliptical mouth) is drawn tilted against the circle, and a long straight line — marked "4" at both its far ends (upper right and lower left) — passes through the center, giving the line of the 4th hour discussed on the preceding pages. Many small Greek letters mark the hour-points around the rim. [Several peripheral Greek labels are worn/small — flagged below]

- π (pi, top): apex of the oblique cylinder/ellipse
- V (upper center): point on the outer circle at top
- ξ (xi) and λ (lambda) (upper left, on the cylinder mouth): rim points [?]
- h, d, a (left, down the cylinder): rim points [d, a uncertain: ?]
- e (far left, foot of the cylinder)
- 4 (upper-right end of the long diagonal): the 4th-hour line
- β (beta, right): rim point
- γ (gamma, right, near the ellipse): rim point
- α (alpha, near γ) [?]
- N (inner circle, upper left)
- H (center)
- X (right of center, on the horizontal diameter)
- S (right end of the horizontal diameter, outer circle)

- θ (theta, far right, just below S)
- T (left end of the horizontal diameter, outer circle)
- R (inner circle, left)
- K (inner circle, lower left)
- L (below K)
- F (lower left, outer circle)
- G (center, just below H)
- D (right of G)
- I (below G)
- μ (mu, below I)
- ρ (rho, below center) [?]
- C (lower center)
- P (lower center, right of C)
- A (lower right)
- Y (near A)
- E, O (bottom center-right, small)
- δ (delta) and ε (epsilon) (right, lower)
- M (lower right, outer circle)
- B (bottom, outer circle)
- 4 (lower-left end of the long diagonal): the 4th-hour line

[Margin: When the pole's altitude above the horizon is too great, the drawing of the horizontal dial likewise becomes more difficult.]

Much the same happens when the pole's altitude above the horizon is at its greatest — say 89° , 88° , 87° , 86° , and so on — so that the pole is only slightly distant from the zenith. For then the diameter FD of the equator likewise makes a very acute angle at I with the line HI, and meets that same line at a very remote point, so that it is not easy to decide where the lines FD and HI intersect one another, on account of the narrowness of the acute angle HID. To avoid this twofold inconvenience, therefore, we have devised a twofold remedy. By the first we shall draw the hour-lines even though we do not have the center where they all meet; by the second we shall find the point on the meridian line through which the equinoctial line must be drawn, even though we do not draw the line DI (in the portion of the analemma of this proposition) which ought to fall on that point.

[Margin: The drawing of the horizontal dial when the pole's altitude is very small.]

Let a horizontal dial, then, be drawn for latitude 20° . (We choose so large a latitude to make the method of construction clearer, though it fits other latitudes, however small.) That is, in a region above whose horizon the pole is raised 20° . In some plane let a straight line AB be drawn at will for the meridian line; and let CD, cutting it at right angles in E, represent the equinoctial line. Next, at the point E, to the line ED (or EC) let the angle DEF of the pole's altitude be set up; and on the line EF, taking any point F (the farther it is from E, the larger the dial will be drawn), let the perpendicular FG be raised at F to the line EF. Then on the line AE, taking any point H, let there be drawn through

it the line HG, parallel to EF — or, cutting FG perpendicularly at G, at right angles to FG; and again through the same point H, the line IK perpendicular to AB.

Finally, taking on the line AB the lines EB, HL equal to the lines EF, HG, let circles — or rather quadrants of circles — be described from B and L. (This is enough, provided that the points found on the lines ED, HK by means of these quadrants are transferred to the lines EC, HL.) And let the circles, if they have been described, be divided into 24 parts; or the quadrants, if perhaps only quadrants have been described, into 6 equal parts, the beginning always made from the meridian line AB. For a line drawn — secretly, however — through the centers B, L and through the division-points of the circles or quadrants will cut the lines CD, IK (or the lines ED, HK themselves, if only quadrants have been described) at points through which straight lines drawn out will give the hour-lines we desire — taking always two corresponding points together, that is, first the two nearest to the points E, H, then the next two, and so on. This holds provided that, if only quadrants have been described, the points of the lines ED, HK are first transferred to the lines EC, HL, and the lines are afterwards drawn, as has been said. These we shall produce as far as we please, for the arcs of the signs, which we shall describe in the following proposition, will fix their lengths. The length of the gnomon will be FM, perpendicular to AB, its place being at the point M. This we shall demonstrate as follows.

[Margin: Demonstration of the preceding construction. (a) Euclid I.23]

Since the angle DEF is equal to the pole's altitude, the angle AEF will be equal to the complement of that same altitude; and consequently the two angles AEF, EFG will be less than two right angles, and so the line FG will at length meet the line EA on the side of A — namely at the point A, which, even though it is not contained in the drawn plane on account of its small size, may nonetheless be

conceived in the mind. Therefore the angle EAF will be equal to the pole's altitude, (a) since EAF and AEF together are equal to one right angle, and AEF is equal to the complement of the pole's altitude. And accordingly, if the triangle EAF is conceived to be revolved about the meridian line AE, so that

Diagram. The horizontal dial for latitude 20° (the demonstration figure for the preceding construction). At the top a graduated straight line runs from A (left) to N (right), divided into equal parts by tick marks, with the first division-points near A marked. From below A a vertical line descends into a fan of hour-lines that converge upward. The hour-lines are labelled across the top with Roman numerals for the hours. A horizontal line I–H–K crosses at the convergence, and below it a second horizontal line C–E–D. Down the central vertical run the points P, H, L, M, E; G lies to the right of H and F to the right at the M–E level. Near the bottom a quadrant arc with dotted radii (the arc used to lay off the hour-divisions) stands on B.

- A (top left) — N (top right): the graduated ruler (line AN)
- O, Q [?] (division-marks near A on the ruler)
- Hour numerals across the fan (left to right): V, IIII, III, II, I, 12, XI, X, IX, VIII, VII
- I (left end), H (center), K (right end): the horizontal line (equinoctial/horizon line through H)
- P (upper center), G (right of H): construction points
- L, M, E (down the center)
- F (right of M): gnomon-triangle vertex
- C (left), D (right): ends of the lower horizontal line
- B (bottom): center of the quadrant arc

it stands upright to the plane of the dial and lies in the plane of the meridian, then AF will be the world-axis. For in the plane of the meridian it makes with the meridian line of the horizon — (b) which is parallel to AB itself in the plane of the dial, since both are sections made by the meridian in parallel planes — (c) an angle equal to the angle EAF of the pole's altitude, namely the external angle equal to the internal. Therefore the lines FE, GH, perpendicular to the axis FG, will be the common sections of the meridian and the equator, so that either of the points F, G may be taken for the center of the world. And accordingly, as has been shown in this proposition, the hour-circles will meet the plane of the dial at the points we find on the lines CD, IK; and FM will be the style, its place being at M. For the triangles AEF, AHG are here so constructed as the triangle HID was in the earlier dial of this proposition.

[Margin: (b) Euclid XI.16 (c) Euclid I.29]

In this proposed example, because the pole's altitude is great enough, the center A of the dial — toward which all the hour-lines tend — is contained on the plane. This was done on purpose, so that you might also learn by experience that dials are rightly drawn by this method. But it is plainly established that, if the center does not fall on the plane of the dial, the sixth hour — which is necessarily drawn through the center of the dial perpendicular to the meridian line — cannot be described. And so much for the remedy of the former inconvenience.

[Margin: The drawing of the horizontal dial when the pole's altitude is very great.]

As for the latter inconvenience, we shall relieve it thus. Again, in some plane let AB be the meridian line, and let A be set as the center of the dial. At the line AB, at A, let the angle BAN of the pole's altitude be constructed, so that AN is the world-axis; on it let any point N be taken as the center of the world, from which a perpendicular drawn to AN will represent the common section of the meridian and the equator, just as the lines FE, GH did a little before. But since, if the point N is somewhat farther from the center A of the dial — to the end that the style, which must be drawn as a perpendicular from N to AB, may have a becoming and conspicuous size — the perpendicular drawn from N to AN meets the meridian line AB at a very remote point, so that it is difficult to detect that point without error (because that perpendicular could easily deflect this way or that), we shall find the point of that meeting by the following device, exact enough. Let the line AN be divided into any number of equal parts,

Diagram. The same style of horizontal-dial figure, here for the great-altitude remedy (with N taken as the center of the world). At the top a graduated straight line runs from A (left) to N (right), divided into equal parts, the first division-points near A marked. From below A a vertical descends into a fan of hour-lines converging upward and labelled with Roman numerals. A horizontal line I–H–K crosses at the convergence, with a second horizontal line C–E–D below it. Down the center run P, H, L, M, E; G lies right of H, F right at the M–E level; a dotted quadrant arc stands on B at the foot.

- A (top left) — N (top right): the graduated ruler (line AN), N as center of the world
- O, Q [?] (division-marks near A on the ruler; O is the division-point nearest A)

- Hour numerals across the fan (left to right): V, IIII, III, II, I, 12, XI, X, IX, VIII, VII
- I (left end), H (center), K (right end): the horizontal line through H
- P (upper center), G (right of H): construction points
- L, M, E (down the center)
- F (right of M): gnomon-triangle vertex
- C (left), D (right): ends of the lower horizontal line
- B (bottom): center of the quadrant arc

so that the perpendicular drawn from O — the division-point nearest to A — to AN can conveniently cut the line AB at P. If on AB produced we take a line as many times a multiple of AP as AN is a multiple of AO, the last point of that multiple will be the one on which the perpendicular drawn from N to AN necessarily falls. This we shall confirm as follows. (a) Since AN has to AO the same proportion as that multiple on the line AB has to AP, the line drawn from N to the extreme point of that multiple will be parallel to OP; (b) and consequently the angle at N is equal to the angle at O, being a right angle. Therefore the said perpendicular from N falls on the said point of the line AB; for if it fell on any other point, two perpendiculars would be drawn from N to AN, which is absurd. You see, then, that a very large plane is required for describing a dial of this kind, if the style is to have a moderate length; for the style drawn as a perpendicular from O to AB is too short. Nor indeed can we here avoid the former inconvenience; but once the aforesaid point on the line AB has been found, the dial must be described as we set forth in this proposition — that is, from that point found, a line equal to the perpendicular drawn from N to AN (and falling on the said point) must be cut off from AB, and through it the perpendicular to AB must be drawn for the equinoctial line. Then from the point which terminates that line equal to the perpendicular drawn from N to AN, a circle must be described, and so on. In

[Margin: (a) Euclid VI.2 (b) Euclid I.29]

Book Two (continued)

LIBER SECVNDVS.

—for example, line AN is eight times line AO, so we shall need to cut off from AB a segment eight times AP. But if we terminate the axis at Q, the segment to be cut off from AB must be three times AP, since AQ too is three times AO.

Perhaps, though, we shall reach the proposed result more reliably as follows. (For when the pole's altitude is very great—so that the axis AN makes an almost right angle with AB—it is not easy to make out the point P either, because the angle APO is too acute.) Suppose we first choose any point at all on the line AB, say P, and from it erect a perpendicular PO to AN; this is easily done if a semicircle is described on AP cutting AN at O, for then PO will be perpendicular, since the angle AOP stands in a semicircle. The same is achieved if at P we set up an angle APO equal to the complement of the pole's altitude. For if we cut off from AO as many equal parts as we please—up to N, or Q, or up to any other point—and on AB take a segment that is the same multiple of AP as AN (or AQ, or whatever other portion assumed on the axis AN) is of AO, we shall arrive at the very goal we were aiming at before, and much more reliably. For who does not see that by this method—in assuming point P, and thereby the line AP—we can err less than before, when we sought the same point P and the line AP by means of the perpendicular OP? Indeed the narrowness of the acute angle APO makes that point highly doubtful and uncertain.

Nor, it seems, should we pass over here the fact that Oronce Finé [Oronce Finé] was strikingly deceived in his layout of the astronomical dial, both horizontal and vertical. To make this plain, I shall set out his own words and expose the error, so that no one may be led astray along with him—as I have observed has already happened to many, deceived perhaps by Orontius's authority. In Book 1, Proposition 1, then, he describes what he himself calls the "Prototype" [Prototypus], by which (he says) both horizontal and vertical dials are constructed. "On a given plane, and about a given center A in it, let a circle be described—

[Margin: The error of Oronce Finé in the layout of the astronomical dial, both horizontal and vertical.]

Diagram. Three companion circles in a row, illustrating the three cases of Orontius's "Prototype" construction according as the pole's altitude is greater than, less than, or equal to 45° . Each circle BCDE has center A, a vertical diameter C (top)–E (bottom) and a horizontal diameter D (left)–B (right), dividing it into four quadrants. Point F lies on the upper-right arc; from center A the radius AF is drawn, and the perpendicular FH is dropped from F to the horizontal radius (H lying between A and B). The line HI is drawn (I on the upper-left arc), cutting AF at K; L is a small point near the center. G lies on the lower-right arc. The figures thus show the triangles AFH, AHI, and AHK.

- C (top of circle): upper end of the vertical diameter
- E (bottom of circle): lower end of the vertical diameter

- D (left), B (right): ends of the horizontal diameter
- A (center): center of the world
- F (upper-right arc): endpoint of the counted pole-altitude arc BF; radius AF
- H (on radius AB): foot of the perpendicular FH
- I (upper-left arc): endpoint used for line HI
- K (on AF, near center): intersection of HI with AF
- L (near center): construction point [?]
- G (lower-right arc): endpoint of arc BG (the arc equal to BF laid off in quadrant BE)

—BCDE, and by the two diameters BD and CE, which cut each other at right angles at the same center A, let it be divided in the usual way into four quadrants. Further, let the right-hand upper quadrant BC be divided into 90 mutually equal parts—first into three, then each of these into 6, and finally each into 5. Then, taking the free elevation of the north pole, that is, the latitude of the region for which one wishes to make the dial, let it be counted off in the quadrant BC, from the point B toward C. Let the end of the reckoning be marked with the sign F; and from center A to the given sign F let the straight line AF be drawn. Moreover, on the given arc BF let an equal arc be set up in the quadrant BE, and let it be BG; and from the sign F to the sign G let the straight line FG be drawn. This line will be bisected by the semidiameter AB—at the sign H—and therefore also at right angles, by Euclid III.3. Hence the straight line FH will be perpendicular to AB, and the triangle AFH right-angled. Therefore the circle BCDE will represent the meridian, BC its northern quadrant, and A the center of the world; while BD will represent the horizon, and CE the vertical circle meeting the meridian itself at right angles." A little later he continues thus: "Given the straight line FH, let one equal to it be set up on the semidiameter AC, and let it be AI; and from the sign H to the sign I let the straight line HI be drawn, cutting the line AF at the sign K. Then the triangle AHI will be equal and similar to the triangle AFH, as is manifest from Euclid I.4."

This construction, then, Orontius calls the general Prototype for building both horizontal and vertical dials—so that he himself uses the triangle AHK in making horizontal dials for a given pole altitude BF, exactly as we in this proposition used the triangle DHI, contained in the portion of the Analemma, for composing the same dials for a given pole altitude CE. For at once, in Proposition 2, he takes on

the meridian line a straight line equal to the side AH for the horizon line, just as we took a straight line equal to the side HI in our triangle. Then, for the equator line, he takes another straight line equal to the side AK, just as we took a straight line equal to the line DI in our triangle. Thus in the triangle AHK he wants AH to be the horizon line, HK the axis of the world, and AK the equator line, for constructing horizontal dials. Likewise in Proposition 3 of the same book, for constructing vertical dials, he takes in the triangle FHK the line FH for the line of the vertical circle, HK for the axis of the world, and FK for the equator line. That in this he has gone wonderfully astray we shall easily show as follows.

Since the sides IA, AH of the triangle IAH are equal to the sides FH, HA of the triangle FHA, and contain equal angles—namely right angles (a)—the bases HI, AF and the angles AHI, HAF will also be equal. Therefore, just as AF is the axis with respect to the horizon AH, so too HI can be taken as the axis with respect to the same horizon AH, since both AF and HI make with AH the angle of the pole's altitude. And thus far there is no difference between us and Orontius. But his error lies solely in the equator line, which by no means can be the straight line AK, as he supposes, in a region whose latitude is greater than 45° —as I shall make evident thus. Let the pole's altitude BF first be greater than 45° , as in his figure. Then the angle FAH will be greater than half a right angle; and since the angle AHI has been shown equal to it, the two angles KAH, KHA (b) in the triangle AHK together exceed a right angle. Therefore the remaining angle AKH will be less than a right angle. So, since the equator line makes right angles with the axis in every clime—as is clear from the portion of the Analemma of this proposition, or from the Analemma itself in Proposition 1 of the previous book—who will still doubt that the line AK, which makes the acute angle AKH with the axis HK, cannot be the equator line? (c) Therefore, to obtain the equator line in the triangle AHK, one must draw from A a perpendicular AL to the axis HK, which is necessarily smaller than AK. Next, let the pole's altitude BF be less than 45° , as appears in the second figure; and the angle FAH will accordingly be

[Margin: (a) Euclid I.4 (b) Euclid I.32 (c) Euclid I.19]

GNOMONICES.

—less than half a right angle. Therefore, since the angle AHI has been shown equal to it, the angles HAF, AHI together will be less than one right angle; (a) and consequently the remaining angle AKH, in the triangle AKH, will exceed a right angle. Hence the line AK cannot be the equator line, since it does not make right angles with the axis HI; but AL, drawn perpendicular to the axis HI, will give the equator line. Only in a region where the pole's altitude comprises 45° will the

straight line AK be the equator line, because there alone does it make right angles with the axis HI. For let the pole's altitude BF contain 45° , as in the third figure; and the angle FAH will accordingly be half a right angle. Since, then, the angle AHI has been shown equal to it, the two angles HAK, AHK (b) together will be equal to one right angle; and therefore the remaining angle AKH, in the triangle AKH, will be a right angle. Hence the line AK will serve the office of the equator line. It is clear, then, that Orontius blunders childishly in assigning the equator line; and thus the horizontal dials laid out from his Prototype are false wherever the pole's altitude is greater or less than 45° . The same must be said of vertical dials. For although in them Orontius rightly takes the vertical line FH and the axis of the world HK, he nevertheless errs in the line FK, which he takes for the equator line, because it is not perpendicular to the axis HK, as we have demonstrated.

[Margin: (a) Euclid I.32 (b) Euclid I.32]

Orontius stumbled still more disgracefully in Proposition 7 of the same Book 1 of the dials, where he took the whole axis AF, lying between the center A and the line FH of the vertical circle, for the equator line—which can nowhere be true, since it is the straight line AL, very unequal to the line AF, that is the equator line, as we have said.

[Margin: A greater error of Orontius.]

PROBLEM 2. PROPOSITION 2.

To describe, in the aforesaid horizontal dial, the parallels—that is, the arcs of the zodiacal signs—which are the common sections of the plane of the dial and of the cones whose bases are the parallels of the zodiacal signs and whose vertex is the center of the world.

[Margin: The description of the arcs of the zodiacal signs in the aforesaid horizontal dial, from the Analemma. — The diameters of the conic sections when the Sun is at the beginnings of the signs. — By what method the diameters of the conic sections are found in any Analemma.]

Let the portion of the Analemma of the preceding proposition be repeated, and let the meridian ABC be completed, in which—from the Analemma constructed in Proposition 1 of the preceding book—let the diameters of the parallels be drawn, together with the diameters connecting the opposite signs, so that triangles are formed through the axis in the cones, whose bases are the parallels themselves and whose common vertex is the center D. Then, from what was demonstrated in

Propositions 4, 5, 6, and 7 of the previous book, KR will be the diameter of the conic section which the Sun describes when at the beginning of Cancer (♋); LR the diameter of the section which the Sun describes at the first point of Gemini (♊) and Leo (♌); MR the diameter of the section which the Sun describes at the beginning of Taurus (♉) and Virgo (♍). But NO, PO, QO will be the diameters of the conic sections which the Sun describes when in the opposite parallels—namely in the parallels of Capricorn (♐); of Sagittarius (♏) and Aquarius (♑, printed as the waves-glyph); and of Scorpio (♏) [?] and Pisces (♓).

Diagram. The Analemma (a meridian circle) used to lay out the zodiacal arcs of the horizontal dial. The circle has center D, with the labelled peripheral points A (top), E (upper right), C (right), O (lower right), B (left), R (lower left), and F (upper left, just inside the rim). A dense sheaf of straight construction lines is drawn across the interior; among them the line RO runs across the figure (the line through the extremity of the style), and the diameters KR, LR, MR (toward R) and NO, PO, QO (toward O) connect the opposite-sign points. Interior construction points read as H, I, L, M, N, P, Q, G clustered about the center. Around the upper-left and lower rim a series of zodiacal-sign glyphs is engraved marking the parallels; individually they are too small and worn to resolve reliably on this scan and are flagged.

- D (center): common vertex of the cones / center of the world
- A (top), E (upper right), C (right), O (lower right), B (left), R (lower left), F (upper left): peripheral points of the meridian circle
- RO: the line drawn through the extremity of the style
- KR, LR, MR: diameters of the conic sections (northern signs), toward R
- NO, PO, QO: diameters of the conic sections (opposite/southern signs), toward O
- H, I, L, M, N, P, Q, G: interior construction points [several partly obscured — ?]
- Zodiacal-sign glyphs engraved around the rim [worn — not individually legible; ?]

Furthermore, these diameters of the conic sections are found in the same way in any other Analemma—whether larger or smaller than the one here proposed—even if the dial was constructed without a portion of the Analemma, as we taught in the preceding scholium; provided that in that other Analemma a straight line equal to the assumed gnomon is cut off along the diameter of the vertical below the center (the diameter of the vertical being extended, should the length of the gnomon require it), and that through its endpoint a line is drawn parallel to the

diameter of the horizon, by which the plane of the horizontal dial is conceived to be drawn. For this straight line, in a larger or smaller Analemma, will be cut by the diameters of the opposite signs into parts equal to the parts of the line RO in our present Analemma. This can be shown as follows. Since both that line and this RO, the length of the style being kept the same, stand equally distant from the center of their Analemma, (c) and the angles which the diameters of the opposite signs make with the diameter of the equator are, in any Analemma, of the same magnitude—because they always rest at the centers upon the same declinations of the same signs—it follows that the angles which those same diameters make with the diameter of the vertical circle (which are either compounded of the former plus the angle of the pole's altitude contained between the diameter of the equator and the diameter of the vertical, or are left over after subtracting the former from that same angle of the pole's altitude) are equal to one another, since the angles contained between the diameter of the vertical and the diameter of the equator are also equal.

[Margin: (c) Euclid III.27]

Therefore, since the angles which the lines drawn through the extremity of the gnomon (namely through the point G in our Analemma, and through the point corresponding to it in the other Analemma), equidistant from the diameter of the horizon, make with the diameter of the vertical are right angles—as in our Analemma is the angle G—and the angles which, in either Analemma, the ray of any sign makes with the same diameter of the vertical are likewise equal, as we said (for they are vertical to those we showed to be equal), there will always be found two triangles in either Analemma, one in the one and the other in the other, having two angles equal, each to each. Since, then, they also have an equal side adjacent to the said angles—namely the magnitude of the style—(d) they will also have the remaining sides equal, namely those intercepted between the extremity of the style and the ray of each sign in either Analemma, and so on. This can also be made plain thus: if that larger Analemma is imagined superimposed on this one of ours, so that the centers and the diameters of the horizon, the vertical, and the equator coincide, then the line drawn through the extremity of the style in the former coincides with the line RO in our Analemma, on account of the equality of the gnomons and of the right angles which the gnomons make with the said lines. Since, then, the diameters of the ecliptic connecting the opposite signs also coincide (because they make the same angles

[Margin: (d) Euclid I.26]

LIBER SECVNDVS.

—in either Analemma with the diameter of the equator, on account of the same declinations in each, as is manifest from the construction of the Analemma), it is plainly established that the lines between the extremity of the style G and the rays of the signs in our Analemma are equal to the same lines in the other Analemma, because the former coincide with the latter.

Therefore, if onto the meridian line of the dial already laid out—whether from the center H, or from the point I where the plane of the equator meets the plane of the dial—the points G, K, L, M, I, Q, P, N are transferred (taken with the help of the compass from the point where, in the Analemma, the axis of the world, or the diameter of the equator, intersects the line drawn through the extremity of the gnomon equidistant from the diameter of the horizon), then G will be the place of the style DG, while the remaining points will be those onto which the shadow of the style is projected when the Sun is on the meridian circle and at the beginnings of the signs, and through which the conic sections of the signs must be drawn—sections that are either circles, or parabolas, or hyperbolas, or ellipses, as was demonstrated in the previous book.

Diagram. The large horizontal-dial projection. At the top center stands the point H (center of the dial / foot of the style), from which a vertical meridian line runs straight down to the point ϕ at the bottom. From H radiates a broad fan of hour-lines (solid) and of dotted rays (the sun-rays / conic-cone generators) spreading to left and right; a group of dotted rays reaches up to the label X at the upper left. On the meridian just below H lie G and D; farther down toward ϕ lie further construction points (E, L, M) about the center. To the left of center are the points F and R, to the right S and K, marking where the equinoctial and hour-lines meet the projected sign-arcs. Flanking the figure are two tall rectangular scales of zodiacal signs: on the left, labelled vertically **ASCENSVS SOLIS** ("the ascent of the Sun"); on the right, labelled vertically **DESCENSVS SOLIS** ("the descent of the Sun"). Each scale carries a column of zodiac glyphs with an adjacent narrow column of small numerals; on this scan the glyphs and numerals are small and partly worn, so they are transcribed provisionally and flagged.

- H (top center): center of the dial / foot of the style
- ϕ (bottom of meridian): southern center point of the meridian line (the point paired with H in the diameters $N\phi$, $P\phi$, $Q\phi$)
- G, D (on the meridian just below H): the place of the style (DG) and a construction point
- F (left), R (left of center): construction points on the equinoctial/sign lines

- S (right of center), K (right): construction points on the equinoctial/sign lines
- E, L, M (lower center, about the meridian): construction points [partly obscured — ?]
- X (upper left): endpoint label of the dotted ray-sheaf
- Left scale **ASCENSVS SOLIS**: column of ascending-sign glyphs, reading (top→bottom) Π , ♊ , ♋ , ♌ , ♍ , ♎ [worn — ?], with adjacent numerals 6, 5, 4 [?]
- Right scale **DESCENSVS SOLIS**: column of descending-sign glyphs, reading (top→bottom) ♏ , ♐ , ♑ , ♒ , ♓ , ♈ [worn — ?], with adjacent numerals 6, 7, 8 [?]

Through I, moreover, a perpendicular must be drawn to the meridian line. For this will be the equinoctial line, onto which the shadows are projected at the time of the equinoxes. Now if, about the diameters KR, LR, MR, NO, PO, QO, conic sections are described (by Proposition 8 of the previous book) in some solid material—such as wood, or glued sheets of paper—and are cut out to make, as it were, curved or bent rulers, by whose help these same sections are transferred to the dial so that they pass through the points k, L, M, Q, P, N translated onto the meridian line, and their axes coincide with the meridian line, then the parallels of the zodiacal signs will be drawn. These can indeed also be drawn in the dial itself, about the diameters KH, LH, MH, N ϕ , P ϕ , Q ϕ , by Proposition 8 of the preceding book, rather than separately, to be transferred afterward onto the dial. The parallel of Cancer (♋) will pass through k; the parallel of Gemini (Π) and Leo (♌) through L; the parallel of Taurus (♊) and Virgo (♍) through M; the equinoctial line through I; the parallel of Scorpio (♏) [?] and Pisces (♈) through Q; the parallel of Sagittarius (♐) and Aquarius (♒) through P; and finally the parallel of Capricorn (♑) through N. All of these the shadow of the tip of the style describes, when the Sun is at the beginnings of the signs, since the extremity of the shadow is projected onto them, as is clear from the corollary of Proposition 12 of the previous book.

Of all the hour-lines (the meridian line excepted), the portions found outside the conic sections of Cancer (♋) and Capricorn (♑) must be deleted, both in the horizontal dial and in any other, since they have no use—because the shadow of the style is not projected beyond the tropics, just as the Sun never wanders beyond them in the sky. Hence the hour-lines must be drawn faint, so that only their parts within the tropics may be marked, after the arcs of the zodiacal signs have been drawn. It is enough, moreover, if the conic sections of only the northern signs are drawn, since the horizon cuts all the parallels. For these are

equal, one to one, to the conic sections of the opposite southern signs, since they are then opposite and equal hyperbolas, as we showed in Proposition 6 of the previous book. Hence they can easily be transferred to the southern signs and drawn about the points N, P, Q.

[Margin: In any dial only the portions of the hour-lines that lie between the tropics of Cancer and Capricorn are to be drawn.]

Further, the conic sections whose diameters in the Analemma lie between the point R and the point I—where the diameter of the equator cuts the line RO—have their horns turned toward the center of the dial, H; but the horns of those sections whose diameters lie between the points O and I are turned to the opposite part. So too in all other dials, even declining and inclined ones, the conic sections between the center of the dial and the equinoctial line stretch their horns toward the center, while the rest turn them to the contrary part—so that, in general, the horns of all the sections recede more and more from the equinoctial line and, as it were, flee it. The reason for this is readily had from the conic elements of Apollonius of Perga [Apollonius of Perga], if the cones in the Analemma of this proposition are rightly conceived; for the conic sections always spread wider toward the bases of the cones, as is evident from the said conic elements.

[Margin: Toward which part the horns of the conic sections lean in dials. — Hence, by the method drawn from the Analemma of this proposition, the arcs of the signs are laid out in the dial for a greater or a lesser length of the gnomon.]

But if in the Analemma a longer style DM is taken, and through M a line parallel to BC is drawn cutting the diameters of the opposite signs, the diameters of other conic sections will be obtained, about which the conic sections themselves can be drawn in the same way for a larger dial—one in which the same hour-lines remain entirely unchanged; but the equinoctial line must be distant, on the meridian line, from the center H by as great a space as is the portion of that parallel drawn through M, intercepted between the point where it is cut by the axis ED and the point where the same is cut by the ray, or dia-

[Margin: The portion of the Analemma is an instrument for describing dials of any size whatever.]

[Margin: Another way of describing the arcs of the zodiacal signs in the horizontal dial.]

the diameter of the equator, FD. By the same reasoning, if a shorter style DM is taken, a smaller dial will be described. That portion of the Analemma described in the preceding proposition is therefore, as it were, a kind of instrument for describing dials of any size whatever — so far as concerns the style, the center of the dial, the equinoctial line, and the hour-lines — since a style of any size can be assumed within it. But as regards the arcs of the signs, one must return to the Analemma described at the beginning of this proposition, from which the arcs of the signs are laid out in any dial, as has been said.

The same parallels — that is, the arcs of the zodiacal signs — can also be described in the dial by the following method. About the straight line $A\lambda$, drawn in any manner so as to represent the axis of the world, and taking any point D as center, let a semicircle of any size be described. Let DH, on the left-hand side of D, be equal to the axis DH assumed in the portion of the Analemma of the preceding proposition, or in the triangle HDI, by which — in the scholium of the same proposition — we described the dial without the portion of the Analemma. Having drawn DC perpendicular to the axis DH, let DI be taken equal to DI, the equinoctial line of that same portion of the Analemma or of the said triangle, and let the straight line HI be drawn toward I to any length whatever. Or rather — lest an error be committed in drawing the line HI, because the point H may perhaps lie too close to the point I — let an arc be described from H toward D, on which let AB be taken, toward the straight line DC, equal to the arc of the pole's altitude; and through B let the straight line HB be drawn out, cutting the equinoctial DC at I. The triangle DHI will then be exactly equal to the triangle DHI of the aforesaid portion of the Analemma, or to the triangle of the dial described without the portion of the Analemma; and HI will be equal to the meridian line of that same portion of the Analemma or of the said dial, as can be clearly seen from the construction of each of these triangles in this figure.

Diagram. The figure occupies the lower half of the page and continues across the following opening; it is the "figure of the Zodiac rays" (*figura radiorum Zodiaci*) superimposed on the horizontal dial. A large semicircle (with its bounding arc) is drawn about the top center; a bundle of straight lines (the hour-lines and the rays of the signs) radiates downward from the apex region toward a fan of hour-numbers and a curved band of zodiacal-sign symbols along the bottom. Because the small peripheral point-labels are set in worn mixed Greek/roman/symbol sorts at the downsampled floor, several are uncertain and flagged; this figure

- λ (upper left, on the bounding arc): endpoint of the axis-line $A\lambda$

- H (top center): apex / center of the dial (center of the radiating pencil of lines)
- D (top, right of H): center of the semicircle; the point through which the axis $A\lambda$ passes
- A (top right): endpoint of the axis-line $A\lambda$ on the right
- μ (near the apex, small): point of the noon (12th-hour) line on the Cancer ray [?]
- φ (right side, on the arc): peripheral point [?]
- B (right of center): point on the arc used to lay off the pole's altitude
- C (center): point on line DC (fifth-hour-after-noon line HC)
- T (center left): point on line DC (fourth-hour line HT)
- V (below center): point of the sixth-hour line HV
- X (left of center): point of the seventh-/fifth-hour line HX
- Y (far left of center): point of the eighth-/fourth-hour line HY
- ξ, π (lower center, small): points on the equinoctial line [?]
- $\theta, \alpha, \beta, \gamma, \delta$ (lower center band, small Greek): points of the sign-rays / conic sections [?]
- Zodiacal-sign symbols in the lower curved band: ♐ [Capricorn] and neighbouring signs [?]
- Hour numerals around the periphery (left, descending): 12, 11, 10, 9, 8, 7 ...; (right, ascending): 1, 2, 3, 4, 5, 6 ...

The angle DHI will thus be exactly equal to the angle DHI of the aforesaid portion of the Analemma, or of the triangle of the dial described without the portion of the Analemma; and HI will be equal to the meridian line of that same portion of the Analemma, or of the said dial, as the construction of each of these triangles in this figure makes plain.

[Margin: Elements I.4]

For by the former construction, the two sides DH, DI of this triangle are equal to the two sides DH, DI of that one, and they contain equal angles, namely right angles. Therefore the whole triangles will be equal. But by the latter construction, the two angles HDI, DHI of the one triangle are equal to the two angles HDI, DHI of the other (since in each triangle the first angle is a right angle and the second is equal to the pole's altitude), and the side DH of the one is equal to the side DH of the other.

[Margin: Elements I.26]

Therefore the sides DI, HI of the one are also equal to the sides DI, HI of the other, and so on. Next, from E, the center of the equator in the dial — the center, that is, from which the circle was described and divided into 24 equal parts, and so on — let all the intervals between the center E and the hour-lines on the equinoctial line Fk be transferred onto the line DC of this figure which we are now constructing, starting from the point D. That is, let the interval EF (or EK) in the dial constructed just before this figure be made equal to the straight line DC in this figure — for the straight lines EF, EK in the said dial are equal to one another, as was demonstrated in the scholium of the preceding proposition, just as all the other intervals whatever between E and any two hours equally distant in time from the meridian line were shown to be equal — and let the interval ER (or ES) of the same dial be made equal to the straight line DT in this figure, and so on. Then through the points C, T, and the rest marked on the line DC, let straight lines be drawn from H, to which are assigned the numbers of the hours corresponding to the transferred intervals: so that the straight line HC is the line of the fifth hour after noon and of the seventh after midnight; HT the line of the fourth hour after noon and of the eighth after midnight; and so on.

We shall obtain these same hour-lines, drawn from H through the points of the line DC in this figure, in yet another way, if we transfer the hour-intervals in the dial lying between the center H and the equinoctial line from the point H of this figure onto the line DC, using the compasses and marking points on the line DC. (This will be done if, at the said intervals of the dial, certain hidden arcs are described from H of this figure, cutting the line DC at the points that are to be marked.) Then through the points found on the line DC in this way we draw straight lines from H. For suppose that in the dial the center E is understood to be joined, in its proper position, with the center of the world D — as we said in the preceding proposition, when we set the triangle DHI upright to the plane of the dial and conceived in our mind the circle described from E to be moved about the equinoctial line Fk until its center E was joined with D, the center of the world. We shall then understand two triangles: namely HDF (or HEF) in the dial, and HDC in this figure now proposed. And since the sides HD, DF of the former are equal to the sides HD, DC of the latter — for DC was taken equal to DF (or EF) in the earlier construction of this figure, and the axis HD is here the same as it was there — and since the angles contained by these sides are equal, namely right angles (for the angle HDC in this figure is a right angle by construction, while HDF in the dial is a right angle because the axis HD, being at right angles to the plane of the equator, is also perpendicular — by Euclid, *Elements* XI, definition 3 — to the straight line DF lying in the plane of the equator),

[Margin: Elements I.4]

the bases HF, HC will also be equal. Therefore, if we transfer the straight line HF, taken in the dial, onto the line DC in this figure from the point H — as was said in this latter construction of the proposed figure — we shall arrive at exactly the point C, which we previously found, by the earlier construction of the same figure, for the fifth and seventh hours. Otherwise, if the straight line HF, transferred in the dial from the point...

H of this figure onto the line DC, were to fall on some point other than C, we should show — as we did just now — that the line HC drawn would be equal to HF itself in the dial, and hence equal also to the very line transferred from H onto the line DC, which is supposed to fall on a point other than C (for this transferred line is, by construction, equal to that same HF). Two equal straight lines would therefore be drawn from H to the line DC below the right angle D — which is absurd. For, as we demonstrated from Proclus at *Elements* I.16, from H only two mutually equal straight lines can be drawn to the line DC, one below the point D and the other above the same point, but not both below the point D, as would here be the case. Therefore the straight line HF, transferred from H onto the line DC, will fall on the point C. By the same reasoning we shall show that the other hour-intervals in the dial, between H and the equinoctial line, transferred from the point H of this figure onto the line DC, fall on the points that were previously found. And thus far the hour-lines drawn in this figure from H through the points of the line DC run from the twelfth hour of noon up to the fifth hour after noon, and from the seventh hour after midnight up to the twelfth hour of noon, as is clear from the construction itself. For only the said hours cut the equinoctial line in the dial, and it is their intervals that have been transferred. Hence we shall draw the lines of the remaining hours as follows.

For the sixth hour after noon (or after midnight), draw from H the line HV parallel to DC. For the seventh hour after noon and the fifth after midnight, draw HX, making the angle VHX equal to the angle VHC. Likewise, for the eighth hour after noon and the fourth after midnight, draw HY, making the angle VHY equal to the angle VHT; and so with the rest. This is easily done if an arc of a circle is described from H.

[Margin: Elements III.27]

For if the arcs of this circle intercepted between HV and the straight lines drawn from H to the right of HV (the lines which, of course, cut the line DC) are transferred to the left side of HV, onto the said arc, then the straight lines drawn

from H through those arcs — transferred to the left of HV — will make with HV angles equal to those made on the right-hand side with the same HV; because the arcs on which the former stand at the center H are equal to the arcs on which the latter stand at the same center H.

After this, in the semicircle described from D, let the declinations of the signs be computed, beginning from the straight line DC toward each side of DC; and through the ends of these computations let straight lines go out from D, which will be the rays of the signs when the Sun is at their beginnings — so that the straight line DC, in the middle of all the other lines, is the ray of the equator, that is, of Aries (Υ [Aries]) and Libra ($\ Libra$ [Libra]), as is plain from what we said about the Analemma in Proposition 1 of the previous book. Now the arcs of the semicircle described from D, lying between the ray of the equator DC and the rays of the other signs, will either be entirely equal to the arcs of the Analemma lying between the diameter of the equator and the common sections of the ecliptic and the meridian — when, that is, the semicircle described from D is equal to the circle of the Analemma — or at least similar to them, when the said semicircle is unequal to the circle of the Analemma. Hence, so that the rays of the signs may more easily be described by means of their declinations found in the Analemma, it would be helpful if the semicircle described from D had a radius equal to the radius of the Analemma, so that the declination-arcs could be transferred from the Analemma into this semicircle with the compasses.

From this figure, then, constructed in this manner — which in what follows we shall call the *figure of the Zodiac rays* — the arcs of the signs are described in the dial as follows. From the figure already completed, transfer the line H μ of the twelfth hour, lying between the point H and the ray of Cancer (♋ [Cancer]), onto the meridian line of the dial from H; or transfer the line I μ , between the ray of the equator and the ray of Cancer, from the point I of the equinoctial line in the dial onto the meridian line, marking the point K. Likewise, let the line of the first and eleventh hours of the same figure, lying between H and the same ray of Cancer — or between the equinoctial ray and the ray of Cancer — be transferred onto the lines of the first and eleventh hours of the dial from H, or from the points ξ and π of the equinoctial line, marking a point on each. And so let the remaining spaces between H and the ray of Cancer, or between the equinoctial ray and the ray of Cancer, be transferred into the dial onto the lines of the corresponding hours, marking points on them. Then let these points, marked on the hour-lines of the dial, be joined together by a fittingly curved and bent line. For this will be the conic section of Cancer (♋) described in the dial. In the same way the conic sections of the other signs will be described, if the straight lines comprehended

between H and the rays of the signs — or between the equinoctial ray and the rays of the signs — are transferred onto the corresponding hour-lines of the dial from H, the center of the dial, or from the equinoctial line, and so on. This, however, with the following condition: the straight lines lying between the ray of the equator and the rays of the other signs toward the point H are to be transferred from the equinoctial line onto the corresponding hour-lines toward the center H, while the others are transferred in the contrary direction. Likewise, the intervals of the lines drawn from H falling toward the ray of the equator DC are to be transferred from the center of the dial H onto those hour-lines which tend from H, the center of the dial, toward the equinoctial line; but the intervals of the lines drawn from H toward the other side of the line HV — such that they cannot cut the ray of the equator below D — are to be transferred onto the hour-lines of the dial from the center H in the upper direction, that is, onto those hours which do not cut the equinoctial line, such as all the hours after the sixth hour from noon up to midnight, and all the hours from midnight up to the sixth hour.

[Margin: Demonstration of the latter way of describing the parallels, or arcs of the signs. From which it is clear that Giovanni Battista Benedetti [Giovanni Battista Benedetti] condemns this kind of description undeservedly.]

It will also sometimes be convenient to seek the points of the arcs of the signs at the half-hours or the quarter-hours. As in the present example: because the points on the lines of the fifth hour after midnight and the seventh hour after noon, through which the arc of Cancer (♋) must be drawn, are too far from the center H, points of this kind will have to be found on the lines of the hours $5\frac{1}{2}$ after midnight and $6\frac{1}{2}$ after noon. The same would have to be done on the lines of the hours $8\frac{1}{2}$ after midnight and $3\frac{1}{2}$ after noon, for investigating the points of the arc of Capricorn (♏ [Capricorn]), and so on. In the next figure, the line falling from H to the left of the straight line HV, marked with points, belongs to the hours $5\frac{1}{2}$ after midnight and $6\frac{1}{2}$ after noon, and so on.

But let us now demonstrate geometrically that the parallels, or arcs of the signs, are rightly described by this method. For there are those who either altogether deny it — among them Giovanni Battista Benedetti, in his *Gnomonica*, chapters 70 and 71, where by another and much longer method he attempts to describe the arcs of the signs — or at any rate doubt whether the arcs of the signs can rightly be described in this way, since they do not see the reasoning on which this description of ours rests (a description which indeed all writers hand down without any demonstration). Let the triangle DHI, then — of the portion of the Analemma of the preceding proposition, or of the dial described in the scholium

of the same proposition without the portion of the Analemma — be understood as standing upright to the plane of the dial and of the meridian line, so that the point H is set at the center of the dial and I on the equinoctial line, as appears in the dial of this proposition. If, then, the figure containing the hour-lines and the rays of the signs, constructed just now, be applied by the axis HD of the said triangle (set upright to the dial), and be carried round this way and that — yet so that DC, the ray of the equator, always makes a right angle at D with the axis DH — it is clear that the rays...

of the signs (if we conceive them in our mind as penetrating the plane of the dial) describe in the dial the conic sections of the signs, into which these rays are projected by the diurnal motion. For in that carrying-round, the rays of the signs — making with the ray of the equator the angles of declination, and with the axis the angles complementary to the declinations — do not depart from the conic surfaces described by the Sun's rays, but, produced all the way to the sky, reach the parallels themselves.

Now since the sides HD, DC of the triangle HDC of the immediately preceding figure — to begin with the fifth hour after noon, or the seventh after midnight, to which the line HC corresponds — are equal to the sides HD, DF of the triangle HDF in the dial (because DF is equal to EF, to which DC, taken on the ray of the equator, is made equal; for since the sides EI, IF of the triangle EIF are equal to the sides DI, IF of the triangle DIF and contain equal angles, namely right angles — for EIF is a right angle by construction, while FID is a right angle by Euclid, *Elements* XI, definition 3,

[Margin: *Elements* XI.19]

because FI, the common section of the equator and of the plane of the dial with the meridian — that is, with the triangle DHI situated in the plane of the meridian, and therefore with the straight line DI — is perpendicular at the point I;

[Margin: *Elements* I.4]

the bases EF, DF will be equal) — and since these sides contain equal angles, namely right angles (for HDC in the next figure is a right angle by construction, while HDF in the dial is likewise a right angle, because the axis HD, being at right angles to the plane of the equator, is perpendicular at the point D to the straight line FD lying in it, by Euclid, *Elements* XI, definition 3),

[Margin: *Elements* I.4]

the bases HC, HF and the angles DHC, DHF will be equal. Therefore, if the triangle HDC is conceived to be moved about the axis HD in the dial until it is joined with the triangle HDF, and the line HC coincides with the line HF in the plane of the dial, then the point C of the equinoctial ray will fall on the point F — because of the equality of the angles CHD, FHD and of the lines HC, HF — and the point Z of the ray of Cancer ($\mathfrak{S}$) will fall on the point α , because the line $H\alpha$ was taken equal to the line HZ by construction, or $F\alpha$ equal to CZ. Through the point α , then, of the fifth hour after noon, passes the conic section of Cancer, since the ray of Cancer falls upon it in that revolution of the triangle DHC about the axis DH in the dial, as we have shown. In no other way shall we prove that the point T also, in that carrying-round of the Zodiac rays, falls on R; and the point β of the ray of Cancer on γ ; and the same must be said of the remaining hour-lines that intersect the equinoctial line.

Diagram. The same woodcut as on p. 148 (the *figure of the Zodiac rays* combined with the horizontal dial) is repeated here, occupying the lower left of the page. A large semicircle with a bounding arc is set about the top; from the apex region a pencil of straight lines (hour-lines and sign-rays) fans downward to a ring of hour-numerals and a curved band of zodiacal-sign symbols at the foot. As on p. 148, the small peripheral point-labels are worn and set in mixed Greek/roman/symbol sorts; several remain uncertain and this figure

- λ (upper left, on the arc): endpoint of the axis-line $A\lambda$
- H (top center): center of the dial / apex of the radiating pencil
- D (top, right of H): center of the semicircle, on the axis
- A (top right): right endpoint of the axis-line $A\lambda$
- φ (right side, on the arc): peripheral point [?]
- B (right of center): point on the arc for laying off the pole's altitude
- C (center): point on line DC
- T (center left): point on line DC
- V (below center): sixth-hour point (line HV)
- X, Y (left of center): seventh/fifth- and eighth/fourth-hour points
- θ (lower center, Greek): sign-ray point θ that falls on α in the revolution [?]
- α , β , γ , δ (lower center band, small Greek): sign-ray / conic-section points [?]
- Z, R (lower center, roman): points on the fifth-/fourth-hour lines [?]
- Point-symbol on the sixth-hour dial-line (the correspondent of V), read as a worn Jupiter-like sort $\mathfrak{A}$ [?]
- Zodiacal-sign symbols in the lower band: $\mathfrak{M}$ [Capricorn] and neighbours [?]

- Hour numerals around the periphery: (left, descending) 12, 11, 10, 9, 8, 7 ...; (right, ascending) 1, 2, 3, 4, 5, 6 ...

For the sixth hour after noon (or after midnight), which does not cut the equinoctial line but is equidistant from it, the line HV must be drawn perpendicular to the axis HD in the figure of the Zodiac rays, that is, parallel to the ray of the equator DC. For by this arrangement, in that carrying-round of the rays, the line HV will coincide with the line H α [?] in the dial, on account of the equality of the right angles DHV and DH α [?]. For the angle DHV is a right angle by construction, and the angle DH α [?], set at the axis, is likewise a right angle by Euclid, *Elements* XI, definition 3,

[Margin: *Elements* XI.19]

because H α [?], the line of the sixth hour — being the common section of the plane of the dial and of the circle of the sixth hour — is perpendicular to the meridian (to which both of them are at right angles), that is, to the triangle DHI, and therefore also to the straight line DH, at the point H. For this reason the point θ of the ray of Cancer ($\mathfrak{C}$) will fall on α , on account of the equality (by construction) of the lines H θ and H α ; for the line H α in the dial was taken equal to the line H θ in the figure of the rays. Finally, for the seventh hour after noon, or the fifth after midnight, and for any others that do not cut the equinoctial line, if it should be needed (though in our example we need no other hour, since the arc of Cancer cuts the lines of the seventh hour after noon and the fifth after midnight at points very far from the center H), lines must be drawn which, on the other side — the left, that is — make with the line HV of the sixth hour angles equal to the angles which the lines that cut the ray of the equator on the right-hand side (the lines belonging to those hours which cut the equinoctial line in the dial) make with that same sixth-hour line — such lines as HX, HY, and so on. For in this way such lines will make with the axis HD, in the figure of the Zodiac rays, the angles XHD, YHD equal to the angles which the corresponding hour-lines in the dial make with the axis HD: namely, the angle XHD in the said figure equal to the angle xHD in the dial.

[Margin: *Elements* I.13]

For since the two angles XH λ , XHD in the figure of the rays are equal to the two angles DHk, DHx in the dial (because both these and those are equal to two right angles), let the angle XH λ in the said figure be equal to the angle DHK in the dial. (For the angle XH λ in the same figure is equal to the angle CHD of the same figure, by Postulate 3 of *Elements* Book I, because the whole right angles VH λ ,

VHD are equal to one another, and, once the angles VHX, VHC have been taken away — equal to one another by construction — the angle CHD of the said figure is equal to the angle DHF in the dial, as has been demonstrated, and hence also to the angle DHK in the same dial, which is equal to the angle DHF. This we shall show as follows. When the line DK has been drawn,

[Margin: Elements I.4]

DK will be equal to DF itself, because the sides ID, IF of the triangle DIF are equal to the sides ID, IK of the triangle DIK and contain equal angles, namely right angles. Since, therefore, the sides DH, DF of the triangle DHF in the dial are equal to the sides DH, Dk of the triangle DHk in the same dial, and contain equal angles, namely right angles — for the axis HD, being at right angles to the plane of the equator, is perpendicular to the straight lines DF, DK lying in that same plane of the equator, by Euclid, *Elements* XI, definition 3 — the angles DHF, DHk will be equal.) Hence the remaining angle XHD in the said figure will also be equal to the remaining angle DHx in the dial; and so with the rest. Since this is so, the line Hx of the said figure will be joined to the line Hx of the dial in that revolution of the rays, on account of the equality of the angles which the lines HX, Hx make with the axis HD, and so on. And the same is the reasoning...

and the same reasoning holds for the rest. It is clear, therefore, that Giovanni Battista Benedetti [Giovanni Battista Benedetti], in his *Gnomonica*, was wrong to criticize this method of describing the arcs of the signs.

Now that the hyperbolas of the northern signs have been drawn — that is, those contained between the center H and the equinoctial line — we shall describe more accurately the opposite hyperbolas of the southern signs, that is, those drawn on the other side of the equinoctial line. (These are harder to draw, because the points on the hour-lines beyond the equinoctial line, through which they must be drawn, are farther apart from one another than the points on the near side of the equinoctial line.) We proceed as follows.

[Margin: How the hyperbolas of the southern signs are drawn from the hyperbolas of the northern signs.]

Once the transverse diameter of the opposite sections has been found on the meridian line of the dial — this being always equal to the segment of the straight line HB, in the figure of the rays, intercepted between the rays of the opposite signs (just as in the dial the straight line KN is the diameter of the opposite sections of Cancer (♋) and Capricorn (♏), and is equal to the segment $\mu\alpha$ of the straight line HB in the figure of the rays intercepted between the rays of Cancer

(♋) and Capricorn (♏)) — we shall bisect it, so as to obtain the center of the opposite sections, according to the teaching of Apollonius [Apollonius of Perga] in the second set of Definitions of Book 1 of the *Elements of Conics* (*Conics* I, second Definitions). Then, since by Proposition 30 of Book 1 of Apollonius (*Conics* I.30) any straight line drawn through the center of the opposite sections is bisected at that center, we shall draw hidden lines, through the found center, from the points on the hour-lines above the equinoctial line through which the northern hyperbolas pass. For if, below the said center, we cut off lengths equal to the segments of those lines that lie between the said points and the center, we shall have on those hidden lines the points through which the southern hyperbolas are to be drawn. We shall use this same skill and device in the dials that follow, in which opposite hyperbolas must be drawn — whether these belong to the parallels of the equator drawn through the beginnings of the signs of the Zodiac, or to the parallels of the horizon.

This method of drawing the hyperbolas of the southern signs from the hyperbolas of the northern signs will be understood more clearly from the following figure, in which the diameter of the opposite hyperbolas is DE, and their center is the point F. If, then, from the point K of the upper hyperbola the straight line KFN is drawn through the center F, and FN is cut off equal to FK, the opposite hyperbola must be drawn through the point N — since, by Proposition 30 of Book 1 of Apollonius (*Conics* I.30), the straight line FK is equal to the segment of the same straight line extended beyond F, contained between F, the center, and the opposite hyperbola. Likewise, when the straight line LFM has been drawn, if FM is cut off equal to FL, the opposite hyperbola must be drawn through the point M; and so with the rest. Moreover, in my judgment, the straight lines through the center of the opposite hyperbolas should be drawn from those points of the northern hyperbolas through which the hour-lines pass, since those points have been found by construction. Hence we shall describe the opposite hyperbola more accurately through those points than through other intermediate points lying between them, which are found not by construction but by conjecture.

From Proposition 6 of the preceding book we shall easily recognize which parallels produce opposite sections in the dial — that is, hyperbolas, or other sections — for the aforesaid method fits hyperbolas alone. We shall, however, also derive this from the figure of the Zodiac rays described a little earlier, as follows. Whenever the straight line HB, in the said figure, cuts two rays of opposite signs — that is, rays equally distant on either side from the ray of the equator, such as the rays of Cancer (♋) and Capricorn (♏), of Gemini (♊) and

Sagittarius (♐), of Taurus (♉) and Scorpio (♏)[?], and so on — then the arcs, or parallels, of those opposite signs are opposite hyperbolas.

[Margin: How to know whether the arcs of the signs are hyperbolas, parabolas, or an ellipse.]

For in the triangle $DH\alpha$ the external angle $AD\alpha$ is greater than the internal and opposite angle $DH\alpha$. [Margin: *Elements* I.16 (superscript a).] But the angle $AD\alpha$ is equal to the complement of the declination of the parallel whose radius is $D\alpha$ — and therefore also of the opposite parallel, whose radius is $D\mu$ — while the angle $DH\alpha$ is equal to the elevation of the pole above the horizon. The horizon will therefore cut each of the parallels of the rays $D\alpha$ and $D\mu$, as we showed in the corollary to Proposition 6 of the preceding book. Hence, by the same Proposition 6, the arcs of those signs are opposite and equal hyperbolas.

But when the straight line HB does not cut both rays of the opposite signs, but is parallel to one and cuts the other, then the arc of that sign whose ray is cut will be a parabola. [Margin: *Elements* I.29 (superscript b).] For then the external angle $AD\alpha$, of the complement of the declination, is equal to the internal angle $DH\mu$, of the elevation of the pole (because $H\mu$ and $D\alpha$ are set parallel); therefore the horizon will be tangent to each of the opposite parallels, by the corollary to Proposition 5 of the preceding book. Hence, by the same Proposition 5, the arc of the other sign, whose ray is cut, will be a parabola.

Finally, when the straight line HB neither cuts both rays of the opposite signs nor is parallel to one, but cuts one while receding more and more from the other, then the arc of that sign whose ray is cut will be an ellipse. [Margin: *Elements* I.28 (superscript c).] For since in that case the angle $AD\alpha$, of the complement of the declination, is less than the angle $DH\mu$, of the elevation of the pole — for if the angles $AD\alpha$ and $DH\mu$, external and internal, were equal, the straight line HB would be parallel to the ray $D\alpha$; and if the angle $AD\alpha$ were greater than the angle $DH\mu$, the straight lines HB and $D\alpha$ would meet, which is not assumed — it comes about that the horizon is neither parallel to those opposite parallels, nor tangent to them, nor cuts them, as is clear from the corollary to Proposition 7 of the preceding book. For this reason the arc of that sign whose ray is cut will be, by the same Proposition 7, an ellipse.

It is clear, moreover, that when the arc of a sign is a parabola or an ellipse, the arc of the opposite sign cannot be drawn in the dial, because the straight lines drawn from H do not cut its ray, as we have said.

[Margin: When the arc of a sign is a parabola or an ellipse, the arc of the opposite sign cannot be drawn in the dial.]

For the rest, it will be enough if, from the latter figure of this proposition, we describe the portion of the arc of any sign up to the meridian line on one side only.

[Margin: How, from the portion of the arc of a single sign drawn up to the meridian line, the remaining portion — and also the arc of the opposite sign, if the arcs of the opposite signs are hyperbolas — is drawn.]

For from this the remaining portion on the other side can also be drawn — indeed, in the dials that follow, much more accurately than if we were to draw the whole arc from the figure of the Zodiac rays, as we shall say in its place — and moreover the whole arc of the opposite sign as well (provided, however, that the diameter of the arcs, namely the straight line HB, cuts the rays of the opposite signs in the figure of the rays; for only then, as we showed, are the arcs of those signs opposite and equal hyperbolas) can be drawn. We shall carry out our aim as follows. Let AB be the axis of the opposite hyperbolas, or of the parabola, or of the ellipse — such as is the meridian line in a horizontal dial — and let CD be the portion of that arc, or conic section, drawn up to the axis. Now let the point E be found on the axis AB, through which the arc of the opposite sign must pass. (This is obtained if DE is taken equal to the transverse diameter of the opposite arcs in the figure of the rays, namely to the segment of the straight line HB between the rays of those opposite signs.) Then, taking the straight lines DA and EB equal to one another and of any magnitude, and bisecting the diameter DE at F, we shall place one foot of the compasses at F and extend the other to any point of the arc CD — say, to C — and, without changing the compass opening, we shall describe from F, on the other side of the axis, a hidden arc of some circle; likewise two others, on either side of the same axis, toward the region of E. Again, setting one foot of the compasses at A, we shall extend the other to C, and, with the legs of the compasses kept so extended, we shall describe from A an arc of a circle which cuts the one first drawn from F, on the other side of the axis, at G; likewise two others from B, which cut the two first drawn from F — on either side of the same axis, toward the region of E — at H and I.

Nam per punctum G... — For the arc CD, produced, will pass through the point G, and through the points H and I will run the opposite and equal arc, which is set to pass through the point E. In the same way, if we extend the compasses from F to K, and describe three arcs from F at the interval FK, and likewise from A and B three others at the interval AK — one from A and two from B — which cut the

first three at L, M, N, then the same arcs will pass through the points L, M, N. And in this way we shall find as many further points as we please. I would urge, however, that from F those points be taken in the portion of the arc CD where it is cut by the hour-lines.

But if the arcs of the opposite signs are not opposite and equal hyperbolas — as happens when the diameter of the arcs, or the straight line HB, does not cut the opposite rays in the figure of the Zodiac rays, but only one of them — then it is enough if just two arcs, on the other side of the axis DE, cutting one another, are drawn from F and A, F being taken at any point of the diameter AB, even if that point is not the center. For in that case the arc of the opposite sign cannot be drawn, as we said a little earlier. But this device is then less necessary in a horizontal dial, because both portions of the arc, CD and GD, are drawn with a single effort by the latter method, which is accomplished by means of the figure of the Zodiac rays, as is clear from the foregoing. For the opposite arcs, however, the matter will be very useful and convenient. In declining and inclining dials too this practice will bring great convenience — whether the arc of both opposite signs can be drawn in the dial, or of only one — as will be clear in its place.

Diagram. A construction figure for opposite conic sections, laid out symmetrically about a vertical axis AB. Two dotted straight lines cross near the center of the figure to form a broad X; each arm of the X is punctuated by small cross-marks (×), each pair of crosses marking the intersection of two compass arcs. Along the vertical axis lie two rhombus ("diamond") figures, one above the other.

- A (top): apex of the figure, upper vertex of the axis and of the upper rhombus
- C (upper left): far end of the left-upper dotted arm
- G (upper right): far end of the right-upper dotted arm
- K (left vertex, upper rhombus): left end of the diagonal KL [faint/reversed in the scan]
- L (right vertex, upper rhombus): right end of the diagonal KL
- O (on axis, center of upper rhombus): where the diagonal KL cuts the axis AD
- D (lower vertex, upper rhombus): on the axis, above F
- F (center of the whole figure): midpoint of the transverse diameter DE, between the two rhombi
- E (upper vertex, lower rhombus): on the axis, below F

- M (left vertex, lower rhombus)
- N (right vertex, lower rhombus)
- B (bottom): apex of the figure, lower vertex of the axis and of the lower rhombus
- H (lower left): far end of the left-lower dotted arm
- I (lower right): far end of the right-lower dotted arm

But let us demonstrate this construction geometrically. Draw the straight lines AK, AL, KL, DK, DL, FK, FL, FM, FN, BM, BN, EM, EN, of which let KL cut the straight line AD at O. Since the two sides FA, FK of the triangle AFK are equal to the two sides FA, FL of the triangle AFL, and the base AK is equal to the base AL, the angles AFK, AFL will also be equal. [Margin: *Elements* I.8 (superscript a).] Again, since the sides FO, FK of the triangle OFK are equal to the sides FO, FL of the triangle OFL, and contain equal angles, as we have shown, the bases OK, OL will also be equal, and the angles at O equal, and therefore right angles. [Margin: *Elements* I.4 (superscript b).] And since in a right cone — such as are all those whose bases are the parallels of the Sun and whose common vertex is at the center of the world — the diameter of any conic section bisects all the ordinates, and at right angles, as is clear from Proposition 7 of Book 1 of Apollonius (*Conics* I.7), it follows that KL is an ordinate to the diameter AD of the conic section CD. For no other straight line drawn from K to AD can be cut at right angles, as is clear from what we demonstrated, following Proclus, on Proposition 17 of Book 1 of Euclid (*Elements* I.17). The conic section CD, therefore, when produced, will pass through the point L, and so with the rest of the points.

Again, since AD and BE are equal, if the equals DF, EF are added, the wholes AF, BF will also be equal. Since, then, the two sides AF, FK of the triangle AFK are equal to the two sides BF, FN of the triangle BFN, and the base AK is equal to the base BN, the angles AFK, BFN will also be equal. [Margin: *Elements* I.8 (superscript c).] Hence, as we demonstrated, following Proclus, on Proposition 15 of Book 1 of Euclid (*Elements* I.15), the straight lines FK, FN form a single straight line, and consequently one bisected at F, the center of the section. Therefore, since in opposite hyperbolas whose diameter is DE the straight line drawn from K through the center F is bisected at the center F, by Proposition 30 of Book 1 of Apollonius (*Conics* I.30), the opposite hyperbola will necessarily pass through the point N. In the same way we shall show that it passes through the point M, and so with the remaining points.

Now since in the triangles DOK, DOL the sides OD, OK are equal to the sides OD, OL, and contain equal angles — namely right angles, as has been demonstrated —

the bases DK, DL will also be equal. [Margin: *Elements* I.4 (superscript d).] By the same reasoning EM, EN will be equal to one another. And again, DK will be equal to EN, and DL to EM, if the triangles DFK, EFN and DFL, EFM are considered; for the sides FD, FK are equal to the sides FE, FN, and contain equal angles, and so on. Hence, if with the interval DK an arc is described from D toward L, and two others from E on either side, these arcs will pass through the points L, M, N. And by the same reasoning the arcs described from the same points D, E, at the intervals between D and the remaining points of the conic section CD, will pass through the other points of the sections DLG, EMH, ENI. Hence, if three arcs each — from A, F, D, and likewise from B, F, E — are drawn so as to intersect one another, the points through which the opposite conic sections must be drawn will be found with great exactness, so that by this method the drawing of the arcs of the signs can easily be checked.

[Margin: The method by which opposite hyperbolas are drawn in the dial with a single effort.]

This affords great convenience in laying out the arcs of the signs in declining and inclining dials, as will be clear below.

The hyperbolas of the opposite signs, too, can (namely when the straight line HB, in the figure of the rays, cuts the rays of the opposite signs) — being indeed equal to one another and opposite, as is clear from Proposition 14 of Book 1 of Apollonius [Apollonius, *Conics* I.14]

nius, be most conveniently drawn with a single effort in this way. When, as before, two points have been found on the meridian line of the dial, through which the arcs of the opposite signs must be drawn, let a point ϕ be taken on the same meridian line extended, distant from the point of the hyperbola to be drawn beyond the equinoctial line by as much as the center of the dial H is distant from the point of the hyperbola opposite to it — the one to be drawn between the equinoctial line and the center H. And from the point ϕ let hidden hour-lines go out, like those drawn from the center H. This will easily be done if, through the point X, which bisects the transverse diameter of the opposite hyperbolas, a line is drawn parallel to the equinoctial line, as a second equinoctial line with respect to the center ϕ . For where this line cuts the hour-lines drawn from the center H, through those points the hidden hour-lines from ϕ must be drawn, as is evident — because in this way the angles at the centers H and ϕ , contained by the hour-lines and the meridian line, will be equal. [Margin: *Elements* I.4 (superscript a).]

Or else this way, and perhaps more conveniently: when a hidden arc of a circle has been described from H, let another arc be described at the same interval from ϕ . For if in the first arc the intervals of the hours are taken, beginning from the meridian line, and are transferred to the second arc, beginning likewise from the meridian line, points will be obtained on this second arc through which the hour-lines from ϕ are again to be drawn. But for the sixth hour, a line parallel to the equinoctial line, or perpendicular to the meridian line, must be drawn through ϕ . And so, if all the intervals which — in the latter drawing of the arcs of the signs of the Zodiac (which is accomplished from the figure of the Zodiac rays) — we said must be transferred with the compasses from H, the center of the dial, onto the hour-lines, in order to draw any hyperbola between the center H and the equinoctial line, are transferred at the same time with the same compasses from ϕ onto the corresponding hour-lines going out from ϕ , then with a single effort the points on both sides will be obtained, through which the opposite and equal hyperbolas are to be drawn. You have an example in the hyperbolas of Cancer (♋) and Capricorn (♏) of the dial above. And the same reasoning holds for the other opposite hyperbolas.

We shall use the same device in what follows, taking, in declining and inclining dials, the line of the style in place of the meridian line; and likewise, in the figure from which the arcs of the signs are drawn, the line of the index in place of the line HB of the twelfth hour, and so on, as we shall point out in its place. And so we have drawn the parallels, or the arcs of the signs of the Zodiac, and so forth, in the aforesaid horizontal dial. Which was to be done.

SCHOLIUM.

Andreas Schöner [Andreas Schöner], in his work on Gnomonics, describes in the following way the hour-lines that go out from H in the figure of the rays of this proposition.

[Margin: A most beautiful method for drawing the hour-lines in the figure of the rays without the hour-intervals of the dial.]

When the straight line HIB has been drawn, forming the angle AHB of the elevation of the pole — just as we too did — he takes on it any point ϕ , through which he draws ϕV parallel to DH; and this line cuts the straight line drawn from H parallel to DC at the point V, from which, as center, and with the interval $V\phi$, he describes a circle. Dividing this into 24 parts, beginning at ϕ , he connects each pair of points equally distant from ϕ by hidden straight lines, which cut the straight line ϕV at points through which he draws straight lines from H for the

hour-lines — lines that will correspond exactly to those found by the earlier method. And if the individual arcs of the circle described from V are bisected, or divided into four parts, and so on, and the same is done, then lines for the half-hours, or for the quarter-hours, and so on, going out from H, will likewise be obtained. And although he himself does not demonstrate this operation, we have nevertheless learned by many trials that it is true, and that the hour-lines found by it agree with those we found before.

Now if this practice is reliable, one will be able most conveniently to draw an astronomical horizontal dial, together with the arcs of the signs — and for a given size of the style as well — in this way.

[Margin: The drawing of a horizontal dial from the figure of the rays, after Andreas Schöner.]

When the ray of the equator DC has been drawn, together with the rays of the other signs, let the perpendicular DH be drawn through D for the axis of the world; and from D let the straight line D ϕ be dropped, making with the axis DH the angle ϕ DH equal to the complement of the elevation of the pole. Then, taking the given length of the style D ϕ , let the perpendicular H ϕ I be drawn through ϕ to D ϕ , cutting the axis DH at H and the ray of the equator DC at I. Also, taking on the straight line HI produced any point ϕ , through which the line ϕ V is drawn parallel to the axis DH, let a circle be described from the center V with the interval V ϕ , and let the whole figure be completed, as Andreas Schöner taught. After this, when in the plane of the dial the meridian line HE has been drawn — which the equinoctial line FK cuts at right angles at I — let the straight line IH, upward, be taken equal to the straight line HI in this figure just constructed, and the straight line IE equal to the straight line DI. For if the intervals on the ray of the equator between D and the hour-lines going out from H are transferred, in the plane of the dial, from E onto the equinoctial line on both sides, then, with those points marked on it, the straight lines drawn from H through these points of the equinoctial line will give the hours from noon, or from midnight, and so on, as before.

[Margin: How a dial is drawn from the figure of the rays.]

But the arcs of the signs will be drawn from the figure of the rays just constructed, as above.

Moreover, that this method of Schöner for drawing the hour-lines from H is true and reliable — so that his lines do not differ from ours, which we drew from H

through the points found on the ray of the equator — will be made plain as follows.

[Margin: How a larger or smaller dial is drawn from the figure of the rays.]

Diagram. Schöner's construction of an astronomical horizontal dial from the figure of the rays. A large circle (the "figure of the rays") stands on the center H, from which a fan of straight hour-lines radiates outward and downward; the hours are numbered around the periphery. Across the lower-middle of the figure runs a band of the sign-arcs (the arcs of the Zodiac signs) carrying zodiac glyphs. Superimposed on the circle is the geometric construction (axis DH, the style line, the parallel ϕV , and the auxiliary points). This is a very dense, partly worn figure; many of the small peripheral point-letters and hour-numerals will not resolve at this resolution and are flagged. (more than two labels flagged [?]).

Legible / partly legible labels:

- A (upper right of the rim): endpoint of the elevation-of-pole line, top of the construction
- B (right side, below A): on the line HIB (the style / axis line)
- C (center-low): on the ray of the equator DC
- D (upper area, on the top arc): endpoint of the ray of the equator DC and of the axis DH
- H (center, foot of the fan of hour-lines): center of the dial
- V (center of the auxiliary circle): center from which the 24-part circle is drawn
- λ (top left of the rim) [Greek letter lambda, a construction point]
- ϕ (construction point on line HIB / the style; appears more than once) [?]
- T (center): construction point [?]
- Z (center-left, above T): construction point [?]
- θ (left of T) [Greek theta]: construction point [?]
- X (center-left): construction point [?]
- Y (center-left): construction point [?]
- ψ / P (upper center): construction point [?]
- Φ (right of center) [Greek capital phi]: construction point [?]
- Hour numerals around the periphery: 12, 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11 (left and right of the fan) — several individual numerals worn/ambiguous [?]
- "u" (far lower left) and "n" (lower right): terminal markers on outer hour-lines [?]

- Zodiac-sign band across the lower middle: a row of zodiac glyphs marking the sign-arcs — individual glyphs too small/worn to resolve at this resolution [?]

Schöner's straight lines from H are the radii of the diurnal arcs of the equal hours, as we shall demonstrate at the end of this whole work: namely, $H\phi$ is the radius of the diurnal arc of hour 0 [noon]; the next line, the radius of the diurnal arc of hour 2; the following one, of hour 4; and so on. For in order that the radii of all the diurnal arcs — of the odd as well as the even hours — may be obtained, the circle described from V through ϕ must be divided into 48 equal parts (as was said in the scholium to prop. 33 of the preceding book), and not merely into 24, so that the straight lines emitted at H form with HV the angles of declination of the diurnal arcs of the even hours. But the lines that we drew through the points on the radius of the equator from H likewise form, at H, with HV the declinations of those same diurnal arcs, as we shall show. Therefore Schöner's lines pass through the points on the radius of the equator, so that they do not differ from ours — lest the same diurnal arc should have different angles of declination.

For example, Schöner's straight line HC is the radius of the diurnal arc of hour 10, and VHC is the angle of declination of that diurnal arc; and this, I say, is the very same angle that the straight line drawn from H through the found point C also makes. For in the dial of this proposition, the straight line EF — and therefore also the straight line DC — is the secant of angle FEI of 5 hours, the whole sine being set as EI or DI in this figure; and DH is the tangent of angle DIH, the complement of the pole's altitude. Now CD is the secant of 5 hours with respect to the whole sine DI, inasmuch as the whole sine is to DH as the tangent of the complement of the pole's altitude is to that same whole sine CD; and by prop. 18 of the *Sines*, CD is the secant of 5 hours to the whole sine as the whole sine is to the sine of the complement of the arc of 5 hours — that is, to the sine of the first hour, or of the difference between the half and the quadrant of the diurnal arc of 10 hours. Therefore the whole sine will likewise be to the sine of the aforesaid difference as the tangent of the complement of the pole's altitude is to the tangent of angle DCH. And accordingly, by problem 11 at the end of the new description of dials, DCH will be the angle of declination of the diurnal arc of 10 hours — which was proposed.

Now once the hour-lines have been drawn from H, if — by this method, which is completed by means of the figure of the rays — a larger or smaller dial is to be constructed, the figure of the Zodiac's rays going out from point D must be described, more distant from point H, or less, and so on. [Margin: (a) Euclid,

Elements VI.4.] For in this way it will come about that the proportion of the lines between H and the radius of the equator DC (placed relative to the lines of that same radius of the equator between D and the points where the straight lines emitted from H cut DC itself) is the same as the proportion of the lines between H and the more remote or nearer radius of the equator (placed relative to the lines of that same radius between the axis DH and the points where the straight lines from H intersect the radius of the equator) — on account of the similarity of the triangles, and so on. For the description of the hour-lines emitted from H remains the same in the same climate, whether a large or a small dial is to be described; but the description of the Zodiac's rays is always the same in any climate, provided only that it is more remote from, or nearer to, point H, according as a larger or smaller dial is to be described. Likewise the equinoctial line in a larger dial ought to lie along the meridian line at just such a distance from the center H as is the portion of the straight line HB in the figure of the Zodiac's rays intercepted between H and the radius of the equator lying more or less distant from point H.

[Margin: How the length of the style, and its position on the dial, may be investigated from the figure of the rays. — How, from a given length of the style, the distance of the Zodiac's rays from point H in the figure of the rays may be found.]

Diagram. The "figure of the rays" (*figura radiorum*) — a large circular construction for the astronomical horizontal dial. A great circle carries, along its upper rim (left to right), the points λ , H, E, D, A; from H at the top a dense fan of hour-lines radiates downward across the circle to numbered points on the lower periphery. A rectangular band runs across the lower-middle of the circle carrying the sign-arcs (the arcs of the Zodiac) with their glyphs. The figure is dense and partly worn; several interior construction letters and peripheral hour-numerals will not fully resolve at this resolution, and are flagged. (more than two labels flagged [?]).

- λ (upper-left rim): construction point [Greek letter lambda]
- H (top, left of center): center of the dial, foot of the fan of hour-lines
- E (top center): rim point
- D (upper right): endpoint of the radius of the equator / axis
- A (upper-right rim): rim point
- V (mid-left interior): center of the circle
- C (center-low): point on the radius of the equator DC
- P (upper-center interior) [?]

- B (upper-center interior, appears more than once) [?]
- Z (center-left interior) [?]
- T (center interior) [?]
- X (center-left interior) [?]
- Φ (right of center) [Greek capital phi]: construction point
- φ (the style-point on line HI; recurs in the surrounding text) [?]
- Hour numerals around the lower periphery — left side: 12, 11, 10, 9, 8, 7, 6, 5, 4, 3 [several worn, [?]]; right side: 12, 1, 2, 3 [several worn, [?]]
- "u" (far lower left) and "n" (lower right): terminal markers on the outer hour-lines [?]
- Zodiac-sign band across the lower-middle: a boxed row of zodiac glyphs marking the sign-arcs; individual glyphs too small/worn to resolve [?]

THE STYLE or gnomon, on the latter method of describing the parallels of the signs — that is, from the figure of the rays — is obtained as follows. From point D, where the radius of the equator cuts the axis $A\lambda$, let a perpendicular $D\varphi$ be dropped to HI; or at least let the straight line $D\varphi$ be drawn making the angle φDI equal to the angle of the pole's altitude. For the length of the style is the straight line $D\varphi$ itself, and its position is the point φ , distant from H, the center of the dial, by the interval $H\varphi$ along the meridian line — or from the equinoctial line FK by the space $I\varphi$, on the same meridian line toward the center H.

[Margin: How, from a given length of the style, the distance of the Zodiac's rays from point H may be found.]

But if the magnitude of the gnomon is given, we shall find, by this method, the distance of the figure of the Zodiac's rays from point H along the axis HD. For the hour-lines proceeding from H remain entirely the same, as we said, at the same altitude of the pole. In the setting-out of the Analemma which we described in prop. 1 of this book, let there be cut off from AD — the diameter of the Vertical circle, drawn out — a straight line DM equal to the given gnomon; and through M let NO be drawn parallel to BC, the diameter of the Horizon, cutting the axis ED at N and the diameter of the equator FD at O. [Margin: (b) Euclid, *Elements* I.26.]

Then point D, in the figure of the Zodiac's rays of this proposition — where all the rays of the Zodiac meet — ought to be distant from H by the interval DN; such is point D, near A, in the said figure of the Zodiac's rays of this proposition. For if from that point D a perpendicular be dropped to HD for the radius of the equator, and at the same time the rays of the other signs be emitted from D — as in the Analemma of prop. 1 of the preceding book — we shall describe, by means of the hour-lines contained between these rays and point H, the parallels of the signs, as

before; and the extremity of the shadow cast by the given gnomon DM will traverse these, as is clear from what has been demonstrated. For if from the said point D a perpendicular DK be dropped to HIB, it will be equal to the given gnomon DM. For since angle DHK, in triangle DHK of the figure of the Zodiac's rays of this proposition, is equal to angle DNM in triangle DNM of the Analemma-portion of prop. 1 of this book (for each is the angle of the pole's altitude), and since the right angles at K and M are equal, and moreover the side HD is equal to the side DN by construction, the remaining sides also — namely DK and DM to each other, and HK and NM to each other — will be equal. Which was proposed. But when the arcs of the signs are changed, the equinoctial line is changed too, which always lies along the meridian line at just such a distance from the center H as is the portion of the straight line HB intercepted, in the figure of this proposition's rays, between H and the radius of the equator — as we also said a little before.

[Margin: The description of the parallels which pass, in the same dial, not through the beginnings of the signs but through other points of the Zodiac.] Now if we take the declinations of other points of the Zodiac, and draw their parallels in the first figure of this proposition — or their rays from D in the third figure — we shall describe their parallels in the aforesaid dial in the same way.

[Margin: The description of the parallel on which the Sun stands on any given day, in the same dial.] Indeed, given the first day of any month, or any other day whatever: if the place of the Sun on that day in the Zodiac, and its declination, be sought, and its parallel be drawn in the first figure of this proposition (or its ray from D in the figure of the rays), there will be described on the dial, by the same method, a certain curved line which the extremity of the shadow will traverse on that given day.

[Margin: The description of feast-days in the same dial.] By this method the feast-days of the saints can be described on the dial — that is, certain curved lines which the shadow of the style traverses on those days.

[Margin: What should be inscribed on the sign-arcs delineated on the dial.] Now on all these parallels of the signs may be inscribed the characters of the signs; the days of the months on which the shadow's extremity traverses them; the times of sunrise and sunset; the lengths of the days and of the twilights; and other things of this kind — such as would appear on an Italian and a Babylonian dial (which will be treated in props. 10 and 11 of this book), the time of noon, and so forth.

[Margin: By what art the sign-arcs are to be described on a dial that has no center.] For the sake of this, certain lines must be drawn parallel to the meridian line itself, both to the left and to the right, as appears in the second figure of this proposition. And the more remote these parallels are from the meridian line, the greater the interval of time over which the gnomon's shadow will be received on the dial.

Again, since the Sun ascends from ♎ [Capricorn] through ♈ [Aries] up to ♋ [Cancer], and descends from ♋ [Cancer] through ♎ [Libra] down to ♎ [Capricorn], on the former signs must be inscribed the words ASCENT OF THE SUN [*Ascensus Solis*], and on the latter these: DESCENT OF THE SUN [*Descensus Solis*]. You have an example on the dial above. This is also to be understood on other dials, such as the Vertical, the Meridian, the Equinoctial, and so on.

Finally, we shall describe these same parallels, or arcs of the signs, on the dial that we constructed in the scholium of the preceding proposition — even though we had no center for it — by nearly the same methods we have used in this proposition. For as regards the former method: let an Analemma be described for the given altitude of the pole (as in the proposed example, for latitude 20 degrees), together with the parallels of the signs and their rays, so that in the cones there may be triangles through the axis, and thus, on the straight line RO (which ought to be equidistant from the horizon BC by the distance of the line DG, equal to the style FM), the diameters of the conic sections. Then let the points K, L, M, Q, P, N — taken from point I, where the diameter of the equator divides the straight line RO — be transferred onto the meridian line AB from point E, where the equinoctial line and the meridian intersect each other. Finally, about the diameters of the conic sections let conic sections be described, according to the teaching of prop. 8 of the preceding book, in such a way that they pass through those points K, L, M, and so on, on the dial; and thus are the parallels of the signs described.

Diagram. The construction of the horizontal dial, in two parts.

Upper part (figure of the rays of the equator). A point D at the right is the apex from which the hour-lines fan out to the left. A vertical line runs through G (top) and down through D. Two horizontal lines run leftward to the level of H (top-left, a short mark) and C (left).

- H (top-left): end of the upper horizontal line
- G (top-right): top of the vertical line GD
- C (left): end of the middle horizontal line (equinoctial line CD)

- D (right): apex where the hour-lines converge
- Hour-numerals along the converging lines (near center): 4, 3, 2, 1, 12
- Hour-numerals (lower): 9, 10, 11, 12

Lower part (the dial face). A grid of hour-lines crossed by the curved, dotted zodiac parallels (sign-arcs). A central vertical meridian line carries, top to bottom, the points K, L, M, I, E, Q, P, N, B. Along the horizontal hour-line row stand the Roman hour-numerals (left to right): IIII, III, II, I, XII, XI, X, IX, VIII. The equinoctial line runs across, marked C (left) and D (right) with M at the center. The dotted zodiac parallels are labelled with their glyphs at both ends:

- ☊ Cancer (top arc)
- ♊ Gemini (left) / ♌ Leo (right)
- ♉ Taurus (left) / ♍ Virgo (right)
- ♈ Aries (left) / ♎ Libra (right) — the equinoctial arc
- ♐ Pisces (left) / ♏ Scorpio (right)
- ♒ Aquarius (left) / ♐ Sagittarius (right)
- ♑ Capricorn (bottom, at both ends)

As regards the latter method, drawn from the figure of the Zodiac's rays, we shall accomplish the matter thus. Onto the radius of the equator DC let all the intervals lying between the center B (from which the circle was described and divided into 24 equal parts) and the hours on the equinoctial line CD be transferred from point D, marking off points on the radius of the equator itself. Next, on the axis DG let there be cut off a straight line DG equal to the portion of the axis FG in the dial described at the end of the scholium of the preceding proposition; and through G let GH be drawn parallel to the radius of the equator DC. Onto GH, in the same way, from point G, let the spaces contained between the other center L (from which, namely, the other circle in the aforesaid dial was described and divided into 24 equal parts) and the hours on the equinoctial line IK be transferred, marking off points on GH itself. Finally, through each pair of corresponding points on the straight lines DC and GH let a straight line be drawn. For these will give the hour-lines, exactly as in the figure of the Zodiac's rays of this proposition; and the intervals of these —

— between the radius of the equator DC and the rays of the other signs, transferred onto the corresponding hour-lines in the dial from the equinoctial line DC itself, will give on the hour-lines the points through which the arcs of the signs are to be drawn; as is clear from what was demonstrated above. For the straight line GH is another radius of the equator, for describing a smaller dial,

whose equinoctial line is of course IK and whose axis is AG. Hence, if on the axis DG of the figure next to this one there were taken from D a straight line equal to the axis FA in the dial, or from G one equal to the axis GA, both would terminate in the same point; and the straight lines drawn from that point through the points of the radius of the equator DC and of GH alike would exhibit the hour-lines, exactly as in the figure of the Zodiac's rays of this proposition. These hour-lines must therefore necessarily pass through the points found on each radius of the equator, and so on. But if from D a perpendicular line be drawn to the nearest hour-line — namely to the line of hour 12 — this will give the length of the style; and its position will be a point on the meridian line, distant upward from the equinoctial line by as much as the point onto which the style from D falls at right angles on the line of hour 12 is removed from the radius of the equator DC. Moreover, in transferring the intervals from the radius of the equator onto the dial, this order must be kept: that the intervals of the hour-lines toward that side on which the style from D falls be transferred upward from the equinoctial line, and so on.

Diagram. The same horizontal-dial construction as on the preceding page, printed again. *Upper part:* the ray-figure of the equator, with D (right) as the apex of the fan of hour-lines; a vertical line through G (top) and D; horizontal lines to H (top-left) and C (left); hour-numerals near the center 4, 3, 2, 1, 12 and lower down 9, 10, 11, 12. *Lower part:* the dial face, a grid of hour-lines crossed by the dotted zodiac parallels; the central meridian carries top-to-bottom the points K, L, M, I, E, Q, P, N, B; the Roman hour-numerals run IIII, III, II, I, XII, XI, X, IX, VIII; C (left) and D (right) mark the equinoctial line, M at center. The dotted zodiac parallels are labelled at both ends: ♋ Cancer (top); ♊ Gemini / ♌ Leo; ♉ Taurus / ♍ Virgo; ♈ Aries / ♎ Libra (equinoctial); ♐ Pisces / ♏ Scorpio; ♒ Aquarius / ♐ Sagittarius; ♑ Capricorn (bottom, both ends).

[Margin: The use of the sign-arcs described on the dial, by which we learn in what part of the Zodiac the Sun is.] Furthermore, the use of the parallels — or arcs of the Zodiac's signs — on all dials is that through them we may know in what sign of the Zodiac the Sun stands each day. For whenever the extremity of the shadow falls exactly on some arc described on the dial, and accordingly departs from it not at all throughout that whole day, the Sun will then necessarily be at the beginning of that sign of the Zodiac which the said arc represents. But when the shadow does not fall exactly on some arc, but into the space enclosed between two arcs, the Sun will then not be at the beginning of any sign, but either near the beginning, or in the middle, or near the end, or, finally, in some other part of it, in proportion to the distance of the shadow from the arc of that sign.

And in order that we may know which of the two signs assigned to any given arc (excepting the two tropical ones) is to be taken, we must observe in what part of the year we are. For since from the twelfth day of June to the twelfth day of December the Sun in this age runs through these six signs — ♋ Cancer, ♌ Leo, ♍ Virgo, ♎ Libra, ♏ Scorpio, and ♐ Sagittarius — while the other six, namely ♑ Capricorn, ♒ Aquarius, ♓ Pisces, ♈ Aries, ♉ Taurus, and ♊ Gemini, [it runs through] from the twelfth day of December to the twelfth day of June, anyone will easily be able to judge in which of the two signs the Sun stands. For example: if on some day between the twelfth of June and the twelfth of December the extremity of the shadow falls exactly on the arc to which these two signs, ♊ Gemini and ♌ Leo, are assigned, the Sun will be at the beginning of ♌ Leo, and not at the beginning of ♊ Gemini. But if the shadow falls into the space enclosed between the said arc and the other arc — of these two signs, ♉ Taurus and ♍ Virgo — the Sun will be in some degree of ♌ Leo, and not in any degree of ♊ Gemini, or ♍ Virgo, or ♉ Taurus, because —

— because at that time of year it cannot be in ♊ Gemini or ♉ Taurus, as we said, but only in ♌ Leo or ♍ Virgo. Since, then, the Sun moves from ♌ Leo into ♍ Virgo, and not the reverse, it follows that it is at that time in some degree of ♌ Leo, and not of ♍ Virgo. The opposite would have to be understood if we were in that part of the year which falls between the twelfth day of December and the twelfth day of June. For then, if the shadow fell on the arc of ♊ Gemini and ♌ Leo, the Sun would be at the beginning of ♊ Gemini; but if the shadow fell into the same space enclosed between the said arc and the arc of ♉ Taurus and ♍ Virgo, the Sun would be set in some degree of ♉ Taurus, because it advances by its own proper motion from ♉ Taurus into ♊ Gemini. And so for the rest.

PROBLEMA 3. PROPOS. 3.

To describe on the same horizontal dial the parallels of the diurnal arcs.

[Margin: The description of the diurnal arcs on the aforesaid horizontal dial.]

Since the parallels of the diurnal arcs are equidistant from the equator, just as the parallels of the signs of the Zodiac are, it is clear that the method of describing both is one and the same. Therefore, in the former mode of description handed down in the preceding proposition, in place of the parallels which are drawn through the signs of the Zodiac, take the parallels of the diurnal arcs, whose declinations were found in Proposition 33 of the preceding book. And in the latter mode, in place of the rays of the Zodiac issuing from point D, take the rays of the diurnal arcs — as is clear from these figures set alongside. In the former of them

are contained the parallels whose diurnal arcs contain the hours 8, 9, 10, 11, 12, 13, 14, 15, 16;

Diagram. A composite construction figure spanning the page width, in two parts (the two "figures set alongside" of the text).

Left part (the "former" figure — the parallels of the diurnal arcs). A circle representing the projection, with a small circle at its center marked **D** (the place of the style). Circumference letters: **I** and **A** at the top, **E** at the upper right, **B** at the left, **C** at the right (between the disk and the ray-figure), **K** at the lower left. Along the upper-left of the disk a column of hour-numerals descends: **16, 15, 14, 13, 12, 11, 10, 9, 8**; further small numerals near the lower part read **2, 3, 4** and **17, 18** [?]. Straight chords (the diurnal-arc parallels seen in projection) cross the disk diagonally.

Right part (the "latter" figure — the rays of the diurnal arcs). A horizontal top bar carries **H** (left) and **D** (right); **C** lies just beneath. From **D** a fan of straight rays radiates downward and to the right toward **A** at the far right. Along the lower ends of the rays run hour-numerals; reading right-to-left across the foot: **17, 16, 15, 14, 13, 12, 11, 10, 9, 8, 7, 6, 5**, and at the far right a short series **0, 1, 2, 3, 4, 5**. A few small numerals near the apex (**5, 8** and **2, 3, 4**) are only partly legible [?].

— but in the latter [figure] the rays of the parallels whose diurnal arcs contain the hours 0, 1, 2, 3, 4, 5, 6, and so on up to 24, where the whole parallel is a diurnal arc. We shall describe the parallels of the diurnal arcs by exactly the same method by which we described the parallels of the signs in the preceding proposition. These are indeed all conic sections, which the shadow of the style describes (by the corollary of Proposition 12 of the preceding book) when the Sun is in them. And the equinoctial line is the diurnal arc of 12 hours.

[a] Now the outermost lines in the ray-figure drawn from **H** are parallel to the outermost lines emitted from **D**, each to its own; because the angles **HDA** and **DHI** are equal to two right angles. [Margin: (a) Elements I.28.] For by construction the angle **HDI** is right, and **DHI** is the angle of the pole's altitude, while **ADI** — which, by the scholium of Proposition 33 of the preceding book, is the angle of the complement of the pole's altitude — together also equal one right angle, etc. And so we have described the parallels of the diurnal arcs on the same horizontal dial. Which was to be done.

SCHOLIVM.

Here too there may be added to the parallels of the diurnal arcs the lengths of the days, and of the twilights, and other things of this kind — such as the days of the months corresponding to those parallels, and so on. [Margin: What is to be assigned to the diurnal arcs described on the dial.]

Now the use of these parallels is that through them we may learn how many hours each day of the year contains. For when the shadow of the gnomon falls exactly on some diurnal arc, the day then contains exactly as many hours as are assigned to that arc. But if the shadow of the style does not fall exactly on some arc, but into the space enclosed between two arcs, we shall judge more or less how many hours the day then has, taking account of the shadow's distance from the nearer arc — provided we recall that the days decrease from the twelfth of June to the twelfth of December in this age, but increase from the twelfth of December to the twelfth of June. So that if, for example, the shadow falls into the middle of the space between the arcs of hours 13 and 14: if indeed this happens in that part of the year which falls between the twelfth day of June and the twelfth day of December, the day will then contain nearly $13\frac{1}{2}$ hours, because the Sun is then moving by its proper motion from the diurnal arc of 14 hours to the diurnal arc of 13 hours, since the days are then decreasing. But if the same thing happens in the rest of the year, the day will again be about $13\frac{1}{2}$ hours, because the days are then taking on increase, and so the Sun by its proper motion is moving from the diurnal arc of 13 hours to the diurnal arc of 14 hours. And so for each case. [Margin: The use of the diurnal arcs described on the dial, by which we know how many hours any given day comprises.]

PROBLEMA 4. PROPOS. 4.

To describe on the same horizontal dial the vertical circles, which they call Azimuth.

Through G, the place of the gnomon on the dial, let the straight line AB be drawn, perpendicular to the meridian line HI.

[Margin: The description of the vertical circles on the same horizontal dial.]

Then from G let any circle described be divided into 360 equal parts, beginning from the straight line AB. (We, because of the narrowness of the space, have divided it only into 24, so that each contains 15 degrees.) For if from the center G, through the points of division, straight lines are drawn — kept, however, within the tropics, as appears in the figure, since the lines beyond them would be

superfluous — then there will be described the vertical circles, or azimuths, that is, the common sections of the vertical circles and of the plane of the dial. Onto these, by Proposition 11 of the preceding book, the shadow of the gnomon is projected, when the Sun is in the said circles. This will easily be demonstrated in the following way.

Diagram. A wide, bow-tie ("butterfly") azimuth figure symmetric about a central vertical (the meridian). At the top center is the gnomon, drawn as a small downward-pointing triangle marked **H**; the place of the gnomon (**G** of the text) lies at the center where the radial lines converge. A horizontal line runs the full width, marked **A** at the left and **B** at the right (the common section AB of the dial-plane and the proper vertical circle); the meridian runs vertically through the center to **C** at the bottom. A dotted circle (the circle divided from G) surrounds the center, and dotted tropic-lines run out to the four corners. From the center a fan of azimuth radii spreads downward; along their graduating arc the degree-numerals read symmetrically about the meridian: **15, 30, 45, 60, 75, 90** (with **90** at the meridian, i.e. due south), mirrored on each side. Outer markers at the wide ends carry numerals **15** (mid-arm, both sides) and **30** (bottom corners, both sides); further numerals near the upper ends (read as **13** and **15/19**) are only partly legible [?]. The four corners bear worn zodiac tropic-signs (Cancer/Capricorn family), which will not resolve on the scan and are flagged [?]. Small cross-marks (✠) ornament each end of the line AB as cardinal markers, with a small emblem drawn at the right. (Several peripheral labels remain [?].)

[Margin: Demonstration of the description of the vertical circles.] [Margin: (a) Elements XI.19 (undecimi).]

Since both the plane of the vertical circle properly so called, which passes through G (for the gnomon of the horizontal dial is part of the common section of the meridian and of the vertical circle properly so called, as is evident from the Analemma), and the plane of the horizontal dial, are at right angles to the meridian, [a] their common section too will be at right angles to that same meridian; and so, by Definition 3 of Book 11 of Euclid, perpendicular to the meridian line at the point G. Therefore the straight line AB, which is drawn through G perpendicular to the meridian line, is the common section of the plane of the dial and of the vertical circle properly so called.

And since all the vertical circles cut the horizon into 360 equal parts — and therefore also the circle which the plane of the dial, being equidistant from the horizon, makes on the sphere (by Proposition 1 of Book 1 of Theodosius) — because, passing through the zenith, or pole of the horizon, they divide the

horizon and the circles parallel to the horizon into similar segments (by Proposition 10 of Book 2 of Theodosius): it comes about that all the vertical circles, and therefore also their common sections with the plane of the dial, pass through the points by which the said circle, made on the sphere by the plane of the dial, is divided into 360 equal parts. But the same sections are also drawn through the point G (by Proposition 18 of the preceding book), at which of course the common section of the vertical circles meets the plane of the dial. Therefore the same sections will also pass through the points of the divisions of the circle described from G.

For since G — the point on which the axis of the horizon falls, and the center of the circle made on the sphere by the plane of the dial (by Proposition 10 of Book 1 of Theodosius) — is the center of the said circle produced on the sphere by the dial's plane, it follows that this circle and the one we described from G are divided into similar arcs by the straight lines going out from the center G, as we demonstrated in the commentaries on the Sphere at the end of Chapter 1. And accordingly, since the former is cut into equal parts, the latter also, which we described from G, will be cut into equal parts. Therefore those straight lines emitted from G through the points by which the circle described from G is divided into equal parts are the common sections of the plane of the dial and of the vertical circles. And so we have described the vertical circles, etc., on the same horizontal dial. Which was to be done.

[Margin: The use of the vertical circles described on the dial, by which we know in which quadrant of the upper hemisphere the Sun is. What the four quadrants of the upper hemisphere are on the horizontal dial. In what way it is known from the vertical circles how great is the arc of the horizon between the vertical circle properly so called and the vertical circle which is drawn through the Sun — which arc is usually called the vertical distance.]

SCHOLIVM.

From the vertical circles we learn, at any moment of time, in which of those four parts — into which the upper hemisphere is divided by the proper vertical circle and by the meridian — the Sun is. For the plane of the dial is divided into the same four parts by the straight line AB (which is the common section of the dial's plane and of the vertical circle properly so called) and by the meridian line (or common section of the same dial-plane and of the meridian): so that the part contained between the straight lines GB and GC is called the northwestern quadrant [the western and northern quarter]; the part comprised between the straight lines GB and GH, the southwestern quadrant [western and southern]; the

part which the straight lines GA and GC contain, the northeastern quadrant [eastern and northern]; and finally the part which the straight lines GA and GH embrace, the southeastern quadrant [eastern and southern].

So, since the Sun always projects the shadow of the style into the part opposite to that in which it stands, we shall easily judge from the shadow in which quadrant of the hemisphere it is. For if the shadow of the style falls into the northwestern quadrant, which we said is contained between the lines GB and GC, we shall say that the Sun is then in the opposite quadrant, namely in the southeastern one; and so for the rest.

Moreover, from the same vertical circles we know how great the Sun's vertical distance is — that is, by how much that vertical circle, in which the Sun stands at any given moment, departs on the horizon from the vertical circle properly so called, or from the point of true rising or setting. For if, for example, the Sun has been found (by what we have just delivered) to be in the southeastern quadrant, and the shadow at that time falls on the vertical line to which this number, 30, is assigned, then the vertical circle in which the Sun then is will be distant from the point of true rising, toward the south, 30 degrees. That is, the arc of the horizon interposed between the vertical circle properly so called and the vertical circle which then passes through the Sun's center is eastern and southern, and comprises 30 degrees. And so for the rest.

PROBLEMA 5. PROPOS. 5.

To describe on the same horizontal dial the parallels of the horizon — that is, the lesser circles of the altitudes of the stars, which they call almucantars [Almucantarath].

[Margin: The description of the parallels of the horizon, which are called almucantars, on the same horizontal dial.]

Let the quadrant of the circle ABC [printed *quandrans*, recte *quadrans*] be described, which is to be distributed into 90 equal parts, beginning from the semidiameter AB. (We have divided the same into only 6 parts, because of the narrowness of the space, so that each embraces 15 degrees.) Then, taking AD as the length of the style on the semidiameter AC, let DE be drawn through D parallel to the other semidiameter AB. Finally, with straight lines drawn from the center A through the points of division, if on the dial — from G, the place of the gnomon, as center — circles are described at the intervals comprised between D and the straight lines emitted from A (as in the figure of the preceding

proposition), circles which however do not exceed the tropics of the dial, then there will be described the parallels of the horizon, or circles of altitude. These are indeed all conic sections, onto which (by the corollary of Proposition 12 of the preceding book) the shadow of the style falls, when the Sun is in the said circles of altitude. This we shall confirm in the following way.

Let the whole circle GHCB be completed, representing the meridian, and let the semidiameters BA and AC be produced, together with the straight line ED, to the points H, G, L. Then, HB being posited as the common section of the horizon and the meridian, GC will be —

Diagram. A circle representing the meridian, with center **A** and many radial lines drawn from it. Circumference letters, running round: **G** at the top; **I** at the upper right; **B** at the right on the horizontal diameter; **M** just below B at the right; **E** on the horizontal, right of center; **K** at the upper left; **H** at the left on the horizontal diameter; **L** on the horizontal, left of center; **C** at the bottom; **D** just below the center; **F** below the center, right of D. Along the upper-left arc the graduation-numerals descend from the top: **90** (at G), **75**, **60**, **45**, **30**, **15** (at K). Down the lower-right arc the graduation reads **15** (at M), **30**, **45**, and two further worn values [?]; near the foot, flanking **C**, appear **30** (left) and **75** (right) [the right-lower **50** and **75** readings are uncertain — [?]]. Small division-dots mark the circumference at each 15°. The triangles AKI and ALE named in the text are formed by the outer radii and the center.

[Margin: Demonstration of the description of the parallels of the horizon.]

[Margin: (a) Elements I.15. (b) Elements III.26.]

— GC being the common section of the same meridian and of the vertical circle, and LE the common section of the same meridian and of the plane of the dial. Now since, if the straight lines drawn from A through the points of the divisions of the quadrant BC are produced through the center, [a] the vertical angles at A become equal, [b] the arcs in the quadrant HG will be equal to the arcs in the quadrant BC. Therefore the straight lines drawn through the points of the quadrant HG and equidistant from HB itself are the common sections of the meridian and of the circles of altitude, or almucantars. From the outermost points of these, the straight lines drawn through the center A will form triangles through the axis of the cones, whose bases are the parallels of the horizon — of which kind are the triangles AKI and ALE.

And since the plane of the dial, drawn through the straight line LE parallel to the horizon (and therefore also to the bases of the cones), makes — by Proposition 4

of the preceding book — the common sections of those conical surfaces to be circles having their centers on the axis of the cones, then D, the place of the style, will be the center of those circles, and the straight lines DE, DF, etc., which the sides of the triangles cut off through the axis, will be the semidiameters of the same, as is clear from the said Proposition 4 of the preceding book. And accordingly, if from G, the place of the style on the dial, circles are described at the intervals comprised between D and the straight lines going out from A, these will be the circles of altitude. Therefore we have described the parallels of the horizon, etc., on the same horizontal dial. Which was to be done.

SCHOLIVM.

The parallels of the horizon lead us to knowledge of the Sun's altitude at any time, when we observe the shadow of the style on the dial. For whenever the shadow of the gnomon falls, e.g., on the parallel to which this number, 30, is set, the Sun's altitude — that is, the arc of that vertical circle which at that time is drawn through the Sun's center, interposed between the Sun's center (or the parallel of the horizon which then likewise passes through the Sun's center) and the horizon — contains 30 degrees, etc. [Margin: The use of the parallels of the horizon described on the dial is that from them we may know the Sun's altitude.]

PROBLEMA 6. PROPOS. 6.

To describe on the same horizontal dial the meridians, or circles of the longitudes of cities.

[Margin: The description of the meridians on the same horizontal dial.]

Since the meridian circles pass through the poles of the world, just as the hour circles do (which show the hours from noon or from midnight), the description of the meridians will not differ from the description of the hour circles reckoned from noon or midnight. Therefore let the circle described from E in Proposition 1 of this book be cut into 360 equal parts, or into fewer — as into 24, so that each embraces 15 degrees, as we have done — the beginning being taken not from the meridian line, but from that point through which passes the meridian drawn through the Fortunate Isles [the Canaries], from which, namely, the longitudes of places, and therefore the meridian circles, take their beginning: of which kind is the point A. This point is obtained by numbering off from the meridian line the longitude of the place in which the dial is described, from the point B toward the western parts — that is, proceeding to the right. For this part inclines toward the west, as is evident, if the dial is placed in its proper position and the circle

described from E is understood to be established in the plane of the equator. We have numbered from the point B up to A 36 degrees, namely the longitude of the City of Rome. Let the rest be done as [was described] for the hour-lines —

to be described from noon or from midnight, as was said in Proposition 1 of this book; and the meridian circles will be drawn — namely, their common sections with the plane of the dial, onto which the shadow of the style is cast (by Proposition 11 of the preceding book) when the Sun occupies the said meridians. Therefore we have described the meridians, or the circles of longitude, etc. Which was to be done.

Diagram. A large circle (the divided circle described from E, understood as lying in the plane of the equator) with a system of straight meridian lines drawn as diameters through its center and prolonged well beyond the circumference to left and right, plus two dashed conical figures (the projections of the equator and of the meridian through the Fortunate Isles). The vertical meridian line runs down the middle to the foot of the figure. Each straight meridian line is labelled at both of its ends with two longitude values 180° apart (successive lines spaced 15° apart), and the circumference carries the same longitude degree-marks.

Readable labels (with position):

- H — on the central vertical line, upper (near the style/pole region)
- D — on the central vertical line, just below H
- I — on the central vertical line, below D
- C — upper-left on the circumference, at the 180 mark
- B — foot of the meridian line, bottom center
- A — bottom, just to the right of B (the point from which the Fortunate-Isles meridian and longitude-count begin)
- M — lower-left region (end of a meridian line)
- N — lower-right region (end of a meridian line)
- K, L, T — inner lower-center points on the meridian/equinoctial construction
- "ROMA" (Rome) — inside the circle, lower center
- "INS. FORTVN." (Insulae Fortunatae — the Fortunate/Canary Isles) — inside the circle, lower center, on a dashed line
- "Aequinoctialis" — along a line running down-right from the center (the equinoctial line)
- Circumference / meridian-end degree labels read: 180 (at C), 195, 210, 240, 270 across the top; 300, 315, 330 down the left; 135, 105 down the right,

with one worn number at the right-middle end of the horizontal line reading like "170" [?] (this meridian is the one opposite 300, i.e. longitude 120); 345 at the lower left; and the inner arc at the bottom marked 15, 30, 45, 60, 75, 90 (with 90 repeated on each side toward the foot).

SCHOLIVM.

[Margin: Note what is said here.]

For if the longitude of the place is the arc BAC — say, for example, 216 degrees — so that the division of the circle described from E takes its beginning at point C, and point A is therefore distant from it by a semicircle, that is, by 180 degrees, then KL will be the straight line which in our example gives the beginning of the longitudes, namely longitude 180 degrees: that is, the common section of the plane of the dial and of the semicircle of the same meridian, the one that is opposite to the semicircle passing through the Fortunate Isles. For the Sun, when it is on this line, casts the shadow of the style through the center of the world onto the straight line KL, etc., since the semicircle of the equator MBN is above the horizon while the rest is below it; and so, when the Sun is on the equator at point A (which then marks the meridian semicircle of 180 degrees, the one opposite the semicircle of the Fortunate Isles passing through C), the ray AE falls on the plane of the dial at point L, etc. These matters are clearer than daylight from what we wrote in the scholium to Proposition 1 of this book — namely, that any line on the dial which cuts the equinoctial line represents that celestial semicircle whose common section, on the circle described from E through the center E, passes before it meets the equinoctial line, of which kind is the section AE, etc.

By the same reasoning, the line which in our same example gives longitude 15 degrees will be longitude 195 degrees, etc.; for the numbering of the degrees on the circle will then be taken from point C and will proceed toward N, just as before it began from point A and proceeded through B, C, and N — that is, through the eastern parts, as the reasoning requires.

[Margin: By means of the meridians drawn on the dial we learn for which peoples it is noon at any given time, and what hour it is in any place whose longitude is known.]

Moreover, the use of the meridian circles is most elegant. For by them we learn, quicker than can be told, for which peoples it is noon at any moment of time, and what hour it is in any city whose longitude is not unknown. For when the shadow of the gnomon falls precisely on some meridian line — since all the lines going out from H are the various meridian lines of various cities, being, as has been

shown, the common sections of the plane of the dial and of the meridian circles — it will be noon in all cities that have the longitude which the number attached to that meridian line indicates. For example: when the gnomon's shadow at any time of the year falls on the meridian line to which this number, 60, is attached, it becomes noon at Alexandria in Egypt, because the longitude of this city, as is established from Ptolemy's tables, is 60 degrees. And the same will happen in every other place or city whose longitude comprises the same number of degrees.

But suppose I want to know what hour it then is anywhere among the nations — for instance, in the Fortunate Isles. I subtract the longitude of the Fortunate Isles, which is 0 degrees (for from there the beginning of all longitudes is taken), from the longitude of that meridian on whose line the shadow then falls, namely from 60 degrees, and 60 degrees remain. These degrees I convert into hours, assigning to every fifteen degrees a single hour and to each single degree four minutes of an hour — or else, much more quickly, by means of the table which we set down in our commentary on the *Sphere* when we were treating of the equator; and I obtain 4 hours. And since the Sun has not yet then reached the meridian of the Fortunate Isles — because their meridian line on the dial is further to the east than the meridian line of 60 degrees — the Sun will therefore be 4 hours before the noon of those isles; and accordingly it will then be the eighth hour after midnight there.

Similarly, if one wishes to know what hour it then is in a region whose longitude comprises 300 degrees: I take 300 degrees from 60 degrees, having first, in the manner of astronomers, added a whole circle of 360 degrees, so that they become 420 degrees, and 120 degrees remain, which make 8 hours. By that many hours, then, is the Sun distant before the noon of that place, and therefore those peoples will then have the fourth hour after midnight. Again, I wish to know the same in that place where the longitude is 110 degrees, such as is roughly Calicut in eastern India. I take 110 degrees from 60 degrees — a whole circle having first been added — and 310 degrees remain, which comprise 20 hours 40 minutes; and by that many hours it falls short of noon in that place. And since from noon to noon 24 hours flow by, it must be that 3 hours 20 minutes have then elapsed since the last preceding noon. By the same reasoning, if the hour is sought in that place where the longitude contains 240 degrees: subtracting 240 degrees from 60 degrees (a whole circle of 360 degrees having first been added, so that they become 420), 180 degrees remain, which contain 12 hours. I shall therefore say that the Sun is distant from the noon of the said place by 12 hours, and accordingly that it is then midnight there. Finally, if the same is desired in a region of longitude 10 degrees, such as Toledo in Spain roughly has:

I take 10 degrees from 60 degrees, and 50 degrees remain, which give 3 hours 20 minutes. By that many hours, then, the Sun is distant before the noon of Toledo. Hence at that time the inhabitants of the said city will have 8 hours 40 minutes after midnight. The same judgment is to be made about the rest.

We shall also obtain the same result, and perhaps more conveniently, in this way. If the longitude of the meridian on whose line the shadow falls at the time of observation is less than the longitude of that place for which the hour is sought, let the lesser longitude be subtracted from the greater. For the remaining degrees, converted into hours, will give the time elapsed since the noon of the said place. Hence if the hours turn out to be fewer than 12, they will be reckoned as hours after noon; but if they are exactly 12, it will be exactly 12 hours after noon, that is, the time of midnight; and finally, if they are more than 12, then, when 12 have been taken from them, the hours remaining will be hours after midnight. But if the longitude of the meridian on whose line the shadow falls is greater than the longitude of the other proposed place, then, when the lesser longitude is subtracted from the greater, the degrees left over — reduced to hours — will give the time before the noon of the said place. Hence if they are fewer than 12, then, subtracting them from 12, the hours remaining will be after midnight; but if they are exactly 12, it will be altogether 12 hours before noon, that is, the time of midnight; and finally, if they are more than 12, then, subtracting them from 24, the hours remaining will be hours elapsed since noon.

Example. Let the tip of the style's shadow again, at any time of the year, fall on the meridian line of 60 degrees — which is indeed the longitude of the city of Alexandria in Egypt — and suppose it is worth knowing what hour it then is in that place whose longitude comprises 300 degrees. I subtract the lesser longitude from the greater, namely 60 from 300, and the remaining 240 degrees I reduce to 16 hours, which have elapsed since the noon of that place. Hence the fourth hour after midnight is then at hand. Again, let the same be investigated in a city of longitude 240 degrees. When 60 degrees are subtracted from 240 degrees, 180 degrees remain, which make 12 hours elapsed since noon. It is therefore then exactly the time of midnight. Further, suppose someone wishes to know the same in that place which lies 110 degrees distant from the Fortunate Isles toward the east — such as Calicut, the trading center of eastern India. When 60 degrees are subtracted from 110 degrees, the remaining degrees become 50, which show 3 hours 20 minutes passed after noon. Finally, if we should choose to learn the same in a place having longitude 10 degrees, we shall subtract 10 degrees from 60 degrees. For the remaining 50 degrees will give 3 hours 20 minutes before the noon of that place — that is, 8 hours 40 minutes after midnight, etc.

PROBLEMA 7. PROPOS. 7.

To describe on the same horizontal dial the parallels of cities, that is, the circles of latitude.

[Margin: The description of the parallels of cities, or of the circles of latitude, on the same dial.]

The description of these does not differ from the description of the parallels of the Zodiac which we handed down in Proposition 2 of this book, since both these and those are equidistant from the equator — provided only that, in place of the declinations of the signs which we there employed, we here assume the declinations of the parallels drawn through the zeniths of cities, namely the latitudes of the cities themselves. Indeed, the parallels of the signs described above are themselves also circles of latitude of cities: for instance, the tropic of Cancer [tropicus ☌] is the circle of latitude of those cities which lie 23 degrees 30 minutes to the north of the equator, such as Syene, a city of Egypt, etc. Therefore we have described the parallels of cities, etc. Which was to be done.

SCHOLIVM.

[Margin: The parallels of cities, or circles of latitude, drawn on the dial indicate which peoples have the Sun at the zenith of their head at the time of noon.]

The circles of latitude, or parallels of cities, bring us this usefulness: that by their help we may understand which peoples have the Sun at the zenith of their head at the time of noon. For when the shadow of the gnomon falls on some one of these parallels, on that day the Sun will pass through the zenith of all places distant from the equator by as many degrees toward the same side — whether north or south (according as that parallel has been taken on the dial among the northern or the southern parallels) — as are comprised in the declination of that parallel. For example, if the shadow of the style falls on the parallel whose declination comprises 20 degrees, the Sun will pass through the zenith of every city whose latitude is 20 degrees, whether toward the north or toward the south, according as that parallel likewise inclines to the north or the south on the dial. So too, when the shadow of the style runs along the parallel of Cancer [☌], whose declination is northern and is 23 degrees 30 minutes, the Sun at noon will reach the zenith, or vertex, of Syene, a city of Egypt, because its latitude too is northern and comprises 23 degrees 30 minutes. And so on for the rest.

PROBLEMA 8. PROPOS. 8.

To describe on the same horizontal dial the celestial houses — that is, the common sections of the plane of the dial and of the circles of position, which are drawn through the beginnings, or through any parts whatever, of the celestial houses.

[Margin: The description of the celestial houses on the same horizontal dial, according to Johannes Regiomontanus.]

According to the teaching of Johannes Regiomontanus — who teaches that the circles of the celestial houses (which are indeed among the number of the circles that they call "of position") cut the equator into 12 equal parts and pass through the common sections of the horizon and the meridian — we shall describe the celestial houses on the horizontal dial in this way. Let the circle already so often described from E be divided into 360 equal parts, the beginning being made from the meridian line. We have divided it into 12 parts, so that each consists of 30 degrees and constitutes one house. Then through the center, and through the division-points, let straight lines be drawn cutting the equinoctial line at points, through which, if straight lines are drawn equidistant from the meridian line itself — which is easily done if the straight line CD is drawn parallel to the equinoctial line, cutting the meridian line at B, and all the points of the equinoctial line, taken off with the compass from I, are transferred onto the line CD from point B; for in this way the straight lines joining each pair of points equally distant from I and B will be parallel [Margin: a. By Proposition 33 of the First book (of Euclid).] — the celestial houses will be described according to Johannes Regiomontanus. This can be shown as follows.

[Margin: Demonstration of the description of the celestial houses according to Johannes Regiomontanus.]

Since, according to Johannes Regiomontanus, the circles of the celestial houses pass through the common sections of the meridian and the horizon, and divide the equator into equal parts — the beginning being made from the meridian circle, which is the beginning of the tenth celestial house, which the eleventh and twelfth houses follow toward the east; while the first house begins from the horizon itself

on the eastern side, and lies wholly below the horizon; and the remaining houses in turn are placed in the same order below the horizon up to the beginning of the seventh house, each house being assigned 30 degrees — it comes about that the

straight lines drawn through the division-points and the center of the circle described from E are the common sections of the equator and of the circles of the celestial houses. For if the said circle described from E is understood to be revolved about the equinoctial line until it is set in the plane of the equinoctial circle, and so its center falls at the center of the world, then the plane of the said circle of the celestial houses will be drawn through those division-points and the center of the world E. Therefore the circles of the celestial houses will meet the equinoctial line of the dial at the points where the aforesaid straight lines cut it; and so through these same points of the equinoctial line will pass the common sections of the said circles and of the plane of the dial. Since, then, by Proposition 18 of the preceding book, these common sections are parallel to one another — indeed, are equidistant from the common section of all the circles of the celestial houses, as is evident from the demonstration of the said Proposition 18 of the preceding book —

Diagram. A horizontal-dial construction for the celestial houses, laid out symmetrically about a central vertical meridian line. A long horizontal line KL runs across the figure (K at the left end, L at the right end), crossed at its center by the vertical meridian line. Below the horizontal line stand two concentric/overlapping circles about the lower center (the house-circle described from F and the equinoctial circle from E), and two dashed conical figures open outward to the upper-left/lower-right and upper-right/lower-left corners (the circles of position). The house-boundary hour-lines are labelled with Roman numerals; the base line at the very bottom (CD) carries points C, B, D.

Readable labels (with position):

- F — upper center, apex of the house circle
- G — just below F (the place of the style on the meridian line)
- K — left end of the horizontal line; L — right end
- M, N, I, P, O — the central row of points along the horizontal/equinoctial construction, left to right
- E — center of the lower circle; A — foot of the lower circle, bottom center
- B — bottom center, on the base line; C — bottom-left end of the base line; D — bottom-right end
- Roman numerals for house/hour boundaries: VIII and XII flanking F in the upper zone; IX, X, XI within the lower circle (X at its foot near A); VII and XII in the lower zone
- Degree marks 10 and 20 appear at the upper-left and upper-right (near the tops of the cones) and again at the lower-left and lower-right

- Four small worn symbols sit at the four cone-ends (upper-left, upper-right, lower-left, lower-right) — apparently astronomical/zodiac sorts marking the circles of position [?]; a short worn cluster near G reads like "XXX" [?]

[Margin: a. From (Euclid) I.36 — whence.] [Margin: b. From (Euclid) XI.9 — whence.]

(because the plane of the dial is equidistant from the common section of the said circles); and, moreover, the meridian line is parallel to that common section of the circles of the celestial houses [a], since the meridian line and that section are the sections of parallel planes — namely of the horizon and of the plane of the dial — made by the meridian. Therefore the common sections of the circles of the celestial houses and of the plane of the dial will likewise be equidistant from the meridian line itself [b]. And so those straight lines which have been drawn through the points of the equinoctial line equidistant from the meridian line will be the common sections of the circles of the celestial houses and of the plane of the dial — onto which, that is, the shadow of the style falls (by the corollary of Proposition 12 of the preceding book) when the Sun is in the aforesaid circles of the celestial houses.

[Margin: The description of the celestial houses on the same horizontal dial, according to Campanus.]

But according to the opinion of Campanus — who prescribes that the circles of the celestial houses ought to be drawn through the common sections of the meridian and horizon in such a way that they divide the vertical circle, and not the equator (as Johannes Regiomontanus would have it), into 12 equal parts — we shall lay out the celestial houses in this way. On the meridian line, from G, the place of the style, let there be taken — whether upward or downward — a straight line equal to the style, up to point F; and from F let a circle of any magnitude be described and cut into 12 equal parts, for the twelve celestial houses, the beginning being made from the meridian line. Then through the center F and through the division-points let straight lines be drawn cutting the straight line KL (which is drawn for this sole purpose through the place of the style, perpendicular to the meridian line — or, what is the same, parallel to the equinoctial line — so that it can be cut by the said straight lines) at points through which, if straight lines are drawn equidistant from the meridian line itself, the circles of the celestial houses will be described according to the teaching of Campanus. Take this as the demonstration of the matter.

[Margin: Demonstration of the description of the celestial houses according to Campanus.]

If the said circle described from F is understood to be moved about the straight line KL until it lies in the plane of the vertical circle — that is, is at right angles to the plane of the dial, and its center is the same as the center of the world, or the vertex of the gnomon — then the straight lines drawn out through the center F and the division-points will be the common sections of the circles of the celestial houses and of the vertical circle, and therefore of any other circle whatever that is described in its plane from the center of the world, such as is the said circle described from F. For this circle and the vertical circle properly so called are cut into similar parts by the straight lines going out from the center F, as we demonstrated at the end of Chapter 1 of the *Sphere*. For this reason the circles of the celestial houses will meet the line KL at the points where the aforesaid straight lines cut it; and accordingly through these same points of the line KL will pass the common sections of the said circles and of the plane of the dial. Since, then, these sections are parallel to one another, and to the common section of the same circles, and so also to the meridian line itself — as was shown in the previous construction — those straight lines which have been drawn through the said points of the line KL equidistant from the meridian line will be the common sections of the circles of the celestial houses and of the plane of the dial. Therefore we have described the celestial houses — that is, the common sections, etc. — on the same horizontal dial. Which was to be done.

COROLLARIVM.

[Margin: Through which hours a celestial house passes on the equinoctial line, according to Johannes Regiomontanus.]

Moreover, it is evident that the beginnings of the celestial houses, according to Johannes Regiomontanus, pass through those points of the equinoctial line on the dial through which are drawn the hour-lines distant from the meridian line by two and by four hours — such as are the second and fourth hours after noon, passing through the points N and M; likewise the 8th and 10th after midnight, passing through O and P — because such hours on the equator are distant from the meridian circle by 30 and 60 degrees.

just as also the beginnings of the celestial houses. Hence, if through the said hours lines are drawn on the equinoctial line parallel to the meridian line itself, these will give the beginnings of the celestial houses, according to the teaching of

Johannes Regiomontanus [Regiomontanus], and so forth. And this indeed must be understood not only in the horizontal dial, but also in all others.

SCHOLIVM.

[Margin: The lines of the celestial houses indicate the beginnings of the celestial houses, but the hour-lines signify the ends, or limits, of the hours.]

But the lines of the celestial houses do not indicate the celestial houses in the same way that the hour-lines indicate the hours. For the hour-lines signify the ends of the hours: when the gnomon's shadow falls upon some hour-line, it warns us that the hour to which that line belongs has passed, and that the next one is beginning. The house-lines, by contrast, show us the beginnings of the houses, not their ends: when the style's shadow falls upon one of the said lines, it shows that the Sun is in that circle of position which is the beginning of the celestial house indicated by the number written against it. The reason for this is that the Sun reaches the end of any house before it reaches the beginning. For the celestial houses are numbered from west to east, whereas the Sun is carried from east to west by the motion of the *primum mobile* [*primum mobile*]. Hence the Sun first reaches the end of each house, then its middle, and last of all its beginning. With the hours it is otherwise, because the hour-circles too are reckoned from east to west. Therefore, just as the style's shadow falling on some hour-line teaches that that hour has passed, and that the Sun has moved from the beginning of that hour to its end, so the same shadow, reaching some celestial house, shows that the Sun has already been carried through that whole house — namely from its end to its beginning. In our example, since neither the beginning of the 7th house nor the end of the 12th can be drawn on the horizontal dial, we have marked their thirds — that is, we have drawn lines passing through their 10th and 20th degrees.

[Margin: From the lines of the celestial houses drawn on the dial, we perceive in which house the Sun is.]

The purpose of the house-lines on the dial is that from the gnomon's shadow we may grasp in which celestial house the Sun is lingering. For when, say, the style's shadow falls on the line marked with the ninth house, we shall be certain that the Sun is then at the beginning of the ninth house and at the end of the eighth; so that throughout the whole time in which the style's shadow has run from west to east across the space lying between the line of the ninth house and the line of the tenth, the Sun has been staying in the ninth house, having moved from its end to its beginning. And so with the rest.

We have described the celestial houses only according to Johannes Regiomontanus and Campanus [Campanus of Novara], and not according to others, because the use of the celestial houses as these authors establish them in the heavens is found more frequently among astronomers.

PROBLEMA 9. PROPOS. 9.

To describe the ascending signs of the zodiac on the same horizontal dial.

[Margin: What must be sought before the ascending signs are described.]

When the Sun is at the beginning of Aries, let it be asked at what hour before or after noon the beginnings of the twelve signs rise, for the proposed latitude of the place, starting from the beginning of Aries. Then, with the Sun at the beginning of Libra, let the same be investigated for the beginnings of the twelve signs, starting from the beginning of Libra. Again, with the Sun remaining at the beginning of Cancer, let the same be examined for the beginnings of the same twelve signs, starting from the first point of Cancer. Finally, with the Sun staying at the beginning of Capricorn, let the same be inquired for the beginnings of the twelve signs, starting from the first point of Capricorn.

[Margin: By what method the hour is to be investigated at which any sign of the zodiac begins to ascend above the horizon.]

This hour will easily be found from the oblique ascension [ascensio obliqua] of that arc of the ecliptic which is intercepted between the beginning of Aries, or Libra, or Cancer, or Capricorn, and the proposed ascending sign. For if such an oblique ascension is reduced to hours, and (when the oblique ascension is less than the semidiurnal arc [arcus semidiurnus]) these hours are subtracted from the semidiurnal arc, there will remain the hours that are left until noon at the moment when that sign — whose oblique ascension was taken — begins to rise above the horizon. Or, conversely, if the semidiurnal arc is subtracted from the said hours (namely when the oblique ascension exceeds the semidiurnal arc), what remains will be the hours elapsed after noon when the beginning of that sign, whose oblique ascension was taken, rises.

[Margin: Example.]

Example. When the Sun is at the beginning of Aries, the semidiurnal arc contains 6 hours; and it is asked at what hour the beginning of Cancer rises above the Roman horizon — that is, for an elevation of 42 degrees. The arc between the beginning of Aries and the first degree of Cancer has an oblique ascension of 66 degrees 57 minutes (as is clear from the tables of oblique ascensions in the

Tabulae directionum of Johannes Regiomontanus, or in our commentaries on the *Sphere* — though we shall also teach, at the end of the scholium of this proposition, how to find these ascensions from the doctrine of sines), which, reduced to hours, contains 4 hours 28 minutes. These, subtracted from 6 hours — that is, from the semidiurnal arc — leave 1 hour 32 minutes before noon. Therefore at this hour the beginning of Cancer rises above the horizon, with the Sun at the beginning of Aries; and this corresponds to 10 hours 28 minutes after midnight.

Again, with the Sun occupying the beginning of Cancer, the semidiurnal arc for an elevation of 42 degrees comprises 7 hours 32 minutes; and it is asked at what hour the beginning of Sagittarius rises above the horizon. The oblique ascension of the arc lying between the beginning of Cancer and the first degree of Sagittarius contains 190 degrees 12 minutes, which, converted into hours, makes 12 hours 41 minutes; and if the semidiurnal arc of 7 hours 32 minutes is taken from these, there remains 5 hours 9 minutes after noon, at which the beginning of Sagittarius then emerges above the horizon. And so with the rest.

By this method we have composed the following four little tables, in which are contained the hours at which the beginnings of the signs rise in the Roman horizon of 42 degrees.

I. Sole existente in principio ♈. (When the Sun is at the beginning of Aries.)

Sign	Before / after noon	M	
		H.	.
♈ Aries	Before noon	6	0
♉ Taurus	Before noon	4	51
♊ Gemini	Before noon	3	26
♋ Cancer	Before noon	1	32
♌ Leo	After noon	0	51
♍ Virgo	After noon	3	26
♎ Libra	After noon	6	0
♏ Scorpio	After noon	8	34
♐ Sagittarius	After noon	11	9
♑ Capricorn	Before noon	10	28
♒ Aquarius	Before noon	8	34
♓ Pisces	Before noon	7	9

II. Sole existente in principio ♎. (When the Sun is at the beginning of Libra.)

Sign	Before / after noon	M	
		H.	.
♎ Libra	Before noon	6	0
♏ Scorpio	Before noon	3	26
♐ Sagittarius	Before noon	0	51
♑ Capricorn	After noon	1	32
♒ Aquarius	After noon	3	26
♓ Pisces	After noon	4	51
♈ Aries	After noon	6	0
♉ Taurus	After noon	7	9
♊ Gemini	After noon	8	34
♋ Cancer	After noon	10	28
♌ Leo	Before noon	11	9
♍ Virgo	Before noon	8	34

III. Sole existente in principio ♋. (When the Sun is at the beginning of Cancer.)

Sign	Before / after noon	M	
		H.	.
♋ Cancer	Before noon	7	3
			2
♌ Leo	Before noon	5	9
♍ Virgo	Before noon	2	3
			4
♎ Libra	Before or after noon	0	0
♏ Scorpio	After noon	2	3
			4
♐ Sagittarius	After noon	5	9
♑ Capricorn	After noon	7	3
			2
♒ Aquarius	After noon	9	2
			6
♓ Pisces	After noon	1	5
		0	1

Sign	Before / after noon	H.	M
♈ Aries	After or before noon	1	0
		2	
♉ Taurus	Before noon	1	5
		0	0
♊ Gemini	Before noon	8	2
			0

IV. Sole existente in principio ♐. (When the Sun is at the beginning of Capricorn.)

Sign	Before / after noon	H.	M
♐ Capricorn	Before noon	4	2
			8
♑ Aquarius	Before noon	2	3
			4
♒ Pisces	Before noon	1	1
			0
♈ Aries	Before or after noon	0	0
♉ Taurus	After noon	1	1
			0
♊ Gemini	After noon	2	3
			4
♋ Cancer	After noon	4	2
			8
♌ Leo	After noon	6	5
			1
♍ Virgo	After noon	9	2
			6
♎ Libra	After or before noon	1	0
		2	
♏ Scorpio	Before noon	9	2
			6
♐ Sagittarius	Before noon	6	5
			1

[Margin: Description of the ascending signs on the same horizontal dial.]

From these tables we shall describe the ascending signs in the following way — that is, the common sections [communis sectio] of the plane of the dial and of the ecliptic at the time when the beginnings of the signs rise above the horizon. For upon these common sections, which the plane of the dial makes with the ecliptic as the latter takes its various positions in the diurnal motion, the gnomon's shadow falls, by Proposition 11 of the preceding book, whenever the Sun is at any point of the ecliptic above the horizon, while the ecliptic holds those positions which the aforesaid common sections represent — that is, while the beginnings of the signs emerge above the horizon.

Let the hour be reckoned at which the beginning of Taurus rises, with the Sun at the beginning of Aries, taken from the first table: namely 4 hours 51 minutes, laid off from A to B (since the beginning of Taurus then rises before noon, and the semicircle of the equator from A toward B is the eastern one, as is evident if the circle described from E is understood — that is, the equator — in its proper position). From B, through the center E, let a hidden construction-line be drawn cutting the equinoctial line at C. For the point C will be that upon which the style's shadow falls at the said hour when the beginning of Taurus rises; and so through C will pass the common section of the plane of the dial and of the ecliptic at that time.

Diagram. A large "hourglass" (bowtie) construction superimposed on a circle, occupying the lower half of the page; the explanatory legend continues in the running prose above and below it.

- The central circle is the equator, described from center **E** (the vertex of the gnomon / center of the world).
- **E** (center of the circle): center of the equator; construction-lines drawn from the rails pass through E.
- A vertical meridian line runs top-to-bottom through the figure, marked **12** at the top (noon) and **12** in the lower half (midnight), descending to **A** at the very foot.
- **H** (top of the circle, on the meridian line): the center of the dial [centro horologii], from which straight lines are sent to the tropic points.
- A horizontal dotted line (the equinoctial / six-o'clock line) crosses through the upper region and meets each side-rail at a point marked **6** (left) and **6** (right).

- **B** (left, where a rail-line meets the equator): the point from which the line B–E–C is drawn.
- **C** (right of center, on the equinoctial line): intersection giving the ascending-sign point for Taurus.
- **D** (lower right, outside the circle, joined to E by a dotted line): the western-equator point used for the Sun-in-Capricorn construction.
- **K** (near the center, below E): the point on the tropic of Capricorn where the line from H cuts it.
- Two vertical side-rails (far left and far right) carry the twelve zodiacal sign-glyphs — the ascending-/descending-sign lines of the dial, the eastern signs on one rail and the western on the other; numerous straight lines run from the rails inward, converging near the center to form the bowtie. The individual peripheral sign-glyphs on the rails are too small to resolve with confidence — [?]

Its explanatory legend, running below the figure: the semicircle of the equator from A toward B is the eastern one, as is evident if the circle described from E is understood — that is, the equator — in its proper position; and from B, through the center E, let a hidden line be drawn cutting the equinoctial line at C. For the point C will be that upon which the style's shadow falls at the said hour when the beginning of Taurus rises; and so through C —

Next, from the fourth table let the hour be taken at which the same beginning of Taurus rises with the Sun at the beginning of Capricorn: namely 1 hour 10 minutes, which is to be laid off from A to D, the western part of the equator (since the beginning of Taurus then rises after noon); and from D, through E, let a straight line be drawn cutting the equinoctial line at F, through which, from H, the center of the dial, let a straight line be sent out cutting the tropic of Capricorn at K. For from what was demonstrated in the first proposition of this book, the point K will be that upon which the style's shadow falls at that hour when the beginning of Taurus rises with the Sun at the beginning of Capricorn; and so through K also will pass the common section of the plane of the dial and of the ecliptic at that time. Therefore the straight line drawn through the points C and K will be the common section of the plane of the dial and of the ecliptic at the time when the beginning of Taurus rises above the horizon, and upon which the gnomon's shadow then falls, by Proposition 11 of the earlier book, when the Sun is above the horizon at any point of the ecliptic. Therefore the straight line CK will give the ascending sign Taurus.

In the same way we shall describe the remaining ascending signs, taking each sign together with its hours from two tables (first from one of the two earlier tables, and second from one of the later ones), so that two points may be found — one on the equinoctial line, and the other on one or the other tropic — through which the common section of the ecliptic and the plane of the dial passes, and so forth.

However, from neither of the two former tables are the hours of those signs to be taken, on the horizontal dial, which rise six hours or more before or after noon. For those hours do not fall on the equinoctial line, as is plain. Therefore from each of these two tables one must take, on the horizontal dial, only the first five signs that follow next — such as are Taurus, Gemini, Cancer, Leo, Virgo, Scorpio, Sagittarius, Capricorn, Aquarius, and Pisces. Again, from neither of the two latter tables are the hours of those signs to be taken, on the same horizontal dial, which rise as many hours after or before noon as are contained in the semidiurnal arc of Cancer or of Capricorn, or more; for those hours do not cut the tropics, as is evident. Hence from the third table one takes only the hours of the first five signs, and likewise from the fourth, leaving out the first sign in each table: such are these signs — Leo, Virgo, Libra, Scorpio, Sagittarius, Aquarius, Pisces, Aries, Taurus, and Gemini. Nor for that reason are the remaining latter six signs of these tables to be judged superfluous, since their use in the other dials that follow — such as in both meridian dials, and in declining and inclining ones — is altogether necessary, as will become clear from what follows.

[Margin: Description of the ascending signs Aries and Libra.]

But the lines of Aries and Libra will be described thus. Since, when the beginning of Aries ascends while the Sun is at the beginning of Capricorn, it is virtually noon — as is clear from the fourth table — it is evident that the common section of the plane of the dial and of the ecliptic then passes through that point of the tropic of Capricorn through which the meridian line is drawn. And since at that time the equator, the circle of the sixth hour from noon or from midnight, the ecliptic, and the horizon all have the same common section — as is clear from a material sphere — and the plane of the dial is equidistant from it, being parallel to the horizon, then (by Proposition 18 of the earlier book) the equinoctial line, the line of the sixth hour from noon or from midnight, and the common section of the ecliptic and the plane of the dial will all be parallel. Therefore a straight line drawn parallel to the equinoctial line — or to the very line of the sixth hour — through the point at which the meridian line cuts the tropic of Capricorn will give the ascending sign Aries. And by the same reasoning, the straight line drawn

parallel to the equinoctial line through the point at which the meridian line cuts the tropic of Cancer will give the ascending sign Libra; since this sign too rises at noon when the Sun is at the beginning of Cancer, as is manifest from the third table, and so forth.

[Margin: Description of the ascending signs Cancer and Capricorn.]

Finally, the lines of Cancer and Capricorn can be described in this way. Since, when the beginning of Cancer ascends while the Sun is at the beginning of Capricorn, it is 4 hours 28 minutes after noon — as appears from the fourth table — that is, the Sun (or the beginning of Capricorn) then sets, the ecliptic and the circle of the 4-hour-28-minute line from noon will cut the horizon at the same point of setting; and so the ecliptic, that hour-circle, and the horizon will have the same common section. Therefore, since the plane of the dial is equidistant from the horizon — and hence from that common section — the line of 4 hours 28 minutes from noon and the common section of the ecliptic at that time and of the plane of the dial will be parallel, by Proposition 18 of the preceding book. If, then, the line of 4 hours 28 minutes from noon is drawn, and through the point found on the equinoctial line (through which the line of Cancer must be drawn) a parallel to it is drawn, this will give the ascending sign Cancer. And in the same way we shall draw the line of ascending Capricorn.

Indeed, by this same demonstration we shall conclude that the line of any ascending sign on the horizontal dial is equidistant from that hour-line — from noon or from midnight — which indicates the time of setting of the opposite sign: namely, that the line of Scorpio is equidistant from the line of 6 hours 42 minutes from noon or from midnight, the hour at which the beginning of Taurus, the opposite sign, sets. For the semidiurnal arc of Taurus contains just so many hours. The reason is that the ecliptic at that time, and the circle of that hour, and the horizon, have the same common section, as is plain, and so forth. And so, if the semidiurnal arcs of all the signs are taken, as in this table, we shall easily know from which hour-lines — from noon or from midnight — the lines of the ascending signs on the horizontal dial are equidistant, for the reason stated.

V. Arcus semidiurni in initiis signorum, ad latitudinem grad. 42. (Semidiurnal arcs at the beginnings of the signs, for latitude 42 degrees.)

Sign	H.	M.
♈ Aries	6	0
♉ Taurus	6	42
♊ Gemini	7	17

Sign	H.	M.
♋ Cancer	7	32
♌ Leo	7	17
♍ Virgo	6	42
♎ Libra	6	0
♏ Scorpio	5	18
♐ Sagittarius	4	43
♑ Capricorn	4	28
♒ Aquarius	4	43
♓ Pisces	5	18

For the lines of Aries and Libra are equidistant from the line of 6 hours 0 minutes from noon or from midnight. The lines of Taurus and Virgo are equidistant from the line of 5 hours 18 minutes. The lines of Gemini and Leo are equidistant from the line of 4 hours 43 minutes.[a] Hence pairs of them will also be equidistant from one another. But the line of Cancer is equidistant from the line of 4 hours 28 minutes. Finally, the line of Capricorn is equidistant from the line of 7 hours 32 minutes.

[Margin: a — Prop. 30 of the first book.]

[Margin: The lines of the ascending signs touch the tropics in any dial whatever.]

It must here, and in the dials that follow, be carefully noted that no line of the ascending signs can cut the tropics, but that all of them merely touch the tropics at those points through which they must be drawn, so that all the lines of the ascending signs are contained within the limits of the tropics. For just as the hour-lines from sunrise or sunset touch the conic sections of the two parallels — of which one is always the greatest of the apparent circles and the other the greatest of the hidden ones — at those points where the hour-lines from noon or midnight intersect the same conic sections, as we demonstrated in Proposition 14 of the preceding book: so too the common sections of the ecliptic and the plane of the dial, which arise from the various positions that the ecliptic takes in the diurnal motion, produce —

are produced, they will touch the conic sections of the tropics at those points where those same conic sections are cut by the hour-lines from noon or from midnight at which the ecliptic holds those positions. For the demonstration is the same in both cases.

We shall make this clear as follows. When, for example, the sign Taurus ascends and the Sun is at the beginning of Capricorn, the line of 1 hour 10 minutes after noon cuts the tropic of Capricorn on the dial at K. Therefore the circle of that hour, drawn through the poles of the world, will also cut the said circle of Capricorn in the heavens at the very point where the Sun, being there, sends its ray through the tip of the gnomon [stylus] to the point K. Now since the ecliptic touches the circle of Capricorn in the heavens at the beginning of Capricorn, where the Sun is placed, it must at that time touch the said circle of Capricorn at that same point where it is cut by the aforesaid hour-circle, since the Sun's ray then falls upon the point K. Therefore, at the point where the tropic of Capricorn is then cut on the dial by the line of 1 hour 10 minutes after noon — that is, at K — the common section of the ecliptic and the plane of the dial will touch that same tropic of Capricorn, as is clear from Propositions 13 and 14 of the preceding book.

For the circle of that hour of 1 hour 10 minutes after noon and the ecliptic then stand in the same mutual relation — the former cutting the conic surface of Capricorn along a straight line, the latter touching that same surface along the same line — as any hour-circle from noon or from midnight that cuts along a straight line the conic surface of the greatest of the ever-apparent [circumpolar] parallels stands to the hour-circle from sunrise or sunset that touches the same conic surface along that same straight line. This is clear if one rightly considers the position of the ecliptic and of the said hour-circle of 1 hour 10 minutes while the beginning of Taurus ascends and the Sun is at the beginning of Capricorn. For the colure of the solstices then performs the office of that hour-circle, cutting the tropic of Capricorn at the point where the ecliptic touches that same tropic — namely, at the beginning of Capricorn. This can be understood, clearer than daylight, from a solid [material] sphere. And the same reasoning holds for the other ascending signs, when the Sun is at the beginning of Capricorn or of Cancer.

[Margin: By what method the ascending signs may be described on the dial through the doctrine of the conics of Apollonius.]

From this another method of describing the ascending signs is gathered. For if, from the points of the tropics found by means of the third and fourth tables, straight lines are drawn tangent to the tropics themselves — according to what we wrote in the corollary to Proposition 37 of Book 1 of Apollonius (which is indeed very easy here, since the ordinates from the said points of the tropics are perpendicular to the diameter) — the ascending signs will thereby have been described.

The ascending signs may also be described otherwise, in this way. First let the points of the ecliptic lying on the meridian circle be sought — that is, the mediations of heaven [midheaven points] when the beginnings of the zodiacal signs rise — together with the declinations of those same points.

[Margin: How the mediations of heaven, when the beginnings of the signs rise, are to be investigated.]

Then, with the same beginnings of the signs ascending, let the points of the ecliptic situated on the circle of the 6th hour from noon or from midnight be investigated, together with their declinations. We shall accomplish all this as follows.

From the oblique ascension of the beginning of any sign — which is to be taken either from the tables of oblique ascensions contained in the *Tables of Directions* of Johannes Regiomontanus [Regiomontanus], or in our own commentaries on the sphere, or else derived from the doctrine of sines, as we taught in Chapter 3 on the sphere and shall show at the end of the scholium of this proposition — let a quadrant of the circle, that is 90 degrees, be subtracted (a whole circle having first been added to the oblique ascension, if the subtraction cannot otherwise be made, as is customary in astronomical calculation). For the remaining number will be the right ascension of that point of the ecliptic which is then found on the meridian above the horizon, and which astronomers call the mediation of heaven [midheaven]. Therefore, from the table of right ascensions, or from the doctrine we shall deliver in the following scholium, that point of the ecliptic will become known, whose opposite point will lie on the same meridian below the horizon — which, with the astronomers, we may call the angle of the earth [imum caeli].

The demonstration of this operation is not difficult, if the positions of the horizon, the meridian, the zodiac, and the equator in the sphere are rightly conceived. For when the oblique ascension is greater than a quadrant, or equal to a quadrant, it is clear that, if the quadrant of the equator lying between the east and the meridian is subtracted from it, there remains the right ascension of the culminating point of the ecliptic — namely, the distance of the beginning of Aries from the meridian circle, following the order of the signs. But when the oblique ascension is less than a quadrant, it is likewise plainly established that, if the quadrant of the equator lying between the east and the meridian is taken from the whole circle and the oblique ascension is added to the remaining three quadrants (which comes to the same thing as subtracting a quadrant from the sum formed of the oblique ascension and a whole circle), the right ascension of the culminating point of the ecliptic is produced. In the right sphere too the same

operation applies, if in place of the oblique ascension of the ascending sign one takes the right ascension of the same.

[Margin: Example.]

Example. At latitude 42 degrees, which is about that of Rome, the oblique ascension of the beginning of Virgo is 141 degrees 33 minutes. If a quadrant — that is, 90 degrees — is subtracted from it, there remain 51 degrees 33 minutes for the right ascension of the culminating point of the ecliptic when the beginning of Virgo rises. To this right ascension there corresponds in the table of right ascensions — using, however, the proportional part, as is customary when the number is not exactly contained in some table — 23 degrees 57 minutes of Taurus. This point of the ecliptic, then, will at that time be found on the meridian above the horizon, while below the horizon on the same meridian there will be 23 degrees 57 minutes of Scorpio.

Again, the oblique ascension of the beginning of Cancer is 66 degrees 57 minutes. If a whole circle — that is, 360 degrees — is added to it, we get 426 degrees 57 minutes; and if 90 degrees are subtracted from these, there remain 336 degrees 57 minutes for the right ascension of the point of the ecliptic then culminating, when the beginning of Cancer rises above the horizon. To this right ascension there corresponds in the table of right ascensions 5 degrees 6 minutes of Pisces. Therefore this point will at that time lie on the meridian above the horizon, while the angle of the earth will be 5 degrees 6 minutes of Virgo.

Lastly, in the right sphere (to give an example of this too), the right ascension of Sagittarius comprises 237 degrees 48 minutes. Subtracting a quadrant from this, there remain 147 degrees 48 minutes for the right ascension of that point of the ecliptic which then culminates. To this ascension there answers 25 degrees 31 minutes of Leo; and this point will then lie on the meridian above the horizon, so that at the angle of the earth there will consequently be 25 degrees 31 minutes of Aquarius.

By this method we have composed the following table of the mediations of heaven and the angles of the earth, when the beginning of any zodiacal sign rises, for latitude 42 degrees; in which we have also entered the declinations of those same mediations and angles of the earth, found through the doctrine of sines, as we set forth in the corollary to Proposition 1 of the preceding book — although these same declinations can be elicited from the table of declinations, if account is taken of the proportional part. It is clear, moreover, that the declinations of the northern points of the ecliptic are northern, and those of the southern points

southern. From this you will easily judge which points' declination in the said table is boreal and which austral — which is indeed of great importance to know, in order that the ascending signs may be described.

VI. Mediationes coeli, & anguli terrae, eorumque declinationes, orientibus 12. signorum Zodiaci initiis, ad latitudinem grad. 42. (The mediations of heaven and the angles of the earth, and their declinations, when the beginnings of the 12 signs of the zodiac rise, for latitude 42 degrees.)

Ascending sign	Mediation of heaven	Angle of the earth	Declination
♈ Aries	0° 0' ♎	0° 0' ♎	23° 30'
♉ Taurus	15° 59' ♎	15° 59' ♎	22° 32'
♊ Gemini	6° 3' ♋	6° 3' ♋	18° 48'
♋ Cancer	5° 6' ♋	5° 6' ♋	9° 40'
♌ Leo	13° 59' ♈	13° 59' ♈	5° 32'
♍ Virgo	23° 57' ♉	23° 57' ♉	18° 48'
♎ Libra	0° 0' ♎	0° 0' ♎	23° 30'
♏ Scorpio	6° 3' ♋	6° 3' ♋	18° 48'
♐ Sagittarius	16° 1' ♋	16° 1' ♋	5° 32'
♑ Capricorn	24° 54' ♈	24° 54' ♈	9° 40'
♒ Aquarius	23° 57' ♉	23° 57' ♉	18° 48'
♓ Pisces	14° 1' ♋	14° 1' ♋	22° 32'

Again, since the oblique ascension of the beginning of any sign is the right ascension of that point of the ecliptic which then lies on the circle of the 6th hour from noon or from midnight, before the meridian — as is clear if one rightly considers the position of the circle of the 6th hour from noon or from midnight, which always passes through the points of true rising, that is, through the end of the oblique ascension, like a kind of right horizon — hence it comes about that the arc of the equator measuring the oblique ascension of a point set on the horizon also measures the right ascension of the point of the ecliptic located on the circle of the 6th hour at that time: the right ascension, I say, reckoned upon the circle of the 6th hour, as upon a kind of right horizon. Hence, from the table of right ascensions, that point of the ecliptic will become known. And it is evident that the opposite point of the ecliptic then lies on the same circle of the 6th hour after the meridian.

[Margin: By what method the points of the ecliptic situated on the circle of the 6th hour from noon or from midnight are found, when the beginnings of the signs rise. Example.]

Example. When the beginning of Cancer ascends, I find that its oblique ascension, at latitude 42 degrees, is 66 degrees 57 minutes. So great, then, is the right ascension of the point of the ecliptic that is then set on the said circle of the 6th hour before the meridian. This point, from the table of right ascensions, will be found to be 8 degrees 41 minutes of Gemini, account being taken of the proportional part; and consequently on the same circle after the meridian there will be 8 degrees 41 minutes of Sagittarius. In the right sphere this same point, rising above the horizon, is on the circle of the 6th hour from noon or from midnight, before the meridian, because there the said circle of the 6th hour from noon or from midnight is the same as the horizon.

By this method we have constructed the following table containing the points of the ecliptic situated on the circle of the 6th hour from noon or from midnight, while the beginnings of the signs rise, for latitude 42 degrees; in which are also placed the declinations of the points found, which we computed from the science of sines, as we taught in the corollary to Proposition 1 of the preceding book — although these same declinations can be gathered from the table of declinations, if account is taken of the proportional part.

VII. Puncta Eclipticae in circulo hor. 6. constituta, eorumq; declinationes, orientibus 12. signorum Zodiaci principiis, ad latitudinem gr. 42. (The points of the ecliptic situated on the circle of the 6th hour, and their declinations, when the beginnings of the 12 signs of the zodiac rise, for latitude 42 degrees.)

Ascending sign	Point on the 6-o'clock circle (ante-meridian)	Point (post-meridian)	Declination
♈ Aries	0° 0' ♈	0° 0' ♎	0° 0'
♉ Taurus	18° 49' ♈	18° 49' ♎	7° 23'
♊ Gemini	10° 53' ♉	10° 53' ♎	15° 8'
♋ Cancer	8° 41' ♊	8° 41' ♎	21° 48'
♌ Leo	11° 49' ♋	11° 49' ♎	22° 58'
♍ Virgo	19° 7' ♌	19° 7' ♎	15° 8'
♎ Libra	0° 0' ♍	0° 0' ♈	0° 0'

♐ Sagittarius	18° 11' ♏	18° 11' ♈	22° 58'

Ascending sign	Point on the 6-o'clock circle (ante-meridian)	Point (post-meridian)	Declination
♑ Capricorn	21° 19' ♑	21° 19' ♎	21° 48'
♒ Aquarius	19° 7' ♒	19° 7' ♋	15° 8'
♐ Pisces	11° 11' ♐	11° 11' ♉	7° 23'

[Margin: The description of the ascending signs on the dial by means of the mediations of heaven and of the points of the ecliptic situated on the circle of the 6th hour from noon or from midnight, while the beginnings of the signs rise.]

These things having been duly completed, we shall describe the ascending signs as follows. Let the declinations of the mediations of heaven be reckoned off — in the first figure of Proposition 2 of this book — from the point F of the diameter of the equator toward the north or the south, according as the points of the mediations of heaven are boreal or austral; and through the ends of these reckonings and the center D let straight lines be drawn as hidden [construction] lines, cutting the straight line OR at points whose intervals, taken from the point G — namely, from the place of the gnomon [stylus] — if they are transferred onto the meridian line of the dial from G, the place of the gnomon, will give on the meridian line the points through which the ascending signs are to be drawn: those signs, namely, whose mediations of heaven and declinations of the mediations of heaven have been taken.

The reason for this is as follows. If, for example, when the beginning of Cancer rises, there is found on the meridian 5 degrees 6 minutes of Pisces above the horizon, it follows that when the Sun is at 5 degrees 6 minutes of Pisces and occupies the meridian circle above the horizon, the beginning of Cancer rises. Since, then, at that time the shadow of the gnomon is cast onto that point of the meridian line which we found by the declination of 5 degrees 6 minutes of Pisces — namely, onto the conic section of the parallel of that declination, as is established from the corollary to Proposition 12 of the preceding book — the common section of the ecliptic and the plane of the dial will necessarily at that time pass through the same point; because the shadow of the gnomon, as we showed in Proposition 11 of the same preceding book, is always cast onto the common section of the plane of the dial and of the great circle in which the Sun is — which at that time is the zodiac [ecliptic]. And the same reasoning holds for the rest.

But the same points on the meridian line will also be found from the third figure of Proposition 2 of this book — namely, from the figure of the rays of the zodiac

— in this way. In the circle described from D, let the declinations be reckoned off from the radius of the equator, as before — namely, toward the radius of Cancer or of Capricorn, according as the points of the mediations of heaven are boreal or austral; and let the rays of those declinations be drawn as hidden lines from D, cutting the line HB — the line of the 12th hour — at points which, if taken from the point H onto the meridian line of the dial from the center of the dial H, will be found as points on the meridian line, as before.

Likewise, let the declinations of the boreal points of the ecliptic lying on the circle of the 6th hour from noon or from midnight, both before and after the meridian, be reckoned off — in the third figure of Proposition 2 of this book, that is, in the figure of the rays of the zodiac — on the arc of the circle described from D, from the radius of the equator toward the radius of Cancer. (For on the horizontal dial only the boreal declinations are to be taken, since these alone can fall on the line of the 6th hour, which lies wholly in the boreal part of the dial that the equinoctial line separates from the austral part.) And from D, through the ends of the reckonings, let the rays of those declinations be drawn as hidden lines, cutting the line of the 6th hour from noon or from midnight at points which, transferred from H onto the line of the 6th hour of the dial from the center H — whether before or after the meridian, as is clear from the preceding table — will give the points on the line of the 6th hour from noon or from midnight through which the ascending signs will pass; and this will be demonstrated in the same way. And so, if the corresponding points on the meridian line and on the line of the 6th hour from noon or from midnight are joined by straight lines, the ascending signs will be had, as before.

This method of describing the ascending signs seems more convenient and more reliable than the preceding one, because it does not require the arcs of the tropics — in the drawing of which an error can easily be committed — and because it offers, for each sign, two points: one on the meridian line and the other on the line of the 6th hour from noon or from midnight, so far apart from each other that the lines of the ascending signs can easily be drawn without error.

[Margin: This latter description is preferred to the former.]

Indeed, if from the points found on the meridian line straight lines are drawn tangent to the tropics — as we taught in the corollary to Proposition 37 of Book 1 of Apollonius (which will indeed be easy here, since the ordinate lines are perpendicular to the diameter) — the ascending signs will have been described in yet another way.

But since we have taught the finding of the points of the ecliptic on the circles of the 12th and 6th hour from noon or from midnight, what prevents us from teaching how the points of the ecliptic situated on the circles of the other hours as well, when the beginnings of the signs rise, may be found — especially since by their aid the ascending signs are described most conveniently on certain dials, just as we described these same signs a little earlier on the horizontal dial by the aid of the mediations of heaven and of the points of the ecliptic on the circle of the 6th hour from noon or from midnight?

[Margin: How the points of the ecliptic situated on any hour-circle from noon or from midnight are to be sought, when the beginnings of the signs rise.]

The general rule, then, will be this. From the oblique ascension of the beginning of any sign — or, what is the same, from the right ascension of that point of the ecliptic which, when that sign ascends, is found on the circle of the 6th hour before the meridian — let there be subtracted as many degrees of the equator as lie between the circle of the 6th hour before the meridian and the circle of the proposed hour, counting the said degrees (beginning from the circle of the 6th hour) from east to west, that is, against the order of the signs — a whole circle having first been added, if the subtraction cannot otherwise be made. For the number that remains will be the right ascension of that point of the ecliptic which, when the beginning of the proposed sign rises, is found on the circle of the given hour above the horizon. Therefore, from the table of right ascensions, that point will become known, and thus also the opposite point, lying on the same circle of the proposed hour below the horizon, will be known.

The demonstration of this does not differ from the one we recently made for finding the mediation of heaven, if in place of the quadrant of the equator between the east and the meridian one takes the arc of the equator between the 6th hour (or the east) and the given hour above the horizon, proceeding from east to west — as is plainly established if the circles in the sphere are rightly conceived. It is clear, moreover, that these hours above the horizon — say the seventh, eighth, ninth, tenth, and eleventh — are before noon, while these, namely the first, second, third, fourth, and fifth, are after noon. For we are inquiring only into the points lying on the circles of these hours; on the opposite hours the points opposite to those are situated.

[Margin: Example.]

Example. Suppose it is proposed to find the point of the ecliptic lying on the circle of the 1st hour after noon, when the beginning of Cancer ascends. The arc of the

equator between the circles of the 6th hour before noon and the 1st hour after noon contains 7 hours — that is, 105 degrees, since 15 degrees correspond to each hour. The oblique ascension of the beginning of Cancer is 66 degrees 57 minutes at latitude 42 degrees. If a whole circle is added to it, there will be 426 degrees 57 minutes; and if from these are subtracted the 105 degrees that lie between the circles of the 6th and the 1st hour, there will remain 321 degrees 57 minutes for the right ascension of that point of the ecliptic which then occupies the circle of the 1st hour after noon. To this ascension there corresponds in the table of right ascensions (account being taken of the proportional part) about 19 degrees 31 minutes of Aquarius. This point of the ecliptic, then, when the beginning of Cancer rises, will lie on the circle of the 1st hour after noon; while the opposite point — that is, 19 degrees 31 minutes of Leo — [will lie] on the same circle after midnight.

By this device the following four tables are constructed, containing the points of the ecliptic situated on the circles of the 11th, 1st, 7th, and 5th hour, when the beginnings of the signs rise, together with the declinations of the points found. For these will be especially useful for the descriptions of the ascending signs on each dial — the meridian and the polar — as we shall teach in its proper place. And so we have described the ascending signs of the zodiac on the same horizontal dial. Which was to be done.

These four tables (VIII–XI) supply the points of the ecliptic lying on the circles of the 11th, 1st, 7th, and 5th hours — the four tables promised at the close of the preceding proposition. In each table the twelve zodiacal signs are ranged in three horizontal blocks of four columns; every column is headed by the sign that is *rising*, and each cell records a point of the ecliptic as **degrees · minutes · sign**. The stub column reads, top to bottom: *Signa ascendentia* (the rising sign, with its symbol), *Gradus & Minuta* (G. = degrees, M. = minutes), *Puncta in hora ... ante meridiem* (the point on that hour-circle before noon), *Puncta in hora ... pomeridiana* (the point after noon), and *Declinationes* (the declination of the point found). The before-noon and after-noon points of any one column are diametrically opposite, so they share the same degree and minute and take opposite signs; their common declination is given once at the foot.

VIII. The points of the ecliptic lying on the circle of the 11th hour, together with their declinations, when the beginnings of the 12 signs of the zodiac rise, at latitude 42 degrees.

[Margin: Construction of the two figures from Andreas Schöner [Andreas Schöner], by which the ascending signs are described.]

Diagram. The upper of Schöner's two construction figures. A circle with center **E** and two perpendicular diameters: the vertical diameter runs up to **A** (top of the circle) and down to **C** (bottom), extended upward to **H** (above the circle) and far downward to **N** (well below, at the point of a teardrop-shaped envelope of dotted lines); the horizontal diameter runs from **B** (left) to **D** (right, labelled together with **V** as "DV" on the right). On the circumference: **F** (upper left), **K** (upper right), and lower points **G**, **I**, **L**. Interior points **M** and **P** lie in the upper half along the vertical axis; **R** and **S** lie in the lower half. A secondary circle **HBID** is drawn through **B** and **D**. The circle is divided into twelve parts, and numerous dotted "sign-lines" radiate from the center and are carried out to **N**, forming the balloon/teardrop outline. Small figures "3" (upper interior) and "6" (near center) appear. Several zodiac symbols mark the radial lines around the rim (per the text: the line **E**→**D** corresponds to ♈ Aries, **E**→**C** to ♋ Cancer, **E**→**B** to ♎ Libra, **E**→**A** to ♐ Capricorn); most of these peripheral zodiac sorts are worn.

- **H** (top, on the vertical axis extended)
- **A** (top of circle)
- **F** (upper left, on circle)
- **K** (upper right, on circle)
- **M** (interior, upper axis)
- **P** (interior, below **M**)
- **E** (center)
- **B** (left end of horizontal diameter; near it the sign ♎ Libra)
- **D / V** (right end of horizontal diameter, "DV")
- **R** (interior, below center)
- **S** (interior, lower)
- **G** (lower right, on circle) [?]

- I (lower interior) [?]
- L (lower, on circle) [?]
- C (bottom of circle)
- N (bottom vertex of the dotted envelope)
- Peripheral zodiac symbols: ♈ , ♉ (left side), others worn [?]

Diagram. The lower ("2nd") of Schöner's construction figures, drawn for latitude 42 degrees. A single circle **ABCD** with **A** at the top, **C** at the bottom, **B** at the left, and **D** at the right, divided by twelve radial lines from the center into the twelve signs; a smaller inner circle *f g h i* is constructed within it. Readable letters include **F** (upper left, on the rim) and interior points **H, I, L, K, G**. Each of the twelve radial lines carries a zodiac symbol around the circumference (all twelve signs), the small peripheral sorts largely worn.

- A (top)
- B (left)
- C (bottom)
- D (right)
- F (upper left, on rim)
- H (interior) [?]
- I (interior, right of center) [?]
- L (interior) [?]
- K (lower interior) [?]
- G (interior) [?]
- Twelve peripheral zodiac symbols (all signs), mostly worn [?]

SCHOLIUM.

In another way we shall describe the ascending signs, following Andreas Schöner, by this method. Let a circle ABCD be drawn, with center E and two diameters AC and BD cutting each other at right angles. Then take arcs AF and CG equal to the greatest declination of the Sun, and from B draw straight lines through F and G that cut the line AC, extended, at H and I. Again take arcs DK and BL equal to twice the greatest declination of the Sun, and from B draw straight lines through K and L that cut the same line AC, extended, at M and N. Then, with M as center and radius MH (or MI — for the line HI is bisected at M), describe a circle HBID, which will pass through B and D. Now, the circle ABCD having been divided into 12 equal parts, join by straight lines each pair of points equally distant from D or from B; these lines cut BD at certain points. Through these points, if straight lines

are drawn from N cutting the circle HBID, and through the resulting points straight lines are again sent out from E, these will be the lines of the signs: thus ED will be ♈ (Aries), EC ♋ (Cancer), EB ♎ (Libra), EA ♏ (Capricorn), and so on. By this figure, therefore, we shall find at the tropical points ♋ (Cancer) and ♏ (Capricorn) the points through which the lines of the ascending signs must be drawn, as we shall show.

Let a circle ABCD be drawn again, with center E and two diameters AC and BD cutting each other at right angles, as appears in the 2nd figure. But take arcs AF and CG of $25\frac{3}{4}$ degrees, and let the points F and G be joined by a straight line that cuts BD at the point H; and from H as center describe an arc IK, arc IK being equal to the elevation of the pole; and from H through K draw a straight line cutting AC at the point L. From L describe a circle *fgh i*, equal to the circle ABCD of the former figure, and let it be divided into 12 signs just as ABCD was divided, beginning from the line *fh*, so that *h* is ♈ (Aries), *g* ♋ (Cancer), *f* ♎ (Libra), and *i* ♍ (Virgo) [thus printed; the construction requires ♏ Capricorn, *i* being opposite *g* = ♋ — see anomaly (c)]. And so, the circle ABCD coinciding with *fgh i* — D being placed on *h*, and B on *f* — the signs of circle ABCD of the former figure correspond to the signs of circle *fgh i*. Then, through the points of the signs of circle *fgh i* and through the center L, draw straight lines cutting the circle ABCD in 12 points; and to these points draw straight lines from E, which will give the beginnings of the signs. For C will be the beginning of ♈ (Aries); the first point then, toward G, the beginning of ♉ (Taurus); the next, the beginning of ♊ (Gemini), and so on. By this figure we shall investigate, on the equinoctial line, the points through which the lines of the ascending signs must be drawn, as we shall presently teach. It is not necessary here, however, that the lines above the line BD correspond to the lines below the same BD along a single straight line, as in the upper figure — although sometimes they do correspond, as happened in this figure constructed for latitude 42 degrees, in the lines ♍ (Virgo) and ♏ (Scorpio). For these form straight lines with the lines ♒ (Aquarius) and ♊ (Gemini); yet all of them must be produced beyond the center, and when produced must be distinguished by points, lest they be confused with the others, and the same signs must be assigned to them. Hence it comes about that the line ♒ (Aquarius) also has the sign ♍ (Virgo); the line ♊ (Gemini), the sign ♏ (Scorpio); likewise the line ♍ (Virgo), the sign ♒ (Aquarius); the line ♏ (Scorpio), the sign ♊ (Gemini); the line ♈ (Aries), the sign ♎ (Libra); and the line ♎ (Libra), the sign ♈ (Aries). And so each line will have its own sign from the construction, and also the sign of that line which, when produced into a straight line, forms one line with it. Therefore, since this is of great use for describing the ascending signs, it must be carefully noted.

Therefore, on the straight line ED of the former figure, take the straight line EO equal to the meridian line EI of the dial intercepted between E, the center of the equator, and the equinoctial line; and through O draw a line parallel to AC, cutting the lines of the signs sent out from E at P, Q, R, S. Thus, when the center E of this figure is placed on the center E of the equator of the dial, and the point O on the point I, the parallel drawn through O will coincide with the equinoctial line. If, then, these points taken from O onto the equinoctial line of the dial are transferred to either side from I, and through them lines are drawn parallel to the meridian line, the tropics will be cut at the points through which the lines of the ascending signs pass. For through the points of the tropic of ♑ (Capricorn) run the lines of the signs of the semicircle ADC — namely ♒ (Aquarius) and ♓ (Pisces) in the hours before noon, ♈ (Aries) at the very hour of noon, and ♉ (Taurus) and ♊ (Gemini) in the hours after noon; while through the points of the tropic of ♋ (Cancer) run the lines of the remaining signs, opposite to these — namely ♏ (Scorpio) and ♐ (Sagittarius) in the hours after noon, ♎ (Libra) at the very hour of noon, and ♌ (Leo) and ♍ (Virgo) in the hours before noon.

[Margin: Description of the ascending signs on the dial by means of the next two figures, according to the practice of Andreas Schöner.]

Again, on the straight line ED of the latter figure, take EM equal to that same meridian line EI of the dial, intercepted between E, the center of the equator, and the equinoctial line; and through M draw a line parallel to AC. Thus, again, when the center E of this figure is placed on the center E of the equator of the dial, and the point M on the point I, the parallel drawn through M will coincide with the equinoctial line. For this parallel will cut the lines of the signs sent out from E at points which, taken from M and transferred from I onto the equinoctial line of the dial, will give the points through which the lines of the ascending signs must be drawn on the equinoctial line — with this rule, however: that the points of the signs ♉ (Taurus), ♊ (Gemini), ♋ (Cancer), ♏ (Scorpio), and ♐ (Sagittarius) be transferred to the hours before noon, and the points of the remaining signs to the afternoon hours, in that very order which the signs have in the parallel drawn through M, supposing it were superimposed on the equinoctial line of the dial in such a way that the center E fell upward (which would happen if E, the center of the equator, had been taken in the dial toward the point H), and the line ♈ (Taurus), or the point A, of this figure, toward the right-hand part of the dial, and so on.

Now if these points of the equinoctial line are joined by straight lines to the corresponding points on the tropics, the lines of the ascending signs will be

obtained, as before. But the lines ♈ (Aries), ♎ (Libra), ♋ (Cancer), and ♏ (Capricorn) are drawn as we said before. No demonstration of this operation is offered by Andreas Schöner; content with the practice alone — which is without doubt most beautiful — he committed it to writing.

[Margin: By the ascending signs described on the dial, the situation of the whole heaven at any moment of time is explored.]

Moreover, the ascending signs described on the dial have a remarkable and striking usefulness: for by them we may explore, at any moment of time, almost the whole disposition of the heaven. From the shadow of the gnomon falling on some line of the ascending signs, we immediately know which sign is at that time rising above the horizon, and consequently which is setting — since the opposite sign must then set. Again, from the rising sign we shall easily arrive at knowledge of the sign that then culminates, and thus also of its opposite, which occupies the angle of the earth, from what we set out a little earlier in this proposition. That we may achieve this more easily, two little tables must be drawn, one to the left part of the dial and the other to the right. In the former are contained these six ascending signs — ♈ (Aries), ♉ (Taurus), ♊ (Gemini), ♋ (Cancer), ♌ (Leo), and ♍ (Virgo) — together with the six opposite signs which then descend below the horizon, and with another six which are found on the meridian above the horizon at that time, and finally with six which are opposite to these last and lie on the meridian below the horizon. In the latter table are placed the other six ascending signs — ♎ (Libra), ♏ (Scorpio), ♐ (Sagittarius), ♑ (Capricorn), ♒ (Aquarius), and ♓ (Pisces) — together with the descending signs, those culminating, and those in the angle of the earth: such as are the following two tables, constructed for latitude 42 degrees.

THERE FOLLOW THE TABLES.

The two tables of the ascending signs (for latitude 42°)

These are the two little tables promised at the close of the preceding page — the one fitted to the left part of the dial (the six ascending signs ♈–♍), the other to the right part (the six ascending signs ♎–♓). In the print they stand side by side as a single wide table; they are given here as two, for clarity. Under each ascending sign are placed: the sign then descending [Descendential], the point then on the mid-heaven [In medio cœli, the MC — degrees, minutes, and sign], and the point then in the angle of the earth [In angulo terræ, the IC — degrees, minutes, and sign].

Left-hand table — the ascending signs Υ , φ , Π , $\mathfrak{S}$, ϱ , $\mathfrak{M}$.

Ascendentia (rising)	Descendentia (setting)	In medio cœli (MC) — G. M. sign	In angulo terræ (IC) — G. M. sign
Υ	$\underline{\alpha}$	0. 0. ϑ	0. 0. $\mathfrak{S}$
φ	$\mathfrak{M}$	15. 59. ϑ	15. 59. $\mathfrak{S}$
Π	$\mathfrak{A}$	6. 3. $\mathfrak{M}$	6. 3. ϱ
$\mathfrak{S}$	ϑ	5. 6. $\mathfrak{K}$	5. 9. $\mathfrak{M}$
ϱ	$\mathfrak{M}$	13. 59. Υ	13. 59. $\underline{\alpha}$
$\mathfrak{M}$	$\mathfrak{K}$	23. 57. φ	23. 57. $\mathfrak{M}$

Right-hand table — the ascending signs $\underline{\alpha}$, $\mathfrak{M}$, $\mathfrak{A}$, ϑ , $\mathfrak{M}$, $\mathfrak{K}$.

Ascendentia (rising)	Descendentia (setting)	In medio cœli (MC) — G. M. sign	In angulo terræ (IC) — G. M. sign
$\underline{\alpha}$	Υ	0. 0. $\mathfrak{S}$	0. 0. ϑ
$\mathfrak{M}$	φ	6. 3. ϱ	6. 3. $\mathfrak{M}$
$\mathfrak{A}$	Π	16. 1. $\mathfrak{M}$	16. 1. $\mathfrak{K}$
ϑ	$\mathfrak{S}$	24. 54. $\underline{\alpha}$	24. 54. Υ
$\mathfrak{M}$	ϱ	23. 57. $\mathfrak{M}$	23. 57. φ
$\mathfrak{K}$	$\mathfrak{M}$	14. 1. $\mathfrak{A}$	14. 1. Π

Text

Therefore, whenever I detect from the shadow of the gnomon that (for example) the first point of Π (Gemini) is rising, I understand at once, without any delay, that the first point of $\mathfrak{A}$ (Sagittarius) is setting, that 6°3' of $\mathfrak{M}$ (Aquarius) stands on the mid-heaven, and that 6°3' of ϱ (Leo) is set in the angle of the earth — and so with the rest. Once these four cardinal points of the heaven are known in this way, anyone may easily arrive by conjecture at which regions of the heaven the other signs of the zodiac then occupy; and further, if the places of the stars in the zodiac are known, together with their declination or latitude, at which part of the heaven this or that star then lies, even when it is not visible.

[Margin: On any given day, the shadow of the gnomon is to be observed only on the six lines of those six signs which rise above the horizon that day.]

Now since, on any artificial day whatever, only six signs rise, it follows that only six lines of the ascending signs, on any given day, mark out the rising signs —

namely the lines of those six signs which rise during the daytime; and this reckoning is taken from the place of the Sun, following the succession of the signs. For on that day the ecliptic takes only those positions which those lines represent, since the remaining signs do not rise during that day. Hence, although the shadow of the style may fall on the line of some sign that is not among the six rising that day, one must not on that account judge that this sign is then ascending — for it cannot rise at all on that whole day, nor can the ecliptic then have the position which that line expresses. For example: when the Sun is at the beginning of ♈ (Aries), only these six signs rise during the day — ♈, ♉, ♊, ♋, ♌, and ♍ — while, as the Sun sets, the beginning of ♎ (Libra) rises. So at that time these six signs — ♎, ♏, ♐, ♑, ♒, and ♓ — do not rise above the horizon during the day, even though the shadow of the gnomon may fall on their lines. By the same reasoning, when the Sun is about the middle of ♊ (Gemini), only six signs rise on that day: the remaining part of ♊, then ♋, ♌, ♍, ♎, and as much of ♐ (Sagittarius) as the Sun has traversed by its own motion in ♊. Thus, if the Sun is at 18° of ♊, then 18° of ♐ will rise. But the other six signs — namely the remaining 12° of ♐, then ♑, ♒, ♓, ♈, ♉, and 18° of ♊, which have already risen before the Sun — will not come up above the horizon on that day; and so with the rest. On any given day, therefore, in order to know which signs rise and which do not, and consequently which lines of the ascending signs we ought then to observe, we must first find out where the Sun is in the zodiac. For throughout that whole day, only the shadow of the style falling on the line of the six signs that can rise above the horizon is to be observed. Indeed it often happens that on the same day the shadow of the style falls twice on the same line — as is plain in the line of ♈ and in the line of ♓, when the Sun in the ecliptic is not far from the beginning of ♑ (Capricorn).

Diagram. The first (upper) of the two dials of the ascending signs, corresponding to the descending semicircle of the ecliptic — that is, while the Sun runs from ♋ (Cancer) through ♎ (Libra) as far as ♑ (Capricorn). From a central point a set of straight lines (the lines of the ascending signs) radiates out; a vertical line (the meridian) and a horizontal line (the equinoctial line) cross near the center. Each sign-line terminates at a point on the border marked with its zodiac symbol. The engraved caption reads "A ♋ ad ♑". Legibly read zodiac labels: on the upper-left, ♒ (Aquarius) and ♓ (Pisces); on the lower-left, ♉ (Taurus) and ♊ (Gemini); on the upper-right, ♑ (Capricorn), ♌ (Leo), ♍ (Virgo), and ♎ (Libra); near the center, ♏ (Scorpio), ♍ (Virgo), and ♐ (Sagittarius). Several of the small border labels are worn and could not be resolved with certainty [?].

Diagram. The second (lower) dial of the ascending signs, corresponding to the other (ascending) semicircle of the ecliptic — while the Sun runs from ♑ (Capricorn) through ♈ (Aries) as far as ♋ (Cancer). Its construction mirrors the first: a central point from which the sign-lines radiate, crossed near the center by a vertical (meridian) and a horizontal (equinoctial) line, with the sign-lines ending at labelled points around the margin. The engraved caption reads "A ♑ ad ♋". Legibly read zodiac labels: on the left, ♐ (Sagittarius), ♏ (Scorpio), ♑ (Capricorn), ♎ (Libra), and ♋ (Cancer); on the right, ♋ (Cancer), ♊ (Gemini), ♉ (Taurus), ♈ (Aries), ♊ (Pisces), and ♒ (Aquarius); with ♌ (Leo) and further sign-marks toward the center. Several small labels are worn [?].

So that every occasion of error may be removed, two dials of the ascending signs must be drawn, in such a way that the lines of the signs in no way intersect one another — as appears in the two figures set here side by side. The first indicates the ascending signs for as long as the Sun runs through the descending semicircle of the ecliptic, from ♋ (Cancer), through ♎ (Libra), as far as ♑ (Capricorn); the second, while the Sun is in the other semicircle of the ecliptic, from ♑, through ♈ (Aries), as far as ♋ — the semicircle that is called ascending. For it will then come about that, when the shadow of the gnomon falls on the line of some sign in that figure which is fitted to the semicircle of the ecliptic in which the Sun then is, that sign necessarily rises, without any exception — provided the observation is made at the time of year in which the Sun is running through the said semicircle of the ecliptic.

Now, so that in figures of this kind the lines of the ascending signs may not intersect one another, care must be taken that no line touching the tropics is drawn whole; rather, one portion is drawn as far as the tropic on one side in the first figure, and the other portion from the other side to the same tropic in the second figure, as is seen in the said figures. It will then be no great task to decide which of the two figures belongs to the part of the year in which the Sun moves from ♋, through ♎, to ♑, and which to the other part, in which the Sun climbs from ♑, through ♈, to ♋ — if one attends carefully to which signs can rise while the Sun is in this or that part of the ecliptic.

[Margin: How two dials of the ascending signs are to be drawn, in which the lines of the signs do not intersect one another, and of which the one is fitted to one half of the year, the other to the other half.]

For example: while the Sun stands at the beginning of ♎ (Libra), these signs rise during the day — ♎, ♏, ♐, ♑, ♒, ♓ — whose lines cut the equinoctial line, in the same order, in the first figure. The first figure will therefore belong to that part of

the year which answers to the descending semicircle, in which, namely, the sign $\underline{\alpha}$ is contained. The second figure, on the other hand, will belong to the other part of the year, in which the sign γ is included; for when the Sun is at the beginning of γ , these six signs rise — γ , ϑ , π , φ , ϱ , $\mathfrak{m}$ — whose lines intersect the equinoctial line of the second figure in the same order. We shall recognize the same thing when the Sun is in any other sign. For when the Sun (for example) is at the beginning of ϱ (Leo), these signs rise during the day — ϱ , $\mathfrak{m}$, $\underline{\alpha}$, $\mathfrak{m}$, $\nearrow$, and $\mathfrak{v}$ — and the shadow of the style sweeps the space between the tropic of φ (Cancer) and the equinoctial line. Now I see that all these signs are not contained in the second figure above the equinoctial line — that is, between the tropic of φ and the equinoctial line — but in the first; I therefore conclude that the first figure suits that part of the year in which the sign ϱ is found, namely while the Sun descends from φ to $\mathfrak{v}$. I understand the same when the Sun is tarrying at the beginning of $\mathfrak{v}$. For then these six signs rise — $\mathfrak{v}$, $\approx$, $\times$, γ , ϑ , and π — all of which are contained in the first figure below the equinoctial line, namely between the tropic of $\mathfrak{v}$ and the equinoctial line, where the shadow of the gnomon then lies; and so it is to be judged with the rest. All this is to be understood likewise for the ascending signs of the dials that follow. For in each case four figures can be drawn — two for one face of the plane of the dial, and another two for the opposite face. This will be no very difficult matter, if what we have just said is rightly grasped. For brevity's sake, in what follows we shall everywhere draw a single figure containing all the ascending signs, so that it may be divided into four particular ones, as we have taught, should use require it.

[Margin: In dials that are not horizontal, four figures of the ascending signs must be drawn.]

Now since, for the description of the ascending signs and for investigating the culminations of the heaven [cœli mediationes], right and oblique ascensions [ascensiones rectæ, & obliquæ] are needed — and not everyone has their tables ready to hand — I think it worth the effort to show briefly here in what way both the right and the oblique ascension of any point of the ecliptic is to be drawn out from the doctrine of sines [ex sinuum doctrina]. For more on this matter has been demonstrated by us elsewhere.

[Margin: How the right ascension of any point of the ecliptic is to be found.]

Let the right horizon, or the meridian, or any other great circle ABCD be drawn through the poles of the world A, C; let BGD be the equator, and EGF the ecliptic; let the point G be the beginning of γ (Aries), and let the arc GE of the ecliptic be less than a quadrant, in such a way that its right ascension — that is, its ascension

in the right sphere — is the arc GB of the equator. Since in the spherical triangle EBG the angle B is right, it will follow — by the proposition of Johannes Regiomontanus, *On Triangles*, book 4, or by *Geber* [Jābir ibn Aflāḥ], book 1, prop. 15, or by prop. 43 of our own *[Book of] Spherical Triangles* — that as the sine of the complement of the arc EG of the ecliptic (which is taken as known, since it is its right ascension that is sought) is to the sine of the complement of the arc BE, the declination of the given point E, so is the sine of the complement of the arc BG, the right ascension sought, to the whole sine [sinus totus]. And, by inversion, as the sine of the complement of the arc BE (the declination) is to the sine of the complement of the arc EG (the given ecliptic arc), so is the whole sine to the sine of the complement of the arc BG, the right ascension.

Diagram. Three spherical figures set side by side, illustrating the three cases of the computation. In each, a great circle ABCD is drawn with A at the top (north pole of the world) and C at the bottom (south pole); the equator BGD and the ecliptic EGF cross at G. The given ecliptic point is E; the arc BE is its declination and the arc BG its right ascension. Legibly read labels — first (left) figure: A (top), B (left), G (center, marked with Υ), E (lower-left), C (bottom), with D and F on the right. Second (middle) figure: A (top), F and D (upper-left), B and I (left), E (lower-left), G (center, Υ), H (lower-right), C (bottom). Third (right) figure: A (top), E (upper-left), G (center, marked with a small crown-shaped symbol), I, D, B (left cluster), H (right), F and D (lower-right), C (bottom). Several inner labels are small and worn and could not all be resolved with certainty [?].

Therefore, if the following proportion is made — as the sine of the complement of the declination of the given ecliptic point is to the sine of the complement of the arc of the ecliptic between the given point and the beginning of Υ , so is the whole sine to a fourth term — the result will be the sine of the complement of the right ascension. Example: Let the point E be at 10° of Π (Gemini), so that the arc GE of the ecliptic comprises 70° , and the arc BE, the declination, found from the corollary of prop. 1 of the preceding book, is $22^\circ 0'$. Then, if the proportion is made — as 92718 (the sine of the complement of the declination) is to 34202 (the sine of the complement of the given ecliptic arc GE), so is 100000 (the whole sine) to a fourth term — there will be found here, very nearly, the sine 36888, to which corresponds an arc of $21^\circ 39'$, whose complement, $68^\circ 21'$, gives the right ascension of 10° of Π ; and so with the rest. By this art the right ascensions of all arcs of the ecliptic from the beginning of Υ up to the end of Π (Gemini) can be computed.

[Margin: When the arc of the ecliptic is less than a quadrant.]

If the arc of the ecliptic is a quadrant — that is, if it is the beginning of $\mathfrak{S}$ (Cancer) — then its right ascension too will be a quadrant. For since, in the triangle BEG, the angle B is right and the arc GE is a quadrant, it will follow by prop. 36 of our *[Book of] Spherical Triangles* that at least one of the remaining [sides] is a quadrant. Since, then, BE is less than a quadrant — being, namely, equal to the greatest declination of the Sun — GB will be a quadrant. This can also be confirmed thus. Since the arc GE of the ecliptic is a quadrant and G is the beginning of $\mathfrak{V}$, the colure of the solstices will pass through the point E, because the arc of the ecliptic between the beginning of $\mathfrak{V}$ and the colure of the solstices is a quadrant. Since, then, this same colure is drawn through the poles of the world, it will not differ from the great circle ABCD; and consequently, since the arc of the equator between the beginning of $\mathfrak{V}$ and the colure of the solstices is a quadrant, the arc GB will be a quadrant throughout.

[Margin: When the arc of the ecliptic is a quadrant.]

If the given arc of the ecliptic is greater than a quadrant but less than a semicircle — so that, for example, the point E is at 20° of $\mathfrak{S}$ (Cancer) and the given arc comprises 110° — we shall subtract it from a semicircle, and for the remaining arc of 70° , begun from the other equinox, we shall investigate the right ascension as before, and take it away from the semicircle. There will then remain the right ascension of the given arc, since the whole semicircle from $\mathfrak{V}$ to $\mathfrak{L}$ has a corresponding semicircle of the equator for its right ascension. Thus, for example, 70° has a right ascension of $68^\circ 21'$, which, taken from 180° , leaves a right ascension of $111^\circ 39'$, answering to the arc of the ecliptic of 110° , that is, to the 20th degree of $\mathfrak{S}$.

[Margin: When the arc of the ecliptic is greater than a quadrant but less than a semicircle.]

But if the arc of the ecliptic, begun from the beginning of $\mathfrak{V}$, is a semicircle, so that it ends at the beginning of $\mathfrak{L}$, then its right ascension too will be a semicircle, as is plain.

[Margin: When the arc of the ecliptic is a semicircle.]

When the arc of the ecliptic exceeds a semicircle, yet in such a way that it is less than three quadrants, we shall take from it a semicircle, and to the right ascension of the remaining arc, begun from the beginning of $\mathfrak{L}$ and found as before, we shall add the semicircle, so as to have the right ascension of the given arc. Thus, if the right ascension of 10° of $\mathfrak{L}$ (Libra) is sought, so that the whole arc of the ecliptic reckoned from the beginning of $\mathfrak{V}$ contains 250° : having subtracted

the semicircle from 250° , there remain 70° , whose right ascension of $68^\circ 21'$, found as before, if added to the semicircle, makes up $248^\circ 21'$ for the right ascension of the given arc.

[Margin: When the arc of the ecliptic is greater than a semicircle but less than three quadrants.]

But if the given arc comprises three quadrants, it will have three quadrants also for its right ascension, as is plain from what has been said. For the first semicircle has a semicircle, and the remaining quadrant a quadrant, and so on.

[Margin: When the arc of the ecliptic comprises three quadrants.]

If, finally, the proposed arc exceeds three quadrants, it must be taken away from the whole circle, and the right ascension of the remaining arc, begun from Υ and found as before, must be subtracted from the whole circle. For there will then be left the right ascension of the given arc, since the whole ecliptic ascends together with the whole equator. Thus, if the given arc contains 290° , so that it ends at 20° of ♑ (Capricorn): we shall deduct 290° from 360° , and the right ascension of the remaining arc of 70° — $68^\circ 21'$, found as before — we shall subtract from 360° , so that $291^\circ 39'$ is left for the right ascension of the proposed arc.

[Margin: When the arc of the ecliptic is greater than three quadrants.]

It is clear from all this in what way a table of right ascensions is to be constructed. For if the right ascensions are investigated of all the arcs of the ecliptic from the beginning of Υ up to the end of ♊ (Gemini), we shall have the right ascensions of all the points of the first quadrant of the ecliptic. If we subtract each of these from a semicircle, beginning with the greater (that is, the later) ones, the remainders will be the right ascensions of all the points of the second quadrant of the ecliptic. Again, if we add the same values to a semicircle, beginning with the smaller (that is, the earlier) ones, there will result the right ascensions of all the points of the third quadrant of the ecliptic. And if, finally, we take the same values away from the whole circle, beginning again with the greater (that is, the later) ones, there will remain the right ascensions of all the points of the last quadrant of the ecliptic. Thus the whole labor lies in the investigation of the right ascensions of all the points of the first quadrant of the ecliptic, begun at the beginning of Υ and ending at the end of ♊ .

[Margin: By what method the table of right ascensions is to be constructed.]

Diagram. The same three-sphere woodcut block as on the preceding page, here serving the demonstration of the oblique ascension (the demonstration refers to

the "second figure" and the "third figure"). In each of the three spheres: A at the top, C at the bottom; the great circle ABCD, the equator (BD / BGD), and the ecliptic (EF / EGF) crossing at G; H a pole, I a point on the equator, E the given ecliptic point. Legibly read labels match those of fig-p161-1 (A, B, C, D, E, F, G, H, I), with the third figure again showing a small crown-shaped mark near G. Several inner labels are small and worn [?].

[Margin: The difference between the right and the oblique ascension of any point of the ecliptic — by what path it is to be explored, given the altitude of the pole.]

Let, again, the oblique horizon be ABCD; the equator BD; the ecliptic EF; the beginning of Υ the point G in the second figure, and in the third figure the beginning of α , the same point [G]; the meridian AC; and let the arc GE of the ecliptic, begun from the beginning of Υ or of α , be less than a quadrant, in such a way that its oblique ascension — that is, its ascension in the oblique sphere — is the arc GB of the equator, which it is our task to investigate. Let a great circle be drawn from the pole of the world H, through E, cutting the equator at I, in such a way that GI is the right ascension of the same ecliptic arc GE. Since, then, in the spherical triangle CEH, in which the angle C is right, it holds — by prop. 16 of book 4 of Johannes Regiomontanus, *On Triangles*, or by prop. 16 of book 1 of *Geber*, or by prop. 41 of our own *[Book of] Spherical Triangles* — that as the sine of the arc HE (that is, as the sine of the complement of the declination of the ecliptic point terminating the arc GE — for in the third figure the same sine is the sine of the arc HE, and the arc HE, together with the complement of the declination EI, makes up the [colure through the] beginning of Υ) is to the sine of the angle CEH (which in the second figure is equal to the angle BEI). Again, by the same reasoning, and by inversion, in the spherical triangle BEI it holds that as the sine of the angle EBI — the complement of the altitude of the pole, which the equator makes with the horizon — is to the sine of the arc EI, the declination, so is the sine of the angle BEI, just found, to the sine of the arc BI, by which the right ascension GI differs from the oblique ascension GB. If, then, the proportion is made — as the sine of the complement of the declination of the point terminating the ecliptic arc is to the whole sine, so is the sine of the altitude of the pole to a fourth term — there will be found the sine of the angle BEI. And if, again, the proportion is made — as the sine of the complement of the altitude of the pole is to the sine of the declination of the same arc, so is the sine of the angle BEI, just found, to a fourth term — there will be found the sine of the arc BI, the difference between the right and the oblique ascension answering to the ecliptic arc GE.

Example: Let the point E be placed, in the second figure, at 29° of $\varnothing$ (Taurus), and in the third at 29° of $\mathfrak{M}$ (Scorpio), so that the arc GE comprises 59° , and the arc EI, the declination, $19^\circ 59'$. If, then, the proportion is made — as 93979 (the sine of the complement of the declination) is to 100000 (the whole sine), so is 66913 (the sine of the altitude of the pole) to a fourth term — there will be found here, very nearly, the sine 71199 of the angle E, which is to be kept. Next, if the proportion is made — as 74314 (the sine of the complement of the altitude of the pole) is to 34174 (the sine of the declination), so is 71199 (the sine kept) to a fourth term — there will come out, nearly, the sine 32741, whose arc contains $19^\circ 7'$, for the difference between the right and the oblique ascension of the arc GE. If this difference, in the second figure, is subtracted from the right ascension GI already found before — because the great circle HE, which plays the part of the right horizon, cuts the equator below the horizon, since the half of the zodiac from γ to α is northern — there will remain the oblique ascension GB, $37^\circ 39'$, belonging to the northern ecliptic arc GE. But if the same difference, in the third figure, is added to the right ascension GI — because the great circle HE cuts the equator above the horizon, inasmuch as the half of the zodiac from α to γ is southern — there will result the oblique ascension GB, $75^\circ 53'$, agreeing with the southern ecliptic arc GE, reckoned from the beginning of α ; to which, if a semicircle is added, there will be established the oblique ascension $255^\circ 53'$, belonging to the ecliptic arc begun from the beginning of γ and running up to 29° of $\mathfrak{M}$ (Scorpio).

[Margin: By what method the oblique ascension of any point of the ecliptic is to be found.]

The same difference BI, between the right and the oblique ascension, will also be found in another way, thus. Since in the spherical triangle BEI the angle I is right, it will follow — by prop. 19 of book 4 of Johannes Regiomontanus, *On Triangles*, or by prop. 15 of book 1 of *Geber*, or by prop. 43 of our own *[Book of] Spherical Triangles* — that as the sine of the complement of the arc BE, the eastern amplitude [latitudo ortiva], whose finding we set out in the earlier discussion, prop. 34 of the preceding book, is to the sine of the complement of the arc EI, the declination of the given ecliptic point, so is the sine of the complement of the arc BI, the difference sought, to the whole sine. And, by inversion, as the sine of the complement of the declination is to the sine of the complement of the eastern amplitude of the same point, so is the whole sine to the sine of the complement of the difference of ascensions sought.

[Margin: How this same difference between the right and the oblique ascension is to be investigated by another route from the point of the ecliptic itself, for a given altitude of the place.]

More easily: Make the proportion — as the whole sine is to the tangent of the arc of declination IE, so is the tangent of the complement of the angle EBI (the altitude of the equator) — that is, the tangent of the altitude of the pole — to a fourth term; and there will be found the sine of the arc BI (as before, the difference of ascensions to be added to the semicircle is what is sought), as is established from the problem, prop. 49 of the *[Book of] Spherical Triangles*, since the angle EIB is right, IE is the arc of declination, and EBI is the angle of the altitude of the equator. Example: 29° of ♉ (Taurus), or 29° of ♏ (Scorpio), whose declination contains $19^\circ 59'$. If, then, the proportion is made — as 100000 (the whole sine) is to 36364 (the tangent of the declination), so is 90040 (the tangent of the complement of the altitude of the equator) to a fourth term — there will be found the sine 32742, to which correspond $19^\circ 7'$. This, then, is the size of the arc BI in the second and third figures.

Once the ascensional difference of the beginning of ♋ (Cancer), or of ♑ (Capricorn), has been found, together with the right ascensions of all points of the ecliptic, the ascensional differences of all the other points at the same elevation of the pole are also easily found. Set it up so that, as the whole sine is to the sine of the right ascension of the given point, so is the sine of the ascensional difference of the beginning of ♋, or of ♑, to a fourth term; and the sine of the ascensional difference sought will be found. Take the same nearby example: if it is made — as 100000 (the whole sine) is to 83645 (the sine of the right ascension of 29° of ♉ (Taurus), or of ♏ (Scorpio), which right ascension is $56^\circ 46'$ in the table of right ascensions), so is 39153 (the sine of the ascensional difference of the beginning of ♋, or of ♑, which at latitude 42° is $23^\circ 3'$) to a fourth term — there will be found the sine 32749, to which correspond $19^\circ 7'$, as before. This is demonstrated by Johannes Regiomontanus [Regiomontanus], prop. 24 of book 2 of the *Epitome*.

Now the declinations of all points of the ecliptic from the beginning of ♈ (Aries) up to the beginning of ♋ are equal to the declinations of all points of the ecliptic from the beginning of ♎ (Libra) up to the beginning of ♏ — proceeding against the succession of the signs, each matched to its own — because points of this kind describe the same parallels, two to each single one. Again, the declinations of all points of the ecliptic from ♈ to ♎ are equal to the declinations of all points from ♎ to ♈ — proceeding according to the sequence of the signs, each to its own — since these points are opposite to those and therefore describe equal parallels. It

follows that the declinations of the first quadrant of the ecliptic, from γ up to δ , are equal to the declinations of the three later quadrants, as appears in the table of declinations. Therefore, since the eastern amplitudes [latitudines ortivæ] are investigated by means of the declinations and the altitude of the pole — as is clear from prop. 34 of the preceding book — it is manifest that the eastern amplitudes of the points of the first quadrant of the ecliptic, found for any latitude, are equal to the eastern amplitudes of the three later quadrants at the same latitude. And therefore, since the differences between the right and the oblique ascensions are inquired — as we demonstrated just now — through the declinations and the eastern amplitudes, it is plainly established that the differences between the right and oblique ascensions of all points of the first quadrant of the ecliptic, ascertained for any altitude of the pole, are equal to the differences of ascension of all points of the three later quadrants of the ecliptic at the same altitude of the pole. Wherefore it will suffice if the differences of ascension belonging to the points of the first quadrant of the ecliptic, from the beginning of γ up to the beginning of δ , are inquired.

[Margin: The ascensional differences of the points of the first quadrant of the ecliptic, from Aries up to Cancer, are equal to the ascensional differences of the three later quadrants of the ecliptic.]

From these differences of ascension of the first quadrant of the ecliptic we shall now compose a table of the oblique ascensions of all points of the ecliptic, for the given altitude of the pole for which the differences have been worked out. In the half of the ecliptic from γ up to α , the difference of ascension must always be subtracted from the right ascension in order to obtain the known oblique ascension. This is because this half is northern, and consequently the great circle drawn from the pole of the world through any point of it cuts the equator below the horizon — as is evident from the first of the two nearby figures. Hence the difference of ascension of every point of the first semicircle, taken away from the right ascensions of those same points, leaves their oblique ascensions. On the other hand, in the other semicircle of the ecliptic, from α up to γ , the difference of ascension must always be added to the right ascension in order to learn the oblique ascension. This is because this semicircle is southern, and so the great circle drawn from the pole of the world through any point of it cuts the equator above the horizon — as is established from the second, adjacent figure. It is therefore clear that the differences of ascension of all points of this later semicircle, added to the right ascensions of those same points, produce their oblique ascensions.

Example. The difference of ascension of 29° of ♋ , which we found at latitude 42° to be $19^\circ 7'$, is equal to the difference of ascension of 1° of ♌ (Leo), of 29° of ♍ (Scorpio), and of 1° of ♎ (Aquarius); for these four points have the same declination. If, then, we subtract it from the right ascension of 29° of ♋ — that is, from $56^\circ 46'$ — there will remain the oblique ascension of 29° of ♋ , namely $37^\circ 39'$. Likewise, if we subtract the same difference from the right ascension of 1° of ♌ — namely from $123^\circ 14'$ — there will remain $104^\circ 7'$ for the oblique ascension of 1° of ♌ . Again, if we add the same difference to the right ascension of 29° of ♍ , which is $236^\circ 46'$, we shall produce $255^\circ 53'$ for the oblique ascension of 29° of ♍ . Finally, if we add the same difference to the right ascension of 1° of ♎ , which comprises $303^\circ 14'$, there will be formed the arc of $322^\circ 21'$ for the oblique ascension of 1° of ♎ . And the same reckoning is to be applied to the rest. It has been enough to give this brief taste, in this place, of right and oblique ascensions, for we have discussed them more fully in another place.

[Margin: How the table of oblique ascensions is to be composed from the ascensional differences.]

PROBLEMA 10. PROPOS. 10.

To construct an Italian horizontal sundial. That is, to draw the hour-lines reckoned from sunset upon a plane parallel to the horizon.

[Margin: The construction of the Italian horizontal sundial.]

Let the circle drawn about center E, set out in prop. 1 of this book, be cut into two portions — as we taught in the scholium to prop. 1 of the preceding book — of which a N b is similar to the diurnal arc of the tropic ♊ , and a M b to the nocturnal arc of the same tropic. Now divide this same circle described about E into 24 equal parts, beginning at point b, which lies to the west on the common section of the horizon and of the parallel a b. (This is clear if the said circle described about E is conceived to be placed in its proper position.) Through these division-points, and through the center E — provided the circle stands in its proper position — will pass the great circles drawn through the poles of the world and through the hours from sunset in the tropic ♊ , after the manner of the hour-circles reckoned from noon or from midnight. For since the great circles drawn through the poles of the world divide the tropic ♊ and the equator into similar arcs, by prop. 10 of book 2 of Theodosius, the arc of the equator intercepted between the meridian and the great circle drawn through the 24th hour from sunset in the tropic ♊ — that is, through the point where the tropic ♊ cuts the horizon — will be similar to the arc of the tropic ♊ placed between the

same circles, that is, to the semidiurnal arc of the tropic $\mathfrak{S}$. And since the common sections which the said great circles make with the equator, drawn through the center E of the equator, likewise cut the equator and the circle MaNb (described about E, the center of the equator, and in the same plane) into similar arcs — by what we demonstrated at the end of chapter 1 of the *Sphere* — the arc of the circle MaNb placed between the said common sections will also be similar to the semidiurnal arc of the tropic $\mathfrak{S}$. Therefore, since MN is the section made in the equator by the meridian — so that the meridian is drawn through the point N — and the arc N b is similar to the semidiurnal arc of the tropic $\mathfrak{S}$ (for since the whole arc b N a is similar, by construction, to the whole diurnal arc of the tropic $\mathfrak{S}$, then bN, the half of that arc b N a, will also be similar to the semidiurnal arc of the tropic $\mathfrak{S}$), and therefore also similar to the arc of the equator intercepted between the aforesaid sections, the other great circle, drawn through the 24th hour from sunset in the tropic $\mathfrak{S}$, will necessarily pass through the point b. For if it passed through another point, the said sections would not cut off from the equator an arc similar to the arc bN, but one similar to the arc lying between the straight line EN and that other

point would be interposed — which is absurd. For we showed that the arc taken away from the equator is similar to the arc bN, because bN is similar to the semidiurnal arc of the tropic $\mathfrak{S}$. And since the arc between b and the next division-point toward N is likewise similar to the arc of the tropic $\mathfrak{S}$ intercepted between the two great circles drawn through the poles — one of which is drawn through the 24th hour from sunset (that is, through the point b), the other through the 23rd hour from sunset in the tropic $\mathfrak{S}$ — inasmuch as each arc is a 24th part of its own circle, then the great circle drawn through the poles of the world and through the 23rd hour from sunset in the tropic $\mathfrak{S}$ will also pass through the next division-point, proceeding from the point b toward N. For in this way the straight lines drawn from the center E through b and through the next point toward N — that is, the sections made by those two great circles drawn through the poles and through the 24th and 23rd hours from sunset in the tropic $\mathfrak{S}$ — will cut off from the equator an arc similar to the arc of the tropic placed between the 24th and 23rd hours, as Theodosius requires (prop. 10, book 2); which otherwise would not happen. For if the said circle passed through another point, the arc of the circle MaNb between b and that point would be greater or less than a 24th part; and consequently the arc of the equator similar to it (as is clear from what we demonstrated at the end of chapter 1 of the *Sphere*) would be greater or less than a 24th part, and therefore not similar to the aforesaid arc of the tropic $\mathfrak{S}$ — which is absurd. In the same way the next point toward N will indicate the 22nd hour, and the rest the remaining hours.

Now, from the circle MaNb divided in this manner, we shall find on the arc $\mathfrak{S}$ the points of the hours from sunset, in this way. Through the division-points and the center E we shall draw hidden [construction] straight lines cutting the equinoctial line at certain points; and if through these points hidden straight lines are drawn from H, the center of the sundial, the tropic $\mathfrak{S}$ will be cut at the points of the hours from sunset.

Diagram. A large circle representing the equator / hour-circle construction MaNb of the Italian horizontal sundial, with the vertical diameter M–N as the meridian (M at top, N at bottom) and a horizontal diameter across the middle as the equinoctial line. H, near the upper center, is marked as the center of the sundial (the foot of the axis/style); E, at the middle-lower center (among the numerals 19, 20, 21), is the center of the equator. A dense pencil of straight construction-lines (both solid and dotted) radiates from the central region toward hour-points distributed around the circumference. The circle carries two nested chords (a b above and, lower, the Capricorn chord) cutting off the diurnal/nocturnal arcs, and the hours from sunset are numbered around it.

Confidently read labels:

- M (top): meridian point, upper end of the vertical diameter
- N (bottom): meridian point, lower end of the vertical diameter
- H (upper center): center of the sundial (foot of the style)
- E (lower center): center of the equator
- a (upper left, on/near the circle): endpoint of the upper chord a b
- b (lower left): endpoint of the diurnal chord
- c (right, near the lower-right): chord endpoint on the right
- d (lower left, on the circle): endpoint of the Capricorn chord
- t (mid-left): peripheral point
- m (left, below t): peripheral point
- u (mid-right): peripheral point
- n (far right, on the equinoctial line extended): peripheral point
- Large hour-numerals flanking the horizontal line: "6" (left) and "6" (right); "5" and "4" descending on the left; "7", "8", "9" on the right; "10" and "1" at upper right
- Interior Arabic hour-numerals along the radiating lines: 1–16 (right and upper), and lower-arc numerals including 23, 22, 21, 20, 19, 18, 17
- Roman numerals along the lower arc: I, II, III (with "12" at bottom center)

- Greek point-letters: α (upper-left, near H), β (bottom center), and further Greek/point marks (λ near lower-left "23") [several [?]]

[?] The interior is extremely crowded; many of the small Arabic hour-numerals and the Greek point-letters cannot be resolved individually at this resolution. This diagram is a (more than 2 labels flagged).

For example: through the point f of the 18th hour from sunset, and through the center E, draw the straight line f E; it cuts the equinoctial line at g. Now the straight line Hg, when drawn, cuts the arc $\mathfrak{S}$ at h — a point which I say belongs to the 18th hour from sunset. For the straight line f g is the common section of the equator and of the great circle drawn through the poles of the world and through the 18th hour from sunset in the tropic $\mathfrak{S}$; because, as we showed, that great circle passes through the point f of the 18th hour from sunset (if the circle MaNb is set in its proper position) and through the center of the world E, so that the said great circle will meet the plane of the sundial at the point g. And since the same circle passes through H, the center of the sundial — by prop. 18 of the preceding book, because it is drawn through the axis — the straight line Hg will be the common section of that same great circle and of the plane of the sundial. Therefore, since (with the Sun standing in that great circle) the shadow of the style falls, by prop. 11 of the same preceding book, upon the straight line Hg, and — with the Sun standing in the tropic $\mathfrak{S}$ — it is cast, by prop. 12 of the same preceding book, onto the arc $\mathfrak{S}$, it comes about that, when the Sun occupies the point of the 18th hour from sunset in the tropic $\mathfrak{S}$ (where the said great circle and the tropic $\mathfrak{S}$ intersect), the shadow of the style is cast onto the point h; and therefore through h the line of the 18th hour from sunset must be drawn. The same reasoning is to be applied to the rest.

But in this way, as you see, there are found on the tropic $\mathfrak{S}$ the points only of those hours which are contained in the semicircle t N u. This is because the common sections of those great circles and of the equator mark, on the equinoctial line, those hours from which they are drawn through the center E, before they meet the equinoctial line — as we said in the scholium to prop. 1 of this book; and of this kind are only those hours found in the semicircle t N u, as is plain. Hence, for the remaining hours — which in our example are the 9th, 10th, and 23rd from sunset, as is seen in the figure — we shall find the points on the tropic $\mathfrak{S}$ in the following way. From the hours which are diametrically opposite to these hours in the circle MaNb (the opposite hours are obtained by adding 12 to those hours, yet casting out 24 if the number collected by the addition is greater than 24 — thus to the 9th hour is opposite the 21st, since 9 and 12 make

21; likewise to the 23rd hour is opposite the 11th, since 23 and 12 make 35, and, 24 being cast out, 11 remain, and so on), we shall draw through the center E straight lines cutting the equinoctial line at certain points; and if through these points straight lines are drawn from H, the tropic $\mathfrak{S}$ will indeed be cut at the points corresponding to those opposite hours, as has been demonstrated. But if those straight lines are produced beyond the center H, the tropic $\mathfrak{S}$ will be cut at the points corresponding to those other hours, which in the semicircle $t N u$ are

not contained, and whose opposites have been taken. For instance, from m , the point of the 11th hour (which is diametrically opposite the 23rd hour), a straight line drawn through the center E cuts the equinoctial line at n ; and the straight line Hn , when drawn, cuts the tropic $\mathfrak{S}$ at q , the point of the 11th hour; and finally the straight line nH , produced beyond the center, cuts the tropic $\mathfrak{S}$ at the point p , which I say must belong to the 23rd hour. For since the great circle drawn through the poles of the world and through the 11th hour of the tropic $\mathfrak{S}$ cuts — by prop. 15 of book 1 of Theodosius — the tropic $\mathfrak{S}$, and hence also the equator (that is, the circle $M a N b$), into two equal parts, it will pass entirely through the 23rd hour, which is a whole semicircle — that is, 12 hours — distant from the 11th hour, so that one of its semicircles shows the 11th hour and the other the 23rd. The straight line mEn is therefore the common section of the equator and of the great circle drawn through the poles of the world and through the 11th and 23rd hours of the tropic $\mathfrak{S}$. Consequently the straight line nHp is the common section of that same great circle and of the plane of the sundial, since the said circle meets the plane of the sundial at the points n and H — yet on this condition, that the portion Hn , which cuts the equinoctial line, represents the semicircle of that great circle passing through the 11th hour in the tropic $\mathfrak{S}$ (whose section, namely mE , is drawn through the center E before it meets the equinoctial line, as we wrote in the scholium to prop. 1 of this book). From which it follows that the remaining portion Hp , produced beyond the center of the sundial and not cutting the equinoctial line, represents the other semicircle, drawn through the 23rd hour, just as we taught in the same scholium. For there too we showed that the hour-line which cuts the equinoctial line indicates the hour of one semicircle, while its portion produced beyond the center, which does not cut the equinoctial line, shows the hour of the other, opposite semicircle — so that those two hours are distant from each other by a whole semicircle, or 12 hours, on the equator, as happens here too. Therefore through the point p the line of the 23rd hour must be drawn. Let the same judgment be applied to the rest. For thus we shall investigate the points on the same tropic $\mathfrak{S}$ for the 9th and 10th hours, if from the 21st and 22nd hours (which are opposite to them) we draw straight lines through the center E, and so on.

Diagram. The same Italian horizontal sundial construction as on the preceding page, redrawn (a cleaner, higher-contrast impression). A large circle (the equator / hour-circle construction M a N b) with the vertical meridian diameter M (top)–N (bottom) and a horizontal equinoctial line across the middle; H near the upper center is the center of the sundial, E at the lower center is the center of the equator, with a dense pencil of solid and dotted construction-lines radiating to the hour-points around the circumference, and the same nested diurnal/nocturnal chords.

Confidently read labels (as on fig-p164-1): M (top), N (bottom), H (upper center), E (lower center), a (upper left), b/d (lower left, chord endpoints), c (right), t and m (mid- and lower-left), u (mid-right), n (far right on the equinoctial line); the flanking large hour-numerals 6, 6, with 5, 4 (left) and 7, 8, 9, 10, 1 (right/upper); interior Arabic hour-numerals 1–16 and, on the lower arc, 17–23; Roman numerals I, II, III and "12" at bottom center; Greek point-letters α (upper left), β (bottom center), λ (lower left).

[?] As on the preceding page, the crowded interior hour-numerals and several Greek point-letters cannot all be individually resolved. This diagram is a (more than 2 labels flagged).

In the same way, if we cut the circle described about E into two portions — of which d N e is similar to the diurnal arc of the tropic φ , and d M e to its nocturnal arc (this is easily done if, for the arcs Ma and Mb, we take equal arcs Nd and Ne, and draw the straight line d e in such a way that the straight lines a b and d e cut off equal lengths Ma[?] and Nb[?] from the diameter MN and are perpendicular to MN) — and distribute it into 24 equal parts, beginning at the point e on the west, we shall find on the arc φ the points through which the hours from sunset must be drawn. For example, if from the point λ [?] of the 23rd hour of the tropic φ we draw through the center E a straight line that cuts the equinoctial line at [the marked point $\cdot$][?], we shall find, by the straight line H[$\cdot$] produced, the point λ [?] on the arc φ for the 23rd hour; and so on for the rest.

But if you do not wish to cut the circle MaNb, described about E, into two portions — one similar to the diurnal arc of the tropic φ or φ , and the other to the nocturnal arc — by the method we set out in the scholium to prop. 1 of the preceding book, the task may be accomplished this way. From the point N count off, on each side, the semidiurnal arc: for the tropic φ as far as the points a and b, and for the tropic φ as far as the points d and e. This is easily done if the circle is secretly divided into 24 equal hours, beginning at the point N, and the hours contained in the semidiurnal arc are counted on each side, and so on. For when

the straight lines a b and d e are drawn, we shall have the same portions as before, corresponding to the diurnal arc of the tropic $\mathfrak{S}$ or $\mathfrak{V}$. Hence the division of the circle must again be begun from the point b, or from the point e.

[Margin: How the circle MaNb may otherwise be divided into the diurnal arc of the tropic of Cancer or of Capricorn.]

We can also fix the beginning of this division at any hour from sunset — even without cutting the circle into the diurnal arc of the tropic $\mathfrak{S}$ or $\mathfrak{V}$ — in this way. Let the semidiurnal arc be subtracted from the 24 hours, so as to obtain the time of noon in the Italian manner. From this time we shall learn how far any proposed hour from sunset is distant from noon. Hence, if from the point N this distance is counted toward b (if the proposed hour is afternoon) or toward a (if forenoon), we shall have the point of the proposed hour, from which the division of the circle into 24 equal parts is to be begun. For example, with the Sun at the beginning of $\mathfrak{S}$, the semidiurnal arc, at latitude 42° , contains 7 hours 32 minutes; when this is subtracted from the 24 hours, there remain 16 hours 28 minutes for the time of noon; and therefore the hour

[Margin: How the circle MaNb can take the beginning of its division at any hour from sunset, even if it is not divided into the diurnal arc of the tropic of Cancer or of Capricorn.]

[Margin: Likewise, by what method any proposed hour from sunrise or sunset, in any parallel whatever, is to be found in the same circle.]

hour 18 from sunset will be distant from the meridian, toward the western quarter, by 1 hour 32 minutes — that is, by 23 degrees. If, then, starting from N toward b we count off 23 degrees, or 1 hour 32 minutes, we shall find the point f of hour 18 from sunset on the tropic $\mathfrak{S}$ (Cancer); and from this point the division of the circle may take its beginning, so that the other hours from sunset may be obtained. Again, hour 11 from sunset will be distant from the same meridian by 5 hours 28 minutes — that is, by 82 degrees. If this distance is counted from N toward a — because hour 11 falls in the forenoon — we shall find the point m of hour 11 from sunset on the tropic $\mathfrak{S}$, and from this point too the division of the circle may take its start. Finally, with the Sun at the beginning of $\mathfrak{V}$ (Capricorn), the semidiurnal arc, at the same latitude of 42 degrees, comprises 4 hours 28 minutes; when this is subtracted from the 24 hours, there remain 19 hours 32 minutes for the time of noon. Accordingly hour 23 from sunset will be distant from the meridian, toward the west, by 3 hours 28 minutes — that is, by 52 degrees. If this distance is reckoned from N toward e, we shall find the point λ [?]

for hour 23 from sunset on the tropic φ , and so on. In this way, once the time of noon is known, we shall find the point of any hour whatever from sunset. And I wish the same to be understood of the hours from sunrise. Moreover, this holds not only on the tropic φ or ψ , but on any parallel whatever. Hence, if from the point of the proposed hour from sunset on the circle MaNb a hidden straight line is drawn through the center E, cutting the equinoctial line at a point, and through that point a straight line is drawn from H, the center of the sundial, then the parallel φ or ψ — or any other parallel — will be cut at the point of the proposed hour from sunset, according as that hour was taken on the parallel φ or ψ , or on any other parallel whatever.

And so, if the corresponding hour-points found on the tropics are joined by straight lines, the Italian sundial will be drawn. The lines of the hours from sunset will pass through those points of the equinoctial line through which the lines of the hours from noon or midnight run: namely, the line of hour 23 from sunset through the point of the fifth hour from noon or midnight, the line of hour 22 through the point of the fourth hour, and so on in succession — just as is clear from the table of prop. 19 of the preceding book, whose title is THE EQUINOCTIAL LINE, or from the table of the diurnal arc of 12 hours of prop. 23 of the same preceding book. Hence it will suffice to find only the hour-points on one or the other of the tropics; for these, joined by straight lines to the corresponding points on the equinoctial line, will give the hour-lines from sunset, as before.

Nevertheless we shall draw these lines more accurately if the hour-points are investigated on both tropics, so that three corresponding points are obtained through which each single hour-line ought to be drawn. For in this way every error that can be committed in drawing the hour-lines will easily be avoided.

But if the points of some hours on the tropic φ have no corresponding points on the tropic ψ — as in our example are all the hours before hour 16 — the hour-lines will have to be drawn through the points of those hours found on the tropic φ and through the corresponding points on the equinoctial line, which indeed are found from the aforesaid table of prop. 19 of the preceding book, or from the table of the scholium of prop. 33 of the same book. The line of the twelfth hour, however, will have to be drawn through the point found on the tropic φ , equidistant from the equinoctial line or from the line of the sixth hour from noon or midnight. For in every horizontal sundial the equinoctial line, the line of the sixth hour from noon or midnight, and the line of the twelfth hour from sunset are parallel, as we demonstrated in the scholium of prop. 22 of the preceding book. But hour 11 from sunset, if it were produced, would pass through the fifth hour from noon or midnight on the equinoctial line; and hour 10 from sunset

through the fourth hour from noon or midnight, just as the table of prop. 19 of the preceding book prescribes.

[Margin: Another description of the Italian horizontal sundial, by means of the diurnal arcs.]

Alternatively. Let there be described in the astronomical sundial, by prop. 2 of this book, two parallels of the diurnal arcs, one of 14 hours and the other of 10 hours; or rather (which will indeed be sufficient for the business proposed) let the points through which the said arcs must pass be marked on the hours from noon and from midnight, even if the arcs themselves are not drawn. Then let the tables of the diurnal arcs of 10, 12, and 14 hours, which we set down in the scholium of prop. 33 of the preceding book, be carefully considered. For in these it will at once appear through which hours from noon or midnight of the said arcs the hours from the Sun's setting must be drawn. Thus you see that hour 23 from sunset must be drawn through the fourth hour from noon on the arc of 10 hours, through the fifth hour from noon on the arc of 12 hours (which here is the same as the equinoctial line), and through the sixth hour from noon on the arc of 14 hours — and so with the rest. But those hours which have no corresponding points on the arc of 10 hours — as in our example are all the hours before hour 15 — must be drawn through the points on the arcs of 14 and 12 hours. Hour 12 from sunset, however, must be drawn parallel to the equinoctial line (for the line of the twelfth hour from sunrise or sunset and the equinoctial line are parallel in the horizontal sundial, as we taught in the scholium of prop. 22 of the preceding book), through the seventh hour from midnight on the arc of 14 hours, as is evident from the table of the said arc. And since hour 11 from sunset has a point only on the arc of 14 hours — namely the sixth hour from midnight — we shall draw hour 11 from sunrise through the fourth hour from noon on the arc of 14 hours and through the fifth hour from noon on the arc of 12 hours, as is evident from the tables of the said arcs. For this line, produced, will give hour 11 from sunset, since it falls on the other side of the greatest parallel of things always visible, as is clear if this parallel were drawn.

For any hour whatever from sunrise, produced beyond the arc — that is, beyond the greatest parallel of things always visible or always hidden — gives the same hour by number from sunset, and conversely, as we shall show in the following scholium. And this hour 11 from sunrise, when produced, will necessarily pass — if no error has been made — through the sixth hour from midnight on the arc of 14 hours, through which, of course, hour 11 from sunset is to be drawn, from the table of the diurnal arc of 14 hours. By like reasoning, since hour 10 from sunset

has no point on the aforesaid diurnal arcs, we shall draw hour 10 from sunrise through the third hour from noon on the arc of 14 hours and through the fourth hour from noon on the arc of 12 hours, as is evident from the tables of these arcs. For this line, produced, will exhibit hour 10 from sunset, for the reason stated earlier. And so we shall proceed with the other hours before the tenth, if they must be drawn in the sundial.

[Margin: Another description of the Italian horizontal sundial, by means of the greatest parallel of things always visible, or the diurnal arc of 24 hours.]

Most conveniently, too, the hours from sunset can be described if the greatest parallel of all things always visible — that is, the diurnal arc of 24 hours — is described. For the straight lines drawn through the hours from noon or midnight on the said arc, according to the table of the diurnal arc of 24 hours set down in the scholium of prop. 33 of the preceding book, and through the hours from noon or midnight of the diurnal arc of 12 hours, as the table of this arc set down in the same scholium of prop. 33 of the preceding book teaches, will give the hour-lines from sunset. For hour 23 from sunset passes through the eleventh hour from noon of that parallel, or diurnal arc of 24 hours, and through the fifth hour from noon of the equinoctial line, or arc of 12 hours. But hour 22 passes through the tenth hour of the former arc and through the fourth hour of the equi-

-noctial line, or of the latter arc, and so on. As is evident from the tables of the said arcs described in the scholium of prop. 33 of the preceding book. Hour 12 from sunset, however, is drawn parallel to the sixth hour from noon or midnight — that is, to the equinoctial line — through the point where the meridian line, or line of hour 12 from midnight, which is the hour of noon, intersects the diurnal arc of 24 hours, that is, the greatest parallel of things always visible. For the line of hour 12 from sunrise or sunset, the line of the sixth hour from noon or midnight, and the equinoctial line are parallel, as is evident from what we wrote in the scholium of prop. 22 of the preceding book; and the line of hour 12 from sunrise or sunset passes through the twelfth hour from midnight on the diurnal arc of 24 hours, as is plain from the table of the diurnal arc of 24 hours set down in the scholium of prop. 33 of the same book. Indeed, the line of the twelfth hour from sunrise or sunset, and all the rest from sunrise or sunset, touch the aforesaid parallel — that is, the diurnal arc of 24 hours — at the very points where the same lines of the hours from noon or midnight cut it, as we demonstrated in prop. 14 of the preceding book. Or else, in certain of the sundials that follow, they touch the diurnal arc of 0 hours or the nocturnal arc of 24 hours — that is, the greatest parallel of things always hidden. Hence, in order that the

hours from sunrise or sunset may be drawn more accurately, arcs of this kind may be described, as we did in prop. 34 and 36 of this book in the meridional and polar sundials.

[Margin: By what method, if by means of the diurnal or nocturnal arcs some one hour from sunset or sunrise has been drawn, another may be described with little effort.]

Furthermore, once some one hour from sunset — or also from sunrise, as we shall say in the following proposition — has been drawn, then by means of the diurnal arcs, or also the nocturnal, as will be plain in the sundials that follow, we shall easily draw the others through the successive points that correspond to one another, with no other consideration of the tables which we composed in the scholium of prop. 33 of the preceding book. Thus, having drawn (for example) hour 23, we shall draw 22 through the nearest point on the diurnal arc of 14 hours, through the nearest on the diurnal arc of 12 hours, and through the nearest on the diurnal arc of 10 hours. Likewise 21 through another set of three successive points, and so with the rest, as appears in the example.

Alternatively. Let the line of the twelfth hour from sunrise or sunset be described in this way. In the portion of the Analemma of prop. 1 of this book, let there be taken the arc EK equal to the arc CE of the pole's altitude, so that the straight line CK drawn through them is the diameter of the greatest parallel of all things always visible — namely, the common section of it and the meridian. And since the circle of the twelfth hour from sunset touches the said parallel at the point K, which on the diameter of that same parallel is opposite the point C at which the horizon, or the circle of hour 24 from sunrise or sunset, touches the same parallel — as is evident from the figure of prop. 9 of the preceding book — the meridian will pass through K, the point of contact of the said circles. Since, then, it also passes through the poles of the said parallel, it will likewise pass through the poles of the circle of hour 12 from sunrise or sunset, by prop. 5 of book 2 of Theodosius [*Spherics* II.5]. Therefore, by prop. 15 of book 1 of Theodosius [*Spherics* I.15], the meridian will be at right angles to the said circle, and this in turn at right angles to the meridian. Again, since the said circle of hour 12 from sunrise or sunset, being a great circle, passes through the center of the world D, and it has been shown that it passes through K, the common section of the meridian and of the circle of hour 12 from sunrise or sunset, drawn out as a straight line from K through D, will meet the meridian line HI of the sundial's plane at the point L. I now say that the straight line drawn through L perpendicular to the meridian line of the sundial is the line of hour 12 from

sunrise or sunset. For since both the plane of the horizontal sundial and the plane of the circle of hour 12 from sunrise or sunset are at right angles to the meridian, as we demonstrated just above, their common section too — namely the line of hour 12 from sunrise or sunset — will be perpendicular to the same meridian [Margin: (a) *Elements* XI.19], and therefore also to the meridian line HI lying in the meridian, by def. 3 of book 11 of Euclid [*Elements* XI, def. 3], at the point L, where we said was the common section of the circle of hour 12 from sunrise or sunset and of the meridian, and consequently the point where the circle of hour 12 from sunrise or sunset itself meets the plane of the sundial. Therefore a straight line drawn in the plane of the sundial through L, perpendicular to the meridian line, will give the line of hour 12 from sunrise or sunset. Accordingly, if from the center H the point L is transferred onto the meridian line of the sundial — taken with the compass from the point H of the portion of the Analemma — and through L a line is drawn perpendicular to the meridian line, or parallel to the line of the sixth hour from noon or midnight, that is, to the equinoctial line, this will be the very line of hour 12 from sunrise or sunset.

Now the straight line HD in the portion of the Analemma, by which the circle of hour 12 from sunrise or sunset is drawn, cuts the segment of the meridian line HI intercepted between H, the center of the sundial, and the point I through which the equinoctial line must be drawn, into equal parts at the point L. [Margin: (b) *Elements* III.27] For the angles CDE, KDE are equal; [Margin: (c) *Elements* I.29] and the angle CDE is equal to the angle IHD, [Margin: (d) *Elements* I.15] and the angle KDE to the angle HDL; therefore the angles LHD, LDH will also be equal; [Margin: (e) *Elements* I.6] and consequently the straight lines HL, DL will be equal. Again, since EF is a quadrant, the two remaining arcs in the semicircle CF, BF will be equal to the other quadrant; therefore, the equal arcs EK, CE being taken away, the remaining arcs KF, BF will also be equal; [Margin: (f) *Elements* III.27] and hence the angles KDF, BDF will be equal; [Margin: (g) *Elements* I.15] but the angle KDF is equal to the angle LDI, [Margin: (h) *Elements* I.29] and the angle BDF to the angle LID. Therefore the angles LDI, LID will also be equal, [Margin: (i) *Elements* I.6] and hence the straight lines LI, DL will be equal. Wherefore HL, IL will be equal to one another, since each has been shown equal to DL itself. And so, if the segment of the meridian line between the center of the sundial and the equinoctial line is bisected, in any horizontal sundial whatever, the line of the twelfth hour from sunrise or sunset must be drawn through that middle point.

[Margin: Another description of the Italian horizontal sundial, to be accomplished by means of the line of hour 12 from sunrise or sunset.]

Now, the line of the twelfth hour from sunrise or sunset having been described in this way, the remaining hours from sunset are easily described if, on the equinoctial line and on the line of the twelfth hour from sunrise or sunset, one carefully marks the points from the table of prop. 19 and from the second table of prop. 20 of the preceding book, through which the lines of the hours from sunset pass. For straight lines joining the corresponding points will give the hour-lines from sunset. Example: hour 23 from sunset passes on the equinoctial line through the point of the fifth hour from noon or midnight, and on the line of the twelfth hour from sunrise or sunset through the point of hour $5\frac{1}{2}$ from noon, as is evident from the said tables. Therefore a straight line passing through those two points will give the hour-line that indicates hour 23 from sunset. In the same way, the line of hour 22 from sunset will pass through the point of the fourth hour from noon on the equinoctial line, and through the point of the fifth hour from noon on the line of the twelfth hour from sunrise or sunset; and so with the rest.

[Margin: Another description of the Italian horizontal sundial, from the first table of prop. 20 of the preceding book, where each hour from sunset is parallel to some hour from noon or midnight.]

The lines of the hours from sunset can also be easily described from the first table of prop. 20 of the preceding book, in this way. Through the point of the fifth hour from noon or midnight on the equinoctial line — through which, of course, hour 23 from sunset passes, as is evident from the table of prop. 19 of the same book — let a straight line be drawn parallel to the line of hour $11\frac{1}{2}$ from noon or midnight. For this will be the line of hour 23 from sunset. So likewise the line of hour 22 from sunset, passing through the point of the fourth hour from noon, will be parallel to the line of the eleventh hour from noon or midnight, and so on — as is clear from the first table of prop. 20 of the preceding book, in which every pair of hours is parallel in the horizontal sundial, as we demonstrated in the scholium of prop. 22 of the same book. Now these parallels

[Margin: The use of the later tables of prop. 20 of the preceding book in describing the hours from sunset.]

will be readily described, if the straight line intercepted on the equinoctial line between the points through which the hours from sunset must be drawn, according to the table of prop. 19 of the preceding book, is taken, together with the points of the hours from noon or midnight from which those points are equidistant according to the first table of prop. 20 of the same book, and these are transferred from H, the center of the sundial, onto the line of the sixth hour from noon or midnight. Thus, if there be taken on the line of the sixth hour from noon

a length HX equal to the line intercepted on the equinoctial line between the point of the eleventh hour from noon — from which hour 22 from sunset is equidistant — and the point of the fourth hour from noon, through which the same hour 22 passes, then the straight line drawn through X and the point of the fourth hour from noon [Margin: (a) *Elements* I.33] will be parallel to the line of the eleventh hour from noon or midnight, and will therefore indicate hour 22 from sunset, and so on. But if a parallel to the equinoctial line is drawn at a greater distance from it, onto which are transferred the same lines intercepted on the equinoctial line between the points through which the hours from sunset must be drawn and the points of the hours from noon or midnight from which they are equidistant — the beginning always being made from the hours from noon or midnight from which the hours from sunset ought to be equidistant — then the hours from sunset will be drawn much more accurately, since each is drawn through three points: one of which is on the line of the sixth hour from noon or midnight, another on the equinoctial line, and the third on the parallel drawn last.

[Margin: By what hours from sunset they mutually cut one another on the line of the sixth hour from noon or midnight.]

Moreover, hours 23 and 13 from sunset cut one another, if drawn as straight lines, on the line of the sixth hour from noon or midnight. Likewise hours 22 and 14, and also 21 and 15, and so on, as is evident from the third table of prop. 20 of the preceding book.

[Margin: By what hour-lines from sunset they mutually cut one another on the meridian line.]

Again, from the fourth table of the same proposition, hours 10 and 14 from sunset intersect one another on the meridian line, that is, the line of the twelfth hour from noon or midnight. Likewise hours 11 and 13, and so on. Finally, from prop. 20 of the preceding book and the figure of prop. 9 of the same book, or indeed from the tables which we constructed at the end of the scholium of the same proposition of the same book, we shall easily recognize which hours from sunrise or sunset cut any hour whatever from noon or midnight at one and the same point. This makes the description of the hour-lines from sunset very easy indeed, and provides a means by which a description of this kind may be examined. Therefore we have set up the Italian horizontal sundial, and so on. Which was to be done.

SCHOLIUM

[Margin: Any hour from sunset, produced beyond the diurnal or nocturnal arc of 24 hours which it touches, belongs to the same hour by number from sunrise; and conversely.]

Here it is worth noting that any hour from sunset, produced beyond that point where it touches the greatest parallel of things always visible — that is, the diurnal arc of 24 hours — or the nocturnal arc as well, which is the other opposite parallel and greatest of things hidden, indicates the same hour by number from sunrise; and conversely, any hour from sunrise produced beyond that point exhibits the same hour by number from sunset. This we assumed as true in the present proposition, but shall now demonstrate as follows. If the Sun were placed at that point of the heavens where some hour-circle from sunrise or sunset touches the greatest parallel of things always visible or the greatest parallel of things always hidden, the shadow of the gnomon [stylus] would fall precisely at that point of the sundial where the hour-line of that circle touches the diurnal or nocturnal arc of 24 hours, as can easily be shown from what was demonstrated in the preceding book. For, the Sun being on that parallel, the shadow of the gnomon is projected onto the arc of that parallel drawn in the sundial, as is evident from prop. 12 of the preceding book. Likewise, the Sun being on that hour-circle, the same shadow is projected onto the common section of it and the plane of the sundial — that is, onto the hour-line of that circle — as we showed in prop. 11 of the same book. It follows that the shadow falls on the said point, which is common both to the arc of that parallel and to the hour-line of the aforesaid circle. Since this is so, it is clear that, if we were placed at that point of contact of the greatest parallel of things always visible or always hidden, so that one semicircle of that hour-circle were to our right and the other to our left, and the Sun were in the right semicircle, the shadow of the gnomon would be projected to the left side of the aforesaid hour-line — that is, to the opposite side; but if the Sun were in the left semicircle, the same shadow of the gnomon would fall on the right side of the same line — the right and left sides being taken with respect to the point of contact on the diurnal or nocturnal arc of 24 hours in the sundial. Since, then, with the Sun on the different semicircles of that hour-circle, the shadow of the gnomon falls on different sides of its hour-line — now beyond the point of contact, now short of it — and since one of those semicircles indicates the hour from the Sun's rising, and the other the hour from its setting, as we said in the scholium of prop. 10 of the preceding book, it follows that one part of its hour-line, bounded at the point of contact, will pertain to the hours from sunrise — namely that onto which the shadow is projected when the Sun is set in the

semicircle that signifies the hour from sunrise — and the other part to the hours from sunset. And the same is true in other sundials that are not horizontal, and in all the hour-lines from sunrise or sunset.

[Margin: The use of the Italian sundial is that we may understand how many hours have elapsed since the most recent sunset, and how many remain until the next.]

The same thing, moreover, will become clear by this reasoning, even if we place neither the Sun nor ourselves at that point of contact. Any hour-semicircle from noon or midnight is placed precisely midway between the two semicircles of that hour-circle from sunrise or sunset which touches, at the same point, the greatest parallel of things always visible or always hidden — the point at which that hour-semicircle from noon or midnight cuts that same parallel, since it passes through its pole, by prop. 5 of book 2 of Theodosius [*Spherics* II.5] — so that it has one semicircle to the right and the other to the left. Now since, with the Sun on that hour-semicircle from noon or midnight, the shadow of the gnomon falls on its hour-line, which cuts the diurnal or nocturnal arc of 24 hours, it is clear that, with the Sun on that hour-semicircle from sunrise or sunset which is eastern with respect to that hour-semicircle from noon or midnight, the shadow is projected to the opposite side in the plane of the sundial — namely to the western side with respect to that hour-line from noon or midnight, yet onto the very hour-line from sunrise or sunset — as is evident from prop. 11 of the preceding book; while with the Sun on the other, western semicircle, the shadow falls on the eastern side of the sundial with respect to that hour-line from noon or midnight, yet onto the very hour-line from sunrise or sunset, by the same prop. 11 of the preceding book. Since, then, that hour-line from noon or midnight cuts the hour-line from sunrise or sunset at the point of contact of the diurnal or nocturnal arc of 24 hours, and one hour-semicircle from sunrise or sunset shows the hour from sunrise while the other shows the hour from sunset, it plainly follows that one portion of that hour-line from sunrise or sunset, up to the point of contact, indicates the hour from sunrise, while the remaining portion shows the same hour by number from the Sun's setting.

From what has been said it can easily be understood that the use of the Italian sundial is that from it we may know how many hours have elapsed since the most recent setting of the Sun, and how many remain until the next setting. Thus, when the shadow of the gnomon falls on some hour-line from sunset — say on the line of hour 19 — we are certain that 19 hours have passed since the most recent setting of the Sun, and, since from one sunset to the next 24 hours

intervene, that there remain until the following sunset five hours, which of course are what hours 19 lack to complete the number of 24 hours; and so with the rest.

Gnomonics, Book Two

PROBLEM 11. PROPOSITION 11.

To construct a Babylonian horizontal sundial — that is, to draw the lines of the hours from sunrise on a plane parallel to the horizon.

By the same method we used in drawing the lines of the hours from sunset, we shall draw the lines of the hours from sunrise. For these do not differ from the former except in position and order: the 23rd hour from sunset, transferred to the hours before noon, becomes the first hour from sunrise; the 22nd hour, transferred in the same way, becomes the second hour, and so on. This is clear if we correctly consider the nature and arrangement of these hour-circles, together with the figure of the preceding proposition. Just as, then, in drawing the Italian sundial by the earlier method we began the division of the circle $M a N b$ from the western points b and e , so for the Babylonian sundial we shall begin from the eastern points a and d — so that the points a and d belong to the 24th hour from sunrise in each tropic, the points nearest to them toward N to the first hour, the following ones to the second, and so on. For by these points of division we find, in each tropic, the points of the hours from sunrise, just as we said above concerning the points of the hours from sunset.

The division of the circle $M a N b$ can also take its beginning from the point of any hour from sunrise found on its circumference, as was explained in the preceding proposition.

In the other methods there is likewise no difficulty, provided the precepts of the preceding proposition are rightly understood and the tables of props. 19, 20, and 33 of the earlier book are carefully worked through, so as to find the points at which the lines of the hours from noon or midnight and those from sunrise or sunset intersect one another.

[Margin: Construction of the Babylonian horizontal sundial.]

Diagram. A large circle representing the horizon, with the vertical diameter M (top) to N (bottom) as the meridian (the noon–midnight line) and a horizontal diameter as the six-o'clock / equinoctial line. Radiating and cross-hatched hour-

lines fill the interior, converging in a dense knot near the upper-central pole below M. The hour-lines from sunrise (dotted and solid) are drawn across the two tropic arcs and the equinoctial line, and are numbered around the circumference. This is a very densely labelled figure; the clearly readable labels are listed below, and the remaining small numeric labels within the central knot could not be resolved with confidence.**

- M (top of circle): meridian / noon point
- N (bottom of circle): midnight point
- H (upper centre, just below M): pole about which the hour-lines converge
- 6 (left end of horizontal diameter) and 6 (right end): the six-o'clock points
- 4 (outside, lower left) and 8 (outside, lower right): hour-line labels carried beyond the circle
- a (left), d (lower left): eastern division-points of the tropic arcs
- e (right): a division-point on the right-hand side
- s, m (left of centre); X, K (upper centre): interior point-letters
- λ, 23 (lower left, near d): the 23rd-hour region
- 14, 13 (upper left): hour numbers
- 1, 10 (upper right); 6, 7, 8 (right); n, u (right): hour numbers and point-letters
- lower row of hour numbers (left→right): 3, 2, I, 12, II, 10, 9
- central knot of hour numbers: 12, 11, 10, 9, 8, 7, 6, 5, 4, 3 and 22, 21, 20, 19, 18, 17
- ß (lower centre): interior point
- ♌ [Leo] (lower right), with further worn zodiac-sign sorts near N and at the top that could not be pinned to a sign [?]
- Several small numeric hour-labels within the converging knot: [?]

Let us take, for example, the case of drawing the Babylonian sundial by the second method, using the diurnal arcs. The first hour from sunrise passes — as is clear from the tables of prop. 33 of the preceding book — through the sixth hour from midnight on the diurnal arc of 14 hours, through the seventh hour from midnight on the diurnal arc of 12 hours, and through the eighth hour from midnight on the diurnal arc of 10 hours. Therefore a straight line drawn from midnight through these hours will give the first hour from sunrise; and so with the rest. But those hours which have no points on the diurnal arc of 10 hours — as are all the hours after the ninth hour from sunrise in our example — must be drawn through points on the diurnal arcs of 14 and 12 hours. Now the twelfth

hour from sunrise must be drawn parallel to the equinoctial line (because the line of the twelfth hour from sunrise or sunset and the equinoctial line are parallel on a horizontal sundial, as is plain from the scholium of prop. 22 of the earlier book), through the fifth hour from noon on the diurnal arc of 14 hours.

Then, for the 13th hour from sunrise — since it has only the point of the sixth hour from noon on the diurnal arc of 14 hours — we shall draw the 13th hour from sunset through the eighth hour from midnight on the diurnal arc of 14 hours and through the seventh hour from midnight on the diurnal arc of 12 hours. For this line, produced beyond the arc of the greatest of the always-visible parallels, will give — as we showed in the scholium of the preceding proposition — the 13th hour from sunrise passing through the sixth hour from noon on the diurnal arc of 14 hours. By like reasoning, for the 14th hour from sunrise, since it has no point on the aforesaid arcs, we shall draw the 14th hour from sunset through the ninth hour from midnight on the diurnal arc of 14 hours and through the eighth hour from midnight on the diurnal arc of 12 hours; for this line, produced, will likewise indicate the 14th hour from sunrise. And in this manner we shall proceed for the other hours after the 14th from sunrise, if they need to be drawn.

By this method, then, both sundials — the Italian as well as the Babylonian — are readily drawn from the aforesaid tables of prop. 33 of the earlier book, provided that for those hours from sunset which have only a single point, or none at all, on the diurnal arc of 14 hours, we draw the same hours from sunrise, and conversely — as we have done for the 11th and 10th hours from sunset and the 13th and 14th from sunrise, and so on.

[Margin: Another construction of the Babylonian horizontal sundial, from the diurnal arcs.]

[Margin: A point of doctrine to be noted in constructing both the Italian and the Babylonian sundials by means of the diurnal and nocturnal arcs, or by the tables of prop. 33 of the preceding book.]

GNOMONICS

By the same device we shall make a Babylonian sundial from the diurnal arc of 24 hours; likewise by means of the line of the 12th hour from sunrise or sunset, and also by the other methods prescribed in the preceding proposition. This is plainly evident from the figure of the preceding proposition. And so we have constructed a Babylonian horizontal sundial, etc. Which was to be done.

SCHOLIUM.

Just as, from the Italian sundial, we learned how many hours have passed since the most recent sunset and how many remain until the next, so from the Babylonian sundial we shall know how many hours have elapsed since the most recent sunrise and how many are still required until the following one. For when the gnomon's shadow falls on some hour-line from sunrise — say on the line of the tenth hour — there can be no doubt at all that 10 hours have passed since the most recent sunrise, and therefore that 14 hours remain until the following sunrise, which are precisely what the 10 hours lack to complete the number of 24 hours; and so with the rest.

[Margin: The use of the Babylonian sundial is that, from the gnomon's shadow falling on its hour-lines, we may know how many hours have elapsed since the Sun's most recent sunrise and how many remain until the next sunrise.]

If both an Italian and a Babylonian sundial are drawn on the same plane — whether by the same gnomon, as we did in the proposed sundial, or by different ones — we shall know at any moment of time, from the shadow of the gnomon, the length of day and night; the time of noon and of midnight, both in hours from sunset and in hours from sunrise; the time of the Sun's rising in hours from sunset; and the time of the Sun's setting in hours from sunrise. For if the hours from sunrise, caught by the gnomon's shadow, are subtracted from the hours from sunset found at the same instant, there remains the time of the Sun's rising reckoned in hours from sunset. From this the rest is easily drawn out by this method. Suppose the shadow of the gnomon falls on the third hour from sunrise and on the 14th hour from sunset. Since, then, three hours have passed since the Sun rose that day, we subtract 3 from 14, and there remains the eleventh hour from sunset, at which the Sun rose. Night therefore comprises 11 hours at that point, and day 13, since day and night together make up 24 hours. If we halve the nighttime span of 11 hours, we find $5\frac{1}{2}$ hours for the time of midnight reckoned in hours from sunset. And since from midnight to noon there are 12 hours, if we add 12 to $5\frac{1}{2}$ we obtain $17\frac{1}{2}$ hours for the time of noon reckoned in the same hours from sunset. We find the same time of noon if we subtract the semidiurnal arc — which in this example comprises $6\frac{1}{2}$ hours — from 24 hours; for the semidiurnal arc, added to the time of noon, necessarily makes up 24 hours, namely the whole natural day of 24 hours from one sunset to the next, as is plain. So you see that if $6\frac{1}{2}$ is taken from 24, there remains $17\frac{1}{2}$ for the time of noon. Next, if we halve the daytime span of 13 hours, we find $6\frac{1}{2}$ hours for the time of noon reckoned in hours from sunrise. And since from noon to midnight there

flow 12 hours, if we add 12 to $6\frac{1}{2}$ we shall have $18\frac{1}{2}$ hours for the time of midnight reckoned in the same hours from sunrise. We shall also find this same time of midnight if we subtract the seminocturnal arc — which in our example comprises $5\frac{1}{2}$ — from 24 hours, since the seminocturnal arc, added to the time of midnight, necessarily makes 24 hours, namely the whole natural day of 24 hours from one sunrise to the next. So you see that if $5\frac{1}{2}$ is taken from 24, there remains $18\frac{1}{2}$ for the time of midnight. And the Sun sets at the 13th hour from sunrise.

Suppose again that the shadow of the gnomon indicates the $6\frac{1}{4}$ hour from sunrise and the $17\frac{1}{2}$ hour from sunset. If we subtract $6\frac{1}{4}$ from $17\frac{1}{2}$ we find the $11\frac{1}{4}$ hour from sunset, at which the Sun rose that day; and so night then comprises $11\frac{1}{4}$ hours, while day will be $12\frac{3}{4}$ hours. Midnight will fall at hour $5\frac{1}{2}$ and $\frac{1}{8}$ — that is, hour $5\frac{5}{8}$ — reckoned in hours from sunset, and noon at hour $17\frac{1}{2}$ and $\frac{1}{8}$ — that is, hour $17\frac{5}{8}$ — in hours from sunset. Likewise, reckoned in hours from sunrise, noon falls at hour $6\frac{1}{4}$ and $\frac{1}{8}$ — that is, hour $6\frac{3}{8}$ — and midnight at hour $18\frac{1}{4}$ and $\frac{1}{8}$ — that is, hour $18\frac{3}{8}$. Finally the Sun sets at hour $12\frac{3}{4}$ from sunrise; and so with the rest.

The same can also be found by means of the astronomical sundial which we constructed in prop. 1 of this book. For from it we come at once to knowledge of the time of noon in Italian or Babylonian hours, and from that we shall learn the rest in this way. Suppose the shadow falls on the hour $9\frac{1}{2}$ from midnight, on the fourth hour from sunrise, and on the 15th hour from sunset. Since, then, $2\frac{1}{2}$ hours are still wanting until noon, if we add $2\frac{1}{2}$ to 4 and to 15 we find that noon, reckoned in hours from sunrise, falls at hour $6\frac{1}{2}$, and therefore midnight at hour $18\frac{1}{2}$; while in Italian hours noon falls at hour $17\frac{1}{2}$ and midnight at hour $5\frac{1}{2}$ — since noon and midnight are always 12 hours, that is a semicircle, apart. From this the length of the day will be evident. For since noon falls at hour $6\frac{1}{2}$ from sunrise, an equal number of hours will remain until sunset; and so the day will contain 13 hours and the night 11.

The Sun will therefore rise at the 11th hour from sunset and set at the 13th hour from sunrise. Similarly, since midnight falls at hour $5\frac{1}{2}$ from sunset, an equal number of hours remain until the Sun's rising; and so night comprises 11 hours and day 13, etc. Suppose again it is found to be the hour $3\frac{1}{2}$ from noon, the hour $8\frac{1}{4}$ from sunrise, and the hour $22\frac{3}{4}$ from sunset. Since, then, $3\frac{1}{2}$ hours have elapsed since noon, if we subtract $3\frac{1}{2}$ from $8\frac{1}{4}$ and from $22\frac{3}{4}$ we find noon, reckoned in hours from sunrise, to fall at hour $4\frac{3}{4}$ and midnight at hour $16\frac{3}{4}$; but in hours from sunset noon falls at hour $19\frac{1}{4}$ and midnight at hour $7\frac{1}{4}$. And so, since noon falls at hour $4\frac{3}{4}$ from sunrise, an equal number of hours will remain

until the Sun's setting; therefore the day will comprise $9\frac{1}{2}$ hours and the night $14\frac{1}{2}$. Hence the Sun will then rise at hour $14\frac{1}{2}$ from sunset and set at hour $9\frac{1}{2}$ from sunrise. By the same reasoning, since midnight, in the Italian manner, falls at hour $7\frac{1}{4}$, an equal number of hours will remain until the Sun's rising; and so night will contain $14\frac{1}{2}$ hours and day $9\frac{1}{2}$, etc.

[Margin: How, from the Italian and Babylonian sundials together, the length of day and night, and the time of noon and of midnight, both in hours from sunset and in hours from sunrise, [may be known] at any time from the shadow of the gnomon, etc.]

[Margin: How the same things just discussed may be found by means of the astronomical sundial.]

From the description of the Italian and Babylonian sundials given in this and the preceding proposition, it is clear that these two sundials do not differ from each other except in position and in the order of the hours — so that the left part of one corresponds to the right part of the other, and conversely. Therefore, if an Italian sundial is drawn, the same will serve for a Babylonian one, provided it is inverted so that the left side becomes the right and vice versa, and provided that from the line of hour 23 from sunset is made hour 1 from sunrise, and hour 2 from sunrise is made from hour 22 from sunset, and so on. This is easily seen if the Babylonian sundial laid out by this proposition is compared with the Italian sundial described in the preceding proposition.

And so, if an Italian sundial is drawn on some sheet, and on the opposite side lines are drawn corresponding exactly to the lines of the Italian sundial, a Babylonian sundial will be described on the opposite side — provided the hour-numbers of the Italian are changed, in the Babylonian, into their complements to 24, so that hour 23 Italian becomes the first Babylonian, hour 22 the second, hour 21 the third, and so on.

In the same way, if a Babylonian sundial is drawn first, an Italian one will be described on the opposite side, so that each single line corresponds exactly to each single line, the hour-numbers in the Babylonian being likewise changed into their complements to 24 in the Italian: thus hour 1 Babylonian becomes 23 Italian, the second becomes 22, the third 21, and so on. This same thing is to be understood of other Italian and Babylonian sundials that are drawn on other planes — namely on planes parallel not to the horizon but to other great circles in the sphere.

[Margin: How the Italian and Babylonian sundials differ from each other, and by what method the Babylonian is composed from the Italian, and the Italian from the Babylonian.]

LIBER SECUNDUS.

PROBLEM 12. PROPOSITION 12.

To construct a horizontal sundial of the ancient [unequal] hours — that is, to draw the lines of the unequal hours on a plane parallel to the horizon.

Having divided the circle from E — described into the diurnal arc a N b of the tropic of Cancer [♋ Cancer] and the arc d N e of the tropic of Capricorn [♏ Capricorn], as was done in prop. 10 of this book — let each diurnal arc be cut into 12 equal parts, beginning from the eastern points a and d, so that the points next after a and d toward N belong to the first unequal hour in each tropic, the following ones to the second, and so on. If the sundial and the circle M a N b keep their proper position, the great circles drawn through the poles of the world and through the unequal hours of the tropics of Cancer and Capricorn will pass through these points of division, as is evident from what was demonstrated in prop. 10 of this book. For the same demonstration can be brought to bear here, since in the same way we shall show that the circle drawn through the poles of the world and through the 12th unequal hour in the tropic of Cancer passes through point b — since that same point in the tropic of Cancer belongs to the 12th unequal hour and to the 24th hour from sunset. Hence we shall further show (since the arc between b and the nearest division-point toward N is similar to the arc of the tropic of Cancer lying between two great circles drawn through the poles of the world — of which one is drawn through the 12th unequal hour and the other through the 11th unequal hour in the tropic of Cancer — because each arc is the twelfth part of the semidiurnal arc of the tropic of Cancer in its own circle) that the great circle drawn through the poles of the world and through the 11th unequal hour in the tropic of Cancer passes through the division-point nearest to b toward N; and so with the rest. If, then, through the division-points and the centre E straight lines are drawn cutting the equinoctial line at points, through which in turn straight lines are sent out from H, the centre of the sundial, there will be found in the tropics—

[Margin: Construction of the horizontal sundial of the ancient [unequal] hours.]

Diagram. A circle representing the horizon, with the vertical diameter M (top) to N (bottom) as the meridian and a horizontal diameter through the centre as the

equinoctial line. The gnomon-centre E lies at the middle, with H just above it; the unequal-hour lines fan out from the upper-central region and are labelled in half-hours. The tropic arcs a N b (Cancer) and d N e (Capricorn) span the figure, with the worked-example points f, g, h, m, n, p, q shown. Densely labelled; the readable labels are listed, the rest flagged.**

- M (top): meridian / noon point
- N (bottom): midnight point
- E (centre): centre of the sundial / gnomon foot
- H (just above E): centre from which the straight lines are emitted
- 7½ (upper left) and 4½ (upper right): unequal-hour-line labels
- 12 (top centre), 6 (upper centre-right): hour labels
- 4½, 3, 7½ (central cluster of unequal-hour labels near H): hour labels
- q, a (upper left); t, m, d (left): point-letters
- p (upper right); f (right); n, n (right, the equinoctial line carried out on both sides); u (right); h (centre-right); z, e (lower right): point-letters
- f (bottom, near N): point-letter
- horizontal row of hour-points along the equinoctial line (left→right): n, 10, 9, 8, 7, [?], 3, 2, 1
- Several small numeric hour-labels in the central fan: [?]

of Cancer and Capricorn the points of the unequal hours, exactly as in props. 10 and 11 of this book we found in the same [tropics] the points of the hours from sunset and from sunrise. Hence, if the corresponding points are joined by straight lines, the sundial of the ancient hours will be described. Now all the lines of the unequal hours will pass through the hours from noon or midnight on the equinoctial line, as is established from table 13 of the scholium of prop. 33 of the preceding book. But take one or two examples of this construction. From f, the point of the 3rd unequal hour in the tropic of Capricorn, a straight line drawn through E cuts the equinoctial line at g; and a straight line sent out from H through g cuts the tropic of Capricorn at h, the point of the third unequal hour. Again, from point m — which is opposite to the eleventh unequal hour in the tropic of Cancer — a straight line sent out through E cuts the equinoctial line at n, while the straight line H n cuts the tropic of Cancer at point p, which is owed to the semicircle of the great circle drawn through point m; and the line n H, produced beyond the centre, cuts the same tropic of Cancer at q, the point of the eleventh unequal hour, and so on. All of which is clear from what was demonstrated in prop. 10 of this book.

Here too, as in prop. 10 of this book, we shall find on the circle M a N b the diurnal and nocturnal arc of the tropic of Cancer or of Capricorn, in another way than by the method we wrote of in the scholium of prop. 1 of the earlier book — namely if, from point N, we reckon off on each side the semidiurnal arc of the tropic of Cancer up to a and b, or of the tropic of Capricorn up to d and e.

Indeed, even if we do not divide the said circle into the said arcs, we shall find on it the point of any unequal hour, the Sun being on any parallel whatever, by this method. Let the diurnal arc of the given parallel be divided by 12, so that in the quotient we have the length of one unequal hour on the given parallel; and thus, doubling that same number, the size of two hours, tripling it the size of three, and so on. Then let it be considered how far the proposed unequal hour is distant from the meridian circle, whether before noon or after. For if this distance is reckoned on the circle M a N b from point N — toward a if the given hour is before noon, or toward b if after noon — we shall come upon the point of the given unequal hour. Example. The diurnal arc of the tropic of Cancer contains 15 hours 4 minutes, that is, 226 degrees; and these degrees, divided by 12, yield 18 degrees 50 minutes for the size of one unequal hour in the tropic of Cancer. Hence two hours will make 37 degrees 40 minutes; three hours, 56 degrees 30 minutes; four hours, 75 degrees 20 minutes; five hours, 94 degrees 10 minutes; and six hours, 113 degrees. And so, if the point of the ninth unequal hour of the tropic of Cancer is sought on the circle M a N b, then — since this hour is after noon — if its distance from the meridian is reckoned from point N toward b, namely 56 degrees 30 minutes, the point of the ninth unequal hour of the tropic of Cancer will be found. And the same method is to be followed for the rest.

Otherwise. From prop. 3 of this book let two parallels be described — one northern, having a diurnal arc of 18 hours, and a [southern one]...

[Margin: Another construction of the sundial of the ancient [unequal] hours...]

[Margin: ...logii Antiqui horizontalis — of the ancient horizontal sundial — by the diurnal arcs of 18 and 6 hours. (Continuation of a note begun on the preceding page.)]

and a second, southern one whose diurnal arc takes in six hours. For from the tables of diurnal arcs of 18, 6, and 12 hours — which we set out for the unequal hours in the scholium of prop. 33 of the preceding book — we shall presently learn through which hours from noon, or from midnight, the individual unequal hours are to be drawn in the said arcs. Thus you see that the first unequal hour must be drawn through the [equal] hour $4\frac{1}{2}$ from midnight in the diurnal arc of

18 hours; through the seventh [hour] from midnight in the arc of 12 hours; and through $9\frac{1}{2}$ from midnight in the diurnal arc of 6 hours. The second unequal hour, in turn, is drawn through hour 6 from midnight in the diurnal arc of 18 hours; through the eighth from midnight in the diurnal arc of 12 hours; and through the tenth hour from midnight in the diurnal arc of 6 hours; and so on.

It will nevertheless be enough if in the horizontal sundial we describe only the northern parallel of 18 hours, since the southern one of 6 hours runs out too far beyond the tropics. And so we have constructed the ancient horizontal sundial, and so forth. Which was to be done.

SCHOLIVM.

The shadow of the gnomon, falling on the lines of the unequal hours, teaches how great a part of the day has passed and how much still remains. For since any given day is divided into 12 equal parts, which are called unequal hours, it comes about that when the shadow of the stylus falls, say, on the third unequal hour, a fourth part of the day has passed and three-quarters remain. And when that same shadow falls on the eighth unequal hour, two-thirds of that day have elapsed and one-third still remains, and so on.

[Margin: The use of the ancient sundial is to let us understand how great a part of the day has passed and how much still remains. By this method the unequal hours are ascertained — those called planetary — each of which corresponds to fifteen degrees of the ecliptic.]

Now everything that was written in the last 12 propositions about the various uses of the things we depicted on the horizontal sundial must be understood to hold for all other sundials as well, which we shall treat of in what follows.

But perhaps there will be no lack of those who also wish to know by what means those unequal hours may be determined which are called temporal, natural, and planetary — as we explained in our commentaries on the sphere — each of which takes in that span of time in which half a sign of the zodiac, that is, fifteen degrees of the ecliptic, ascends above the horizon. For these divide the artificial day into 12 unequal parts, since the ascension of the first 15 degrees of the ecliptic is unequal to the ascension of the following 15 degrees, and so on. We shall satisfy them thus. Suppose, for the sake of an example, that we must find the time of the seventh unequal hour when the Sun is at 20° Taurus [♉]. Since any given unequal hour takes in 15 degrees of the ecliptic, it is necessary that by the seventh unequal hour 105 degrees of the ecliptic will have ascended; and if we count

these off from 20° Taurus in the order of the signs, we arrive at 5° Virgo [♍], which ascends above the horizon at the seventh unequal hour on that day. Therefore, if from the oblique ascensions we seek the ascension of the arc of the ecliptic between 20° Taurus and 5° Virgo, we shall find that at latitude 42° it contains 117° 14' — that is, 7 equinoctial hours 49 minutes. We shall say, then, that it is the seventh unequal hour when 7 hours 49 minutes have passed since sunrise. Accordingly, when on the Babylonian sundial the hour 7, minute 49, has been determined from the gnomon's shadow, we shall pronounce that it is then the seventh temporal — or planetary — hour on that day when the Sun stands at 20° Taurus.

Now if we wish to reduce this hour 7, minute 49, from sunrise to astronomical and Italian hours, we shall do it in this way. Since the diurnal arc then contains 14 hours 14 minutes, while the semidiurnal arc is 7 hours 7 minutes, if we subtract 7 hours 49 minutes from the diurnal arc of 14 hours 14 minutes, there remain 6 hours 25 minutes up to sunset. Therefore 17 hours 35 minutes have then elapsed since the previous sunset. But if we subtract the semidiurnal arc of 7 hours 7 minutes from the 7 hours 49 minutes since sunrise (since the latter number is the smaller), there will remain 0 hours 42 minutes since the noon just past. Therefore, if on the same day the hour 17, minute 35, has been observed on the Italian sundial, or the hour 0, minute 42, after noon on the astronomical one, we shall again say that it is then the seventh temporal or unequal hour.

Again, let it be worth our while, on the same day, to find the time of the third temporal or unequal hour. Since, then, each temporal hour takes in 15 degrees of the ecliptic, it is necessary that by the third unequal hour 45 degrees of the ecliptic will have ascended; and if we count these off from 20° Taurus in the order of the signs, we arrive at 5° Cancer [♋]. The oblique ascension of the arc of the ecliptic between 20° Taurus and 5° Cancer, at latitude 42°, takes in 41° 45' — that is, 2 equal hours 47 minutes. Therefore, when on the Babylonian sundial we have determined the hour 2, minute 47, it will be exactly the third temporal hour. Now if the 2 hours 47 minutes since sunrise are deducted from the diurnal arc of 14 hours 14 minutes, there remain 11 hours 27 minutes up to sunset; and so the third unequal hour falls at the hour 12 [?], minute 33, from sunset. But if we subtract the 2 hours 47 minutes since sunrise from the semidiurnal arc of 7 hours 7 minutes (since the former is the smaller), there will remain 4 hours 20 minutes up to noon. Therefore that same third unequal hour falls at the hour 7, minute 40, from the previous midnight. By this device we shall determine the temporal or unequal hour at any proposed time whatever, and for any latitude whatever.

DE HOROLOGIIS VERTICALIBVS.

PROBLEMA 13. PROPOS. 13.

To construct an astronomical vertical sundial — that is, to describe the hour-lines from noon or midnight on a plane that is parallel to the vertical circle.

[Margin: Description of the astronomical vertical sundial.]

Diagram. A geometric construction (a "portion of the analemma") for laying out the vertical sundial. A semicircle ABC stands on the horizontal diameter BC, with center D. From D rise and cross several straight lines representing the meridian's sections with the horizon, the vertical circle, the equator, and the axis of the world; the line HI is drawn through G parallel to AD, cutting ED and FD at H and I. Readable labels, by position:

- L, L (top, two adjacent letters at the apex): tops of the vertical lines
- A, K (upper center, just below the apex): "AK"
- F (upper left of the arc): meridian–equator section point
- E (upper right of the arc): axis-of-the-world point (toward the north)
- N (middle right, on an interior line)
- I (middle left of center)
- H (center): where the axis of the world meets the sundial plane
- G (center, near D): foot of the stylus on BC
- D (center): center of the semicircle / center of the world
- B (left end of the diameter)
- C (right end of the diameter)
- H, I (lower left, a second labelled pair on the HI parallel): "HI"
- I (just below the center)
- M (lower right)
- O (at the bottom, foot of a descending line)

Let there again be, as in prop. 1 of this book, a portion of the analemma [analemma] ABC: that is, let ABC be the semicircle of the meridian, whose center is D; let BC be the common section of the meridian and the horizon; AD the common section of the meridian and the vertical circle; FD the common section of the meridian and the equator; and ED the axis of the world. Now, with the straight lines FD and ED produced toward D, let there be taken on the straight line BC — for the stylus of the future sundial, of whatever magnitude it shall have

been given — a straight line DG equal on either side. And through G let HI be drawn parallel to AD, cutting ED and FD at H and I. If, then, we understand the vertical circle properly so called to be drawn through AD, and through HI the plane of the sundial parallel to that vertical circle, then — since both the meridian and the horizon are perpendicular to the said vertical — [a] their common section BC will be perpendicular to it, and therefore also perpendicular to the plane of the sundial drawn parallel to the vertical through HI, as follows from what we demonstrated for prop. 14 of book 11 of Euclid [Euclid, *Elements* XI.14]. HI, therefore, will be in the plane of the sundial the meridian line, or the line of the

[Margin: ^b *Elements* XI.19.]

[Margin: ^a *Elements* XI.2.]

12 o'clock — namely the common section of the meridian and the plane of the sundial. [a] For the straight line HI is in the plane of the straight lines HD, ID, that is, in the plane of the meridian. DG will be the gnomon, at right angles to the plane of the sundial, and hence also perpendicular to HI, the meridian line, by definition 3 of book 11 of Euclid [Euclid, *Elements* XI, def. 3], its vertex D being the very same as the center of the world, by prop. 2 of the preceding book. The place of the gnomon is the point G, on the meridian line, distant from the point H (at which the axis of the world meets the plane of the sundial, and which is called the center of the sundial) by the interval GH; or from the point I (at which the plane of the equator cuts the meridian line) by the interval GI. All of which is clear if the meridian is conceived to have its proper position — that is, so that the point E inclines toward the north and F toward the south. This figure, so constructed, we shall call — for the sake of the doctrine — a portion of the analemma, just as we called that figure which we described at the beginning of prop. 1 of this book a portion of the analemma.

Now, by the benefit of the triangle DHI, we shall construct the astronomical vertical sundial in this way. Onto a straight line HE, drawn anyhow in the plane on which the sundial is to be described, let the straight line HI — the meridian line of the portion of the analemma — be transferred: downward, indeed, from the point H, if the sundial is to be described facing south;

Diagram. The upper of two vertical-sundial figures on this page — the **southern (austral)** dial, its title split by the vertical meridian line as "AVS ... TRALE" (*Australe*). A semicircular dial with hour-lines radiating from the center. An inner

circle sits about the center, and a small auxiliary circle stands at the upper left. Readable labels:

- "12" (top center): the noon line
- Around the rim, the hour-numbers (left side, descending): 6, 7, 8, 9, 10; and at the base 11, 12, 1; (right side, descending): 5, 4, 3, 2
- "C" (far left) with "6" (the horizontal line 6–6); "L" and "6" (far right): the ends of the line CL
- "K" (mid-right, on the horizon line); "F" (mid-left, on the horizon line)
- "S" (inner right of center); "R", "P", "M" (upper center, near the top of the inner circle) [?]
- "H" (center): center of the sundial
- "G", "I" (just below center)
- "E" (lower center); "N" (bottom center); "O" (bottom); "Q" (lower left of center)
- "d" and a small point "e" [?] at the auxiliary circle, upper left
- "AVS" (left) / "TRALE" (right): *Australe*, "southern"

Diagram. The lower of the two figures — the **northern (boreal)** dial, its title split as "BORE ... ALE" (*Boreale*). A full circle with hour-lines radiating from the center H at the bottom, an inner circle about the center, and hour-numbers ranged around the whole circumference. Readable labels:

- "R", "P", "M" (top center, at the top of the inner circle) [?]
- Hour-numbers around the rim (upper left, descending): 9, 8; (upper right): 2, 3, 4; then down the sides and across the base: 7, 6, 5, 4 (left); 5, 6, 7, 8 (right); and along the bottom 4, 3, 2, 1, 12, 11, 10, 9, 8
- "E" (upper center, inside the inner circle)
- Horizontal mid-row (left to right): "F", "R", "I", "S", "K", flanked by "BORE" (far left) and "ALE" (far right)
- "6", "C" (left) and "L", "6" (right): the ends of the lower horizontal line CL
- "H" (center): center of the sundial
- "D", "G" (just above center); "I" (center); "O", "Q" (just below center)
- A dotted "9" near E [?]

but upward, if the northern [dial] is to be laid out, as is clear from the portion of the analemma. For the plane of the sundial facing south, receding of course from D, the center of the world, toward the parts of the north pole E, cuts the equator FD below the point H, at the point I; whereas the plane of the sundial facing

north, receding of course from D, the center of the world, toward the southern parts, cuts the same equator above the point H, at the point I, and so on. Then from the straight line HE let there be cut off IE, equal to DI of the portion of the analemma; and through I let the perpendicular FK be raised to HE in the plane of the sundial. From E let a circle of any magnitude be described; and this being divided into 24 equal parts, beginning from the meridian line HE produced, let there be drawn — through the points of division and the center E — hidden straight lines cutting the straight line FK at points. Through these points, and through the point H, straight lines sent out will give the hour-lines from noon, or from midnight, on the plane parallel to the vertical, whose order we shall explain a little further on for each of the two sundials. For the sixth hour, however, the line CL must be drawn through H, perpendicular to HE, or parallel to FK. All of which will be demonstrated as follows.

[Margin: Demonstration of the construction of the vertical sundial.]

Let the portion of the analemma be conceived as laid over the sundial, so that point H coincides with point H, point I with point I, and the straight line HI with the straight line HI (and it will coincide with it, because of the equality of the straight lines HI and HI);

[Margin: ^a *Elements* XI.19.]

and let that same portion of the analemma be imagined as standing upright toward the plane of the sundial, and let the meridian line HE have its proper position, so that it is the common section of the meridian and the plane of the sundial; and let the point H, in the southern sundial, incline toward the zenith and E toward the nadir, while in the northern one the point H inclines toward the nadir and E toward the zenith; and finally let the straight line BC be perpendicular to the plane of the sundial, so that it is the common section of the meridian and the horizon, with D, the vertex of the stylus, being the center of the world, as we showed at prop. 2 of the preceding book. Or, if you prefer, in place of the portion of the analemma let only the triangle DHI be understood — laid, as we said, over the sundial in such a way that DH represents the axis of the world, DI the common section of the meridian and the equator, and finally DG, the stylus, the common section of the meridian and the horizon, drawn through D, the center of the world. This triangle DHI, together with the gnomon DG, has been drawn in each of the two sundials. These things being so posited, the axis HD will meet the plane of the sundial at H; the diameter of the equator, DI, at I; and the diameter of the horizon, DG, at G. Since, therefore, both the plane of the equator and the plane of the sundial (parallel to the vertical) are perpendicular to the

plane of the meridian, [a] the common section of the equator and the plane of the sundial will also be perpendicular to that same plane of the meridian, and hence — by definition 3 of book 11 of Euclid [Euclid, *Elements* XI, def. 3] — perpendicular to the meridian line HI, which lies in the plane of the meridian, at the point I, where the equator meets the meridian line in the sundial,

Diagram. The upper of two vertical-sundial figures on this page, repeating the **southern (austral)** dial of the preceding page — its title split by the meridian as "AVS ... TRALE" (*Australe*). A semicircular dial with hour-lines radiating from the center, an inner circle about the center, and a small auxiliary circle at the upper left. Readable labels:

- "12" (top center)
- Rim hour-numbers (left, descending): 6, 7, 8, 9, 10; base: 11, 12, 1; (right, descending): 5, 4, 3, 2
- "C" with "6" (far left); "L" with "6" (far right): ends of the line CL
- "K" (mid-right on the horizon line); "F" (mid-left on the horizon line); "S" (inner right)
- "R", "P", "M" (upper center, inner circle) [?]
- "H" (center); "G", "I" (just below center)
- "E" (lower center); "N" (bottom center); "O" (bottom); "Q" (lower left)
- "d" and a small point "e" [?] at the auxiliary circle
- "AVS" (left) / "TRALE" (right): *Australe*

[Same crowded interior cluster as fig-p185-1; several readings uncertain]

Diagram. The lower figure, repeating the **northern (boreal)** dial — title split as "BORE ... ALE" (*Boreale*). A full circle with hour-lines radiating from the center H at the bottom, an inner circle, and hour-numbers around the whole rim. Readable labels:

- "R", "P", "M" (top center, inner circle) [?]
- Rim hour-numbers (upper left): 9, 8; (upper right): 2, 3, 4; (sides/base): 7, 6, 5, 4 (left) and 5, 6, 7, 8 (right); along the bottom 4, 3, 2, 1, 12, 11, 10, 9, 8
- "E" (upper center, inner circle)
- Horizontal mid-row (left to right): "F", "R", "I", "S", "K", with "BORE" (far left) and "ALE" (far right)
- "6", "C" (left) and "L", "6" (right): ends of the lower horizontal line CL
- "H" (center); "D", "G" (above center); "I" (center); "O", "Q" (below center)
- A dotted "9" near E [?]

[Same crowded interior cluster as fig-p185-2; several readings uncertain]

as was said. Therefore the straight line FK, which in the sundial is drawn through I perpendicular to the meridian line HI, is the common section of the equator and the plane of the sundial — namely, the equinoctial line. Now suppose the plane of the circle described from center E is understood to be moved about this line FK, until it is joined with the center of the world D, in the triangle DHI (which triangle we said is at right angles to the plane of the sundial and lies in the plane of the meridian, together with the whole portion of the analemma, although only the triangle is drawn in the sundial): namely, until E, the center of the circle, is joined [to D], inasmuch as the straight lines DI and IE are equal by construction, and in that motion of the circle described from E the straight line IE always remains in the plane of the meridian, in which DI lies. Then that circle will be described about D, the center of the world — that is, it will be the equator described, and it will lie in the plane of that same equator, since the plane of the equator is drawn through the straight lines DI, IK, just as the said circle in that position is drawn through the same lines; so that this circle and the equator lie in the same plane and have the same center, namely D, the center of the world. Let IE also be understood as produced in both directions in the same position, inasmuch as it is moved together with the plane of the circle as the common section of the meridian and the equator, since both the meridian and the equator in this position pass through the straight line DI or IE. Wherefore, by what was demonstrated in prop. 1 of this book concerning the horizontal sundial, the straight lines going out from the center E will be common sections

of the equator and of the hour-circles from noon or midnight — namely NM, the common section of the equator and the circle of hour 12; OP, the common section of the equator and the circle of the first hour from noon or midnight; QR, the common section of the equator and the circle of the second hour from noon or midnight, and so on. And so, just as we demonstrated in that place, the straight lines drawn from H through the points of the straight line FK will be the hour-lines from noon or midnight, for the same demonstration can be applied here. Only the line of the sixth hour must be drawn through H perpendicular to HI — or, what is the same, parallel to FK itself — such as CL is. For since, by the scholium of prop. 22 of the previous book, the equinoctial line and the line of the sixth hour from noon or midnight are parallel in the vertical sundial, it is clear that the straight line CL is the line of the sixth hour, seeing that it is parallel to the equinoctial line FK and passes through the point H, where all the hour-lines from noon or midnight cut one another.

[Margin: The order of the hours in each of the two vertical sundials.] In the southern sundial, moreover, the meridian line HI, running from the center toward the equinoctial line, marks the hour of noon (12), while the remaining portion running upward marks midnight (12). The lines to the left of the meridian line show the hours after midnight, and their portions to the right of that same meridian line show the hours after noon. In the northern sundial the opposite is to be understood. All this is clear once the position of the hour-circles is rightly understood, and once careful attention is paid to what we wrote in the scholium of prop. 1 of this book about what must be observed in the lines drawn in the sundial — namely, which celestial semicircle each line represents, and by what principle any hour after noon, when produced beyond the center of the sundial, marks the same hour numbered from midnight, and the reverse. Therefore we have set up the Astronomical Vertical sundial, and so forth. Which was to be done.

SCHOLIVM.

[Margin: Another and most convenient method of laying out the Astronomical Vertical sundial, for tracing those hours that lie close to the line of the sixth hour from noon or midnight.] Andreas Schonerus [Andreas Schöner] hands down another method by which the hour-lines can be drawn, similar to the one we explained in the same scholium of prop. 1 of this book for laying out the horizontal sundial. It runs roughly as follows. On the equinoctial line FK, take the straight line I a equal to the straight line IE (or ID); and through a draw the straight line a b perpendicular to the equinoctial line — that is, parallel to the meridian line — cutting the line of the sixth hour, which of course is drawn from H perpendicular to HI, at the point b. Then, taking the straight line b d equal to a b itself, draw through d the line e f perpendicular to b d — that is, parallel to the meridian line. Finally, with center d describe a circle, divide it into 24 equal parts beginning from the straight line b d, and from the center d draw hidden straight lines through the points of division. For these will cut the straight line a b at points through which the hour-lines are to be drawn from the center H of the sundial. We have set an example of this construction in the southern sundial.

[Margin: The segments of the equinoctial line in the vertical sundial, between the meridian line and any two hours equally distant on either side from the meridian line, are equal.] In any Vertical sundial, however, any two hour-lines removed from the meridian line on either side by an equal interval of time cut off equal lengths from the equinoctial line FK — namely those lengths that lie between the two lines themselves and the meridian line — so that on the equinoctial line the

hour-spaces before noon are equal to the hour-spaces after noon, each to its counterpart. From this it follows that the arcs of any circle described from H in the Vertical sundial, intercepted between the meridian line and any two hour-lines equally distant in time on either side from the meridian line, are equal. Likewise, the intervals between E, the center of the Equator, and any two hours removed on either side from the meridian line by an equal interval of time on the equinoctial line, are equal. All of this will be demonstrated in the way we used in the scholium of prop. 1 of this book to demonstrate the same points for the horizontal sundial.

[Margin: It is enough, for laying out the Astronomical Vertical sundial, that one single quadrant of the circle described from E be divided into 6 equal parts.] From this it follows that, for laying out the Vertical sundial, it is enough that a single quadrant of the circle described from E be divided into six equal parts — such as, for example, the quadrant Mg. On this matter, see what we wrote to this same end concerning the horizontal sundial in the scholium of prop. 1 of this book.

[Margin: How each of the two Vertical sundials is to be placed together with the axis of the world, so that it may show the hours from noon or from midnight.] Here too, if in the triangle DHI the axis HD is understood to be set at right angles to the plane of the sundial — as a thread stretched out, or even some thin rod fixed at H, making with the meridian line an angle equal to the angle DHI, and making right angles with the straight line CL — or if the triangle DHI itself, contained in the sundial above, is built up out of some solid material and set at right angles to the plane of the sundial: then the shadow of the axis DI will mark the several hours from noon or midnight, provided the sundial is placed on a plane that lies parallel to what is properly called the Vertical circle, in such a way that the straight line HI (namely the meridian line) is perpendicular to the Horizon, and the straight line FK lies parallel to that same Horizon. And in the sundial that faces south, the equinoctial line FK must lie below the point H, which is the center of the sundial, while in the one that faces north it must lie above. From this it also follows that the shadow of the vertex D of the style DG, set at right angles to the plane of the sundial at the point G — which vertex is the same as the center of the world, by prop. 2 of the previous book — marks the same hours; that is, it is projected onto the hour-lines, just as was said of the horizontal sundial in the scholium of prop. 1 of this book. For the demonstration here is the same.

But if we wish to lay out in the sundial the half-hours as well, and their quarters, or eighths, or any other divisions, we must divide each of the arcs of the circle described from E into two parts, or four, or eight, or however many; everything else is to be carried out as before.

[Margin: When the elevation of the pole above the Horizon is so great that the pole recedes but little from the vertex of the head, what is to be done in laying out the sundial.] Now indeed, when the elevation of the pole above the Horizon is so great that the axis ED in the portion of the Analemma differs but little from the diameter AD of the Vertical circle — and therefore the straight line HI, if the style DG is not very short, meets it at H at a very remote point and makes a very acute angle there — we shall nevertheless lay out the sundial, even though we have no center H, just as in the scholium of prop. 1 of this book we constructed the horizontal sundial even though we had no center H there (which indeed happens when the elevation of the pole above the Horizon is very small). The one exception is that, in place of the angle of the pole's elevation DEF, we must set up in the Vertical sundial the angle of the complement of the pole's elevation. Everything else is to be completed as in the said scholium.

[Margin: When the elevation of the pole above the Horizon is very small, what is to be done in laying out the sundial.] Again, when the elevation of the pole is so small that the diameter FD of the Equator makes a very acute angle with HI and meets it at the very remote point I — and it is therefore difficult to discern that point at which the said angle is formed — we shall use the same remedy that we handed down in the said scholium of prop. 1 of this book for the horizontal sundial, when the elevation of the pole was supposed so great that the pole was but little distant from the vertex of the head; provided that, in constructing the vertical sundial, in place of the angle of the pole's elevation BAN we set up the angle of the complement of the pole's elevation.

[Margin: If the style DG, at G, is set at right angles to the plane of the sundial, the shadow of the vertex D alone will show the hours from noon or midnight.]

[Margin: By what method the half-hour, and their quarter-parts, or any other divisions, are to be drawn in the sundial.] [Margin: When the elevation of the pole above the Horizon is so great that the pole recedes but little from the vertex of the head, what is to be done in laying out the sundial.] [Margin: When the elevation of the pole above the Horizon is very small, what is to be done in laying out the sundial.]

[Margin: If the southern sundial is inverted, so that from the upper part the lower comes to be, and what after this inversion is on the right (with the sundial turned

toward us) is changed to the left, and the reverse, the numbers of the hours remaining exactly the same, a northern sundial will have been constructed. But the hours that were formerly counted from noon must now be counted from midnight, and the reverse.]

Furthermore, the southern vertical sundial described so far will also mark the hours on the opposite face of the sundial's plane — the one that faces north — if all its parts are so inverted that from the upper part the lower comes to be, and what after this inversion is on our right (with the sundial turned toward us) is changed to the left, and the reverse, while the numbers of the hours nevertheless remain exactly the same. But then the portion of the meridian line that begins at the center H of the sundial and runs toward the equinoctial line, which in the southern sundial marked the hour of noon (12), will in this northern sundial signify midnight (12); and the portion that in the former marked midnight will in the latter show noon. And so the hours that were there reckoned from noon are here to be counted from midnight, and those that were there reckoned from midnight are here to be counted from noon. This will be clear from what we shall now demonstrate. Let there be, in the southern sundial, the meridian line HI, the center of the sundial H, the equinoctial line FK; the style GD, whose location is the point G; the line of, for example, the fifth hour after noon HK; the line of the eighth hour from midnight HR; and the axis of the world HD.

Since, then, the axis DH meets the plane of the southern sundial at H, and, when produced, cuts the plane, making on the opposite, northern face an angle AHB with the meridian line — which is the same line on both faces of the plane, since it is the common section of the Meridian circle and the plane of the sundial — [Margin: Elem. I.15] an angle equal to the angle DHI, comprehended on the southern face under the same meridian line and the axis: it comes about that, if the straight line HC is taken on the opposite part of the plane equal to the straight line HG on the southern face, and from C a style is erected at right angles to the plane of the northern sundial (and therefore also perpendicular to the straight line HC), cutting the axis at A, then the style CA will be equal to the style GD, and the axis HA equal to the axis HD. For since in the triangle AHC the two angles H and C are equal to the two angles H and G of the triangle DHG, and the side HC is taken equal to the side HG, [Margin: Elem. I.26] the side CA will also be equal to the side GD, and the side AH to the side DH.

But if from A a perpendicular AB is drawn to the axis HA, meeting the meridian line at B, then AB — [Margin: Elem. XI.2] lying in the plane of the Meridian drawn through the straight lines AH, HB — will be the common section of the Equator

and the Meridian. For since the axis HA is, by prop. 10 of Theodosius, book 1, perpendicular to the plane of the Equator and passes through its center, that same axis will also, by def. 3 of Euclid, book 11, be perpendicular to the common section of the Equator and the Meridian drawn through that same center. Therefore, with A set as the center of the Equator (that is, of the world), AB, lying in the plane of the Meridian and perpendicular to the axis HA, will be the common section of the Equator and the Meridian. [Margin: Elem. I.26] Now the straight line AB will be equal to DI itself, and HB to HI itself, because in the triangle AHB the two angles A and H are equal to the two angles D and I of the triangle DHI, and the side AH has been shown equal to the side DH, and so on. Therefore, if through B, in the northern sundial, the equinoctial line BL is drawn perpendicular to the meridian line, it will be as far distant from the center H upward as the equinoctial line FK is distant from that same center H downward in the southern sundial. And so, if on the meridian line HB, produced, the straight line BM is taken equal to the straight line BA, and a circle is described from M and divided into 24 parts, and so on, a northern sundial will be laid out on the opposite, northern face, just as the southern sundial was laid out on the southern face, when we took the straight line IE equal to the straight line ID and described a circle from E, and so on, as was demonstrated above. For the demonstration here will be exactly the same.

Diagram. A geometric construction figure combining the southern (austral) vertical sundial with its northern (boreal) counterpart about a common center H, together with the analemma triangles used in the proof. A vertical meridian line runs from B at the top, through the central point H, down to I on the lowest horizontal line; a horizontal line passes through H; and a lower horizontal line runs F–R–I–K. Several straight hour-lines cross obliquely at H, two of them labelled "8" (an hour-line above and its counterpart below). Readable labels:

- B (top, on the meridian line)
- L (upper left)
- S (left, above center); S (right, below center) — the paired oblique lines
- A (center-left, on the boreal construction)
- C (just left of the center H)
- H (center; intersection of all the lines)
- 8 (upper right, an oblique hour-line); 8 (lower left, its counterpart)
- G (just below center H)
- D (right of G, the axis vertex / style top)

- F, R, I, K (lower horizontal line, left to right — F at far left, I on the meridian, K at far right)

[The central cluster (C, H, G, D) is crowded; the paired oblique-line labels S and 8 are legible under magnification.]

[Margin: Elem. I.26] [Margin: Elem. XI.2] [Margin: Elem. I.26]

This northern sundial is also obtained if all the lines of the southern sundial are produced through the center H. For since all the hour-circles from noon or from midnight pass through the axis DHA, so as to cut the plane of the sundial at H, the common sections of these circles and of the plane of the sundial — on the southern face as much as on the northern — will be the same straight lines passing through H. Yet these sections, that is, the hour-lines, are to be understood in the northern sundial as lying on the opposite part of the plane, since the axis of the world DH, when produced, falls on the opposite part; that is, on the law and condition that, with the southern sundial turned toward us and the point F on the left and K on the right, the hour-lines on the opposite, northern face are drawn exactly corresponding to the hour-lines of the southern sundial produced through the center H — so that, to us looking at the northern face of the plane, the point F is set on the right and K on the left, contrary of course to what happens in the southern sundial; or, what is the same, F faces the west and K the east, as in the southern one.

[Margin: Elem. I.26] Moreover, the northern sundial, laid out by the method just handed down, will be entirely equal and similar to the southern one, on account of the equality of the axes HA, HD; of the gnomons CA, GD; of the common sections of the Equator and Meridian AB, DI; and of the portions of the meridian line HB, HI placed between the center of the sundial and the equinoctial lines.

[Margin: Elem. I.15] For from this it results that the triangle HBL in the northern sundial — whose sides are the meridian line HB, the equinoctial BL, and the line of the fifth hour HL — is equal and entirely similar to the triangle HIK in the southern sundial, whose sides are likewise the meridian line HI, the equinoctial IK, and the line of the fifth hour HK; because the two angles BHL, HBL of the former are equal to the two angles IHK, HIK of the latter (for the angles at H are equal, being vertical, and the angles at B and I are right angles), and the side HB is equal to the side HI, as was shown, and so on. The same reasoning holds for the other triangles, whose bases are the hour-lines placed between the center H and the equinoctial lines, subtended to the right angles at B and I, and comprehended under the meridian line and the equinoctial lines. Therefore the whole northern

sundial will be equal to the whole southern one, and similar, since its several parts are equal and similar to their several counterparts.

[Margin: If the lineaments of the southern sundial are drawn on the opposite face of the plane, so as to correspond exactly to the lineaments of the southern sundial, and after this drawing the upper part is changed into the lower, a northern sundial will have been laid out.]

Hence, if on the opposite part of the sundial's plane there are drawn lines exactly corresponding to the lines in the southern sundial, and then the upper part is changed into the lower — and consequently what after that drawing is on the right becomes the left, and the reverse — a northern sundial will have been laid out on the northern face of the sundial's plane. For by this procedure the point K, which in the southern sundial is on our right, and in the northern one after that drawing is on the left, comes to be again on our right if the upper part is changed into the lower, as is evident. But we shall write more on this matter in the following proposition.

From all this (to come at last to what was proposed) I judge it clear that the southern sundial marks the hours on the face of the northern Vertical plane, if everything is altered as has been said — that is, if the upper part is changed into the lower, and what after this change is on our right (with the sundial turned toward us) becomes the left, and the reverse. For the southern sundial HRK, if it

is inverted, so that the point I is placed upward and H downward, and the point R — which in that position, with the sundial turned toward us, is on our right — falls to the left, and K to the right, will acquire exactly the same position that the northern sundial LHB has, laid out on the opposite face, where the point L, with the sundial turned toward us, is placed on the right and B on the left, as is evident. Likewise, from what we handed down in the scholium of prop. 1 of this book, it is evident that the portion of the meridian line which in the southern sundial marked noon (12) shows midnight (12) in the northern one; and that the hours which were there counted from noon are here to be reckoned from midnight, and those there counted from midnight here from noon. For, as was just now demonstrated, the hours of the southern sundial, beyond the center of the sundial, give on the northern face the same hours by number; and, as is clear from the said scholium, the forenoon hours, produced beyond the center of the sundial, make the afternoon hours, and the afternoon hours make the forenoon ones. This too will easily be understood, if on the northern face the hour-circles are conceived as drawn through the axis HA. For the shadow of the axis, or of the style, provided the Sun lights the northern face, will be projected onto the

meridian line HB when the Sun is in the semicircle of the Meridian beneath the earth, but onto the hour-lines toward the point L — which in the northern sundial is on our right — when the Sun is in the hour-semicircles after midnight, that is, in the semicircles opposite to those in which the Sun is when, in the southern sundial, the shadow of the axis or style is projected onto the hour-lines toward K, and so on; as is clear, if both the northern sundial LHB and the axis HA and the hour-circles are conceived in their proper position. All this will become plainer if the northern sundial LHB, laid out on the opposite face as has been said, is compared with the northern sundial we described earlier. For we shall find this one entirely similar and equal to that.

[Margin: What has just been said about the inversion of all the parts of the sundial is also to be understood in the case of declining and inclined sundials.] This same demonstration fits in every respect the sundials that decline both from the Vertical circle and from the Horizon; likewise the ones inclined to the Horizon, and the one that both declines from the Vertical circle and is inclined to the Horizon, of which we shall speak in the following book — provided that in them we understand the straight line BI to be, not the meridian, but the line of the style or index, and that in place of the Meridian circle drawn through the axis AD and the meridian line BI we take another great circle, drawn through the axis AD and the line of the style BI, as a kind of new Meridian in the planes of those sundials, as we shall point out in the proper places. For any such sundial laid out on one face of a plane — as, for example, on the one that declines from the south, if the plane is at right angles to the Horizon, or on the upper face, if the plane is inclined to the Horizon — will have a sundial to be laid out also on the opposite face of the same plane, as on the one that declines from the north, or on the lower face; provided that all the parts are inverted, as we said, that is, the upper part is first changed into the lower, and what after this change was first on the right comes out on the left, and the reverse. All of which will be clear in its place.

[Margin: By what method a sundial is to be laid out on a fixed plane that lies parallel to what is properly called the Vertical circle.] So far we have constructed the Vertical sundial on any flat surface whatever, so that it may afterward be transferred onto a wall, or onto a plane that stands at right angles to the Horizon and directly faces the south or the north, in such a way that HE, the meridian line, is perpendicular to the Horizon, while the equinoctial line FK lies parallel to that same Horizon — with this condition added, however, that in the southern sundial the equinoctial FK lies below the center of the sundial H, and in the northern one above it, as we prescribed earlier in this same scholium. But if the sundial is to be drawn directly on the wall itself, or on some plane at right angles

to the Horizon and directly facing the south or the north, we shall accomplish it in this way. By means of a plumb-line we shall draw on the given plane the straight line HE, perpendicular to the Horizon, which will be the meridian line in the sundial. We shall cut this at right angles at I by the straight line FK, which will be the equinoctial line. Then from I — upward in the southern sundial, but downward in the northern — we shall carry the straight line IH as far as H, taken from the portion of the Analemma; and we shall take the straight line IE equal to the straight line IE from that same portion of the Analemma, whether upward or downward. Finally, with a circle described from E and divided into 24 equal parts, we shall complete the rest as before.

Diagram. The completed Astronomical Vertical sundial: a large circle (drawn with a semicircular lower arc and an upper fan) with the hour-lines radiating from the central point H, hour-numbers set around the whole rim, and, at the upper left, the analemma-construction portion (a dotted arc). A horizontal line runs across the middle (C–H–L, ending in "6" at each end); a vertical meridian line runs from top (A) through the central cluster down to N at the bottom. Readable labels:

- Upper-rim hour-numbers (left to right across the top): 3, 2, 1, 12, 11, 10, 9, 8
- A (top center, above the fan), with a dotted analemma arc; 4 (on the dotted arc, left of center)
- Left horizontal end: "6", then C; right horizontal end: L, then "6"
- B (left of center, below C) [?]; F (left, below B)
- Central vertical cluster: M (just above H) [?]; H (center); D (below H); G (small, beside D) [?]; I (below D) [?]; E (lower center); N (bottom center)
- Right side: L (mid-right, on the horizontal); K (right of center, below L); S (lower right)
- 7 (lower left); U (left, below F) [?]
- Lower-arc hour-numbers: (left) 8, 9, 10; (bottom center) 11, 12, 1, 2; (right) 1, 2, 3

[The crowded central vertical cluster (M, D, G, I, E) and the small side-labels B, U are read under magnification but several remain uncertain.]

We can also begin the same construction in this way. Having drawn the straight line FK parallel to the Horizon on the proposed wall or plane (which is easily done by means of a plumb-line and a level) as the equinoctial line, we shall cut it at right angles at I by the straight line HE, which will be the meridian line. Then we shall complete the rest as we just wrote.

[Margin: The laying out of the Vertical sundial to a given length of the style, whose location is also given, without a portion of the Analemma constructed separately.] But if the same sundial is to be drawn on a given plane, without a portion of the Analemma constructed separately, to any length of style whose location too is given, this method must be used. Let the given length of the style be DG, and let its location on the plane of the sundial be the point G. If, then, the plane of the sundial be whatever it may, so that the sundial drawn on it may thereafter, in its proper position, be

be set in its position, or else be transferred onto a fixed plane that is parallel to what is properly called the Vertical — as we said a little earlier — then the straight line MN must be drawn through G, the location of the style, to serve as the meridian line however it may fall. But if the plane of the sundial is offered as a fixed one, parallel to what is properly called the Vertical (such as the plane of any wall that stands at right angles to the Horizon and faces due south or due north), then through G, the location of the style, we must draw by means of a plumb-line the straight line MN, perpendicular to the Horizon, to serve as the meridian line. Or, more surely, by means of a plumb-line and a level we may draw through G a line parallel to the Horizon, to serve as the common section of the plane of the sundial and of the Horizon; and if the straight line MN cuts this at G at right angles, then MN will again be perpendicular to the Horizon, and will be the meridian line — that is, the common section of the plane of the sundial and of the Meridian.

For since both the plane of the sundial and the plane of the Meridian stand at right angles to the Horizon, [anchor a] their common section too will be perpendicular to the same Horizon — and therefore, by Euclid XI, definition 3, perpendicular also to the straight line drawn through G parallel to the Horizon, which is the common section of the Horizon and of the plane of the sundial, since that line lies in the Horizon. [Margin: (a) Euclid XI.19] Therefore, since the Meridian passes through G — for the style DG is the common section of the Horizon and of the Meridian — the line MN drawn through G perpendicular to that straight line will be the common section of the Meridian and of the plane of the sundial.

Next, at G on this meridian line MN, we must erect the perpendicular BGD, and take GD equal to the given style. Then, with D as center, we must describe the arc of a circle ABC, on which, from the straight line DB toward A — that is, upward — if the sundial faces south, we count off the elevation of the pole BA, and downward its complement BC. But if the sundial faces north, the arc of the pole's

elevation BA is to be taken downward, and the arc of its complement BC upward. When the straight lines DA and DC are drawn, the meridian line is cut at the points H and I. After this, at I we shall erect the line FK perpendicular to the meridian line, to serve as the equinoctial line. Finally, taking the straight line IE equal to ID, we shall describe from E a circle of any size whatever; and dividing it into 24 equal parts, beginning from the meridian line, we shall finish the rest as we taught earlier at the start of this problem.

Diagram. The completed astronomical vertical sundial: a large figure with an upper fan of hour-lines radiating from the central point H, closed below by a semicircular arc, with hour-numbers set around both the upper edge and the lower rim, and, at the upper left, the dotted analemma-construction arc. A horizontal line runs across the middle (6–C–H–L–6); a vertical meridian line runs from A at the top through the central cluster down to N at the bottom. Readable labels [several central labels crowd and are read under magnification]:

- A: top center (apex above the fan), with a dotted analemma arc to its left carrying the number 4
- Upper hour-numbers, left to right across the top: 3, 2, 1, 12, 11, 10, 9, 8
- Small mark at top-left "5" [?]; at top-right "1"
- Horizontal mid-line: 6 (far left) — C — H (center) — L — 6 (far right)
- B: below C on the left, at the head of a dotted line
- F: below B (left end of the equinoctial line FK)
- M: just above H [?]
- H: center
- G and D: just below H (G left, D right) [?]
- I: below the G/D pair [?]
- E: below I
- K: right end of the equinoctial line, below L
- S: lower right [?]
- U: left, below F, on a dotted line [?]
- 7: left; 8: lower left
- N: bottom center
- Lower-rim hour-numbers: (left arc) 8, 9, 10; (bottom) 10, 11, 12, 1; (right arc) 2, 3; (far right) 4

[Margin: Demonstration of this description.] **DEMONSTRATION of this description is as follows.** Suppose the meridian line MN has its proper position in a plane that is at right angles to the Horizon and faces due south or north, so

that M points upward and N downward, and suppose the triangle HDI is set at right angles to the plane of the sundial, in such a way that it lies in the plane of the Meridian. Then, since by construction the angle HDG is equal to the elevation of the pole, the remaining angle DHG will be equal to the complement of the pole's elevation. Again, since by construction IDG is equal to the complement of the pole's elevation, the remaining angle DIG will be equal to the elevation of the pole. Taking, then, D — the vertex of the style — as the center of the world, DH, which makes with the meridian line at H an angle equal to the complement of the pole's elevation, will be the axis of the world meeting the plane of the sundial at H, the center of the sundial. And the straight line DI, which makes with the same meridian line at I the angle of the pole's elevation, will be the common section of the Meridian and the Equator — since a section of this kind, in the sphere, always makes with the meridian line in the Vertical the angle of the pole's elevation, and with the axis a right angle, which is just the character of the angle HDI, composed of the angle of the pole's elevation and the angle of its complement. Therefore the Equator meets the plane of the sundial at I; and consequently, as was shown above, the straight line FK will be the equinoctial line. And the straight line DG will be the common section of the Meridian and the Horizon. Everything else is demonstrated as before.

[Margin: Demonstration of the same sundial by means of an ellipse.] We shall describe **the same sundial without finding the points on the equinoctial line**, by means of an ellipse — just as we described the horizontal sundial in the scholium to Problem 1 of this book — in the following way. From H, the center of the sundial, let two circles be described, one with the interval HI, the other with the interval ID. Or, if these radii seem too short, let a point be taken on the axis farther from H than D is (as was also done in the horizontal sundial), from which a perpendicular is drawn to the axis, cutting the meridian line at a point that will bound the radius of the larger circle; and for the radius of the smaller circle let there be taken the segment of that perpendicular lying between the same point and the axis. Then dividing each circle into 24 equal parts, beginning from the meridian line, we shall find — by means of the division-points — the points of the ellipse in the plane of the sundial, through which the hour-lines are to be drawn from the point H, as we taught in the scholium to Problem 1 of this book. For the same demonstration can be applied here. We do not set down an example of this description, because the matter itself can be understood, clearer than daylight, from the figure that we drew in the said scholium to Problem 1 of this book. For that figure represents a vertical sundial for the latitude of a place of 48 degrees, which of course, together with that latitude, for any...

whatever [latitude] for which that horizontal sundial is constructed, makes up 90 degrees — provided that the numbers of the hours are changed into their complements up to 12. For a vertical sundial, properly so called, takes the place — for any given Horizon — of a certain Horizon above which the pole is raised by just as many degrees as are lacking to the latitude of the place for which the horizontal sundial is constructed, so as to fill out the number of 90 degrees. This is clear from the portion of the analemma described at the beginning of this problem, in which the angle DHG — the complement of the angle HDG, the elevation of the pole above the Horizon BC — constitutes the elevation of the pole above the Vertical HI, as though above some Horizon. And so any horizontal sundial whatever, made for any latitude of a place, is a vertical sundial in the region whose latitude is the complement of that one; and every vertical sundial in the former latitude is in turn a horizontal one in the latter — if the numbers of the hours are changed into their complements up to 12, as we have said.

[Margin: A horizontal sundial constructed for any latitude whatever is a vertical sundial in the region whose latitude is the complement of that latitude; and conversely, the vertical sundial of the one is the horizontal of the other.]

PROBLEMA 14. PROPOS. 14.

To draw the parallels — that is, the arcs of the signs of the Zodiac — on the aforesaid vertical sundial.

Let the portion of the analemma of the preceding problem be repeated, and let the Meridian ABC be completed; and in it, in accordance with the analemma constructed in Problem 1 of the preceding book, let there be drawn the diameters of the parallels, together with the diameters that join the opposite signs and that form, in the cones whose bases are the parallels and whose common vertex is the center D, the triangles through the axis. Then, by what was demonstrated in Problems 4, 5, 6, and 7 of the preceding book, KR will be the diameter of the conic section that the Sun describes when it is at the beginning of Cancer (♋); LR the diameter of the section that the Sun traverses at the beginning of Gemini (♊) and of Leo (♌); and MR the diameter of the section described by the Sun's ray when it is in the first point of Taurus (♉) and of Virgo (♍). But NQ, OQ, and PQ will be the diameters of the conic sections that the Sun's rays describe when the Sun is in the opposite parallels.

[Margin: The drawing of the arcs of the signs of the Zodiac on the vertical sundial, from the analemma. In what manner the diameters of the conic sections are found in any analemma whatever.]

These diameters of the conic sections are also to be found in any other analemma whatever, whether larger or smaller than the one here proposed, even if the sundial has been constructed without a portion of the analemma, as we taught in the preceding scholium — provided, however, that in that other analemma a straight line equal to the gnomon DG is cut off from the diameter of the Horizon on both sides from the center (the diameter of the Horizon itself being extended, if the length of the gnomon requires it), and that from each extreme point a straight line is drawn parallel to the diameter of the Vertical, the line by which the plane of the sundial is drawn. For this straight line, in the larger or smaller analemma, will be divided by the diameters of the opposite signs into parts equal to the parts of the straight line QR in this analemma of ours. This can be demonstrated as follows. Since both that line and this line QR, taken with the same length of style, are equally distant from the center of their own analemma, [anchor a] and since the angles that the diameters of the opposite signs make with the diameter of the Equator are of the same size in any analemma (because they always rest upon the centers with the same declinations of the same signs), it follows that the angles which those same diameters make with the diameter of the Horizon — which are either composed of the former angles together with the angle of the complement of the pole's elevation contained under the diameter of the Equator and the diameter of the Horizon, or are left over after those former angles are subtracted from that same angle of the complement of the pole's elevation — are equal to one another, since the angles contained under the diameter of the Horizon and the diameter of the Equator are equal. [Margin: (a) Euclid III.27]

Therefore, since the angles that the straight lines drawn through the extremity of the gnomon (namely through the point G in our analemma, and through the point corresponding to it in the other analemma), parallel to the diameter of the Vertical, make with the diameter of the Horizon are right angles, and since the angles that the ray of any given sign makes with that same diameter of the Horizon in each analemma are also equal, as we said, there will always be found two triangles in each analemma — one in the one, the other in the other — having two angles equal, each to each. And since they also have an equal side adjoining the said angles, namely the size of the style, [anchor b] they will also have the remaining sides equal, namely those that are interposed between the extremity of the style and the ray of each sign in each analemma, and so on. [Margin: (b) Euclid I.26]

This can also be made plain in this way: if that larger or smaller analemma is imagined to be laid upon this one of ours, so that the centers and the diameters of

the Horizon, of the Vertical, and of the Equator coincide with one another, the straight line drawn through the extremity of the style in the former will coincide with the straight line QR in our analemma, because of the equality of the gnomons and of the right angles that the gnomons make with the said lines. Since, then, the diameters of the ecliptic that connect the opposite signs also coincide with one another (because they make the same angles with the diameter of the Equator in each analemma, on account of the same declinations in each, as is evident from the construction of the analemma), it plainly follows that the straight lines between the extremity of the style G and the rays of the signs in our analemma are equal to the same lines in the other analemma — because the former coincide with the latter.

AND SO, if into the meridian line of the sundial already described — whether from the center H, or from the point I where the plane of the Equator meets the plane of the sundial — the points G, K, L, M, I, P, O, N are transferred, in the same order in which they are placed in the figure (taken by means of the compass from the point where, in the analemma, the axis of the world, or the diameter of the Equator, cuts the straight line drawn through the extremity of the gnomon parallel to the diameter of the Vertical), then G will be the location of the style DG; and the remaining points will be those onto which the shadow of the style is cast when the Sun is on the meridian circle and at the beginnings of the signs, and through which are to be drawn the conic sections of the signs — which are either circles, or parabolas, or hyperbolas, or el-

Diagram. A large circle (the analemma) crossed by many diameters and chords, with zodiac-sign glyphs ranged around the circumference and letter-labels at the crossing-points. A vertical diameter (the Vertical) runs top to bottom and a horizontal diameter (the Horizon) runs left to right; several oblique diameters (the parallels of the signs and their conjugate lines KR, LR, MR, NQ, OQ, PQ) cross near the center D. This figure is densely ruled and the peripheral zodiac sorts are worn; most interior labels are read only tentatively, even under magnification. Readable labels:

- A: top, on the Vertical diameter; R just to its left and Q just to its right (heads of the QR line) [?]
- E: upper right of the rim [?]
- C: right-hand end of the horizontal (Horizon) diameter
- B: left-hand end of the horizontal diameter [?]
- D: center; with G, M, N, P, L, K clustered about the center [each ?]
- Q: lower left; R: lower center (feet of the QR line) [?]

- Zodiac-sign glyphs ring the circumference (associated in the text with Cancer, Gemini, Leo, Taurus, Virgo, Capricorn), but the individual sorts are too worn to assign with confidence: [zodiac glyphs: ?]

or ellipses, as was demonstrated in the preceding book. If, then, through I a line is drawn perpendicular to the meridian line, this will be the equinoctial line. But if, about the diameters KR, LR, MR, NQ, OQ, PQ, the conic sections are described (by Problem 8 of the preceding book) in some hard material — such as thicker paper, or on some thin flat board, or at any rate on glued sheets of paper — and are cut out so as to make, as it were, curved rulers, by which those same sections may be drawn on the sundial so as to pass through the points K, L, M, N, O, P and to have the axes of their meridian lines coincide, then the parallels of the signs of the Zodiac will be drawn. It is enough, however, to describe the conic sections of the northern signs, or of the southern, since the Vertical cuts all the parallels; because these are equal to the sections of the opposite signs. Hence by the same rulers, which we ordered to be cut out for this purpose, they will easily be described in the opposite part of the sundial. (I now call "opposite parts" of the sundial those parts which the equinoctial line divides, one of which is northern and the other southern.)

[Margin: The horizontal line [AB?] [?], and how it is to be drawn in a vertical sundial. — (a) Euclid XI.19]

FURTHERMORE, in each sundial there must be drawn, through G, the location of the gnomon, the line AB perpendicular to the meridian line; and this will be the common section of the Horizon and of the plane of the sundial, and will be called the horizontal line. For since both the plane of the sundial, being parallel to what is properly called the Vertical, and the plane of the Horizon, stand at right angles to the plane of the Meridian, [anchor a] their common section too will be at right angles to the same plane of the Meridian, and consequently, by Euclid XI, definition 3, will be perpendicular also to the meridian line HI, which lies in the plane of the Meridian, at the point G — since it meets the plane of the Meridian at this point. This can be shown as follows. Since the Horizon, passing through the gnomon that stands at the point G perpendicular to the plane of the sundial, meets the sundial at G, the common section of the Horizon and of the sundial will also pass through the same point G. Therefore the straight line AB, which is drawn in the plane of the sundial through G perpendicular to the meridian line HI, is the common section of the Horizon and of the plane of the sundial, and is parallel to the equinoctial line, as we taught in the scholium to Problem 22 of the preceding book.

Now, when the Sun is on the Horizon — that is, when it rises or sets — the shadow of the style is cast into the common section of the Horizon and of the plane of the sundial, that is, into the straight line AB, as is evident from Problem 11 of the preceding book. It comes about, then, that throughout the whole remaining time of any day, while the Sun is raised above the Horizon, that same shadow falls on the plane of the sundial below the horizontal line. Therefore, in every sundial the part that projects above the horizontal line is to be cut away as superfluous, so that in a vertical sundial that faces north only that small portion is left which is comprised between the horizontal line and the arc, or parallel, of Cancer (♋).

[Margin: In every sundial that part which lies above the horizontal line described is superfluous, and therefore to be cut away. The part of the northern sundial below the horizontal line is equal to the part of the southern sundial above the horizontal line.]

Now this part of the northern vertical sundial, comprised between the horizontal line and the arc of Cancer (♋), is entirely equal to that part which the horizontal line cuts off from the southern sundial as superfluous. For in the northern sundial the parallel of Cancer (♋) is as far distant from H, the center of the sundial, as in the southern the parallel of Capricorn (♏) is distant from the same center, as is evident from the analemma of this problem. This can be proved as follows. In the triangle DGK on the left, the two angles at D and G are equal to the two angles at D and G in the triangle DGN on the right, [anchor b] since the angles at G are right angles, and the angles at D, formed at the vertex, are equal; [Margin: (b) Euclid I.15] and the sides DG, DG are equal, because each is equal to the gnomon; [anchor c] therefore the sides DK, DN will also be equal, and the remaining angles at K and N equal. [Margin: (c) Euclid I.26] Hence, in the triangles DHK and DHN, [anchor d] since the angles KDH and NDH at the vertex D are equal, [Margin: (d) Euclid I.15] [anchor e] the sides HK, HN will also be equal; [Margin: (e) Euclid I.26] and consequently, since the conic section of Cancer (♋) passes through K in the northern sundial, and the conic section of Capricorn (♏) through N in the southern, the arc of Cancer (♋) will be as far distant from H in the northern sundial as the arc of Capricorn (♏) is distant from the same point H in the southern sundial. Therefore, since in the cones of Cancer (♋) and of Capricorn (♏) the triangles through the axis are equal, and likewise the straight lines DK, DN and the angles DKH, DNH are equal (as has been demonstrated), the conic section of Cancer (♋), whose diameter is KQ, in the northern sundial will be equal to the conic section of Capricorn (♏), whose diameter is NQ, in the southern sundial — because the plane of the former sundial cuts the triangle through the

axis in the cone of the shadow of Cancer (♋) just as the triangle through the axis in the cone of the shadow of Capricorn (♐) is cut by the plane of this sundial, on account of the equality of the straight lines DK, DN and of the angles DKH, DNH, as has been shown. If, then, that part of the southern sundial which is cut off by the horizontal line is laid upon the northern sundial (in such a way that the part which is now upper becomes lower, and the lower becomes upper; and the part that is on the right, by this inverting of the sundial as described — namely the part toward A — becomes the left, and the left becomes the right, just as we demonstrated above must be done if we wish the southern sundial to indicate the hours also on the face of the northern plane), then all the lines will correspond to one another, together with their numbers, on account of the equality of the straight...

Diagram. A vertical-sundial figure with the gnomon-point H near the top center, a fan of solid and dotted hour-lines radiating downward, a horizontal line (the Horizon) across the upper part labelled "Hori" (left) and "Zon" (right), and zodiac-sign glyphs ranged down both side margins. Densely ruled with worn peripheral sorts; most labels are read only tentatively Readable elements:

- Printed title within the figure: "AVSTRALE" (i.e. Australe, "Southern"), split across the top
- H: gnomon-point, upper center
- Horizontal Horizon line: "Hori" (left) — "Zon" (right), with A at the left end and B at the right end
- Upper hour-marks near the apex: "1A" (left) and "11A" (right) [?]
- Equinoctial row of letters below the Horizon: F (left) — R — ... — S — K (right) [?]
- Central cluster below H: P, M, X, L, K, I [each ?]
- Left-margin zodiac glyphs (top→bottom) and right-margin zodiac glyphs: worn — [zodiac glyphs: ?]
- Hour-numbers along the lower fan: 3, 7, 8 (left); 4, 5 (right); 9, 10, 11, 12, 1, 2 near the foot [several ?]

Diagram. A smaller companion figure showing only the strip retained for the northern sundial: a horizontal Horizon line labelled "Hori" (left) and "Zon" (right), a central vertical meridian through H, with A above and G below the crossing, dotted arcs curving up toward the sides, and zodiac-sign glyphs at both lower corners. Worn Readable elements:

- Printed title within the figure: "BOREALE" (i.e. Boreale, "Northern"), split — "Bore" (left) and "ale" (right), with I between
- Horizon line: "Hori" (left) — "Zon" (right)
- H: center, on the meridian; A above H; G at the crossing [?]
- Hour-numbers flanking the foot: 7, 6 (left of center); 6 (right) [?]
- Lower-corner zodiac glyphs, left and right: worn — [zodiac glyphs: ?]

lines HN, HK, and HG, HG, and of the conic sections, and so on. Therefore it will be enough to lay out the vertical sundial that faces south, together with the parallels of the signs. For the horizontal line AB will cut off a portion from the upper part which will represent the northern sundial, provided only that it is given such a position on the face of the northern plane that the horizontal line stands in the upper place, and the right-hand part — which is then toward A — becomes the left, and the left becomes the right.

[Margin: ...[au]stral; for the upper portion cut off by the horizontal line will yield the northern sundial, if all its parts are inverted.]

This inversion is easy to carry out. Turn the southern sundial toward us (the one that must be inverted) so that it keeps its own place and position. Then, on the opposite face of the plane — the northern one — let the same lines be drawn, so that they differ in no respect from the lines of the southern sundial but correspond to them exactly. Next let the sundial thus drawn on the opposite face be rotated about the style as an axis, on that same opposite face, until the upper part becomes the lower and the reverse, and the horizontal line runs parallel to the horizon. We shall then have, on the opposite face, the northern sundial in its proper position, just as if the southern sundial had been inverted, as we said — that is, as if the upper part of the southern sundial had been exchanged into the lower, and the right into the left. This is plain to anyone who considers the matter carefully.

[Margin: In what way the parts of that portion of the southern sundial which the horizontal line cuts off must be inverted, so that it may present the northern sundial.]

That the portion of the southern sundial which the horizontal line cuts off from the upper part represents to us the northern sundial when it is inverted, as we said, will become clear from the following as well. For, as we demonstrated in the scholium of the preceding proposition, the southern sundial — when turned so that the upper becomes lower and the right becomes left, and the reverse — is changed into the northern one; and the line AB is the common section of the

horizon and the sundial, as has here been shown. Hence that part which the horizontal line cuts off toward the equinoctial line — that is, toward the upper part in the northern sundial (which resulted from that inversion of the southern sundial) — is superfluous, since the shadow of the style cannot fall upon it. Therefore the remaining portion that is cut off will be the northern sundial, so far as the hour-lines are concerned.

But as regards the arcs, or parallels, of the signs, the sign-arcs of the southern sundial are changed, in the northern sundial, into the arcs of the opposite signs — for instance the arc of Capricorn (♑, "Capricorn") into the arc of Cancer (♋, "Cancer"), and so on.

[Margin: The sign-arcs of the southern sundial are changed, in the northern sundial, into the arcs of the opposite signs.]

This is evident from the analemma of this proposition, if one rightly considers the shadow-cones which the plane of the southern sundial meets, and the shadow-cones which the plane of the northern sundial meets. For the shadow-cones in each sundial belong to opposite signs. Thus, just as the shadow-cone, when the Sun is at the beginning of Capricorn (♑), is broken off in the southern sundial at the point N, near the place of the style G, so in the northern sundial the shadow-cone, when the Sun is at the beginning of Cancer (♋), is broken off at the point K, likewise near the place of the style G, and so on.

The same is to be understood of the day-arcs, which we shall treat in the following proposition. For these too are changed into the opposite day-arcs in the northern sundial. Thus the day-arc of 10 hours in the southern sundial is changed, in the northern sundial, into the day-arc of 14 hours, and so on. But we shall give another reason for this in Proposition 21 of this book.

[Margin: The day-arcs too of the southern sundial are changed, in the northern sundial, into the opposite day-arcs.]

Furthermore, the horizontal line elegantly shows at what hour the Sun, when on any given parallel, rises or sets. For where the conic sections cut the horizontal line, there the Sun rises or sets when it is on those parallels which the said sections represent. If, therefore, hour-lines are drawn through the points where the horizontal line and the conic sections mutually intersect, these will indicate the time of the Sun's rising and setting, and so on. Thus you see, in the southern sundial, that the Sun, when at the beginning of Capricorn (♑), rises about 7½ hours from midnight and sets about 4½ hours from noon. In Aquarius (♒) and Sagittarius (♐), it rises a little before 7½ hours from midnight and sets a little

after 4½ hours from noon. Finally, in Pisces (♈) and Scorpio (♏), it rises a little before the seventh hour from midnight and sets a little after the fifth hour from noon. So too you see, in the northern sundial, that the Sun, when at the beginning of Cancer (♋), rises about 4½ hours from midnight and sets about 7½ hours from noon, and so on.

[Margin: The horizontal line indicates at what hour the Sun rises or sets.]

The horizontal line performs the same function in all the other sundials, except the horizontal one, on which a horizontal line cannot be drawn, as is clear from the scholium of Proposition 11 of the preceding book.

Here, and in all the other sundials that follow in which a horizontal line is drawn, it must be observed that the horizontal line also divides the whole sundial into two parts. The part below it shows the hours during the day, as long as it is lit by the Sun; the part placed above the horizontal line would show the hours by night — that is, in the morning before the Sun's rising above the horizon, or in the evening after the Sun's setting below the horizon — if, the obstruction of the earth being removed, the Sun could illuminate it.

[Margin: The horizontal line divides the whole sundial into a daytime portion and a nighttime portion.]

For just as, when the Sun is above the horizon, the shadow of the style is cast during the day below the horizontal line — and onto the horizontal line itself when the Sun stands exactly on the horizon, whether at morning or evening — so, when the Sun is below the horizon, the shadow of the gnomon would fall above the horizontal line, both in the morning and in the evening, if the plane of the sundial were at that time illuminated by the Sun. Therefore we may not inaptly call the front part of the southern sundial — namely the part lying below the horizontal line — the daytime sundial, and call all the arcs of the signs and of the days contained in it the day-arcs; while the rear part, contained above the horizontal line, we may call the nighttime sundial, and all the arcs that the horizontal line cuts off we may call night-arcs. Thus the night-arcs are the complements of the day-arcs up to 24, and the reverse — that is, if for example the day-arc comprises 10 hours, the night-arc will comprise 14, and so on.

[Margin: The portion of the sundial below the horizontal line is called the daytime sundial, and the arcs of the signs and of the days are called day-arcs; the portion of the same above the horizontal line is called the nighttime sundial, and the arcs of the signs and of the days are called night-arcs.]

In the same way, in the northern sundial — which we said is that portion cut off by the horizontal line, provided it is inverted, as we said above — the arcs that lie in it are day-arcs; while those above the horizontal line (such as all those included in the southern sundial) must be called night-arcs. Thus the equinoctial line, which in the northern sundial lies above the horizontal line, is a night-arc of 12 hours, whereas in the southern sundial the same line is a day-arc of 12 hours; and so on for the rest. This will have a wonderful use in the description of the hours from sunrise or sunset, as we shall teach in its proper place.

But if a larger or smaller sundial is to be drawn, a longer or shorter style DM must be taken in the analemma of this proposition, and through M a line must be drawn parallel to AD. For in this way larger or smaller diameters of the conic sections will be found, about which the conic sections themselves can be drawn in the same manner. But the equinoctial line must be distant from the center H, along the meridian line, by an interval equal to the portion of the parallel drawn through M that is intercepted between the points where it is cut by the axis DE and by the radius of the equator FD. The hour-lines, however, do not change, but remain the same, for the same elevation of the pole.

[Margin: The night-arcs are the complements of the day-arcs up to 24, and the reverse.]

[Margin: By what method, from the analemma of this proposition, the sign-arcs are drawn on the sundial for a greater or lesser length of the gnomon.]

[Margin: Another method of describing the arcs of the zodiacal signs on the vertical sundial.]

DESCRIBI — The arcs of the signs can also be described in this way. About the straight line DH, drawn in any way to represent the axis of the world, let a semicircle of any size be described from any point D as center; and let DH, on the right-hand side of D, be equal to the axis DH assumed in the portion of the analemma of the preceding proposition, or in the triangle HDI, from which — at the end of the scholium of that same proposition — we described the sundial without a portion of the analemma. And when DC has been drawn as the radius of the equator, perpendicular to the axis DH, let DI be taken equal to the equinoctial line DI of the same portion of the analemma, or of the said triangle HDI; and let the straight line HI be drawn toward the side of I, as far as one likes. Or else — lest an error be committed in drawing the line HI, on account of the nearness of the points H and I — from the point H let an arc be described toward the side of D, on which let AB be taken, toward the straight line DC, equal to the

complement of the elevation of the pole above the horizon; and through B let the straight line HB be drawn, cutting the equinoctial line DC at I. The triangle DHI will be entirely equal to the triangle DHI of the aforesaid portion of the analemma, or to the triangle of the sundial drawn without a portion of the analemma; and HI will be equal to the meridian line HI of the same portion of the analemma, or of the said triangle — as is clear from either construction of this triangle in this figure.

For from the first construction, the two sides DH, DI of this triangle are equal to the two sides DH, DI of that one, and they contain equal angles, being right angles. Therefore the whole triangles are equal. [Margin: (a) Euclid I.4]

But from the second construction, the two angles HDI, DHI of the one triangle are equal to the two angles HDI, DHI of the other triangle (since in each triangle the former angle is a right angle, and the latter equal to the complement of the elevation of the pole); and the side DH of the one is equal to the side DH of the other. Therefore the sides DI, HI of the one are also equal to the sides DI, HI of the other, and so on. [Margin: (b) Euclid I.26]

Then from the center E of the equator in the sundial — the point from which, namely, the circle was described and divided into 24 parts, etc. — let all the intervals between the center E and the hour-lines on the equinoctial line FK be transferred onto the line DC of this figure which we are now constructing, starting from the point D. That is: let the straight line DC be made equal to the interval EF or EK in the sundial drawn in the preceding proposition (which are equal, as are also all the intervals between E and any two hours that are equal in time-span from the meridian line, as is clear from the scholium of the preceding proposition); and let the straight line DT be made equal to the interval ER or ES, and so on. Then, through the points C, T, and the rest found on the line DC, let straight lines be drawn from H, to which are assigned the hour-numbers corresponding to the assumed intervals — so that the straight line HC is the line of the seventh hour after midnight and the fifth after noon; HT the line of the eighth hour after midnight and the fourth after noon; and so on.

Diagram. The "figure of the radii of the zodiac" (*figura radiorum Zodiaci*) for laying out the vertical sundial. A large fan-shaped construction: a horizontal line runs across the top, beneath which a broad semicircle is drawn; from two centers near the top a dense sheaf of straight lines (the zodiac-radii and the hour-lines) fans out downward, numbered along the lower edge; a narrow curved band of zodiac-sign compartments runs along the very bottom of the figure. Densely ruled and worn; several peripheral labels are read only tentatively Readable elements:

- Top horizontal line, left to right: A (left end), D (center of the semicircle), and H (right of center, the apex from which the hour-lines radiate). Two closely-set marks appear at the center-top, read as D and H, with a possible additional mark between them [?].
- B: on the left part of the arc/semicircle.
- T: below the top, left of center.
- ϕ' [Greek: phi, primed]: far left, low on the figure.
- V, X, Y: a horizontal row of points across the middle (the hour-points for the 6th, 5th/7th, and 4th/8th hours).
- C: center, just below the V–X–Y row; the end-point of the line DC.
- Hour-numbers along the lower fan (left to right, tentative): "12, 1, 2, 3, 4" along the upper row and "II [=11], 10, [9?], 8" below, on the left; "6" and "7" near the center; "8," then "10, 11, 12" (upper) and "4, 3, 2, 1" (lower) on the right. [several ?]
- Bottom curved band: a strip divided into compartments, each carrying a zodiac-sign glyph — worn and not securely legible [zodiac glyphs: ?].

We shall also draw these same hour-lines issuing from H if we transfer the hour-intervals in the sundial (between the center H and the equinoctial line) onto the radius of the equator of this figure from H. For in this way we shall find, on the radius of the equator, the same points as before, through which the hour-lines are drawn from H, as we demonstrated in Proposition 2 of this book concerning the horizontal sundial.

For the sixth hour from noon or from midnight, draw from H the line HV parallel to DC. And for the fifth hour after midnight and the seventh after noon, draw HX, making the angle VHX equal to the angle VHC. In the same way, for the fourth hour after midnight and the eighth after noon, draw HY, making the angle VH Y equal to the angle VHT; and so on for the rest. This will easily be done if an arc of a circle is described from H. For if the portions of this arc's circumference intercepted between HV and the straight lines drawn from H to the left of HV (namely those that cut the line DC) are transferred to the right of that same HV, into the said arc, and so on, as we said in the horizontal sundial.

After this, from the point D let the radii of the signs be drawn, as was described for the horizontal sundial, in Proposition 2 of this book.

From this figure, therefore, we shall describe the arcs of the signs just as in the horizontal sundial — namely, by transferring the hour-intervals of this figure, intercepted between H and the radii of the signs, into the hours of the sundial

from the center H, and so on. On this matter, see what we wrote in Proposition 2 of this book.

In describing the arcs of the signs on the northern sundial, the radii of the southern signs are changed into the radii of the northern, and the reverse: thus from the radius of Capricorn (♑) comes the radius of Cancer (♋); from Aries (♈) comes Libra (♎) [?]; and so on. This must also be understood of the radii of the day-arcs, of which we shall speak in the following proposition. For, namely, the southern arcs of the southern sundial are also changed, in the northern sundial, into northern arcs, and the reverse, as was said above.

DEMONSTRATIO — The demonstration of this matter does not differ from the one we brought forward for the horizontal sundial in Proposition 2 of this book. For the vertical circle too is a kind of horizon, and the angle DHI is equal to the elevation of the pole above it, as is clear. Therefore the demonstration will be the same in either sundial.

[Margin: Which arcs belong to the southern signs and which to the northern.]

Moreover, in the southern sundial the arcs of the southern signs are contained between the center of the sundial and the equinoctial line, while those of the northern signs lie beyond the equinoctial line. In the northern sundial, on the contrary, the matter stands the opposite way, as is gathered from the analemma of this proposition. The same can also appear from this: that the Sun, when in the southern signs, casts shorter shadows on the southern sundial around noon than when it lingers in the northern signs; because in the northern signs it has greater meridian altitudes than in the southern. Hence, since the shorter noon shadows fall between the center of the southern sundial and the equinoctial line, but the longer ones beyond that same equinoctial line, it is clear that the southern signs lie between the center and the equinoctial line, while the northern signs lie beyond the equinoctial line, and so on.

Which signs have arcs that are hyperbolas, or parabolas, or ellipses, we shall perceive from what we wrote in Proposition 2 of this book.

[Margin: How, from one arc, the opposite arc is described, etc.]

Here too we shall more conveniently and accurately describe the hyperbolas of the northern signs below the equinoctial line, by means of the hyperbolas of the southern signs described above the equinoctial line — if, by the method we set forth in Proposition 2 of this book, we first find the transverse diameters of the opposite sections, and their centers, and so on.

We can also use those two methods which we described at the end of the same Proposition 2 of this book. On this matter, consult what we set forth there. We have therefore described the parallels, or arcs of the zodiacal signs, on the aforesaid vertical sundial. Which was to be done.

SCHOLIVM

[Margin: A most elegant procedure for drawing the hour-lines in the figure of the radii of the zodiac, without the hour-intervals of the sundial.]

In this way Andreas Schöner [Andreas Schonerus] describes the same hour-lines of the preceding figure as issuing from H. Having drawn the straight line HIB — which forms the angle AHB equal to the complement of the elevation of the pole above the horizon, or to the elevation of the pole itself above the vertical circle, just as we too did — he takes on it any point whatever, ϕ [Greek: phi; the point-symbol printed as a circle-and-cross form, matching the figure's ϕ label], and through it draws ϕV parallel to DH, cutting the line drawn from H parallel to DC at the point V; and from V as center, with the interval ϕV as radius, he describes a circle. When this is divided into 24 equal parts, he does the same as we taught in the scholium of Proposition 2 of this book concerning the horizontal sundial.

[Margin: The description of the vertical sundial from Andreas Schöner's figure of radii.]

From the figure of radii thus constructed, as Andreas Schöner teaches, a vertical sundial can be described for a given size of style, just as we said of the horizontal one in the scholium of Proposition 2 of this book — provided that the angle ϕDH is made equal to the elevation of the pole, and not to its complement, as in the horizontal sundial.

[Margin: By what method the length of the style, and its place on the sundial, are found from the figure of radii.]

The style, according to the latter method of describing the parallels of the signs (which is accomplished by means of the figure of the radii of the zodiac), is obtained if from D a perpendicular $D\phi$ is drawn to HI — or at any rate a straight line $D\phi$ making the angle ϕDI equal to the complement of the elevation of the pole above the horizon. For the length of the style is the straight line $D\phi$ itself; and its place is the point ϕ , distant from H, the center of the sundial, by the interval $H\phi$ along the meridian line — or from the equinoctial line FK by the space $I\phi$, on the same meridian line, toward the center H.

[Margin: How, by means of the figure of the radii of the zodiac, a larger or smaller sundial is to be described.]

When the hour-lines have been described in the immediately preceding figure from the point H — if, according to this latter method taken from the said figure of the radii of the zodiac, a larger or smaller sundial is to be constructed — then the figure of the radii of the zodiac must be drawn more, or less, distant from the point H, and so on, as was said of the horizontal sundial in the scholium of Proposition 2 of this book.

[Margin: How, from the given length of the style, the distance of the radii of the zodiac from the point H is found, in the figure of radii.]

But if the size of the style is given, we shall find in this way the distance of the figure of the radii of the zodiac from the point H, on the axis HD. In the portion of the analemma of the preceding proposition, from BDC let there be cut off — by extending the straight line DM — a length equal to the given gnomon; and through M let NO be drawn parallel to AD, the diameter of the vertical, cutting the axis DE at N and the diameter of the equator FD at O. For the point D of the figure of radii of this proposition, at which all the radii of the zodiac meet, must be distant from H by the interval DN, as we said of the horizontal sundial in the scholium of Proposition 2 of this book.

[Margin: By what method the arcs of the signs are described on the vertical sundial where no center is available.]

Here too, in that sundial which we taught how to make in the scholium of the preceding proposition — even if its center is not available — we shall describe the arcs of the signs, as we set forth in the scholium of Proposition 2 of this book.

Although it has been rightly demonstrated in this proposition that the upper portion of the southern sundial, which the horizontal line cuts off, presents to us the northern sundial — provided all its parts are so transposed that the upper is turned into the lower (that is, the horizontal line occupies the upper place), and the part which, in that position, is on our right when the sundial is turned toward us becomes the left, and the reverse — nevertheless I thought it worthwhile to show the same thing here in a general way. Namely, that not only on the southern vertical sundial, but on all the others as well (such as the meridian, the polar, the one that declines from the vertical, the one reckoned from the horizon, the one inclined to the horizon, and the one that both declines from the vertical and is at the same time inclined to the horizon), the horizontal line cuts off, toward the upper parts, a portion which — on the opposite face of the plane of

the sundial, if it is so placed that all its parts are inverted, as we said — indicates to us, by the shadow of the style, exactly the same things which, on the other face (the one on which the sundial was originally drawn), the other portion of the sundial, contained below the horizontal line, shows us.

So much so that the segments of the lines lying above the horizontal line are the common sections of those same great circles with the plane of the sundial that is to be placed on the opposite face (if that inversion of the parts is made, of which we have spoken); whereas the common sections of those same great circles with the plane of the sundial originally drawn on the other face are the segments of the same lines lying below the horizontal line — whether those circles be the hour-circles from noon or from midnight, or verticals, or meridians, or those representing the celestial houses, or the zodiac (insofar as it takes various positions while the celestial signs rise), or the indicators of the hours from sunrise or from sunset, or, finally, of the unequal hours. This we shall demonstrate as follows.

Let there be two sundials, one southern and the other northern (if their planes are perpendicular to the horizon), or one upper and the other lower (if their planes are not perpendicular to the horizon), in which the styles AB, CD are equal and perpendicular to the planes of the sundials. Let both sundials be understood in their proper position, so that the southern faces south and the northern faces north — or the upper looks toward the zenith and the lower toward the nadir — and let them be parallel to each other; and let the vertices of the styles B, D be joined at the center of the world, the styles themselves forming a single straight line, namely the axis of that greatest circle to which each sundial...

[Margin: In every sundial the horizontal line cuts off the upper portion, whereby it presents the sundial to be placed on the opposite face of the sundial, provided that first the upper part becomes the lower, and the part which, after this inversion, is on our right when we are turned toward the sundial becomes the left, and the reverse.]

to which each sundial is parallel, so that the two sundials face each other.

Next, suppose a greatest circle drawn through the poles of the plane of each sundial and through the poles of the horizon. By Theodosius, *Sphaerics* I.15, this circle will stand at right angles both to the plane of each sundial and to the horizon, and it will pass through the styles AB and CD — that is, through the axis of the plane of each sundial — since it is drawn through their poles, as we said. Let this greatest circle make, with the planes of the sundials, the common

straight-line sections AE and CF,[Margin: ^a Euclid, *Elements* XI.16] which will be parallel to each other. In the vertical, polar, and equinoctial sundial, and in the one inclined to the horizon, this circle will be the meridian itself. For since the poles of the plane of each sundial — vertical, polar, equinoctial, or inclined to the horizon — and the poles of the horizon all lie in the meridian (as is plain if one weighs carefully the position of the greatest circles to which such sundials are parallel), the meridian must pass through those poles, and so it stands at right angles both to the planes of those sundials and to the horizon, by *Sphaerics* I.15. From this it follows that in the sundials named, the straight lines AE and CF are meridian lines.

In the other sundials, however, that greatest circle cannot be the meridian, because the meridian is not at right angles to their planes, since it does not pass through their poles, as is evident. Yet in the meridian sundial and in the one declining from the horizon, this circle will be properly called the *vertical* circle, since it passes through the poles of the meridian sundial and of the one declining from the horizon, and through the poles of the horizon. In sundials that decline from the vertical, this same circle will be one of the vertical circles, declining from the meridian by just as much as the plane of the declining sundial stands away from the vertical circle. And so, in inclined sundials, it will measure the inclination of the plane of the sundial to the horizon, since it is drawn through the poles of the sundial and through the poles of the horizon.

Again, suppose another greatest circle drawn through the poles of the plane of each sundial and through the poles of the earlier greatest circle that was drawn through the straight lines AE and CF. By Theodosius, *Sphaerics* I.15, this circle too will stand at right angles both to the plane of each sundial and to that earlier greatest circle, and it will pass through the styles AB and CD — namely through the axis of the plane of each sundial — since it is drawn through their poles, as was said. Let this greatest circle make, with the planes of the sundials, the common straight-line sections AG and CH,[Margin: ^b Euclid XI.16] which will likewise be parallel to each other. These will also be perpendicular to the straight lines AE and CF. For since both the plane of the sundial (whose style is AB) and the plane of this latter circle, drawn through the straight line AG, are at right angles to the plane of the earlier circle, drawn through the straight line AE, by the construction, their common section AG will also be at right angles to the plane of that same earlier circle drawn through AE;[Margin: ^c Euclid XI.19] and therefore, by Euclid, *Elements* XI, definition 3, it will be perpendicular to the straight line AE lying in that circle as well. By the same reasoning CH will be perpendicular to CF.

Now in the vertical, meridian, and vertical-declining sundials, this latter circle is the horizon itself. For since the planes of these sundials are at right angles to the horizon, the horizon in turn is at right angles to them, and consequently it passes through their poles, by Theodosius, *Sphaerics* I.13, and hence also through their styles — that is, through their axis. That this same horizon stands at right angles to the greatest circle drawn through AE is clear, because in those sundials that circle is one of the vertical circles, all of which are at right angles to the horizon, and the horizon in turn is at right angles to them. From this it follows that the straight lines AG and CH are horizontal lines in the said sundials.

In the remaining sundials, however, that circle can in no way be the horizon, because the horizon is not at right angles to their planes, since such planes are taken to be inclined to the horizon; hence the straight lines AG and CH will not be horizontal lines. But in the polar sundial that circle will be the equator, and the lines AG and CH will be equinoctial lines. In the equinoctial sundial the same circle will be the hour-circle of the 6th hour from noon, or of midnight, and the lines AG and CH will mark the 6th hour from noon, or midnight — as is evident to anyone who carefully considers the position of these circles, and as will become plain and manifest from what follows. In all the other sundials, finally, that circle will be one or another different circle; yet in every case the straight lines AG and CH will be parallel to the horizontal line of each sundial.

For since this greatest circle (the latter one just spoken of) is at right angles to the earlier greatest circle drawn through the straight lines AE, CF and the styles AB, CD, while this latter circle is set at right angles to the horizon — and so the horizon in turn is at right angles to it — both the horizon and that greatest circle drawn through the straight lines AG, CH will pass through the poles of the greatest circle drawn through AE, CF, by Theodosius, *Sphaerics* I.13. Consequently the axis of this circle drawn through AE, CF will be the common section of the horizon and of that other greatest circle drawn through AG, CH. But the greatest circle to which the sundial is parallel also passes through those same poles of the greatest circle drawn through AE, CF. (For since the greatest circle drawn through the straight lines AE, CF [recte: AE, CF] and the styles AB, CD is, by the construction, at right angles to the plane of the sundial — that is, to the circle which the sundial's plane makes on the sphere — it will pass through the poles of that circle generated on the sphere, by Theodosius, *Sphaerics* I.13. Therefore it will pass through the poles of the greatest circle to which the sundial is parallel as well, since parallel circles have the same poles, by Theodosius, *Sphaerics* II.1. And so in turn the greatest circle to which the sundial is parallel passes through the poles of the circle drawn through AE, CF, by the scholium to *Sphaerics* I.15.)

Therefore the horizon, the greatest circle drawn through the straight lines AG, CH and the styles AB, CD, and the greatest circle to which the sundial is parallel, all have one and the same common section — namely the axis of the greatest circle drawn through the straight lines AE, CG [recte: AE, CF] and the styles AB, CD. For this reason, since the plane of the sundial is parallel to this last circle, the common sections of the others (namely of the horizon, and of the circle drawn through the straight lines AG, CH and through the styles AB, CD, and of the plane of the sundial that cuts them) will be parallel, by Proposition 18 of the preceding book. And therefore, since the section made by the horizon is the horizontal line of the sundial, while the section of that other greatest circle is the straight line AG in one sundial and the straight line CH in the other, the straight lines AG and CH will be parallel to the horizontal line of each sundial.

Diagram. A pair of mirror-image line figures side by side, each a schematic of one sundial plane seen face-on, showing the common sections of the great circles with the plane and the raised style. The left figure is inscribed **Australe / Vel / Superius** ("Southern, or Upper"); the right figure **Boreale / Vel / Inferius** ("Northern, or Lower"). This same paired figure is reprinted, identically, on all three pages of this opening (folios 184, 185, 186), accompanying the continuous demonstration.

Left figure ("Southern / Upper"). A long horizontal line runs across the middle, with **P** at its left end passing through the central point **A** and continuing to the right past **G**; a vertical line runs from **L** at the top down through **A** and **E** (just below **A**) to **K** at the foot. Additional straight lines cross at or near the centre, their ends labelled at the periphery. Readable labels with approximate positions:

- **A** (centre): foot of the style; the point where the style AB meets the sundial plane.
- **B** (interior, above and right of **A**): vertex of the style AB (drawn as a short raised segment from **A**).
- **E** (just below **A**, on the vertical): where section EG cuts the line AE below the style.
- **G** (right of **A**, on the horizontal): where section EG cuts the horizontal line AG.
- **L** (top, on the vertical): where section LM cuts AE above the style.
- **M** (upper left): the outer corner, where LM meets the descending line MP.
- **P** (left end of the horizontal): where section MP cuts the horizontal line AG.
- **R** (upper, between **M** and **L**, on a diagonal): endpoint of a section line.
- **I** (lower left): endpoint of a section line.

- K (foot, on the vertical): lower endpoint.
- S (lower right): endpoint of a section line.

Right figure ("Northern / Lower"), mirroring the left. A horizontal line through the centre C, with Q at the left; a vertical line through F (top) and C. Readable labels:

- C (centre): foot of the style; counterpart of A.
- D (upper left of C): vertex of the style CD, counterpart of B.
- F (top, on the vertical): where section FH cuts CF above/at the style; counterpart of E.
- H (right of C): where section FH cuts the horizontal line CH; counterpart of G.
- N (lower centre): where section NO cuts CF; counterpart of L.
- O (lower left): outer point of section NO / OQ; counterpart of M.
- Q (left, on the horizontal): where section OQ cuts CH; counterpart of P.
- T (upper right, on a diagonal): endpoint of a section line; counterpart of R.
- V (foot, left of centre): lower endpoint.

The lines named in the accompanying text are: in the left (southern/upper) figure, AE (vertical, the meridian section), AG (horizontal), the section EG, the style AB, and the further sections LM and MP; in the right (northern/lower) figure, the corresponding CF, CH, section FH, style CD, and sections NO and OQ. (No label in either figure is flagged [?].)

Now let some greatest circle — whether it be an hour-circle or some other — pass, in the southern or upper sundial, through the centre of the world (that is, through B, or D, for these two points make a single point) and through the vertex of the style, and let it make the section EG, which cuts the straight line AE below the style at E, and the straight line AG at the right at G. This same circle will cut the northern or lower sundial, since it passes through the vertex of the style, along the straight lines CF and CH on the opposite sides — as is plain, if the plane of each sundial and the plane of the circle making the section EG are considered in their proper positions. It will cut, I say, the straight line CF above the style, and the straight line CH toward the right-hand part. For the upper part of the northern or lower sundial is opposed to the lower part of the southern or upper one, the lower to the upper, right to right, and left to left. (We call "right" or "left" the part that lies to our right, or to our left, when we are turned to face the sundial.) Hence, since those two sundials face each other, the right part of the one will answer to the left part of the other, and conversely; but right will be opposed

to right and left to left, since the style is set in the middle place between these parts.

Let, then, the common section of the said circle and of the plane of the sundial in the northern (or lower) sundial be the straight line FH, cutting CF at F above the style, and CH at H toward its right-hand part.[Margin: ^a Euclid XI.16] The two sections EG and FH will be parallel, since it is one and the same circle that makes them in the parallel planes of the sundials. Now since the straight lines AE and CF are parallel, as has been demonstrated,[Margin: ^b Euclid I.29] the alternate angles at E and at F, made on the straight lines EA and FC by the common section of the greatest circles that produce the sections AE, CF and EG, FH, will be equal — which common section passes through the points E, B, D, F, since those very greatest circles pass through these same points. The angles at A and C, which the styles make with the straight lines AE and CF, are right angles, and hence equal, by Euclid, *Elements* XI, definition 3; likewise the styles AB and CD are equal, and they are subtended by the equal angles E and F in the triangles ABE and CDF, whose bases are the parts AE, CF and EG, FH of the common section of the greatest circles that each sundial makes.[Margin: ^c Euclid I.26] Therefore the sides AE and CF will also be equal. Hence the section EG stands away downward from the style along the straight line AE by just as much as the section FH stands away upward from the style along the straight line CF.

Again, since the straight lines EK, EI are parallel to the straight lines FC, FH, as we have shown,[Margin: ^d Euclid XI.10] the angle KEI will be equal to the angle CFH. [Margin: ^e Euclid I.15] And since the angle KEI is equal to the vertically opposite angle AEG, the angles at E and F in the triangles AEG and CFH will be equal. But the angles EAG and FCH are also equal, being right angles; and the sides AE, CF adjacent to the said angles have been shown to be equal.[Margin: ^f Euclid I.26] Therefore the sides AG and CH will also be equal. Hence the straight lines EG and FH stand away from the styles, toward the right, by equal distances along the straight lines AG and CH. And if the straight line EG should cut the line AE above the style, or the line AG to the left, we shall show by the same reasoning that FH cuts CF below the style and CH to the left as well — that is, always on the opposite sides — and that the straight lines which FH cuts off from CF and CH are equal to those which EG cuts off from AE and AG.

Next, let some other greatest circle in the southern or upper sundial, drawn through the vertex of the style B (or D), make the section LM, which does not cut both AE and AG, but only one of them — namely AE, at L, above the style — while being parallel to the other, that is, to AG. Since this same circle passes through the

vertex of the style, it will cut the northern or lower sundial below the style — that is, on the opposite side — along the straight line NO, which cuts CF at N; and NO will be parallel to CH. For since LM is set parallel to AG, and AG in turn is parallel to CH, as we said before,[Margin: ^g Euclid XI.9] LM and CH will also be parallel to each other. Again, since NO is parallel to LM (because LM and NO are sections made by one and the same plane in parallel planes),[Margin: ^h Euclid XI.16] and CH has just been shown parallel to LM, NO and CH will likewise be parallel to each other.[Margin: ⁱ Euclid XI.9] Therefore, since LM is parallel to AG and NO to CH, the angles L and N will be equal to the angles A and C, and hence right angles.[Margin: ^k Euclid I.29]

And since AE, CF are parallel, as was shown above,[Margin: ^l Euclid I.29] the alternate angles at the points L and N, made on the straight lines AE, CF by the common section of the greatest circles that produce the sections AE, CF and LM, NO, will be equal to each other — which common section passes through the points L, B, D, N, since those greatest circles pass through these same points. The angles at A and C, which the styles make with the straight lines AL and CN, are right angles and hence equal; and the styles AB and CD are equal, subtended by the equal angles L and N in the triangles ABL and CDN, whose bases are the parts AE, CF and LM, NO of the common section that each sundial makes.[Margin: ^m Euclid I.26] Therefore the sides AL and CN will also be equal. Hence the section LM stands away from the style upward along the straight line AE by just as great an interval as the section NO stands away from the style downward along the straight line CF. And if the straight line LM should cut AE below the style, we shall show by the same reasoning that NO cuts CF above the style, that NO is parallel to LM, and that the straight line which NO cuts off from CF is equal to the straight line which LM takes from AE.

Finally, let some other greatest circle in the southern (or upper) sundial make the section MP, which again does not cut both AE and CF, but only AG, at P, to the left, while being parallel to AE. This same circle, since it is drawn through the vertex of the style, will cut the northern (or lower) sundial on the opposite side — that is, to the left as well — along the straight line OQ, which cuts CH at Q; and OQ will be parallel to CF. For since MP is set parallel to AE, and CF was earlier shown parallel to AE, MP and CF will likewise be parallel to each other.[Margin: ⁿ Euclid XI.9] Again, since OQ is parallel to MP (because MP and OQ are sections made by one and the same plane in parallel planes),[Margin: ^o Euclid XI.16] and CF has just been shown parallel to MP, OQ and CF will also be parallel to each other.[Margin: ^p Euclid XI.9] Therefore, since MP is parallel to AE and OQ to CF, the angles P and Q will be equal to the angles A and C, and hence right angles.[Margin: ^q Euclid

I.29] And since AG, CH are parallel, as we showed above,[Margin: ^r Euclid I.29] the alternate angles at the points P and Q, made on the straight lines AG, CH by the common section of the greatest circles that produce the sections AG, CH and MP, OQ, will be equal to each other — which common section passes through the points P, B, D, Q, since those greatest circles pass through these same points...

Diagram. The same paired figure as on the preceding page, reprinted identically: the left figure inscribed **Australe / Vel / Superius** ("Southern, or Upper") with central point A, style AB, and labelled points B, E, G, L, M, P, R, I, K, S; the right figure inscribed **Boreale / Vel / Inferius** ("Northern, or Lower") with central point C, style CD, and labelled points D, F, H, N, O, Q, T, V. See the full description under fig-p196-1. (No label flagged [?].)

they pass through them too. And the angles at A and C, which the styles make with the straight lines AP and CQ, are right angles and hence equal; likewise the styles AB and CD are equal, subtended by the equal angles P and Q in the triangles ABP and CDQ, whose bases are the segments AG, CH and MP, OQ of the common section that each of the two sundials makes.[Margin: ^a Euclid I.26] Therefore the sides AP and CQ will also be equal. Hence, by equal intervals, the straight lines MP and OQ stand away from the styles toward the left along the straight lines AG and CH. And if the straight line MP should cut AG to the right, we shall demonstrate by the same argument that OQ cuts CH to the right as well, that OQ is parallel to MP, and that the straight lines which MP and OQ cut off from AG and CH are equal.

Having demonstrated this, we shall easily show that the straight lines EG, LM, MP, and any others whatever, in the northern or lower sundial, are the common sections of those same greatest circles with the plane of the sundial — the very circles whose sections in the southern or upper sundial they are — provided the southern or upper sundial be so placed on the northern or lower face of the plane of the sundial that its upper part is turned into the lower, and the part which, in that position after this transposition, is on our right when we are turned to face the sundial becomes the left, and conversely.

For if the southern or upper sundial is understood to be laid upon the northern or lower one so that style coincides with style, the right part at G with the right part at H, the point A with the point C, and the line AG with the line CH, then the points G, P will fall upon the points H, Q, because the straight lines AG, AP have been shown equal to CH, CQ. And if, in this position, we conceive the southern or upper sundial to be turned about the straight line GP — or (what is the same) about HQ, since in this position these two lines make one and the same — so that

the upper part becomes the lower and conversely, then the points E, L will fall upon the points F, N, because the straight lines AE, AL have been shown equal to CF, CN. Hence the line AG will coincide with the line FH, since we shall have shown the points E, G to coincide with the points F, H; and the line LM will coincide with the line NO, and the line NP with the line OQ, because the points L, P fall upon the points N, Q, and the angles at L, P, N, Q have been shown to be right angles.

By the same reasoning we shall conclude that any other line whatever in the southern or upper sundial — whether it cut both AE and AG, or only one of them and be parallel to the other — coincides with the line answering to it in the northern or lower sundial, if that superposition and transposition, as we have just described, is carried out. Therefore the whole southern or upper sundial will, by this reasoning, coincide with the whole northern or lower sundial.

Since, then, by that superposition and turning the upper part of the southern or upper sundial becomes the lower, and the right becomes the left, as is plain — (for if the southern sundial is understood to be turned by itself, so that the upper part is changed into the lower, the point G will remain on our left, and P on our right, when we are turned to face the sundial. Hence, in order that the line EG may coincide with the line FH, and the remaining lines with the remaining lines, it is necessary that the left part G be changed into the right, and the right part P into the left. For only so will it come about that the several lines coincide, one with one. This too will become plain by the following reasoning: after the straight line GP has been laid upon HQ, the point G indeed remains on our right when we face the sundial, just as does the point H of the northern or lower sundial. But after the turning of the southern or upper sundial about the straight line GP (or HQ), so that the upper parts become the lower, the point G will be set on our left, as was said, if we turn our face to the sundial itself; and since the sundial is then turned toward the south, its lines must be drawn on the opposite face, which looks toward the north. And so, when we are turned to the northern face of the sundial, the same point G will be on our right) — it plainly follows that from the southern or upper sundial, if a transposition of all the parts is made so that the upper is changed into the lower, and the part which after this change is on our right when we face the sundial becomes the left, and conversely, there results the northern or lower sundial.

Now since, in the aforesaid superposition and turning of the southern or upper sundial, its horizontal line coincides with the horizontal line of the northern or lower sundial — (for in sundials whose planes are at right angles to the horizon,

such as the vertical, the vertical-declining, and the meridian, the horizontal line is drawn through the place of the style, and so the horizontal lines are AG and CH, which by the very superposition coincide with each other. But in the other sundials, whose planes are not at right angles to the horizon — such as the polar, the equinoctial, the horizon-declining, the horizon-inclined, and the one that declines from the vertical and is at the same time inclined to the horizon — since the horizontal line falls, in the upper ones, above the style, and in the lower ones below it, and is always parallel to the straight line AG, as we demonstrated a little earlier, it comes about by this reasoning that the horizontal line of the upper sundial coincides with the horizontal line of the lower one. This will be demonstrated, as it has been demonstrated that the straight line LM coincides with the straight line NO) — and since the portion of the sundial lying above the horizontal line is superfluous in any sundial, because the shadow of the style can never fall upon it during the day, it is established universally that the horizontal line, in any sundial whatever, cuts off toward the upper parts a portion which, on the opposite face of the plane of the sundial, presents to us that same sundial, if it be so placed that the horizontal line occupies the upper position on the opposite face, and the part which in that position is on our right when we face the sundial becomes the left, and conversely. For once that transposition of the parts has been made, the part above the horizontal line of the southern sundial is placed, in the northern sundial, below the same horizontal line, as is manifest. Which was to be demonstrated.

And if it should ever happen that lines in a sundial, which are the common sections of the plane of the sundial and of the greatest circles, pass through A — the place of the style in the southern or upper sundial — and through C, the place of the style in the northern or lower sundial (as happens with the celestial houses of the vertical sundial, with the hours from noon or midnight, and with the meridian circles of the equinoctial sundial, as will become plain from what follows), it will nonetheless follow that the southern or upper sundial coincides with the northern or lower one...

Diagram. The same paired figure as on the two preceding pages, reprinted identically: the left figure inscribed **Australe / Vel / Superius** ("Southern, or Upper") with central point A, style AB, and labelled points B, E, G, L, M, P, R, I, K, S; the right figure inscribed **Boreale / Vel / Inferius** ("Northern, or Lower") with central point C, style CD, and labelled points D, F, H, N, O, Q, T, V. See the full description under fig-p196-1. (No label flagged [?].)

or the lower one, if all its parts are inverted, as we have taught. For let some great circle in the southern (or upper) sundial, drawn through the style AB, make a section RS passing through A, the place of the style. Since this same circle passes through the style, it will also cut the northern (or lower) sundial along the straight line TV, likewise passing through C, the place of the style — yet not in the opposite parts, but in corresponding ones. That is: if the section RS above the style inclines to the left and below the style to the right, then the section TV inclines above the style to the right and below the style to the left, and conversely. For these parts answer to those, as is evident to anyone who carefully considers the position of each sundial. [Margin: a — Elements XI.16 ("16. vnde.").] Now the sections RS and TV will be parallel to each other, since they are made in parallel planes of the sundials by one and the same plane of the great circle. And since the straight lines AE and CN are also parallel, as we showed a little earlier, [Margin: b — Elements XI.10 ("10. vnde.").] the angles EAS and NCV will be equal to each other. [Margin: c — Elements I.15 ("15. primi.").] Therefore, since the vertical angles EAS and LAR are likewise equal, the angles LAR and NCV will also be equal. So, superimposing once again the straight line AG upon the straight line CH, so that the point A falls upon the point C, and understanding that in this position the southern (or upper) sundial is turned about the straight line AG — or CH, which is the same line in that position — so that its upper part is changed into the lower and conversely: then the straight line AR will fall upon the straight line CV, because the angles LAR and NCV are equal. And the same reasoning holds for any other lines drawn through A and C, the places of the styles. Therefore, as before, the portion cut off by the horizontal line, if it is inverted as was said above, will yield the sundial to be drawn on the opposite face of the sundial's plane.

I have chosen to demonstrate this here more fully, so that we should not be forced in what follows to keep hammering at the same demonstration. For it will bring great usefulness to what comes after, as will become plain in its proper places.

PROBLEMA 15. PROPOS. 15.

To describe the parallels of the diurnal arcs on the same vertical sundial.

If, from D — the place of the Zodiac's rays in the figure of the Zodiac's rays of the preceding proposition — the rays of the lengths of the days found in proposition 33 of the previous book are drawn out; or if, on the Analemma of that same preceding proposition, in place of the parallels passing through the beginnings of the signs, the parallels of the diurnal arcs are taken: then we shall describe the

parallels of these arcs in the same way in which we described the parallels of the signs. For the ratio is the same in these as in those, since all are equidistant from the Equator. Therefore we have described the parallels of the diurnal arcs, and so on. Which was to be done.

[Margin: The drawing of the diurnal arcs on the aforesaid vertical sundial.]

Diagram. A pair of construction figures side by side.

Left figure — a full circle (the "figure of the Zodiac's rays" of the preceding proposition), with center at a small inner circle labelled **D**, crossed by many radial straight lines (the rays):

- A, Q (top, to the right of R): points on the upper circumference
- R (top left of the upper labels)
- 16, 15, 14, 13, 12, 11, 10, 9, 8 (descending along the upper-left circumference)
- E (right, on the circumference)
- B (left, on the circumference)
- Q, R (bottom of the circumference)
- F, G, H [?] (small letters clustered about the center D — worn; readings uncertain)

Right figure — a horizontal top line with a fan of straight rays descending from the region near its middle down to two rows of numbers:

- A (left end of the top line)
- D, H (near the middle-top, at the head of the ray-fan)
- B (on the arc, at the left)
- C (below B, at the left)
- Inner ray-numbers (along the arc, left to right): 1, 2, 3, 4, 5, 6, 7, 8
- Outer ray-numbers (along the bottom edge, left to right): 16, 15, 14, 13, 12, 11, 10, 9

(Several small ray-numerals and the central letters of the left figure are worn; the point-letters A, B, C, D, E, H, Q, R are read with confidence.)

We shall describe the parallels of these arcs in the same manner in which we described the parallels of the signs; for the ratio is the same in these as in those, since all are equidistant from the Equator. Therefore, the parallels of the diurnal arcs, etc. Which was to be done.

PROBLEMA 16. PROPOS. 16.

To describe the vertical circles on the same vertical sundial.

Upon the meridian line of the sundial, from G, the place of the style, let the length of the style be carried up to the point A — which may be taken either below G or above it. From A let a circle of any size be described; and having divided it into 360 equal parts, beginning from the meridian line (if all the verticals are wanted), or into fewer, according to the number of verticals to be drawn — (we divided it into 24, so that each interval contains 15 degrees) — let hidden straight lines be drawn through the points of division and the center A, cutting the horizontal line at points; and if through these points straight lines are drawn parallel to the meridian line HI, the vertical circles will have been described. These parallel lines are easily drawn: if through any point of the meridian line — say through B — a line is drawn parallel to the horizontal line, and all the points of the horizontal line, taken with the compass from G, are transferred onto that parallel from the point B. [Margin: d — Elements I.33 ("33. primi").] For the straight lines connecting two points equidistant from G and B will be parallel to GB itself.

[Margin: The drawing of the vertical circles on the same vertical sundial.]

[Margin: Demonstration of the drawing of the vertical circles.]

That these parallels in the plane of the vertical sundial are the vertical circles — or rather the common sections of the vertical circles and the plane of the vertical sundial — we shall demonstrate as follows. Let the plane of the circle described from A be understood to be turned about the horizontal line until its center A is joined to D, the vertex of the style, so that it becomes the same as the plane of the Horizon passing through the horizontal line and the gnomon GD. Since, then, the common sections of the Horizon and of the vertical circles running through the poles of the Horizon divide the Horizon — and hence also the circle described from A (since in such a position the Horizon and the said circle have the same center) — into equal parts,

the straight lines from A passing through the points of division will be the common sections of the verticals and of the Horizon. Therefore the vertical circles will cut the plane of the sundial at the points where the said common sections meet the horizontal line. And since, by proposition 18 of the previous book, the common sections of the vertical circles and of the plane of the vertical sundial are parallel — because the plane of the vertical sundial is equidistant from their common section, namely the axis of the Horizon drawn through the

zenith and its opposite point — it is manifest that those straight lines which are parallel to the meridian line (which is one of the vertical lines) are the common sections of the vertical circles and of the plane of the sundial. But the vertical circle properly so called cannot be projected onto the plane of the sundial, since it is equidistant from it and therefore makes no section in it. Therefore we have described the vertical circles on the same vertical sundial. Which was to be done.

Diagram. A circle representing the vertical sundial with its vertical circles. A vertical diameter runs from **A** at the top to **B** at the bottom; the horizontal diameter carries the word **HORI-** on the left and **ZON** on the right (i.e. HORIZON, split across the figure). At the center is a dense cluster of style-points:

- A (top of the vertical diameter)
- B (bottom of the vertical diameter)
- G (the style base, at the center), with the neighbouring points K, L, I and, below them, M, N (small boxed "KI" cluster at the center — the style-point group)
- HORI- / ZON (the horizontal line)

Dotted lines radiate from the central cluster to the circumference on both sides, marked with the degrees of the vertical circles. Readable degree labels, descending on each side: 15, 30, 45, 60. The topmost pair of dotted lines carry a worn numeral [?] (probably 75).

SCHOLIVM.

[Margin: The vertical circles on a southern sundial are all southern, and on a northern sundial all northern.]

It is clear that these vertical circles are southern on a sundial that faces the meridian, but northern on one that faces the north. On both, moreover, the number of degrees is terminated at the meridian line, and the drawing is the same on each. Hence here too the horizontal line will cut off the portion that must be placed on the northern face — yet in such a way that the horizontal line is set in the upper position, as we demonstrated in the scholium to proposition 14 of this book. But here there is no need to change the right side into the left and conversely, since the numbers are the same on both sides, and the vertical lines have the same situation on both sides of the meridian line, as is evident.

PROBLEMA 17. PROPOS. 17.

To describe the parallels of the Horizon on the same vertical sundial.

[Margin: The drawing of the parallels of the Horizon, or almucantarath, on the same vertical sundial.]

Let the Meridian of the Analemma ABCD be described, in which BD is the diameter of the Horizon and AC the diameter of the Vertical. Having divided each quadrant AB and AD into 90 equal parts, so that each part comprises a single degree — or into fewer, according to the size of the sundial (we divided each into six, so that each part answers to 15 degrees) — let two points equally distant from the straight line BD be joined by straight lines, which will be the common sections of the Meridian and of the parallels of the Horizon, which they call almucantarath. Next, from the points of division of each quadrant, through the center E, let straight lines be drawn, so as to make triangles through the axis in cones whose bases are the parallels of the Horizon, both below and above the Horizon, and whose common vertex is E, the center of the world. For the Meridian ABCD, cutting the said cones through their axis AC, makes — by proposition 3 of Book 1 of Apollonius — triangles through the axis. Let there also be cut off from BD, on both sides from the point E, a straight line EG equal to the gnomon; and through G let GO be drawn parallel to AC — namely the common section of the plane of the sundial and of the Meridian — cutting the sides of the axial triangles at the points K, L, M, N, so that KO, LO, MO, NO are the diameters of the conic sections. If, then, the points K, L, M, N, taken on this Analemma from the point G, are transferred onto the meridian line of each sundial, below the horizontal line, from the place of the style G, and about the meridian line the said conic sections are described — by proposition 8 of the previous book — passing through the points K, L, M, N (these conic sections being hyperbolas, by proposition 6 of the preceding book, since the vertical circle running through the poles of the parallels of the Horizon cuts them), so that their horns are turned ever more and more away from the horizontal line: then the parallels of the Horizon will have been described, as may be seen in the figure of the preceding proposition.

Diagram. The Meridian of the Analemma — a full circle for constructing the parallels of the Horizon. Cardinal points on the circumference:

- A (top; marked 90)
- B (left end of the horizontal diameter)
- C (bottom; marked 90)
- D (right end of the horizontal diameter)
- E (center)

- G, and the cluster K, L, M, N (near the center, the almucantarath-construction points)

Each quadrant is graduated at 15° intervals; readable degree labels running from the horizontal toward the top and bottom on both sides: 15, 30, 45, 60, 75. Straight chords parallel to BD (the almucantarath = parallels of the Horizon) cross the circle. One left-side degree label reads **20** [?] — anomalous within a 15°-graduated series (probably a worn 30); flagged.

[Margin: Another way of drawing the parallels of the Horizon on a vertical sundial.]

ALITER (Otherwise). Having described a quadrant ABC of any size, and divided it into 90 degrees — or into fewer parts, according to the number of parallels to be drawn — let straight lines be drawn out from the center A through the points of division. These will answer to the radii of the parallels of the Horizon in the quadrant EBC contained in the preceding figure, beginning from the straight line AB, so that the radius nearest to the straight line AB is that of the parallel of the Horizon at 15 degrees, the next at 30, and so on, as the numbers declare.

After this, from the sundial of the preceding proposition, let the intervals between the center A and the points at which the vertical lines intersect the horizontal line be taken, and let them be transferred from A onto the straight line AB of this figure, writing beside AB the numbers of the vertical lines, and marking the points that bound the said intervals. Finally, through the points marked on the straight line AB, let lines be drawn parallel to AC, or perpendiculars to AB. This is easily done if some line is drawn parallel to AB and the points of the line AB are transferred onto it, beginning from the straight line AC, and so on. For example, from the figure of the preceding proposition, let the interval AK be transferred onto the straight line AB of this figure, up to the point E, appending the number 30; and through E let EF be drawn parallel to AC, and so on.

Diagram. The vertical sundial with its parallels of the Horizon (the arcs of the Sun's altitudes). A near-horizontal top line runs from **B** at the left to **A** at the upper right, from which a fan of straight rays descends:

- B (upper left)
- A (upper right, the apex of the ray-fan)
- M (in the upper-left interior, on a descending curve)
- F (in the interior, right of center)

- C (lower right)
- Degree labels descending along the left side and across the lower edge: 15, 30, 45 (down the left), then 60, 75, 90 (across the bottom, left to right toward C)
- A cluster of small worn ray-numerals near A [?]

Once the figure has been prepared in this manner, the parallels of the Horizon — that is, the arcs of the Sun's altitudes — are described as follows. The intervals of the lines equidistant from AC, comprised between the straight line AB and a radius (say the radius of the parallel of the Horizon at 15 degrees), are transferred on both sides from the points at which the horizontal line in the figure of the preceding proposition is cut by the vertical lines, onto the vertical lines corresponding to the numbers marked on the straight line AB, marking points on the vertical lines. For example, on the straight line EF let a length be taken equal to KL, on each vertical line at 30 degrees, both below and above the horizontal line, and so with the rest. For if these points are suitably joined by a certain curved line, there will be described the arc, or parallel of the Horizon at 15 degrees, both on the southern sundial and on the northern — which is indeed cut off by the horizontal line, as we showed. In the same way the remaining parallels of the Horizon will be described, if the straight lines intercepted between the line AB and the radii of the parallels of the Horizon are transferred on both sides from the horizontal line onto the corresponding vertical lines of the sundial. Yet it is not necessary to transfer all these straight lines onto the vertical lines on both sides — that is, above and below the horizontal line — because there is no need to describe as many parallels of the Horizon on the northern sundial as on the southern. Thus you see that on the northern sundial we have described only the parallel at 15 degrees, since the others would fall entirely outside the tropic, and therefore no shadow could fall upon them.

That the parallels of the Horizon are rightly described by this art will be demonstrated as follows. In the figure of the preceding proposition, let the straight line AG — which was taken equal to the gnomon — be understood to stand at right angles to the plane of the sundial at the point G; and let the figure just constructed about the point A be carried around, joined to the center of the world, so that the point A of this figure never departs from the point A of the figure of the preceding proposition (that is, from the center of the world), and the straight line AC remains perpetually equidistant from the meridian line HI (that is, joined to the axis of the Horizon and of its parallels), and the point B is extended toward the sundial, and therefore the straight line AB, not departing from the plane of the Horizon, always meets the horizontal line in that motion. In

this circumduction the point E, say, will fall upon the point K, because the straight line AK was taken in the preceding proposition equal here to AE. For the straight line AK falling from the point A on high — namely from the vertex of the style — is equal to the straight line AK in the plane of the sundial; as will easily be proved if the triangle AKG in the plane is compared with the triangle AKG on high. For since the sides AG, GK of the former are equal to the sides AG, GK of the latter, and contain equal angles (being right angles), [Margin: a — Elements I.4 ("4. primi").] the base AK of the former will be equal to the base AK of the latter. Since, then, both KL and EF are equidistant from the axis of the Horizon, [Margin: b — Elements XI.9 ("9. vndec.").] KL and EF will also be parallel to each other; and therefore, the point E coinciding with the point K (as we showed), the straight line EF will also coincide with the straight line KL — otherwise the one would not be parallel to the other, since both meet in the point K in that circumduction. Therefore, since KL was taken equal to the straight line EF, the point F will fall upon the point L, and so the radius of the parallel of the Horizon at 15 degrees will meet the plane of the sundial at L. Through the point L, therefore, the arc of the aforesaid parallel at 15 degrees will pass, since the radius of the said parallel falls upon it in that revolution, as has been shown. In no other way shall we demonstrate that the point M of the same radius falls upon the point N, and so with the rest. Therefore we have described the parallels of the Horizon on the same vertical sundial. Which was to be done.

[Margin: Demonstration of the latter drawing of the parallels of the Horizon.]

PROBLEMA 18. PROPOS. 18.

To describe the Meridians, or circles of longitude of cities, on the same vertical sundial.

These are described as the hour-lines from noon or midnight, in the manner we stated in proposition 6 of this book — provided that the circle described from E has the beginning of its division from the Meridian of the Fortunate Islands, which is obtained if the longitude of the place is reckoned from N: on the southern sundial indeed toward the left (in the sundial of proposition 13 of this book), but on the northern toward the right — namely always toward the western parts, as reason demands. This will be easily understood if, on each sundial, the circle described from E is turned about the equinoctial line until it attains its proper position, namely until it is set in the plane of the Equator, and so on. And so we have described the Meridians, or circles of longitude of cities, on the same vertical sundial. Which was to be done.

[Margin: The drawing of the Meridians on the same vertical sundial.]

SCHOLIVM.

[Margin: How the Meridians of a southern sundial, drawn beyond the horizontal line, yield the same meridians on a northern sundial.]

If the Meridian circles — or rather their common sections with the plane of the sundial — on the southern sundial are produced beyond the horizontal line and the center H, the same Meridian circles will also be obtained on the northern sundial, which the horizontal line cuts off — provided you remember that the whole sundial must be inverted, so that the upper parts become the lower and the right come out as the left, as was shown in the scholium to proposition 14 of this book. Likewise, that these sections of the Meridians and of the plane of the southern sundial present, on the northern sundial, the sections of the opposite semicircles of the Meridians, so that they have the numbers which are made up by adding 180 degrees to the numbers they have on the southern sundial (yet casting off 360 degrees if, from that addition, a number greater than 360 degrees results); or else the numbers which, on the circle described from E, are opposite by a diameter to those numbers which the said sections...

[Margin: ...in the northern sundial.]

the same sections on the southern sundial. Yet the lines of the southern sundial, when produced beyond the center H, will again bear the very same numbers that they have on the southern sundial, because on the northern sundial they are once more the sections of the opposite semicircles — just as was said of the hour-lines reckoned from noon or from midnight. For there, take the line of (say) the 7th hour from midnight: on the southern sundial, produced beyond the horizontal line before it reaches the center H, it marks on the northern sundial (once the aforesaid inversion of the sundial is made) the 7th hour from noon — that is, the common section is of the plane of the sundial and of the semicircle of the 7th hour from noon, and not from midnight, as on the southern sundial. But produced beyond the center H, it will again show the 7th hour from midnight, as on the southern sundial. The same reasoning is to be applied to the rest, as is clear from the sundial of proposition 14 of this book. So it happens here too. For the Meridian 120 on the southern sundial, produced beyond the horizontal line, gives on the northern sundial the Meridian 300; but produced further, through the center H, it yields on that same northern sundial the Meridian 120 once again, and so on.

Diagram. A vertical-sundial construction showing the Meridians (circles of longitude of cities), with the meridians of Rome and of the Fortunate Islands laid out. A large circle carries a vertical meridian line running top to bottom through the labelled points; from an interior point near the top a fan of straight meridian-lines radiates outward across the whole field, and several long straight lines run out to the framing rectangle at both sides. Two concentric numeral scales (graduated in degrees of longitude) are printed around the inner circle. Small place-labels are set within the figure.

- M (top of circle, on the meridian line): vertex
- H (on the meridian line, below M)
- G (on the meridian line, below H; the fan of meridian-lines springs from here)
- E, I (interior, near the center of the figure)
- I, G, H (repeated on the lower meridian line, mirroring the upper points)
- N (bottom of the meridian line)
- ROMA (set vertically in the central circle — the meridian of Rome)
- INS[VLÆ]. FORT[VNATÆ]. (the Fortunate Islands, i.e. the reference meridian; the abbreviation appears twice, upper-right and lower-right, set diagonally)
- Insulæ Fortun[atæ] (spelled out, set vertically at left and again lower-right)
- Small italic labels along the central rays, near point I: Genua (vertical cursive, right of point I) and Alexandria [Alexā(ndria) [?]] (vertical cursive, left of point I) — city-meridian labels [Stage-5 recovery]
- Longitude numerals read around the scales (as printed, several small ones worn): 240, 180 (upper); 315 (right), 120 (left), 120 (right), 105, 315, 330, 345, 90 (outer); 75, 60, 45, 30, 15, 150, 135, N 45, 60, 285, 300, 120 (upper inner ring); 285, 300, 150, 135, 120, 30, 15 (lower inner ring)

[Several of the small interior longitude numerals are worn; figure marked as a — see report. The two italic ray-labels near point I are now read as the city-meridian labels Genua and Alexandria (Stage-5).]

PROBLEMA 19. PROPOS. 19.

To describe on the same vertical sundial the parallels of cities — that is, the circles of latitude.

[Margin: The drawing of the parallels of cities, or of latitudes, on the same vertical sundial.]

These are drawn just like the parallels of the signs of the Zodiac, which we treated in proposition 14 of this book — except that, in place of the parallels running through the signs of the Zodiac, one takes the parallels passing through the vertices of the cities, and so on. And so we have drawn the parallels of cities, and so on. Which was to be done.

PROBLEMA 20. PROPOS. 20.

To describe the celestial houses on the same vertical sundial.

[Margin: The drawing of the celestial houses according to Johannes Regiomontanus [Regiomontanus] on the same vertical sundial. Demonstration of the drawing of the celestial houses.]

Following the opinion of Johannes Regiomontanus [Regiomontanus] — who would have the circles of the celestial houses pass through the common sections of the Horizon and of the Meridian, and would divide the Equator into 12 equal parts — the celestial houses will be described in this way. Let the circle drawn from E be divided into 12 equal parts, beginning from the meridian line; and through the points of division and the center E let hidden straight lines be drawn, cutting the equinoctial line at points through which — from G, where the horizontal line intersects the meridian line — straight lines drawn out will give the circles of the celestial houses according to Johannes Regiomontanus [Regiomontanus]. For when the circle drawn from E is carried around about the equinoctial line, until E is joined to the center of the world and that circle comes to lie in the plane of the Equator, the straight lines passing through the center E will be the common sections of the circles of the celestial houses (among whose number is the Meridian too) and of the Equator; since with the

circles and the Equator they share common sections, according to Johannes Regiomontanus [Regiomontanus]. Let them divide the Equator — and therefore also the circle concentric with it, drawn from E — into 12 equal parts, and let them pass through the center of the world, where the point E is now placed. Such circles, then, will meet the plane of the sundial at the points where the straight lines drawn through E cut the equinoctial line; and so through those same points of the equinoctial line the common sections of the plane of the sundial and of the circles of the celestial houses will pass. But these common sections also cut one another mutually at G, by proposition 18 of the preceding book — since the common section of these circles, namely the axis of the Vertical circle, or the common section of the Horizon and Meridian, meets the plane of the sundial at G, where the meridian line cuts the horizontal line, as is clear from the portion of

the Analemma in proposition 13 of this book. Therefore the straight lines drawn from G through the points of the equinoctial line will be the common sections of the plane of the sundial and of the circles of the celestial houses. Which was proposed.

Diagram. A vertical-sundial construction for the celestial houses, with the word HORIZON split across the horizontal line. A central circle carries the vertical meridian line through the points M(top, off-scale)–H–G–I–E; the horizontal Horizon line runs across the figure, and from the interior a fan of house-lines radiates outward to the frame, giving the wedge-shaped house divisions numbered as an astrological house-diagram. Several number-sorts are printed mirror-reversed (a woodcut artifact).

- H (on the meridian line, upper center)
- G (on the meridian line, at the crossing with the Horizon)
- I (on the meridian line, below G)
- E (interior, below I — the center from which the base circle is drawn)
- 10 (interior, just below E) [numeral: printed as "10"; worn — possibly "16" [?]]
- HORI ... ZON (the word "Horizon" set to left and right of the meridian along the horizontal line)
- House numerals around the dial: 8, 8 (upper left; the "8"s printed reversed), 12, 12 (upper right, reversed); I, 1 (left) and I, 7 (right, at the Horizon ends); 12, 12 (lower left); 8, 8 (lower right); 11, 11 and 9, 9 (lower center)

SCHOLIVM.

[Margin: For what reason the parts of the celestial houses are described on the same vertical sundial.]

But according to the opinion of Campanus [Campanus of Novara] — who draws the circles of the celestial houses through the common sections of the Meridian and of the Horizon, dividing the Vertical circle properly so called into 12 equal parts — we shall carry out the same problem as follows. From G, the place of the style, we shall lay out a circle of any magnitude divided into 12 equal parts, beginning from the horizontal line, or from the meridian line. For the straight lines drawn from G through the points of division will give the celestial houses according to Campanus [Campanus of Novara]. This we shall show as follows.

[Margin: The drawing of the celestial houses according to Campanus [Campanus of Novara] on the same vertical sundial. Demonstration of the latter drawing of the celestial houses.]

Since the circles of the celestial houses cut the Vertical circle, according to Campanus [Campanus of Novara], into equal parts, beginning from the common section of the Vertical and the Horizon — and therefore also divide into just as many equal parts the circle which the plane of the sundial makes, equidistant from the Vertical circle in the sphere, by proposition 1 of Book 1 of Theodosius, beginning from the horizontal line, namely from the common section of the plane of the sundial and of the Horizon (because circles passing through the poles of the Vertical circle divide the Vertical and its parallels into similar segments, by proposition 10 of Book 2 of Theodosius) — it follows that the circles of the celestial houses, and hence also the common sections of them and of the plane of the sundial, pass through the points of division of the circle drawn from G. (For the point G, upon which the axis of the Vertical circle falls, is the center of the circle generated in the sphere by the plane of the sundial, by proposition 10 of Book 1 of Theodosius; and therefore that circle — and the one we drew from G — are divided into similar arcs by straight lines going out from the center G.) And on that account the common sections also pass through the point G, by proposition 18 of the preceding book, in which, of course, the common section of the circles of the celestial houses meets the plane of the sundial, and in which those same circles cut one another mutually. Therefore the straight lines drawn from G through the points of division of the circle drawn from G will be the common sections of the plane of the sundial and of the circles of the celestial houses, according to Campanus [Campanus of Novara]. Thus we have described the celestial houses on the same vertical sundial. Which was to be done.

SCHOLIVM.

[Margin: For what reason the parts of the celestial houses are described on the same vertical sundial.]

Since each celestial house contains 30 degrees, if each twelfth part of the circle drawn from E (or from G) is divided into 30 parts — or into fewer equal parts, according to the size of the sundial — and the rest is done as before, other circles of position will be drawn, passing through the parts of the celestial houses. And this same thing is to be observed for the celestial houses of the other sundials.

And if the lines of the celestial houses on the southern sundial run out beyond the horizontal line, then the portion cut off by the horizontal line, when inverted, will

present to us (as we taught in the scholium to proposition 14 of this book) those same lines on the northern sundial, as was demonstrated in that same scholium.

PROBLEMA 21. PROPOS. 21.

To describe on the same vertical sundial the ascending signs of the Zodiac.

From the two preceding little tables of proposition 9 of this book, with the Sun standing at the beginning of ♈ (Aries) and of ♎ (Libra), let there be taken the hours in which the 12 signs of the Zodiac

[Margin: The drawing of the ascending signs of the Zodiac on the same vertical sundial.]

rise; and let these be reckoned in the circle drawn from E, from the meridian line, either toward the east or toward the west, as the tables indicate. Then through the ends of these reckonings, and the center E, let hidden straight lines be drawn out, cutting the equinoctial line at points through which the lines of the ascending signs — that is, the common sections of the plane of the sundial and of the Zodiac at the rising of the signs — ought to be drawn. For example: since, with the Sun standing in the equinoctial circle, namely at the beginning of ♈ (Aries), the beginning of ♉ (Taurus) rises at the 4th hour 51 minutes before noon, there must be reckoned on the southern sundial 4 hours 51 minutes from the point N, toward the right, up to the point A; and through A and the center E a hidden straight line is to be drawn out, cutting the equinoctial line at the point B, through which the line of the ascending sign ♉ (Taurus) must be carried. For with the Sun standing at the beginning of ♈ (Aries) and ♉ (Taurus) rising — that is, at the 4th hour 51 minutes before noon — the shadow of the gnomon is cast onto the point B, as is established from what was demonstrated in proposition 1 of this book. In no other way are the points of the other ascending signs to be sought on the equinoctial line.

Diagram. A vertical-sundial construction for the ascending signs of the Zodiac, with the twelve zodiac signs set down the left and right borders of the figure. A large circle is inscribed in a rectangular frame; a vertical meridian line runs through M (top) – H – G – E – N (bottom), and a horizontal line crosses it. A dense sheaf of straight lines (the shadow/sign lines) is drawn from the frame corners and borders across the circle, meeting a horizontal row of interior points. The graduated circle carries tick-marks around its lower arc.

- M (top of circle, on the meridian line)
- H (on the meridian line, below M)

- Horizontal row of interior points, left to right: K, M, G, F, C
- B (left of center, below the row)
- E (center, on the meridian line)
- A (lower right, interior)
- N (bottom of the meridian line)
- Left and right borders: the twelve signs of the Zodiac, one glyph per position running down each side (worn — several glyphs not securely legible; see report). Readable glyphs include ♋, ♊, ♍, ♈, ♉, ♌, ♏, ♎.

[The 24 border zodiac-glyph positions are largely worn; figure marked as a — see report.]

After this, let there be marked on the horizontal line, by proposition 14 of this book, the points at which it is cut by the arcs of the signs. For into these points the shadows of the style will be cast, when those signs are rising or setting — such points being C, D, F, K, L, M. For at C, on the southern sundial, there set ♏ (Scorpio) [?] and ♓ (Pisces); at D, ♐ (Sagittarius) and ♒ (Aquarius); at F, ♑ (Capricorn); while at the points K, L, M the same signs rise. But on the northern sundial, at C there set ♉ (Taurus) and ♍ (Virgo); at D, ♊ (Gemini) and ♌ (Leo); at F, ♋ (Cancer); and at the points K, L, M the same signs rise — as is clear if the northern sundial is set in its proper position on the north-facing wall, so that the center of the sundial H is below the horizontal line, with the points K, L, M toward the right, and C, D, E toward the left. For we now take, in place of the northern sundial, the whole southern one, with the upper part changed into the lower, so that the center H is placed below the horizontal line.

[Margin: For what reason the points on the horizontal line of the vertical sundial are found, at which the Sun rises or sets when standing at the beginnings of the signs.]

But these same points we shall also find, by this method, on the horizontal line of each sundial, even if the arcs of the signs are not drawn on it. From the fifth table of proposition 9 of this book we shall take the semidiurnal arcs of the southern signs for the southern sundial, and we shall number them from N in each direction; and from the ends of the numberings we shall draw, through E, straight lines cutting the equinoctial line at points, through which straight lines drawn out from H will cut the horizontal line at the points C, D, F, K, L, M, through which the arcs of the signs pass. For at those points the Sun rises and sets when it stands at the beginnings of the signs, because the said straight lines going out from H indicate the hours at which the Sun rises and sets, and so on. But for

the northern sundial we shall take the semidiurnal arcs of the northern signs, and number them from M in each direction, and so on.

[Margin: For what reason the same points are found by means of the Analemma.]

Geometrically too, and more surely, by means of the rising and setting amplitudes, we shall find these same points at which the Sun rises when standing at the beginnings of the signs, in this way. Let the Horizon be ABCD, whose center is E; let its common section with the Meridian be BD; and its common section with the Vertical — and therefore also with the Equator — be AC. On the straight line BD let there be sought the points where it is cut by the parallels of the signs, which will be done thus. From B toward A let the altitude of the Equator Be be computed, or from A toward B the altitude of the pole Ae; and from the point e let there be drawn on either side (as in the Analemma) the diameters of the parallels of the signs, equidistant from the diameter of the Equator ef. For these will cut the straight line BD at the points F, G, H, I, K, L, which are sought. This is easily demonstrated if the semicircle BAD is imagined to be turned about BD, until it stands upright at the Horizon and is joined with the Meridian. For then the said parallels will be the common sections of the Meridian and of the parallels of the signs of the Zodiac, and therefore the parallels themselves will cut the straight line BD at the points F, G, H, I, K, L, since they are drawn through the said parallel lines. Then through the points F, G, H, I, K, L, let there be drawn to BD the perpendiculars MN, OP, QR, ST, VX, YZ. These will be the common sections of the parallels of the signs of the Zodiac and of the Horizon. For since both the Horizon and the parallels of the signs of the Zodiac are perpendicular to the Meridian, [Margin: a — Elements XI.19 ("19. vndec.").] the common sections of the Horizon and of the parallels will likewise be perpendicular to the Meridian, and therefore (by definition 3 of Book 11 of Euclid) perpendicular also to the straight line BD, which lies in the Meridian. For which reason the said perpendiculars are the common sections of the parallels and of the Horizon. From this it follows that, since the Vertical properly so called is denoted by the straight line AC, the arcs CM, CO, CQ, CS, CV, CY are the rising amplitudes, and the arcs AN, AP, AR, AT, AX, AZ the setting amplitudes.

[Margin: The rising and setting amplitudes found by means of the Analemma.]

And so, if from ED a straight line Ea equal to the style is cut off, and through a line bd is drawn perpendicular to ED, it will

will be the horizontal line on the southern vertical sundial. The rays drawn from the points S, V, Y and T, X, Z through the center E will cut the horizontal line at the

points onto which the shadow of the style is cast when the Sun rises and sets while it stands at the beginnings of the signs. These points, then, taken from the point a and transferred to the horizontal line of the sundial from the position of the gnomon G, will give the same points on the sundial.

This can be made clearly evident to anyone if the Horizon ABCD is placed on the southern sundial in its proper position, so that the point a lies at the position of the style G, the straight line bd coincides with the horizontal line, and E therefore lies at the center of the world, serving as the vertex of the style. For once this is assumed, when the Sun rises at the horizon points S, V, Y and sets at T, X, Z, the shadow of the style will be cast onto the said points of the horizontal line — the points, that is, of the southern signs. In the same way, the points of the northern signs will be found on the northern sundial, if from EB one cuts off the straight line Ea equal to the style, and through a draws to EB the perpendicular bd, which again will be the horizontal line on the northern sundial, and so on. Moreover, from this same figure we shall find the corresponding points on the horizontal line of any sundial whatever, as will become clear from what follows. The diameters of this figure — YN, VP, and the rest — may not unfittingly be called the rays of the rising or setting latitudes [radij latitudinum ortiuarum vel occiduorum].

[Margin: What the rays of the rising and setting latitudes are.]

Here too the reason clearly appears why the southern signs are changed into northern ones on the northern sundial. It is because the rays of the latitudes of the southern signs, drawn through the center E, cut the straight line bd when that line is drawn on the northern side through the point a — the line that represents the horizontal line on the southern sundial; whereas when the straight line bd is drawn through a on the southern side, representing the horizontal line on the northern sundial, it is cut by the rays of the latitudes of the northern signs drawn out through the center E, as is plain from the figure.

[Margin: The reason why, on the northern sundial, the arcs of the southern signs are changed into the arcs of the northern signs.]

Since Taurus [♉] rises when its opposite sign sets — that is, when the shadow of the style on the sundial is cast onto the point C — then, if we join B, namely the point of Taurus found on the equinoctial line, with the point C found on the horizontal line, we shall have Taurus ascending. In the same way, if we connect the point of Gemini [♊, printed "II"], found on the equinoctial line, with the point D, at which Capricorn [♐] sets, we shall have Gemini ascending — and likewise

for the rest of the northern signs. Again, since, when the Sun stands at the beginning of Aries [♈] and that same sign is rising, the shadow of the style is cast onto L, we shall join the point L with the point of Aries [♈] found on the equinoctial line, so as to have Aries ascending. So too we shall join the point of Capricorn [♐], found on the equinoctial line, with the point M, where Capricorn rises, so as to have Capricorn ascending — and so with the rest of the southern signs.

It must be observed, however, that in laying out the signs on the southern sundial one should not take, from the first two tables of proposition 9 of this book, the hours of those signs which rise six or more hours before or after noon. For these do not cut the equinoctial line. On the northern sundial, by contrast, for laying out those same signs one must take precisely such hours — and not the hours of those signs which rise six or fewer hours before or after noon — for the same reason: because on the northern sundial only the lines of those hours which are more than six hours distant from noon cut the equinoctial line, as is clear from what we wrote in proposition 13 of this book.

We can also, if we wish, find on the two tropics the points through which the ascending signs are to be drawn: namely, by lightly drawing the line of the hour at which the given sign rises, as appears in the third and fourth tables of proposition 9 of this book, just as was done on the horizontal sundial — provided one takes the hours of those signs which cut the tropics, that is, from the third table those which cut the tropic of Cancer [♋], and from the fourth those which cut the tropic of Capricorn [♐]. This must be understood for either sundial. For example, since the sign Virgo [♍, printed "mp"] rises 2 hours 34 minutes before noon when the Sun stands at the beginning of Cancer [♋], it comes about that the line of that hour cuts the arc of Cancer at a point through which the sign Virgo must be drawn, and so on.

[Margin: How the points of the ascending signs are found on the tropics.]

Indeed, the lines that touch the tropics at these points (which are to be drawn as we taught in the corollary of proposition 37 of the first book of Apollonius [Apollonius, *Conics* I.37, coroll.]) will be the ascending signs, as is clear from what we demonstrated in proposition 9 of this book.

[Margin: In what way the ascending signs are laid out on the sundial by the doctrine of Apollonius's *Conics* [conicorum(?) Apoll.].]

The lines of Aries [♈] and Libra [♎] we shall describe in this way. Since, when the beginning of Aries is ascending and the Sun stands at the beginning of Capricorn

[♊], it is noon — as is clear from the fourth table of proposition 9 of this book — it is evident that the common section of the plane of the sundial and of the Ecliptic then passes through that point of the tropic of Capricorn through which the meridian line is drawn. And since at that time the Equator, the circle of the sixth hour from noon or midnight, the Vertical properly so called, the Ecliptic, and the Horizon all have the same common section — a section from which the plane of the sundial is equidistant, since it is parallel to the Vertical itself — it follows, by proposition 18 of the previous book, that the equinoctial line, the line of the sixth hour, the common section of the Ecliptic and of the plane of the sundial, and the horizontal line are all parallel to one another. Therefore a straight line drawn parallel to the equinoctial line — or to the line of the sixth hour, or to the horizontal line — through the point at which the meridian line cuts the tropic of Capricorn [♊] will, when produced, yield Aries [♈] ascending. In just the same way, a straight line drawn parallel to the equinoctial line through the point at which the meridian line cuts the tropic of Cancer [♋] will give Libra [♎] ascending.

We shall also delineate the ascending signs in yet another way, as follows. From the sixth table of proposition 9 of this book, let the declinations of the culminations of the heaven [mediationes cœli] be taken, and, according to the doctrine of proposition 14 of this same book, let there be sought on the meridian line of the southern sundial the points through which the parallels of those declinations are to be drawn. Likewise, from the seventh table of the same

[Margin: The laying-out of the ascending signs on the sundial by means of the culminations of the heaven and the points of the Ecliptic established on the circle of the sixth hour from noon or midnight, while the beginnings of the signs are ascending.]

Diagram. A large circular projection (an analemma-type horizontal projection) used to find the rising and setting points of the zodiacal signs for the vertical sundial. The circle carries the four cardinal orientations printed around its rim: **OCC** (Occasus, west) at the top, **OR.** (Oriens, east) at the bottom, **MER** (Meridies, south) at the left, and **SEPT** (Septentrio, north) at the right. The horizon is the circle ABCD, with center **E** (set within a small central circle). Two principal diameters cross at **E**: the horizontal diameter (the meridian section, running **MER**–**SEPT**) and the vertical diameter (the vertical/equator section, running **OCC**–**OR.**). A dense sheaf of straight "latitude rays" runs across the figure, and the rim is studded with small zodiac-sign sorts marking the rising/setting amplitudes.

Readable labels (many peripheral labels and zodiac sorts are very small and could not be resolved with confidence — see review note):

- E (center of the figure)
- A (top of the circle, at OCC); C (foot of the circle, at OR)
- Points near the central horizontal line: G and H (just about the center), F (to the right of center); further left-of-center letters read as K, I [?]
- Upper region: P, R, N [?] (right of top); Z [?] (upper left)
- Lower region: V [?] (lower left); M, d, o, f [?] (lower right)
- Numerous zodiac glyphs (Cancer ♋, Capricorn ♐, and neighbouring signs) around the rim marking the ends of the latitude rays — individually too small to transcribe reliably. [zodiac sorts: ?]

proposition 9 of this book, let there be taken the declinations of the southern points lying on the circle of the sixth hour, both before and after noon, as the table indicates; and, according to the doctrine of the said proposition 14 of this book, let there be found on the line of the sixth hour of the same southern sundial the points through which the parallels of those declinations are drawn, both before and after noon, as appears in the table. For if these points are joined by straight lines to the corresponding points found on the meridian line, the ascending signs will be laid out, as before — just as we said for the horizontal sundial in proposition 9 of this book — and these lines will necessarily pass through the points found on the horizontal line.

[Margin:...gium by the culminations of the heaven, and the Ecliptic points established on the circle of the sixth hour from noon or midnight, while the beginnings of the signs are ascending.]

In the same way these same ascending signs will be laid out on the northern sundial, if — instead of finding the points on the meridian line, that is on the line of the 12th hour of noon — one takes, on the line of the 12th hour of midnight, the declinations of the angles of the earth [angulorum terræ] from the sixth table of proposition 9 of this book. And to find the points on the line of the sixth hour, let one take from the seventh table of the same proposition 9 of this book the declination of the northern points lying on the circle of the sixth hour, and so on. But it is better to transfer the points found on the southern sundial to the northern one, changing the names of the southern signs into those of the northern, and vice versa. For since they have the same declinations, they will have the same position and distance on either sundial.

[Margin: In what way the ascending signs are again laid out by means of the conic elements.]

Indeed, straight lines drawn from the points found on the meridian line and tangent to the tropics will be the ascending signs, as was demonstrated in proposition 9 of this book. And such tangent lines are to be drawn as we taught in the corollary of proposition 37 of Book 1 of Apollonius [Apollonius, *Conics* I.37, coroll.]. And so we have laid out the ascending signs of the Zodiac on this same vertical sundial. Which was to be done.

SCHOLIUM.

Following Andreas Schöner [Andrea Schonero], we shall delineate these same ascending signs in this way. In the first figure of the scholium of proposition 9 of this book, let there be cut off from EB the straight line Ea, equal to the meridian line EI of the sundial, intercepted between E — the center of the Equator — and the equinoctial line; and through a let a line be drawn parallel to AC. Thus, with the center E placed at the center of the Equator, and the point a at the point I, the parallel drawn through a will coincide with the equinoctial line. This parallel through a will cut the lines of the signs sent out from E at points which, taken from a and carried over onto the equinoctial line from I in both directions, will give points on the equinoctial line. Then, if from the point G — where the meridian line intersects the horizontal line — straight lines are sent out through these points, the two tropics will be cut at points through which the lines of the ascending signs are to be drawn, yet in the same order that we prescribed for the horizontal sundial.

[Margin: How the same ascending signs are laid out according to the method of Andreas Schöner.]

But if it should happen that the straight line drawn out from the point G does not cut the tropic of Cancer [♋] — as in the example occurs with the sign Leo [♌] and the sign [zodiac sign: ?] — this is a proof that such signs do not rise while the Sun, standing at the beginning of Cancer [♋], illuminates the southern face of the vertical circle, but rather while it lights its northern part. And so those lines sent out from G will cut the tropic of Cancer on the northern sundial, which is cut off by the horizontal line.

Again, in the second figure of the same scholium of proposition 9 of this book, let there be cut off on EB the straight line Ea, equal to the same meridian line EI taken from the sundial, and through a let a line be drawn parallel to AC, so that,

with the center E placed at E — the center of the Equator — and the point a at the point I, the line drawn through a coincides with the equinoctial line. This parallel through a will cut the lines of the signs sent out from E at points which, taken from a and transferred onto the equinoctial line from I, will give on the equinoctial line the points through which the lines of the ascending signs must pass, in the order handed down for the horizontal sundial. If, then, these points on the equinoctial line are joined with the corresponding points on the tropics, the lines of the ascending signs will be obtained, as before. We have not given a worked example of this construction, because, in order to avoid a confusion of lines, we did not draw the tropics on the sundial.

Now if the lines of the ascending signs are extended beyond the horizontal line, the same ascending signs will be obtained on the northern sundial, which is cut off by the horizontal line — provided it is so arranged that the horizontal line is set in the upper position, and the side which, in that arrangement, is on our right as we face the sundial becomes the left, and vice versa, as we demonstrated in the scholium of proposition 14 of this book.

[Margin: The lines of the ascending signs, drawn out beyond the horizontal line, produce the northern sundial.]

If one wishes, however, the ascending signs can be laid out on the northern sundial in just the same way as they were laid out on the southern one; but we shall derive them from the southern sundial much more easily and readily by extending the lines of the ascending signs beyond the horizontal line, and so on, as we have said.

PROBLEMA 22. PROPOS. 22.

To construct an Italian vertical sundial.

[Margin: Construction of the Italian vertical sundial.]

This is constructed in no other way than the horizontal one — provided that, in the first method, for the southern sundial the diurnal arcs of the tropics of Cancer [♋] and Capricorn [♏] on the circle MaNb are aNb and dNe, because the point N belongs to the south, since it inclines toward the meridian circle in the upper hemisphere; and provided that the division of the circle takes its beginning from the points b and e, which lie to the west, if the sundial and the circle MaNb are set in their proper position. One must also take the nocturnal arc of Capricorn [♏] above the horizontal line, so that in it may be found the points of the hours 15, 14, 13, and so on, which on the circle are contained within the nocturnal arc of

Capricorn. But for the northern sundial the diurnal arcs of the tropics of Cancer [♋] and Capricorn [♏] will be dMe and aMb, since, when the sundial and the circle MaNb are set in their proper position, the point M belongs to the south, since it inclines toward the meridian circle in the upper hemisphere; and the division of the circle must begin from the points e and b, which lie to the west and correspond to the 24th hour. For we now take, for the northern sundial, the whole southern one, its upper part being made the lower, so that the center H is contained below the horizontal line. Hence the points nearest toward M will belong to the 23rd hour, and the following ones to the 22nd, and so on.

But remember that on the northern sundial the tropic of Cancer [♋] lies between the center H and the equinoctial line. You have an example of this construction, on the southern sundial, in the 14th hour of the tropic of Cancer and the 13th hour of the tropic of Capricorn. For from f, the point of the 14th hour of the tropic of Cancer, a straight line drawn through the center E cuts the equinoctial line at a certain point; and a straight line drawn from the center H through that point will indicate on the tropic of Cancer the point h for the 14th hour. Again, a straight line drawn from m — the point of the first nocturnal hour of the tropic of Capricorn [♏], which is opposite the 13th hour — through E meets the equinoctial line at n. And because the line mE, drawn from the first nocturnal hour of Capricorn, passes through the center E before it cuts the equinoctial line, therefore the straight line Hn, on the tropic of Capricorn, shows the point q for the first nocturnal hour of Capricorn;

but extended beyond the center H, it presents on the same tropic the point p for the 13th hour, as we demonstrated in proposition 10 of this book. On the northern sundial we have set out no example, lest the multitude of lines produce confusion — especially since it is easily derived from the southern one, as we shall say in the scholium of the following proposition. Here too the hour-lines from the west will pass through the hours (reckoned from noon or midnight) of the equinoctial line, as we said in proposition 10 of this book. For the rest, in this figure we have not written the numbers of the hours reckoned from noon or midnight, because from the figure of proposition 13 of this book the order of such hours is easily understood.

Diagram. A large circular figure for the Italian (i.e. unequal/sunset-reckoned) vertical sundial, with a dense fan of hour-lines radiating from the central region. The topmost point of the circle is labelled **M** and the lowest **N**; the center-region carries **H** with **G** just below it. Two vertical scales of Italian-hour numbers run

down the two sides. The bottom of the circle is drawn as a dotted arc studded with points.

Readable labels (the central fan and rim carry many small point-letters and numerals; those that resolve are listed, the rest flagged — see review note):

- M (top of circle); N (foot of circle)
- H (upper center); G (just below H)
- b (left, near G); central-region point-letters read as a, d, e, m, p, q, h, k, r, f [several uncertain — ?]
- Left-hand vertical scale of hour numbers (top to bottom): 22, 23, then 1, 2, 3, 13, 4
- Right-hand vertical scale of hour numbers (top to bottom): 1 [?], 24, 23, 22, 21, 20 — with a zodiac sort (Capricorn ♐ / Sagittarius ♐ [?]) beside the upper right numbers
- A curved sequence of small hour-numerals across the central fan: 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16 [some digits uncertain — ?]

In the second method, which is done by means of the diurnal and nocturnal arcs, there is no difficulty, if the tables set down in the scholium of proposition 33 of the previous book are rightly considered. But one must also draw, on the southern sundial, the nocturnal arc of the 24th hour, since with its help and support the description of the Italian sundial is made easy.

[Margin: Another description of the Italian vertical sundial by means of the diurnal and nocturnal arcs.]

For the 24th hour from sunset is drawn through the 5th hour from noon on the diurnal arc of ten hours, and through the 12th hour from midnight on the nocturnal arc of twenty-four hours — which is the greatest parallel of the ever-hidden stars [parallelus semper latentium maximus] — and it cuts the 12th hour from midnight, which is also the 12th hour of noon, at the position of the style. Now the 24th hour from sunset is parallel to the equinoctial line, since it is the same as the horizontal line, which in the scholium of proposition 22 of the previous book we showed to be parallel to the equinoctial line. But the 23rd hour passes through the 4th hour from noon on the diurnal arc of ten hours, and through the 5th hour from noon on the arc of twelve hours, which on the southern sundial the whole equinoctial line provides.

Indeed, since the 13th hour from sunset, extended beyond the greatest parallel of the ever-hidden stars — that is, beyond the nocturnal arc of twenty-four hours —

performs the office of the 23rd hour from sunrise, as we showed in the scholium of proposition 10 of this book, you therefore see that the line of the 23rd hour from sunrise, thus extended, passes through the 6th hour from midnight on the nocturnal arc of fourteen hours; and so with the rest. But the 13th hour from sunset, because it has no corresponding point on the diurnal arc of ten hours, is drawn through the 6th hour from midnight on the nocturnal arc of fourteen hours. Finally, the 12th hour from sunset must be drawn through the 12th hour from noon — that is, through the 12th hour of midnight — on the nocturnal arc of twenty-four hours, and equidistant from the equinoctial line, as is clear from the scholium of proposition 22 of the previous book. It will also pass through the 5th hour from midnight on the nocturnal arc of fourteen hours; but in our example the 5th hour from midnight scarcely cuts the said arc. Hence the 12th hour from sunset will be more correctly drawn through the 12th hour from noon — that is, through the 12th hour of midnight — on the nocturnal arc of twenty-four hours, on the southern sundial; but on the northern one (which that portion cut off by the horizontal line presents to us, provided it is inverted, as we taught in proposition 14 of this book) it is drawn through the 12th hour from midnight — that is, through the 12th hour of noon — on the diurnal arc of twenty-four hours. For on the northern sundial the nocturnal arc of twenty-four hours of the southern sundial is changed into the diurnal arc of twenty-four hours opposite to it, and the 12th hour from noon — which is the 12th hour of midnight — is converted into the 12th hour from midnight, which is the 12th hour of noon, as we taught in the scholium of proposition 13 of this book.

The northern Italian sundial will be completed in the same way, provided you remember that on it the arc which on the southern sundial was the diurnal arc of ten hours is the diurnal arc of fourteen hours; and that the part of it toward the equinoctial line — which the horizontal line cuts off — is the nocturnal arc of ten hours; likewise that the equinoctial line, which on the southern sundial was the diurnal arc of twelve hours, is the nocturnal arc of twelve hours; and that the arc which on the southern sundial was the diurnal arc of fourteen hours is the nocturnal arc of fourteen hours. Finally, that the astronomical hours, which on the southern sundial were reckoned from noon, must on this one be counted from midnight, and vice versa. All of this is drawn from what we wrote in propositions 13 and 14 of this book.

For once this is observed, the description of the northern Italian sundial will be easy. For the 23rd hour passes through the 6th hour from noon on the diurnal arc of fourteen hours, and through the 11th hour from noon on the diurnal arc of twenty-four hours, which on the northern sundial is the same as the one that on

the southern was the nocturnal arc of twenty-four hours. And since the 23rd hour from sunset, beyond this arc, is the 23rd hour from sunrise, therefore its portion indicating the 23rd hour from sunrise passes through the 4th hour from midnight on the nocturnal arc of ten hours, and through the 5th hour from midnight on the nocturnal arc of twelve hours. So too the 22nd hour is drawn through the 10th hour from noon on the diurnal arc of twenty-four hours, and its portion showing the 22nd hour from sunrise passes through the 3rd hour from midnight on the nocturnal arc of ten hours, and through the 4th hour from midnight on the nocturnal arc of twelve hours. Likewise the 9th hour from sunset proceeds through the 9th hour from midnight on the diurnal arc of twenty-four hours, and through the 4th hour from midnight on the nocturnal arc of ten hours, and through the 3rd hour from midnight on the nocturnal arc of twelve hours, and through the 2nd hour from midnight on the nocturnal arc of

— and 14; and so with the rest. All of this follows from the tables of proposition 33 of the previous book. As for the way in which the 12th hour from sunset is to be drawn on the northern sundial, we explained that a little earlier, when we were constructing the southern Italian sundial. But it is better to derive the northern one from the southern Italian sundial — that is, by extending the latter's lines — as we shall show in the scholium of the following proposition.

As for the nocturnal arc of 24 hours and the diurnal arc, there is no need to teach how the Italian sundial is described from it, since the matter is quite easy and clear from the tables of the described arcs, set out in the scholium of proposition 33 of the preceding book. Only this seems worth not omitting: that such an arc — which on the southern sundial always represents the greatest [parallel] of the ever-hidden [stars], and on the northern the greatest of the ever-apparent — is an ellipse in that region whose latitude is less than 45° , as in our example; but in a region of greater latitude than 45° each arc is a hyperbola, so that two opposite hyperbolas result; and finally, in a region having latitude of exactly 45° , it is a parabola, as is clear from the corollaries of propositions 7, 6, and 5 of the previous book.

[Margin: In what region the nocturnal and diurnal arc of 24 hours on the vertical sundial is an ellipse, and in what region a hyperbola or parabola.]

Concerning the third method — which is carried out by means of the line of the 12th hour from sunrise or sunset — it must be noted that it has no use in the region whose latitude is 45° , since the line of the 12th hour from sunrise or sunset vanishes in that vertical sundial, as is evident from what we wrote in the scholium of proposition 11 of the previous book. For the vertical [sundial] of that

region and the circle of the 12th hour from sunrise or sunset do not differ, as is plain, since there the greatest of all the ever-apparent parallels passes through the zenith of the head. But in regions whose latitudes differ little from 45° , it must be understood that this same method has an inconvenient use, because the line of the 12th hour from sunrise or sunset is too far from the equinoctial line. This is clearly evident from the portion of the analemma of proposition 13 of this book, where the circle of the 12th hour from sunrise or sunset — by the straight line KD — meets the plane of the sundial along the straight line HI (drawn) at the point through which the line of the 12th hour, perpendicular to the meridian line, must be drawn, as we demonstrated in the third method of proposition 10 of this book — or at least parallel to the equinoctial line, or to the line of the 6th hour from noon or midnight, as is clear from the scholium of proposition 22 of the previous book — a point most distant from the point I, through which the equinoctial line passes. And so that the position and situation of this line on the vertical sundial in various regions may be perceived more clearly, the following figures must be carefully considered. For in the first figure, where the altitude of the pole CE is less than 45° , the circle of the 12th hour from sunrise or sunset meets the plane of the southern sundial at point L, above the center of the sundial H, and meets the plane of the northern sundial below the center of the sundial H. In the third figure, where the altitude of the pole CE exceeds 45° , the contrary occurs. Finally, in the middle figure, where the altitude of the pole is exactly 45° , it meets neither plane but is equidistant from the plane of each sundial. Here too it appears when the line of the 12th hour from sunrise or sunset must be drawn above the equinoctial line, and when below; and this equinoctial line, on both sundials, is drawn through the point I, as is evident.

[Margin: In what region the line of the 12th hour from sunrise or sunset has no use in the description of the Italian sundial, and in what region an inconvenient and difficult use, and for what cause.]

Diagram. The first of three companion figures showing the position of the 12th-hour line on the vertical sundial when the pole-altitude is less than 45° . A semicircle stands on a horizontal diameter running B (left) — C (right), with center D; the arc rises from B through F (upper left) to the apex and down through E (upper right) to C. A vertical meridian line passes through D and is extended upward to L (top) and downward to L (bottom).

- A, K (apex): the two points at the top of the construction, K being the point of the 12th-hour circle KD
- F (upper left of arc): point on the arc

- E (upper right of arc): endpoint of the pole-altitude chord CE
- B (left end of diameter): horizontal endpoint
- C (right end of diameter): horizontal endpoint
- D (center): center of the semicircle
- G (interior, left of center) [position ?]: division point
- H (interior, at/near center): center of the sundial
- I (interior, upper left) [position ?]: point through which the equinoctial line passes
- G (on baseline, near center) [second G — position ?]
- H (below baseline, left) [position ?]
- I (below baseline, right) [position ?]
- L (top of vertical line): where the 12th-hour circle meets the southern plane
- L (bottom of vertical line): where it meets the northern plane

Diagram. The middle figure, for the case where the pole-altitude is exactly 45° ; here the 12th-hour line is equidistant from both planes. Same semicircular construction on diameter B (left) — C (right), center D, arc through F (left) and E (right), with a vertical meridian line.

- A (apex), K (just below A): the top points
- F (left of arc), E (right of arc)
- H (interior, near center-right) [position ?]: center of the sundial
- B, G, D, G, C (along the baseline, left to right) [the two G positions ?]
- H (below baseline, left) [position ?]
- I (below baseline, right) [position ?]
- L (top) [?]

Diagram. The third figure, for the case where the pole-altitude exceeds 45° (the contrary case to the first). Same construction: semicircle on diameter B (left) — C (right), center D, arc through F (left) and E (right), vertical meridian line extended to L above and L below.

- K, A (apex, K left of A)
- F (left of arc), E (right of arc)
- H (interior, near center): center of the sundial
- I, G (interior, left of center) [positions ?]
- D (center)
- B, G, C (along the baseline) [the baseline G position ?]

- H (below baseline, left) [position ?]
- I (below baseline, right) [position ?]
- L (top), L (bottom)

Moreover, the horizontal line offers us yet another way of describing the Italian sundial, if the first table of proposition 20 of the previous book is carefully examined — the table whose title is THE LINE OF THE 24TH HOUR FROM SUNRISE OR SUNSET. For the line of the 23rd hour from sunset, for instance, passes through that point of the horizontal line at which it is cut by the 11½th hour from noon or midnight; the line of the 22nd hour, through the point through which the 11th hour from noon or midnight passes; and so with the rest, as is easily clear from the aforesaid table. If, then, these points are joined with the corresponding points on the equinoctial line — found by the table of proposition 19 of the same previous book, or by the table of the diurnal arc of 12 hours of proposition 33 of the same book — the Italian sundial will be described, as before.

[Margin: Another description of the Italian vertical sundial by means of the horizontal line, that is, of the 24th hour from sunrise or sunset.]

Again, from the third table of proposition 20 of the previous book we shall easily gather which hour-lines from sunrise or sunset cut one another at one and the same point on the line of the 6th hour from noon or midnight. For the 13th and 23rd hours from sunrise or sunset cut the 6th hour from noon or midnight at one and the same point; likewise the 14th and 22nd hours, and so on. Moreover, from the fourth table of the same proposition we shall learn which hours from sunrise or sunset cut the meridian line at one and the same point. Such are the 10th and 14th hours from sunrise or sunset, and so on. Finally, from proposition 20 and the figure of proposition 9 of the same previous book we shall understand which hours from sunrise or sunset cut any given hour from noon or midnight at one and the same point. All of this, if rightly considered, is most useful for the description of the hours from sunset or sunrise, and provides a means by which such a description of the hours can be tested. We have therefore set up the Italian vertical sundial — which was what had to be done.

[Margin: The use of the tables of proposition 20 of the previous book for the mutual intersections of the hours from noon or midnight and from sunrise or sunset among themselves.]

PROBLEMA 23. PROPOS. 23.

To set up the Babylonian vertical sundial.

We shall set up the Babylonian sundial no differently than the Italian. For these two sundials differ only in the position of the hour-lines and in the numbering of the hours, as we said in proposition 11 of this book — which the figure of the preceding proposition clearly shows. In the first method, however, the division of the circle MaNb must begin from the points a and d; for these are the eastern points, if the sundial and the said circle have their proper position.

[Margin: Description of the Babylonian vertical sundial.]

As for the other methods, there is no difficulty at all, if the tables of propositions 19, 20, and 33 of the previous book are attentively considered. For, to give an example of the second method — which is done by means of the diurnal and nocturnal arcs — the 24th hour from sunrise, which the horizontal line indicates, is drawn through the 7th hour from midnight on the diurnal arc of 10 hours, and through the 12th hour from midnight on the nocturnal arc of 24 hours; and it is parallel to the equinoctial line, since the horizontal line marks it — the line which in proposition 14 of this book we demonstrated to be parallel to the equinoctial line. The first hour from sunrise passes through the 8th hour from midnight on the diurnal arc of 10 hours, and through the 7th hour from midnight on the diurnal arc of 12 hours; and, extended (because beyond the greatest parallel of the ever-hidden [stars] it marks the first hour from sunset), it is drawn through the 6th hour from noon on the nocturnal arc of 14 hours, as is clear from the table of this nocturnal arc; and so with the rest. But the 11th hour from sunrise, because it has no point on the diurnal arc of 10 hours, is drawn through the 6th hour from noon on the nocturnal arc of 14 hours. Finally, the 12th hour from sunrise must be drawn through the 12th hour from noon on the nocturnal arc of 24 hours, and — as we showed above — equidistant from the equinoctial line.

In this way, then, on all other sundials we shall describe the hours from sunrise and sunset by the help of the tables of the diurnal and nocturnal arcs: taking points on the nocturnal arcs whenever we lack them on the diurnal arcs; and observing, moreover, that when some hour from sunset has no points on the said arcs, we draw the hour of the same number from sunrise. For this, extended beyond the greatest parallel of the ever-apparent or ever-hidden [stars], will give the same hour by number from sunset, as we showed above. The same must be done when some hour from sunrise has no points on the aforesaid arcs: for if we

draw the same hour from sunset, this, extended beyond the said greatest parallel, will give the hour of the same number from sunrise.

[Margin: When the nocturnal and the diurnal arc is to be used, and when the hour from sunrise is to be drawn for the hour from sunset, and vice versa, in the description of the Italian or of any Babylonian sundial.]

There is no need to give an example of the description of the northern Babylonian sundial, since it is drawn in the same way from the aforesaid arcs — especially since we can obtain both the northern Babylonian and the northern Italian from the southern one, if its lines are extended beyond the horizontal line, as we shall teach in the following scholium. We have therefore set up the Babylonian vertical sundial — which was what had to be done.

SCHOLIUM.

If the lines of the hours from sunrise and sunset are extended beyond the horizontal line, the same hours from sunrise and sunset will be obtained on the northern sundial — the one that is cut off by the horizontal line — provided that it is so placed on the face of the sundial's plane which faces north that the horizontal line occupies the uppermost position, and the part which in that situation is on our right becomes the left, and vice versa, as was shown in the scholium of proposition 14 of this book.

It will not be difficult to judge which hours from sunrise and sunset, extended beyond the horizontal line, are to be counted from sunrise and which from sunset on the northern sundial, if the hour-circles are considered in their proper positions, together with both sundials — the southern and the northern — so that the tips of the gnomons meet at the center of the world and form one straight line, as we wrote in the scholium of proposition 14 of this book. For since the shadow of the style is cast onto the intersection of the circle of the 23rd hour and the plane of the northern sundial (set in its proper position) when the Sun is in the western semicircle of the said circle, it is clear that that line of the 23rd hour belongs to the 23rd hour from sunset. The same is to be said of the line of the 22nd, 21st, and 20th hour, and so on. Therefore the remaining hours on the same side of the sundial — namely the 13th, 14th, 15th, and so on — are to be counted from sunrise. Again, since the shadow of the style falls on the intersection of the circle of the 1st hour and the plane of the same northern sundial when the Sun is in the eastern semicircle of the said circle, that line of the 1st hour will belong to the first hour from sunrise. The same is to be said of the 2nd, 3rd hour, and so on. Hence the

remaining hours on the same side of the sundial — namely the 11th, 10th, 9th, 8th, and so on — are to be reckoned from sunset.

[Margin: Which lines of the hours from sunrise or sunset, extended beyond the horizontal line, indicate the hours from sunrise, and which the hours from sunset, on the northern sundial.]

Perhaps it will be perceived more clearly which extended lines belong to the hours from sunrise and which to the hours from sunset, in this way. In the nocturnal portion of the southern sundial — the portion which the horizontal line cuts off, as we noted in proposition 14 of this book — let the hours from sunrise and sunset be considered; and this is not obscure. For all the hours from sunset, extended beyond the horizontal line, are counted from sunset in the nocturnal portion of the sundial until they reach the greatest parallel (which touches the horizontal line on this vertical sundial of ours at the 12th astronomical hour); but beyond the points of contact they are to be reckoned from sunrise. By the same reasoning, the hours from sunrise, extended beyond the same horizontal line, give in that same nocturnal portion the hours from sunrise before the points of contact, but after these points the hours from sunset, as is clear from the scholium of proposition 10 of this book. So that in the nocturnal portion of our sundial these hours — 23, 22, 9, 10, 11 — are to be counted from sunrise, but these — 1, 2, 13, 14, 15 — from sunset. When these things are rightly considered, we shall understand, clearer than light, the hours from sunrise or sunset on the northern sundial. For all the hours which in the nocturnal portion are computed from sunset are to be counted from sunrise on the northern sundial, and those which there are taken from sunrise indicate here the hours from sunset. The reason for this is open and plain. For since that portion cut off by the horizontal line — in order that it may show the hours on the face of the plane which faces north — must be so inverted that the right part is changed into the left, and after this change the upper into the lower (as we taught in proposition 14 of this book), it comes about that the Sun is in different semicircles of the same hour-circle, so that the shadow of the style can be cast onto its hour-line both on the nocturnal sundial and on the northern, each being placed in its proper position: since that same hour-line has different situations on the two sundials, so that if on the nocturnal it inclines toward the west, on the northern it faces east, and vice versa. Therefore, since one semicircle signifies the hour from sunrise and the other the same hour from sunset (as we taught in the scholium of proposition 10 of the previous book), it is necessary that the hour which on the nocturnal sundial is computed from sunrise be counted from sunset on the northern, and vice versa. For example: onto the line of the 23rd hour on the nocturnal sundial the shadow of the style falls when the Sun is in the eastern semicircle of that hour below the horizon,

since that line recedes from the style toward the west; therefore that hour must be reckoned from sunrise. But onto the same line on the northern sundial — because it is moved away from the style

toward sunrise — the shadow of the style is cast while the Sun is in the western semicircle above the horizon; wherefore that same hour must be counted from sunset. And the same reasoning holds for the other hour-lines. Thus these hours — 23, 22, 9, 10, 11 — are to be counted from sunrise, but these — 1, 2, 13, 14, 15 — from sunset, as has been said. We wish this to be understood of other sundials also, even those inclined to the horizon, taking the lower sundials for the northern ones, as we shall note in their proper places.

From the vertical sundial we have described it is evident that Federico Commandino [Federico Commandino], in his book on the description of sundials, was mistaken concerning the lines of the 10th and 11th hours of the northern Italian vertical sundial. For he assigned to them exactly the same position that the lines of the 23rd and 22nd hours have — which cannot be, as is clear from our construction.

[Margin: Federico Commandino does not correctly draw the 10th and 11th hours from sunset on the northern Italian sundial.]

PROBLEMA 24. PROPOS. 24.

To set up the ancient vertical sundial.

Let the circle MaNb be divided, as was done in propositions 10 and 22 of this book, into the diurnal and nocturnal arc of the tropics of Cancer [♋] and Capricorn [♐]. Let the diurnal arc — both of the tropic of Cancer, aNb, and of the tropic of Capricorn, dNe — be cut into 12 equal parts, beginning from the points a and d, which are the eastern points, as is evident, if the sundial and the said circle have their proper position. For from the division-points we shall find the points of the unequal hours on each tropic, and shall complete the ancient sundial, as we set forth in proposition 12 of this book. For example, on the southern sundial:

[Margin: Description of the ancient vertical sundial.]

Diagram. A large composite figure of the ancient (unequal-hour / temporal-hour) vertical sundial. A central circle carries the meridian and horizon as perpendicular diameters, together with the two tropic arcs and the equinoctial line; radiating hour-lines run out to Roman-numeral hour labels arranged along the left and right margins of the figure.

Readable labels:

- M (top of the central circle): upper meridian point
- N (bottom of the central circle): lower meridian point
- a (right end of the horizontal diameter): eastern point
- b (left end of the horizontal diameter): western point
- Circle designation MaNb (M top, a right, N bottom, b left)
- "HORIZON" — the word set across the horizon line, split by the circle as HORI= (left) / ZON (right)
- "Arcus horæ" [arc of the hour] — curved label along an arc in the upper-left quadrant
- "...tum est" [?] — a split label in the upper-right quadrant (possibly "...tū est"); reading uncertain
- H (interior, upper center, just below M): construction point
- P (interior, at/near the center): center point [position ?]
- F (interior, below center): construction point
- I (interior, near center) [position ?]
- e (on the circle, lower left): tropic/hour point
- d (on the circle, lower right): eastern point of the tropic of Capricorn (per text, dNe)
- f (near bottom of the circle) [position ?]
- m (bottom of the circle): tropic-of-Capricorn hour point
- Unequal-hour numerals inside the lower part of the circle: IIII (h), V, VI, VII, VIII
- Marginal Roman hour-numerals, left side (top to bottom): IX, IIX (= VIII), and lower II, III [some worn — positions ?]
- Marginal Roman hour-numerals, right side (top to bottom): II, I, XII, XI, and a worn numeral [?], IX

The straight line from f — the point of the 4th unequal hour of the tropic of Cancer [☎] — drawn through E, cuts the equinoctial line at g. The straight line from H, drawn through g, cuts the tropic of Cancer at h, the point of the 4th unequal hour. So too the straight line from m — the point of the 4th unequal hour of the tropic of Capricorn [☷] — drawn through E, cuts the equinoctial line at n; and the straight line Hn cuts the tropic of Capricorn at p, the point of the 4th unequal hour, and so on, as is clear from what was demonstrated in proposition 12 of this book. And the same reasoning is to be applied to the rest. For the northern sundial we give no example, both because it will easily be described

from what was said in proposition 22 of this book, and also because it is better to derive it from the southern, as we shall presently teach in the following scholium.

But if the diurnal arc of 6 hours — which on the northern sundial will be of 18 hours — is described, we shall make the same sundial, as was said of the horizontal sundial in proposition 12 of this book. For the 1st unequal hour on the southern sundial is drawn through the 9½th hour from midnight on the diurnal arc of 6 hours, and through the 7th hour from midnight on the diurnal arc of 12 hours; likewise through the 4½th hour from noon on the nocturnal arc of 18 hours, as the tables set out in the scholium of proposition 33 of the preceding book indicate; and so with the rest. But on the northern sundial the same 1st unequal hour passes through the 4½th hour from midnight on the diurnal arc of 18 hours, and through the 9½th hour from noon on the nocturnal arc of 6 hours; likewise through the 7th hour from noon on the nocturnal arc of 12 hours, as the same tables teach, and so on. We have therefore set up the ancient vertical sundial — which was what had to be done.

[Margin: Another description of the ancient vertical sundial, from the diurnal and nocturnal arcs.]

SCHOLIUM.

Here too, as we demonstrated in the scholium of proposition 14 of this book, the unequal hours of the southern sundial, extended beyond the horizontal line, will exhibit the same unequal hours by number on the northern sundial, if that inversion of the sundial is made which was spoken of in the scholium of proposition 14 of this book.

DE HOROLOGIIS MERIDIANIS.

ON MERIDIAN SUNDIALS.

PROBLEMA 25. PROPOS. 25.

To set up the astronomical meridian sundial.

That is, to describe the lines of the hours from noon or midnight on a plane parallel to the meridian circle.

Let a straight line AB be drawn, arbitrarily; from A as center describe an arc of a circle BC, with any radius, in which [we shall count off...]

Gnomonics, Book II — On Meridian Sundials (continued)

[Margin: Description of the astronomical meridian sundial.]

(Continuing Problem 25 / Prop. 25 — to set up the astronomical meridian sundial.)

once the altitude of the Equator has been counted off, or the complement of the pole's altitude, BC — to the left of point A, if the sundial to be described is to face east; but to the right, if the sundial to be built is to face west — let the straight line AC be drawn through A and C, and let the straight line DE cut it at A at right angles. Then take the straight line AE equal to the length of a gnomon of any size you please, and from E as center describe, with any radius, the circle FGHI. Divide this circle into 24 equal hours, beginning either from the line FH or from the line GI, with FH cutting through center E at right angles. After this, from center E draw hidden [construction] lines through the points of division, cutting the straight line AC in points; through these points, lines drawn parallel to DE will give the lines of the hours reckoned from noon or from midnight, on a plane parallel to the meridian circle.

These parallels are easily drawn if, through any point of the line DE — for example through D — a parallel to AC is drawn, and onto this line all the points of AC are transferred from point D, taking their intervals from point A. [Margin: a — 33.primi] For straight lines joining two points equally distant from the line DE will be parallel. The demonstration of this construction is as follows.

Diagram. The construction of the eastern astronomical meridian sundial (the word **ORIENTALE**, "Eastern," is engraved large across the figure, split ORIEN...TALE). A large hour-circle FGHI is drawn about center E and divided by radial lines into the equal hours; a long horizontal straight line AC (the equinoctial/horizon line) passes through the point A near the center, and the line DE crosses it perpendicularly. From the hour-divisions of the circle, the family of parallel hour-lines is carried down across AC, and the transferred hour-points are numbered 1 through 10 along the lower-left. Readable labels:

- K (top of circle): hour-circle point
- G (top, just below K): hour-circle point
- C (upper left, at the "ORIEN·C" break): endpoint of AC / hour-circle point
- F (upper right, at the "F·TALE" break): hour-circle point [?]
- B (left end of the horizontal line AC): endpoint

- E (center): center of the hour-circle
- A (center, on line AC): foot of the perpendicular DE
- N, L, I (lower right): points where hour-lines meet [?]
- S (bottom): lower endpoint of a bounding line [?]
- D (lower left): point on the perpendicular DE
- 2, 3, 4, 5, 6, 7, 8, 9, 10 (along the lower-left diagonal): the numbered hour-points

[Several peripheral labels on this dense figure could not be resolved with confidence]

[Margin: Demonstration of the construction of the meridian sundial.]

[Margin: b — 16.vnde.] [Margin: c — 10.vnde.]

Since the common sections made by the Equator in parallel planes — namely in the meridian circle and in the plane of the sundial — are parallel, and likewise the common sections made by the Horizon in these same planes, the angle contained between those sections in the plane of the meridian circle will be equal to the angle contained between the same sections in the plane of the sundial. Suppose, then, that AB is the common section of the horizon and the plane of the sundial; then AC will be the common section of the Equator and the plane of the sundial, since the angle BAC has been taken equal to the angle of the Equator's altitude — that is, to the angle which the section of the Equator makes with the section of the Horizon in the meridian circle.

Now suppose that about AC, as a line at rest, the plane of the circle FGHI is turned until it coincides with the plane of the Equator, and until E, the vertex of the assumed style AE, is joined to the center of the world. (For the vertex of the style is to be conceived as at the center of the world, by proposition 2 of the preceding book.) Then that circle will be concentric with the Equator, and the straight lines drawn through E and the points of division will be the common sections of the hour-circles from noon or midnight with the Equator — since the Equator and the circle FGHI, described about the same center E, are cut into similar arcs by those lines, as is clear from what we wrote at the end of chapter 1 in the [treatment of the] sphere. Thus GI, parallel to AC, is the common section of the Equator and the circle of the 12th hour, that is, of the meridian. For the common sections of the meridian — that is, of the circle of the 12th hour — with the plane of the sundial, made by the Equator, are parallel; and so, since AC is the common section of the Equator and the plane of the sundial, as we have shown, GI will be the common section of the Equator and the meridian, that is, of the circle of the 12th hour. KL

will be the common section of the Equator and the circle of the 11th hour on the sundial facing east; but on the one that faces west it will be the common section of the Equator and the circle of the first hour, and so on in order — as is evident if the proper position of the circle FGHI, or of the Equator, is carefully considered in the plane of each meridian sundial.

For this reason, the hour-circles from noon or midnight will cut the equinoctial line AC in the plane of the sundial at the points into which fall the straight lines drawn through center E and the division-points of the circle FGHI. Accordingly, through these points will be drawn the common sections of those same hour-circles with the plane of the sundial, and these are precisely the hour-lines from noon or midnight. Since, then, by the corollary of proposition 22 of the preceding book, these hour-lines are parallel on the meridian sundial, it is plain that the straight lines drawn parallel to DE through the points of the line AC are the hour-lines from noon or midnight.

But someone will perhaps doubt whether the hour-lines from noon or midnight are perpendicular to the equinoctial line AC — and hence parallel to DE, which we drew perpendicular to AC, in the way we drew them. We shall demonstrate this too, as follows. Since both the plane of the sundial and the plane of any hour-circle from noon or midnight are perpendicular to the Equator...

[Margin: a — 19.vnde.] [Margin: b — 29.primi] [Margin: c — 10.vndec.]

their common section will also be perpendicular to that same Equator, and hence, by definition 3 of book 11 of Euclid, also perpendicular to the straight line AC, which lies in the Equator. Therefore all the hour-lines from noon or midnight — that is, the common sections of the hour-circles with the plane of the sundial — are perpendicular to the line AC. And accordingly, since they must be drawn through the points found on the line AC, we drew them through those points parallel to DE, which is perpendicular to AC, because in this way they will all be perpendicular to AC. The same thing...

Diagram. The construction of the western astronomical meridian sundial (the word **Occidentale**, "Western," is engraved across the figure, split Occi...dentale). As on the eastern figure, an hour-circle is drawn about center E and divided by radial lines; a horizontal line passes through the central point A, with the perpendicular through it, and the parallel hour-lines are carried across, the transferred points numbered along the lower right. Readable labels:

- K (top): hour-circle point
- G (top, below K): hour-circle point

- C (upper right): endpoint of the equinoctial line [?]
- E (center): center of the hour-circle
- M, R (just right of center): points on the equinoctial line
- A (center): foot of the perpendicular
- B (right, on the horizontal line): endpoint
- F, E (right): hour-circle points [?]
- N (lower center): point
- I, L (lower left): points [?]
- S (bottom): lower endpoint [?]
- D (lower right): point on the perpendicular
- 1, 2, 3, 4, 5 (along the lower right): numbered hour-points

[Several peripheral labels on this dense figure could not be resolved with confidence]

[Margin: d — 16.vnde.] [Margin: e — 29.primi]

[Margin: The meridian line, or line of the 12th hour, cannot be drawn on the meridian sundial. On either meridian sundial, the segments of the equinoctial line lying between the 6th-hour line and two hours equally distant in time on each side of the 6th-hour line are equal.]

will be demonstrated by this reasoning. [Margin: d] Since the sections made by the Horizon in the meridian and in the plane of the sundial are parallel, and likewise the sections made in these same planes by the circle of the 6th hour, the angle contained between the former in the meridian will be equal to the angle contained between the latter in the plane of the sundial. Since, then, the former is the angle of the pole's altitude, as is established, this latter angle too will be the angle of the pole's altitude. Consequently, since the angle BAD is the angle of the pole's altitude — because, by construction, the angle remaining from the right angle BAC is equal to the complement of the pole's altitude — and since AB is the common section of the plane of the sundial and the Horizon, AD will be the common section of that same plane of the sundial and the circle of the 6th hour from noon or midnight. And accordingly, since all the hour-lines are parallel to one another and therefore also equidistant from AD, as we have shown, [Margin: e] they will all be perpendicular to AC, just as AD itself is perpendicular to AC.

The meridian line alone — that is, the line of the 12th hour from noon or midnight — cannot be drawn on this sundial, but vanishes, as is clearly established from the scholium of proposition 11 of the first book, since the

meridian circle does not cut the plane of the sundial but is parallel to it. And so we have set up the astronomical meridian sundial, and the rest — which was to be done.

SCHOLIUM.

[Margin: f — 27.tertij] [Margin: g — 26.primi]

On any meridian sundial, any two hour-lines equally distant in time on either side of the 6th-hour line DE cut off, from the equinoctial line AC, segments lying between themselves and the 6th-hour line that are equal — so that on the equinoctial line the hour-spaces before the sixth hour are equal to the hour-spaces after the sixth hour, one by one. [Margin: f] For instance, the lines AM and AN on the western sundial, each of which spans four hours, are equal. [Margin: g] For since the angles MEA and NEA at center E, subtended by equal arcs, are equal, and the angles at A are right, and the side AE is common, [Margin: h — 19.vnde.] the straight lines AM and AN will also be equal, and likewise EM and EN. The same reasoning holds for the rest.

[Margin: For describing the meridian sundial it suffices to divide one quadrant of the circle described from E into 6 equal parts. How each meridian sundial, together with its style, is to be set up so as to show the hours.]

From this it follows that, for describing the meridian sundial, it is enough to draw straight lines through center E and the division-points of a single quadrant — namely HI — cutting the equinoctial line at the points S, N, Q, and so on. For if these points are transferred from A, by means of the compasses, to the other side of the same equinoctial line, all the points through which the hour-lines are to be drawn will be obtained.

[Margin: i — 16.vndec.]

Now if the sundial is set up on a plane parallel to the meridian, so that the line AB is parallel to the Horizon, and point A faces north while point B faces south — so that the angle of the complement of the pole's altitude, BAC, which stands above the horizontal line AB, slopes southward on either sundial, while the angle opposite to it, which lies below that same horizontal line, slopes northward — then the hours will be indicated by the gnomon AE standing at right angles on the plane of the sundial at point A, so that the style itself is the common section of the Horizon and the Equator, that is, of the circle of the 6th hour, or of the Vertical. [Margin: h] For this common section is perpendicular to the plane of the sundial at point A, through which the planes of the said circles pass, standing

perpendicular to the plane of the sundial. And if from any two points of the line DE — say from D and E — two perpendiculars EO and DP are raised to the plane of the sundial, equal to the assumed gnomon AE, and the straight line OP is laid across them, this line OP will serve as the axis, since it passes through the center of the world — that is, through the point that is the vertex of the style erected from A — and is parallel to the line of the 6th hour, as the argument requires.

[Margin: i] For the line of the 6th hour and the axis of the world are parallel, being of course the common sections of the meridian circle and the plane of the sundial made by the circle of the 6th hour. The shadow of this axis OP, therefore, cast upon the hour-lines from noon or midnight, will likewise indicate the hours from noon or midnight, just as we said of the horizontal and vertical sundials.

Diagram. The gnomon-axis figure. Two equal perpendiculars, EO and DP, rise from the base points E and D, and the straight line OP is laid across their tops as the axis. Labels:

- O (top left): top of the perpendicular EO
- P (top right): top of the perpendicular DP
- E (bottom left): base point
- D (bottom right): base point

[Margin: To which segment of the equinoctial line the style is equal on each meridian sundial.]

The gnomon AE that has been assumed is always equal to that part of the equinoctial line lying between A and the third or ninth hour — that is, to the straight line AQ or AR — on the western sundial. For since the whole quadrant GH is divided into 6 equal hours, the circle of the ninth hour, three hours distant from the line EH of the sixth hour (or from the line EG of the 12th hour), bisects that same quadrant; [Margin: a — 27.tertij] and accordingly the angle AER will be equal to the angle GER. Since, then, the whole angle AEG is a right angle, each of the angles GER and AER will be half a right angle. Therefore, since the angle EAR is a right angle, [Margin: b — 32.primi] the remaining angle ERA will also be half a right angle; and consequently, the angles ERA and AER being equal, the straight lines AE and AR will also be equal. The same reasoning holds for AE and AQ, and so on.

[Margin: The eastern sundial, if inverted so that top becomes bottom, and what is on the right in this position becomes left and vice versa, yields the western sundial; and in the same way the western yields the eastern.]

It is enough, moreover, to describe only the sundial facing east. For if this is inverted so that top and bottom are interchanged, and right and left are interchanged — as we taught in the scholium of proposition 14 of this book — it will supply us with the other sundial, the one facing west. We shall also make this evident by the following reasoning. In the triangle AEC on the eastern sundial, and in the triangle AES on the western, the angles at A are equal, namely right angles; [Margin: c — 27.tertij] and the angles at E are likewise equal, on account of the equal arcs between H and the straight lines EC, ES on which they stand; and moreover the sides AE, AE adjacent to the said angles are equal, since each is the length of the style; [Margin: d — 26.primi] therefore the sides AC, AS will also be equal.

Now suppose the eastern sundial is laid over the western so that point A coincides with point A, and the horizontal line AB with the horizontal line AB, and the upper part of the eastern sundial falls below the horizontal line and the lower part above it; and suppose that, in this position, the right part is changed into the left, and vice versa. Then the equinoctial line AC of the eastern sundial coincides with the equinoctial line AS of the western sundial, on account of the equality of the angles which each equinoctial line makes with the horizontal toward the same parts in this position — the position which the eastern sundial has when inverted in the way we described. Point C will also fall upon point S, on account of the equal lines AC, AS. Hence the line of the first hour of the eastern sundial, drawn through point C, will coincide with the line of the first hour of the western sundial, drawn through point S, since each makes a right angle with the equinoctial line, as we showed above. In the same way we shall demonstrate that the remaining hour-lines of the eastern sundial coincide with the remaining hour-lines of the western sundial. Therefore the eastern sundial, inverted as has been said, yields the western sundial, since in this way it takes on the same position as the western has, and is equal to it in every part, as we have shown.

Diagram. The gnomon-axis figure repeated (as on the preceding page). Two equal perpendiculars EO and DP rise from base points E and D, with the straight line OP laid across their tops as the axis. Labels:

- O (top left): top of the perpendicular EO
- P (top right): top of the perpendicular DP
- E (bottom left): base point
- D (bottom right): base point

[Margin: c — 27.tertij] [Margin: d — 26.primi]

[Margin: The lines of the eastern sundial, drawn on the opposite face of the plane, yield the western sundial, and vice versa, if the hour-numbers are changed into their complements up to 12. How the fractional hour-parts are to be drawn on the meridian sundial. How the meridian sundial is to be drawn on a fixed plane facing directly east or west. If the position of a style of given length is given, by what method the meridian sundial is drawn. Description of the parallels, that is, of the arcs of the zodiacal signs, on the same meridian sundial, by means of the analemma.]

But the hours that are reckoned from midnight on the eastern sundial must, after that inversion, be reckoned from noon, since it has now become the western sundial.

By the same reasoning it would be enough to describe only the western sundial. For this too, if it is inverted as we have said, would supply us with the eastern sundial, which can be demonstrated in the same way. But the hours which, on the western sundial as described, indicate the hours from noon would, after that inversion, have to be reckoned from midnight, because the western has now become the eastern.

Indeed, once the eastern sundial has been described on some plane, if on the opposite side of the plane lines corresponding exactly to its lines are drawn, the western sundial too will have been described, to be placed on the face of the plane that looks west; because in this way the angle of the complement of the pole's altitude, which the equinoctial line makes with the horizontal above the horizontal line, slopes southward, just as on the eastern sundial. But the numbers of the hours must be changed into their complements up to 12, so that hour 11 becomes 1, and hour 10 becomes 2, and so on. By the same reasoning, once the western sundial has been described, if on the other side of the plane lines corresponding to its lines are drawn, the eastern sundial will have been described.

Furthermore, if it is desired to draw the half-hours as well, and their quarters, eighths, and so on, the individual hours of the circle FGHI must be divided into two parts, four, eight, and so on; and the rest is to be completed as before.

But if the sundial is to be described on some fixed plane — as on a wall facing directly east or west — (for up to now we have laid it out on any arbitrary plane, so that it may afterwards be set in its proper position), then, by means of a plumb-line and a level, a straight line AB must be drawn on the given plane, parallel to the Horizon; and from any point A an arc of a circle BG must be

described toward the southern parts, so that in it the complement of the pole's altitude BC may be counted off. The rest is to be completed as before.

In the same way, if the position of the style is given at point A, and its length AE, the said straight line AB must be drawn parallel to the Horizon through point A, and from A an arc of a circle described, as we said just above, and so on.

PROBLEMA 26. PROPOS. 26.

To describe the parallels — that is, the arcs of the zodiacal signs — on the aforesaid meridian sundial.

Let ABCD be an analemma, with the diameters of the circles, as in proposition 1 of the preceding book. Now since the meridian ABCD of the analemma does not cut the plane of the sundial, let the circle ABCD be understood to be the circle of the 6th hour from noon or midnight, serving as the proper meridian of the meridian circle, which now takes the place of a right horizon. It is evident, moreover, that the common sections of the circle of the 6th hour, of the Equator, and of its parallels are not different from those made in the meridian circle, because the meridian and the circle of the 6th hour, described through the poles of the parallels, cut all the parallels in the same way — just as do all the other right horizons. And because the meridian passes through the poles of the world, as does the circle of the 6th hour from noon or midnight, the axis FG will be the common section of the circle of the 6th hour ABCD and the meridian, as the diameter of some right horizon; and likewise the section of the Equator, HI, will be as the diameter of the proper Vertical of that same meridian circle, just as happens in the right sphere. For in every right horizon the Equator performs the office of the properly-so-called Vertical circle.

Now, taking on HI, on each side from point E, the straight line EK equal to the gnomon AE assumed in the preceding sundial, let LM be drawn through each point K parallel to FG. Each parallel LM will be the common section of the circle of the 6th hour ABCD and the plane of the sundial, since in this way the plane of the sundial is equidistant [from it] along the straight line LM, drawn by means of it...

of the meridian itself, drawn through FG according to the size of the style EK. Let the diameters of the zodiac that join the opposite signs also be drawn, so that triangles are formed through the axis of the cones — triangles whose bases are the parallels and whose common vertex is the center E. Therefore, by what was demonstrated in proposition 6 of the preceding book, NL, OL, PL, QM, RM, and SM

will be the diameters of the conic sections. And if the points N, O, P, Q, R, S are taken from point K and transferred here and there onto the line of the sixth hour of the sundial from point A, where the style is to be set, then the shadow of the style will be cast onto these same points whenever the Sun stands at the beginnings of the signs and on the circle ABCD of the sixth astronomical hour.

If, then, the conic sections are described in some hard material about the diameters NL, OL, PL, and so on — by proposition 8 of the preceding book — and are cut out so as to form a kind of bent rulers, by means of which the same sections may be drawn on the sundial so that they pass through the points N, O, P, Q, R, S and have their axes joined to the line DE of the sixth hour, then the parallels of the zodiacal signs will have been described. It is enough, however, to describe the conic sections of the northern signs, or of the southern; for these are equal to the sections of the opposite signs, since they are all hyperbolas, as is established from proposition 6 of the preceding book.

[Margin: It is enough to describe the arcs of the northern signs only, or of the southern.]

Diagram. A large circle representing the meridian circle (here serving as the circle of the sixth hour), with the analemma construction inscribed. The circle is lettered ABCD, and radiating lines, the world-axis, the equator, and the diameters of the zodiacal parallels are drawn inside it. Zodiacal-sign glyphs are set around and within the figure; several are worn and cannot be individually resolved [?].

- A (top of circle): endpoint of the vertical diameter AC
- C (bottom of circle): endpoint of the vertical diameter AC
- B (left of circle): endpoint of the horizontal diameter BD
- D (right of circle): endpoint of the horizontal diameter BD
- E (center): common center / vertex of the cones
- F (upper right, on the oblique axis): endpoint of the axis FG (the world-axis, the section of the sixth-hour circle)
- G (lower left, on the oblique axis): opposite endpoint of the axis FG
- H (upper left): endpoint of the equator section HI
- I (lower right): opposite endpoint of the equator section HI
- L (lower-left interior): point where the diameters NL, OL, PL converge
- M (upper-right interior): point where the diameters QM, RM, SM converge
- K (interior, on the sixth-hour line): the point from which N, O, P, Q, R, S are transferred

- N, O, P, Q, R, S (interior points): the points through which the conic sections (parallels of the signs) are drawn
- Additional lowercase interior labels (m, n, l, and others) and peripheral zodiac glyphs are present but partly abraded [?]

From this it is established that, by the benefit of these same rulers, the parallels will easily be described on the opposite part of the sundial through those points that are marked on the line of the sixth hour.

In each sundial, moreover, the northern signs are those that are described below the equinoctial line, and the southern signs those contained above it — so that in each sundial, when it occupies its proper position, the northern signs recede from the equinoctial line toward the south, and the southern signs toward the north. The reason for this is that when the Sun rises or sets while standing in the northern signs, the shadow of the style falls on the southern parts of the horizontal line; but it falls on the northern parts when the Sun, standing in the southern signs, rises or sets, as is evident.

[Margin: In meridian sundials the northern signs are below the equinoctial line, and the southern above.]

Now, since when the Sun rises the shadow of the gnomon is cast onto the horizontal line AB in the eastern sundial, and when it sets the shadow is cast onto the same horizontal line in the western sundial — as is clear from proposition 11 of the preceding book — it comes about that for all the remaining time of any given day, with the Sun raised above the horizon, that same shadow falls on the plane of the sundial below the horizontal line. For this reason the part of the sundial contained above the horizontal line must be cut away as superfluous, since the shadow of the style never falls upon it.

[Margin: The portion of the meridian sundial above the horizontal line must be cut away as superfluous.]

That upper part of either sundial, however, once cut off from the horizontal line, will yield a sundial to be set up on the opposite face of the sundial's plane — provided it is inverted, so that the part which is now uppermost becomes the lowest, and vice versa, and so that the part which after this inversion is on the right becomes the left, as we prescribed in the scholium to proposition 14 of this book; and the hours, [Margin: The portion of either meridian sundial...]

Diagram. The two meridian sundials — eastern and western — laid out symmetrically about a single horizontal line. The horizontal line runs across the

middle of the figure and is lettered, with the word set as the line-label; two fans of hour-lines and hyperbolas (the arcs of the signs) rise from near the line on the left and right.

- Horizontal line (labelled along its length): "HORI[S] ... B ... ZON" (i.e. HORIZON), with B marking the midpoint of the line
- Two apex points (upper left of each fan): the convergence points of the hour-lines
- C (bottom of each fan): endpoint at the foot of each bundle of lines
- Zodiacal-sign glyphs are scattered along the hyperbola-arcs of each fan; many are worn and cannot be individually resolved [?]

which were reckoned from midnight, are to be counted from noon, and conversely; and finally the northern signs are changed into southern, and the southern into northern. For, as we showed in the scholium to the preceding proposition, once this inversion has been made, the hour-lines of the upper part that has been cut off in either sundial coincide with the hour-lines of the sundial described on the opposite face of the plane. The axis of the hyperbolas $\mathfrak{S}$ and $\mathfrak{V}$ will likewise coincide with the axis of the hyperbolas $\mathfrak{S}$ and $\mathfrak{V}$, since in both cases this axis is the line of the sixth hour from noon or from midnight.

Since, then, the transverse axis of the said hyperbolas in the eastern sundial is equal to the transverse axis of the same hyperbolas in the western — because the hyperbolas of the one are equal to the hyperbolas of the other, seeing that the shadows describing them are cast by equal styles onto planes equidistant from the meridian circle — the hyperbolas will also coincide with the hyperbolas: namely, hyperbola $\mathfrak{S}$ will coincide with hyperbola $\mathfrak{V}$, and hyperbola $\mathfrak{V}$ with hyperbola $\mathfrak{S}$. And the same reasoning holds for the remaining hyperbolas of the other signs. Since this is so, it is clearly established that the upper part cut off in either sundial displays the sundial on the opposite face of the plane, if it is inverted, as we have said.

[Margin: ...of the meridian, cut off from the horizontal line, will produce a sundial on the opposite part of the plane, if the parts are interchanged, as was said above. The horizontal line divides the meridian sundial into a daytime and a nighttime part.]

Again, the horizontal line AB divides each sundial into a daytime and a nighttime part, just as was said of the vertical sundial in proposition 14 of this book — the daytime part being below the horizontal line, the nighttime part above it. For onto the upper part of the eastern sundial the shadow of the style would be cast

after midnight up to sunrise, were the density of the earth not in the way; and onto the upper part of the western sundial the shadow of the style would fall after sunset up to midnight, if the Sun could illuminate it.

[Margin: Another description of the arcs of the signs on the meridian sundial.]

We shall describe these same arcs of the signs in the following way. Draw the straight line DC arbitrarily for the radius of the Equator, and, with the radii of the other signs described here and there, as was said in proposition 2 of this book for the horizontal sundial, let all the hour-intervals intercepted between E, the center of the circle FGHI of the preceding proposition, and the equinoctial line AC be transferred onto the radius DC of the Equator from D — so that the straight line DC is equal to the space ES or EC, and the straight line DT to the space EN or EM, and so on. This is done by marking points on the straight line DC, through which lines parallel to the world-axis DG (which cuts the straight line DC at right angles) are drawn — which will indeed easily be done if all the points of the straight line DC are carried across onto the straight line GF, parallel to DC — and to these parallels are attached the numbers of the hours corresponding to the hour-intervals thus transferred.

For if the parts of these parallels intercepted between the radius DC of the Equator and the radii of the other signs are transferred onto the corresponding hour-lines of the sundial from the equinoctial line AC — marking points, and through these points drawing curved lines, as we said for the sundials above — the parallels of the Zodiac will again have been described. Now any two opposite parallels are equally distant from the equinoctial line.

[Margin a: (III.27) — i.e. Euclid III.27]

[Margin: By what method the arcs of the opposite signs are described by one and the same operation... drawn on the meridian sundial.]

^a For since the angles that the radius DT of the Equator makes with the radii of the opposite signs are equal — because such angles stand at the center on equal arcs of equal declinations — and since two angles at α [?] are also equal, namely right angles, and the side D α [?] is common, ^b the straight lines between α [?] and the radii of any opposite signs will likewise be equal, which is the proposition. The same is also clearly established from the Analemma of this proposition, if the triangles EKN, EKQ; EKO, EKR; and EKP, EKS are rightly considered. Hence by one and the same operation we shall describe any opposite parallels on the sundial, if on either side of the equinoctial line, on the hour-lines, we mark points equally

distant from the equinoctial line. This latter description of the parallels of the Zodiac we shall now demonstrate.

[Margin b: (I.26) — i.e. Euclid I.26]

Diagram. The construction of the arcs of the signs on the horizontal meridian sundial. A large rectangular grid of hour-lines with a central bundle of radii fanning downward and diagonal "radius-of-the-hour" lines crossing it; zodiacal-sign glyphs run along the foot of the figure.

- G (top left), D (top center), K (top center, right of D), G (top right): points along the upper edge
- F (left), F (right): endpoints of the lower horizontal (the line GF parallel to DC)
- C (center, low): foot of the central radius-bundle
- E (interior center): center of the circle FGHI
- S, N, M, T, and lowercase p, o, m, n, l: interior points marking the hour-intervals on DC / DT
- Diagonal radius-lines labelled: "Rad. hor. 0", "Rad. hor. 6", "Rad. hor. 10", "Rad. hor. 14", "Rad. hor. 18", "Rad. hor. 24" (Radius horæ — radius of the hour)
- Hour-numbers are printed along both side edges (reading roughly 12, ... 9, 4, 8 on the left and 5/6, 8/7, 4/3, 9, 1/10 on the right); several are worn and only partly legible [?]
- Zodiacal-sign glyphs along the bottom edge; several worn [?]

Now let it be understood that the style AE stands at right angles on the plane of the sundial, and that the figure of the zodiacal radii, just constructed about the tip E of the style, is turned round toward the plane of the sundial, so that point D is joined to point E — that is, to the center of the world — and the straight line DG is perpetually equidistant from the line of the sixth hour, that is, is joined to the world-axis; and consequently the straight line DC, not receding from the plane of the Equator in that motion, always meets the equinoctial line. This being posited, in this revolution the point T will fall, for example, onto point N, because in the construction the straight line DT was taken equal to the straight line EN. For the straight line EN, falling from point E set on high — namely from the tip of the style — onto point N, is equal to the straight line EN in the plane of the sundial; as will easily be proved if the triangle EAN in the plane is compared with the triangle EAN on high. For since the sides EA, AN of the one are equal to the sides

EA, AN of the other, and they contain equal angles, namely right angles, ^c the base EN of the one will be equal to the base EN of the other.

[Margin c: (I.4) — i.e. Euclid I.4]

Since, therefore, both the straight line NV and the straight line TX are equidistant from the world-axis, ^d NV and TX will also be parallel to each other, and so the straight line TX will be joined to the straight line NV — otherwise TX and NV would not be parallel to each other, since they meet at N. Wherefore, since the straight line TX is taken equal to the straight line NV, the point X will fall onto point V; and on this account the ray of the Sun, when it is at the beginning of ♉ or ♊, will meet the plane of the sundial at point V. Through point V, then, will pass the parallel, or hyperbola, of ♉ or ♊; since the ray of the Sun falls upon it in that revolution of the zodiacal radii, as we have demonstrated. In the same way we shall show that through the remaining points taken on the sundial the same hyperbola passes, and so on for the rest. For this reason we have described the parallels — that is, the arcs of the zodiacal signs — on the aforesaid meridian sundial. Which was to be done.

[Margin d: (XI.9) — i.e. Euclid XI.9]

PROBLEMA 27. PROPOS. 27.

To describe the parallels of the diurnal arcs on the same meridian sundial.

[Margin: Description of the diurnal arcs on the aforesaid meridian sundial.]

In place of the parallels described through the beginnings of the signs, let the parallels of the diurnal arcs be taken in the Analemma of the preceding proposition; and in place of the radii of the signs in the figure of the zodiacal radii of that same preceding proposition, let the radii of the diurnal arcs be taken, just as was done in propositions 3 and 15 of this book. Let the rest be done as was said in the preceding proposition, and the parallels of the diurnal arcs will have been described. For the description of these does not differ from the delineation of the arcs of the signs, since both these and those are equidistant from the Equator. We have therefore described the parallels of the diurnal arcs on the same meridian sundial, which was to be done.

SCHOLIUM.

In the last figure of the preceding proposition, the radii of the diurnal arcs were drawn for the hours 0 and 24, 6 and 18, 10 and 14, so that arcs of this kind may be described when the occasion requires it.

PROBLEMA 28. PROPOS. 28.

To describe the vertical circles on the same meridian sundial.

[Margin: Description of the vertical circles on the same meridian sundial.]

Through point A, where the equinoctial line AC cuts the horizontal line AB, let the perpendicular AD be drawn to that same horizontal, which will be the common section of the prime vertical circle and the plane of the sundial. For since the style AE is the common section of the horizon and of the prime vertical, as we said in the scholium to proposition 25 of this book, the plane of the vertical circle drawn through the style AE will meet the plane of the sundial in A, and therefore the vertical line must be drawn through A. And because both the plane of the sundial and the plane of the vertical circle are at right angles to the plane of the horizon, ^a their common section will likewise be perpendicular to that same plane of the horizon, and consequently it will be perpendicular to the horizontal AB at point A, by definition 3 of Book 11 of Euclid. Therefore the straight line AD, which we drew perpendicular to the horizontal line AB, will be the common section of the plane of the sundial and of the prime vertical circle.

[Margin a: (XI.19) — hence]

On this vertical line AD, produced toward A, let the straight line AF be taken above AB — or, if you prefer, below — equal to the gnomon AE set out, and from center F let a circle be described with any interval whatever. Divide this into 360 equal parts, or into fewer if not all the vertical circles are wanted (we divided it into 24, so that each contains 15 degrees), and through the points of division and the center F let hidden [construction] lines be drawn, cutting the horizontal line AB at points, through which, if lines are drawn parallel to the vertical line AD — which will indeed easily be done if a line DG is drawn parallel to the horizontal, and onto it, from point D, all the points of the horizontal line taken from point A are transferred; ^b for the straight lines joining any two points equally remote from the points A and D will be parallel to AD itself — the vertical circles will have been described on each sundial, taking their beginning from the vertical line AD. That this is so, we shall demonstrate in the following way.

[Margin b: (I.33)]

Diagram. Two circles side by side, each showing the layout of the vertical circles on a meridian sundial — the left captioned "Occidentale." (western), the right "Orientale." (eastern). Each circle has a vertical diameter through F at its top, a horizontal line AB across it, and a fan of graduated lines descending below, marked with degree-values.

- Left circle captioned **Occidentale.** (Western); right circle captioned **Orientale.** (Eastern)
- F (top of each circle): center from which the dividing radii are drawn (the point equal to the world-center / style-tip E)
- A, E, L, B (on the horizontal line of each circle): A the intersection of equinoctial and horizontal, E and L intermediate points, B the outer endpoint of the horizontal
- Y (interior, near A): a construction point [?]
- G, K, D (lower interior / foot of each fan): points of the descending construction
- Degree-labels along the descending lines: 15, 30, 45, 60, 75 (each recurring on both sides of both circles)
- Zodiacal-sign glyphs at the lower corners; several worn [?]

Now let it be understood that the plane of the circle described from F is turned about the horizontal line AB, until it coincides with the horizon, so that F becomes the same as the center of the world, or the tip of the style E, because of the equality of the style AE and the straight line AF. This being posited, the straight lines drawn out from center F through the points of division will be the common sections of the horizon and of the vertical circles; because the horizon and the circle described from F, since [they have] the same center

[continuation of the demonstration of Problema 28]

have the same center, they are divided into similar parts, from what we demonstrated at the end of chapter 1 on the sphere. The vertical circles therefore meet the plane of the sundial at the points of the horizontal line onto which the straight lines drawn from F fall. And since the common sections of the vertical circles and of the sundial's plane are parallel — by proposition 18 of the previous book, because the plane of the sundial is equidistant from their common section, that is, from the axis of the horizon — these common sections of the sundial's plane and of the vertical circles will be parallel to AD itself. The meridian circle, however, which is the ninetieth vertical, is not projected onto the plane of the

sundial, since it is equidistant from that plane and so makes no section on it. Thus we have described the vertical circles on the same meridian sundial. Which was to be done.

PROBLEMA 29. PROPOS. 29.

To describe the parallels of the horizon [almucantars] on the same meridian sundial.

[Margin: Description of the parallels of the horizon, or almucantars, on the same meridian sundial.]

Let ABCD be the vertical circle properly so called, with center E; let BD be its common section with the horizon, and AC its common section with the meridian. Divide each of the two quadrants AB and AD into 90 equal parts — or into fewer, according to the size of the sundial. (We divided it into 6, so that each part spans 15 degrees.) Join by straight lines each pair of points equally distant from B and from D; these lines will be the common sections of the vertical circle and of the parallels of the horizon.

Next, from the division points of both quadrants draw straight lines through the center E, forming triangles through the axis within the cones — cones whose bases are the parallels of the horizon, both below and above the horizon, and whose common vertex is the center of the world, E. For the vertical circle ABCD, cutting the said cones through their axis AC, produces (by proposition 3 of Book 1 of Apollonius [*Conics* I.3]) triangles through the axis. Cut off also from BD, on each side, the straight line EF equal to the style of the sundial, and through F draw FK parallel to AC — that is, the common section of the vertical circle and of the sundial's plane — cutting the sides of the triangles through the axis at G, H, I, K, and so on, so that GK, HK, IK, and the rest are the diameters of the conic sections.

If, then, the points G, H, I, K are transferred from A onto the sundial's vertical line AD, below the horizontal line, and the said conic sections passing through the points G, H, I, K are described about the vertical line (by proposition 8 of the previous book) — these conic sections being hyperbolas (by proposition 6 of the preceding book, since the meridian, from which the sundial's plane is equidistant, is drawn through the poles of the parallels of the horizon and so cuts them all) — and always receding further from the horizontal line the further they are produced on each side of the vertical line AD, then the parallels of the horizon will have been described. Which was the thing proposed.

Diagram. A large circle representing the vertical circle ABCD, seen with its full graduation, over which the cone-triangles for the almucantars are laid out.

- A (top): zenith; endpoint of the vertical/meridian diameter AC
- C (bottom): nadir; lower endpoint of AC
- B (left) and D (right): endpoints of the horizontal diameter BD (the horizon line)
- E (center): center of the circle, the center of the world / tip of the style (drawn as a small sun-like ring at center)
- F, F (just below E, one on each side): the two points cut off on BD such that EF equals the style; through them FK is drawn
- G, G / H, H / I, I (stacked in mirror pairs descending from E toward C): the points where the parallel FK cuts the sides of the axial triangles
- K, K (lower, near C): the further such division points
- Degree labels along the arc, each recurring on the left (B) and right (D) sides and in the upper and lower halves: 15, 30, 45, 60, 75, with 90 at the top (near A) and 90 at the bottom (near C) — the almucantar values measured from the horizon BD
- Numerous radial construction lines run from the graduation points through the center E

ALITER [Another method].

[Margin: Another description of the parallels of the horizon on the same meridian sundial.]

Describe a quadrant ABC of any size, and divide it into 90 degrees, or into fewer parts according to the number of parallels to be drawn. From the center A, through the division points, send out straight lines; these will correspond to the radii of the parallels of the horizon contained in the quadrant ECD of the preceding figure. Begin from the straight line AB, so that the radius nearest to AB is that of the parallel of the horizon at 15 degrees, the next at 30, and so on, as the attached numbers indicate.

Then, from the figure of the preceding proposition, take the intervals between the center F and the points at which the vertical lines cut the horizontal line, and transfer these from A, in the present figure, onto the straight line AB; write beside the points the numbers of the vertical lines that bound the transferred intervals on AB, and through these points draw lines parallel to AC. This will easily be done if GH is drawn parallel to AB and the points of the line AB are transferred onto it,

and so forth. For example, from the figure of the preceding proposition transfer the interval FL onto the straight line AB of the present figure, as far as the point D, marking the number 60; and through D draw DE parallel to AC, and so on.

Once the figure has been constructed in this way, the parallels of the horizon will be described as follows. The intervals of the lines equidistant from AC, taken between the straight line AB [and...]

Diagram. A quadrant construction for the alternative method, occupying the lower right of the page.

- A (top right corner): center/vertex of the quadrant, from which the radii are drawn
- B (top left, along the upper horizontal line AB); X (further left of B on the same line)
- C (right side, below A): endpoint of the quadrant arc
- G (bottom right) and H (bottom left): endpoints of the lower horizontal line GH, drawn parallel to AB
- D, E, F (interior, along the upper region near A): construction points; D marked with the number 60, with DE drawn parallel to AC
- The quadrant arc sweeps from B down to the lower right, crossed by radii from A
- Degree labels on the radii / arc: 15, 30, 45, 60, 75 (30 and 60 also appearing along the top line near A)

the radius, say, of the parallel of the horizon at 15 degrees, are transferred from the points at which the horizontal line in the figure of the preceding proposition is cut by the vertical lines, onto the corresponding vertical lines on the straight line AB marked with the numbers, marking the points on the vertical lines. Thus, for example, on the straight line DE take a length equal to LM, on the vertical line of 60 degrees, and so on for the rest. For if these points are suitably joined by a certain curved line, the parallel of the horizon at 15 degrees will have been described. In the same way the remaining parallels of the horizon will be described, if the straight lines lying between the line AB and the radii of the parallels of the horizon are transferred onto the corresponding vertical lines, from the horizontal line, and so on. This we shall demonstrate as follows.

[Margin: Demonstration of the latter description of the parallels of the horizon.]

In the figure of the preceding proposition, let the straight line AF — which was taken equal to the style — be understood to stand at right angles to the plane of

the sundial at the point A; and let the figure just constructed about the point F, which is at the center of the world, be turned toward the sundial, so that the point A is joined to the center of the world, that is, to the point F, and so that the straight line AC remains perpetually equidistant from the vertical line AD — that is, is united with the axis of the horizon and of its parallels — and therefore the straight line AB, not departing from the plane of the horizon, always meets the horizontal line in that motion. For in this turning the point D, say, will fall onto the point L of the horizontal line, because the straight line FL was here taken equal to AD in the preceding proposition. [Margin a: (Euclid I.4)] For the straight line FL falling from the point F on high — that is, from the tip of the style — is equal to the straight line FL in the plane of the sundial, as is clear if the triangle FAL on high is compared with the triangle FAL in the plane of the sundial, in the manner stated in proposition 26 of this book concerning the triangles EAN, EAN.

Since, then, both the straight line LM and DE are equidistant from the axis of the horizon, [Margin b: (Euclid XI.9)] LM and DE will also be parallel to each other; and for this reason the straight line DE will coincide with the straight line LM — otherwise LM and DE would not be parallel, since in that turning they meet at L. And accordingly, since LM was taken equal to the straight line DE, the point E will fall onto the point M; and so the radius of the parallel of the horizon at 15 degrees will meet the plane of the sundial at the point M. Through the point M, therefore, the arc of the parallel of the horizon at 15 degrees will pass, since the radius of the said parallel falls upon it in that revolution, as has been demonstrated. In just the same way we shall show that the point F of the same radius falls onto the point N, and so on for the rest. We have therefore described the parallels of the horizon on the same meridian sundial. Which was to be done.

[Margin: When the vertical lines and the parallels of the horizon have been drawn on one of the two meridian sundials, if on the opposite face of the plane there are painted vertical lines and parallels of the horizon corresponding exactly to those drawn on the sundial, then the same vertical circles and parallels of the horizon will have been described on the opposite face.]

SCHOLIVM.

Since the vertical lines and the hyperbolas of the parallels of the horizon have the same position and the same numbers on each of the two sundials — as is clear both from the description itself and from the figure of the preceding proposition — it is evident that, if on the opposite face of either sundial the vertical lines and parallels of the horizon are drawn corresponding exactly to the vertical lines and parallels of the horizon delineated on the sundial, then a sundial with vertical

lines and parallels of the horizon has likewise been described, to be placed on the opposite face of the plane. For this reason it will be enough to describe one sundial only, either the eastern or the western; for from it we shall easily delineate the other on the opposite face, as has been said.

PROBLEMA 30. PROPOS. 30.

To describe the meridians, or the circles of longitude of cities, on the same meridian sundial.

[Margin: These two circles are to be conceived as equal.]

[Margin: Description of the meridians on the same meridian sundial.]

Diagram. Two large adjoining circles laid out side by side (left and right), each the circle FGHI described from center E, representing the meridian / longitude circles of cities for the eastern and western meridian sundials. A crowded field of dashed meridian lines fans across both circles, carrying longitude-degree labels and a few city names; many peripheral labels are worn and abraded. **This diagram — numerous small worn labels flagged [?].**

- Left circle: center E; a cross/dagger symbol (✚) at the top marking the start of division; rim points F (left), G (upper right); labels B (at the bottom, on the horizontal axis shared with the right circle), I (lower left), C (far lower left, on a line running out below), S (lower, near the "180" mark)
- Right circle: center E; rim points G (upper left), F (upper right, with "135"), H (bottom), I (right)
- City-meridian captions: "**Ins. For.**" (*Insulæ Fortunatæ*, the Fortunate Isles — the prime meridian; appears vertically in the left circle and again in the right); "**Alexandria**" [?] with the value 60 in the right circle
- Longitude-degree labels scattered around and across both circles: 15, 30, 60, 90, 135, 180, 330 (left); 15, 30, 90, 135, 180, 270, 279 [?], 45 (right); and, in a small interior grid of the left circle, 270, 285 [?], 300, 315, 330, 345
- Several further peripheral degree/sign labels are too worn or ink-bled to resolve [?]

The description of these differs in nothing from the description of the hour-circles from noon or from midnight, as we taught in proposition 6 of this book — provided only that the circle FGHI, described from E, has the beginning of its division from the

meridian of the Fortunate Isles; which is obtained if the longitude of the place is reckoned from G — in the eastern sundial described (by proposition 25 of this book) toward H, but in the western toward F, that is, toward the western parts, away from the meridian circle, as the reasoning requires. This will indeed be readily understood if in each sundial the circle FGHI is turned about the straight line AC until it is joined with the plane of the equinoctial circle, and so on. We have therefore described the meridians, or the circles of longitude of cities, on the same meridian sundial. Which was to be done.

[Margin: Description, on either meridian sundial, together with its meridians: if the portion above the horizontal line is inverted, so that the upper parts become lower and the right becomes left, another sundial will be produced, containing the meridian circles, to be placed on the opposite face.]

SCHOLIVM.

If the upper part of the eastern sundial — the part that the horizontal line cuts off — is inverted, as we said in the scholium to proposition 14 of this book, namely so that the lower parts become the upper and the right becomes the left, we shall have the western sundial with its meridians, as we showed in that same scholium; provided that the numbers set on the eastern sundial are changed, on the western, into the numbers that arise from adding 180 degrees to the numbers of the eastern sundial (casting out 360 degrees, however, if from that addition a number greater than 360 results). Or, what amounts to the same thing, they are changed into the numbers that, in the circle described from E, lie diametrically opposite to those numbers set on the eastern sundial.

All this we shall also show by the following reasoning. In the triangle AEC, on the eastern sundial, and in the triangle AES, on the western, the angles at A are right, and therefore equal; [Margin a: (Euclid III.27)] and the angles at E are also equal, on account of the equal arcs intercepted between H and the straight lines EC, ES. (That these arcs are equal we shall establish thus. The arc G[†] on the eastern sundial is equal to the arc G[†] on the western, since each reckons the longitude of the place. And the arc [†]15 in the one is equal to the arc [†]15 in the other. Therefore the remaining arc G15 of the one will be equal to the remaining arc G15 of the other; and so the remaining arc 15.H, from the quadrant GH, will be equal to the remaining arc 15.F, from the quadrant GF. [Margin b: (Euclid III.26)] Since, then, the arc 15.F and the arc intercepted between H and the straight line ES, on the western sundial, are equal — because of the equal vertical angles at E — the arcs 15.H on the eastern and the arc intercepted between H and the straight line ES on the western, that is, the arc placed between the point H and

the straight lines EC, ES, will also be equal.) Likewise the sides AE, AE, which are adjacent to the said angles, are equal; [Margin c: (Euclid I.26)] therefore the straight line AC will also be equal to the straight line AS.

Hence we shall show, as in the scholium to proposition 25 of this book, that if the upper part of the eastern sundial is laid upon the lower part of the western, as we taught in the said scholium, the equinoctial line coincides with the equinoctial line, and the meridian 195, drawn through the point C on the eastern sundial, coincides with the meridian 15, drawn through the point S on the western sundial, which is set diametrically opposite to it. In just the same way we shall show that the remaining meridians contained in the upper part of the eastern sundial coincide with the remaining meridians existing in the lower part of the western sundial — those, namely, which are diametrically opposite to them in the circle described from E.

Therefore the upper part of the eastern sundial, torn away from the horizontal line, if it is inverted as we said, will yield the meridian circles on the western sundial, provided that 180 degrees are first added to each number, and 360 degrees cast out from the sum if the sum exceeds this number, so that we may have, on the western sundial, the number of that semicircle of the meridian which is opposite to the semicircle of the same meridian whose section lies in the upper part of the eastern sundial — just as was done in the case of the hour-lines from noon or midnight. For there too, on the western sundial, are contained the hours from noon, whose semicircles are opposed to the semicircles of the same hours from midnight in the upper part of the eastern sundial: because the first hour, say, on the eastern sundial is reckoned from midnight, while the same hour on the western sundial — once that inversion of the upper part of the eastern sundial has been made — is to be reckoned from noon, and so on.

By the same reasoning, if the upper part of the western sundial is inverted, as we prescribed, we shall have the eastern sundial with its meridians, provided that the numbers are first changed, as we said just above.

PROBLEMA 31. PROPOS. 31.

To describe the parallels of cities, that is, the circles of latitude, on the same meridian sundial.

[Margin: Description of the parallels of cities, that is, of latitudes, on the same meridian sundial.]

In place of the parallels passing through the signs of the Zodiac, take the parallels described through the zeniths of the cities situated within the tropics, and let everything else be done as we said of the parallels of the signs of the Zodiac in proposition 26 of this book; and when they have been described, they will be the parallels of the cities, as is clear from proposition 7 of this book. We have therefore described the parallels of the cities, and so on. Which was to be done.

PROBLEMA 32. PROPOS. 32.

To describe the celestial houses on the same meridian sundial.

[Margin: Description of the celestial houses according to Johannes Regiomontanus, on the same meridian sundial.]

According to the opinion of Johannes Regiomontanus [Regiomontanus], the celestial houses, dividing the equator into 12 equal parts, will be described as follows. Let the circle described from E be cut into 12 equal parts, beginning from the straight line GI, or FH; and let hidden straight lines, sent out through the division points and through the center E, cut the equinoctial line AC at points; the lines drawn parallel to the horizontal line AB through these points will be the lines of the celestial houses.

For when the circle described from E is turned about the equinoctial line until its center E is joined with the center of the world and the circle itself is set in the plane of the equator, the straight lines passing through the center E will be the common sections of the circles of the celestial houses — among whose number is also the meridian, passing through the straight line GI, and the horizon, running through FH — and of the equator. This is so because the common sections of these circles and of the equator, from what has been demonstrated by us for the sphere, divide the equator, and a circle concentric with it described from E, into 12 equal parts, and pass through the center of the world. The circles of the celestial houses will therefore meet the plane of the sundial at the points where the straight lines drawn through E cut the equinoctial line; and so through these same points of the equinoctial line will pass the common sections of those circles and of the plane of the sundial. Since, then, these common sections are parallel (by proposition 18 of the previous book), because the plane of the sundial is equidistant from the common section of those circles — namely, from the axis of the vertical circle — they will be straight lines parallel to the horizontal line [par-]

[Margin: Description of the celestial houses according to Johannes Regiomontanus, on the same meridian sundial. Demonstration of the description of the celestial houses according to Johannes Regiomontanus.]

parallel, and — drawn through the points of the equinoctial line — they are the common sections of the circles of the celestial houses and of the plane of the sundial. Which is what was proposed.

[Margin: Description of the celestial houses according to Campanus, on the same meridian sundial.]

Now, according to the opinion of Campanus, the celestial houses — which divide the vertical circle into 12 equal parts — will be laid out in this way. Through A, drop the perpendicular AD onto the horizontal line AB; this will be the common section of the vertical circle and of the plane of the sundial, as we demonstrated in proposition 28 of this book. Then, on the horizontal line, taking the straight line AB, with the style AE equal to it, describe from B, at any interval, a circle, and cut it into 12 equal parts, beginning from the horizontal line. Through the center B and the division points let hidden straight lines be drawn, cutting the line AD at points; the lines drawn through these points parallel to the horizontal line will be the lines of the celestial houses.

Diagram. A pair of circles set side by side — the celestial-house constructions for the eastern and the western meridian sundial. Both are ruled by a horizontal diameter and by a fan of straight house-lines carrying Roman house-numbers, with small "15" marks for the half-house (15°) subdivisions. Many peripheral tick-marks divide each circle's circumference.

Left circle:

- ♈ (?) (far left on the horizontal diameter): a zodiac glyph, apparently Aries
- B (on the horizontal diameter, left of center): center of the Campanus circle
- A (on the horizontal diameter, at center)
- VII (right end of the horizontal diameter)
- XII, VIII, XI, IX (on the radiating house-lines below the diameter)
- 15 (several, marking the mid-house divisions) [?]
- D (at the foot, center)
- C (at the lower left)

Right circle:

- G (upper left), F (upper right)

- E (upper center, at the crossing of two diagonals)
- I (left of center on the horizontal), A (center), VII, VIII (right of center)
- H (lower left)
- XII, XI, IX (on the radiating house-lines)
- I (right side)
- C (lower right)
- 15 (several, marking the mid-house divisions) [?]

[Margin: Demonstration of the description of the celestial houses according to Campanus.]

For when the circle from B, described about the line AD, is turned until it stands perpendicular to the plane of the sundial, and its center B is joined with the center of the world — so that AB becomes the same as the line of the style, and the circle itself is set in the plane of the vertical circle — then the straight lines passing through the center B will be the common sections of the circles of the celestial houses (among whose number is also the horizon, running along the line AB) and of the vertical circle. For the common sections of these circles with the vertical circle divide the vertical circle, and therefore — from what we have demonstrated for the sphere — also divide the circle concentric with it described from B into 12 equal parts, and they are drawn through the center of the world. The said circles will therefore meet the plane of the sundial at the points where the straight lines emitted from B cut the line AD; and thus through those same points of the line AD will pass the common sections of these circles and of the plane of the sundial. Since, then, these common sections are parallel — by proposition 18 of the previous book, because the plane of the sundial is equidistant from the common section of those circles, namely from the axis of the vertical circle — it is clearly established that the straight lines drawn through the points of the line AD parallel to the horizontal line are the common sections of the circles of the celestial houses and of the plane of the sundial. We have therefore described the celestial houses on the same meridian sundial. Which was to be done.

SCHOLIVM.

[Margin: Through which hours the celestial houses are drawn on the equinoctial line according to Johannes Regiomontanus [Regiomontanus].]

It is clear, moreover, that the lines of the celestial houses according to the former method are drawn through those points of the equinoctial line through which

pass the hour-lines that are distant two and four hours from the horizontal line — such as, in the eastern sundial, the hours 8 and 10 after midnight, and in the western, 2 and 4 after noon. And since each house comprises 30 degrees, if each twelfth part of the circle described from E or B is divided into 30 parts — or into fewer equal parts, according to the size of the sundial — and everything else is done as before, the lines of the other position-circles passing through the parts of the celestial houses will be described. In the example, the individual houses are each divided in two, so that between any two lines there fall 15 degrees, as the figures indicate.

[Margin: The lines of the celestial houses have the same position in both meridian sundials. Hence it is enough that only the eastern or the western sundial be described.]

For the rest, since the lines of the celestial houses are described in the same way in both the eastern and the western sundial — both according to Johannes Regiomontanus and according to the opinion of Campanus — we have accordingly drawn them, in the prior figure, on the eastern sundial. For the same lines, described on the western face and corresponding to those, will give the celestial houses on the western sundial, as the numbers indicate: of these, the ones attached to the tropic of Cancer ☊ belong to the eastern sundial, while the others, assigned to the tropic of Capricorn ☋, pertain to the western. In the latter figure, however, we have drawn the lines of the houses on the western sundial, because the same lines on the eastern face, corresponding to them, give the celestial houses on the eastern sundial. For here the numbers assigned to the tropic of Cancer ☊ refer to the western sundial, while the others, attached to the tropic of Capricorn ☋, look to the eastern.

PROBLEMA 33. PROPOS. 33.

To describe the ascending signs of the Zodiac on the same meridian sundial.

Let there be taken, from the two prior tables of proposition 9 of this book — with the Sun at the beginning of Aries ♈ and of Libra ♎ — the hours

[Margin: Description of the ascending signs on the same meridian sundial.]

at which the 12 signs of the Zodiac rise (in the eastern sundial before noon, in the western after noon). Let these hours be counted, on the circle described from E, from the line GI, either toward the east or toward the west — that is, either toward the forenoon side or toward the afternoon side — as the tables indicate. In the eastern sundial the counting must always be done toward the right, in the

western toward the left — that is, always toward F — as is clear if the circle described from E is considered in its proper position in each sundial.

[Margin: Finding of the points on the horizontal line of each meridian sundial, onto which the shadow of the style falls when the signs rise or set.]

Then, through the ends of the countings and through the center E, let hidden straight lines be drawn, cutting the equinoctial line (whether below the horizontal line or above it) at the points through which the lines of the ascending signs are to be drawn. Afterward, from proposition 26 of this book, mark on the horizontal line the points at which the arcs of the signs cut it. For onto these points the shadows of the gnomon will be cast — in the eastern sundial when the signs rise, and in the western sundial when they set.

[Margin: The reason why, on the same meridian sundial, the shadow of the style falls both when the signs rise and when they set.]

These points we shall also find by this method, even if the arcs of all the signs are not drawn on the sundial. From the fifth table of proposition 9 of this book we shall take the semidiurnal arcs of the signs, and reckon them in each sundial from G toward F; and from the ends of the reckonings, through the center E, we shall draw straight lines cutting the equinoctial line at points, through which points lines drawn perpendicular to the equinoctial line will cut the horizontal line at the points where the arcs of the signs divide it. For when the Sun is at the beginnings of the signs, its style's shadow is cast onto those points as it rises or sets — because the said perpendicular lines indicate the hours of the rising and setting of the Sun when it stands at the beginnings of the signs, as is established from what we demonstrated in proposition 25 of this book. Since, then, at the Sun's rising and setting the shadow of the style is cast onto the horizontal line, it is clear that the Sun rises and sets at those points where the said perpendicular lines cut the horizontal line.

[Margin: How the points on the horizontal line may be found otherwise than before.]

We shall find these same points in the following way. From the straight line EA of the last figure of proposition 21 of this book, subtract a straight line equal to the style of the meridian sundial, and through its extreme point draw a perpendicular to EA; this will be the horizontal line in the eastern sundial. If, then, from the extreme point of the line cut off from EA equal to the style, we take the intervals of all the points at which the said perpendicular is cut by the rays drawn through the center E from M, O, Q, S, V, Y, and transfer them onto the

horizontal line of the eastern sundial from A, in the place of the style, we shall obtain the points that are sought — as is clear if the horizon ABCD in the eastern sundial is conceived in its proper position, so that the extreme point of the straight line taken on EA lies at A, in the place of the style, and the perpendicular drawn through that point becomes the same as the horizontal line in the sundial, and accordingly E is set at the center of the world, as the apex of the gnomon. For thus it will come about that, when the Sun rises at the points M, O, Q, S, V, Y, the shadow of the style is cast onto the said points of the horizontal line in the eastern sundial, as is clear. In the same way, in the western sundial the same points will be found, if from EC of the same figure of proposition 21 of this book a straight line equal to the style is cut off, and through its extreme point a perpendicular to EC is drawn to serve as the horizontal line of the western sundial, and so on.

And so, if the points found on the equinoctial line are joined by straight lines with the points found on the horizontal line — those of the corresponding signs in the eastern sundial, but those of the opposite signs in the western — the ascending signs will be described. For when in the eastern sundial the shadow is cast onto some point of the horizontal line, the sign in which the Sun stands rises; but when the shadow in the western sundial falls onto some point of the horizontal line, the opposite sign rises, since the sign in which the Sun then stands is setting.

[Margin: How the points of the ascending signs are investigated in the tropics.]

We can also find, in the two tropics, the points — from the third and fourth tables of proposition 9 of this book — through which the ascending signs are to be drawn: namely, by secretly drawing the line of the hour at which each of the signs rises. For where this line cuts the tropic, through that point the line of that ascending sign must be drawn, as was done in the horizontal sundial. It is very useful, indeed almost necessary, to find in the tropics the points of those signs whose points found on the equinoctial line lie so close to the horizontal line that the line of the ascending sign can scarcely be drawn through those two neighboring points without some error, unless a third point found on the tropic is added. But if a point is to be found on the tropic above the horizontal line, we shall find it by this method even if the tropic is not drawn above the horizontal line.

Suppose, for example, that a point is to be found for the sign Virgo ♍. Since, with the Sun at the beginning of Virgo ♍, the sign Virgo rises at hour 9 min. 26 after noon — as is clear from the fourth table of proposition 9 of this book — we shall count in the western sundial, from G toward F, 9 hours 26 minutes; or (what is

the same) from point I, since the circle in the western sundial is not drawn complete, [count] toward F the complement of those hours up to 12, that is, 2 hours 34 minutes, as far as point O. Through O we shall draw a straight line passing secretly through the center E, which cuts the equinoctial line at the point L; through L, toward the arc of Capricorn ♑, we shall draw the perpendicular LK to the equinoctial line, which — if the tropic of Capricorn ♑ were drawn — would cut it at the point through which the ascending sign Virgo ♍ would have to be drawn. But because the tropic of Capricorn ♑ is not drawn beyond the horizontal line in the western sundial, we shall cut off from the equinoctial line, below the horizontal line, a straight line AM equal to AL, and from M we shall draw the perpendicular MN to the equinoctial line, which cuts the tropic of Capricorn ♑ at N; and from the line MN we shall cut off a portion equal to LK. The point K, therefore, will be that through which both the tropic of Capricorn ♑ and the ascending sign Virgo ♍ must be drawn, as is clear. The same method is to be observed in the rest.

Nor should it seem strange to you that we have taken some points, both on the equinoctial line and on the tropics, above the horizontal line — even though the part of the sundial that stands above the horizontal line is never illuminated by the Sun. For if the density of the earth did not stand in the way, the plane of the eastern sundial would always be lit by the Sun's rays from midnight until noon, for a full 12 hours, one part of which is contained below the horizontal line and the other above it. The same you will say of the plane of the western sundial, from noon to midnight. Hence at that time those hours would indicate which signs of the Zodiac touch the horizon.

[Margin: By what method the ascending signs may be described through the doctrine of the Conics of Apollonius [Apollonius].]

But if lines tangent to the tropics are drawn through the points found on the tropics — which will be drawn as we taught in the corollary of proposition 37 of book 1 of Apollonius — the ascending signs will again be described, as is established from what was demonstrated in proposition 9 of this book.

[Margin: How the ascending signs of Aries and Libra are described.]

Furthermore, we shall describe the lines of Aries ♈ and of Libra ♎ — which necessarily pass through the point A, where the horizontal line, the equinoctial line, and the line of hour 6 from noon or midnight mutually intersect — in the following way. (They pass through A because, when the Sun is at the beginning of Aries ♈, the beginning of Aries rises above the horizon at hour 6 before noon,

and the beginning of Libra ♎ at hour 6 after noon; whereas when the Sun is at the beginning of Libra ♎, the beginning of Aries rises at hour 6 after noon, and the beginning of Libra at hour 6 before noon, as is clear.) For the ecliptic cuts the equator at the beginning of

Aries ♈ and Libra ♎, and makes with it two angles of 23 degrees 30 minutes — which is indeed the greatest declination of the Sun — if to both sides of the equinoctial line at the point A we set two angles of 23 degrees 30 minutes. (This will be done if from A a circumference of a circle is described, from which two arcs of 23 degrees 30 minutes are taken on either side from the equinoctial line, and from A straight lines are drawn through the ends of the arcs.) The lines of Aries ♈ and Libra ♎ will thus be described; of these, the one that inclines toward the tropic of Cancer ♋ will give the beginning of Libra ♎, and the other the beginning of Aries ♈. This is because in the celestial sphere, when the beginning of Libra ♎ is placed in the east, the ecliptic deflects from the equator northward, toward the parallel of Cancer ♋; but southward, toward the tropic of Capricorn ♏, when the beginning of Aries ♈ is set in the east — as is evident from the material sphere.

Hence it comes about that, when the beginning of Libra ♎ is set in the east, all the points of the northern semicircle of the ecliptic that stand above the horizon — in some one of which the Sun must be, since the beginning of Libra rises in the daytime — cast their shadows into the opposite, namely southern, parts, toward which the tropic of Capricorn ♏ also inclines. But when the beginning of Aries ♈ is set in the east, all the points of the southern semicircle of the ecliptic that stand above the horizon — in some one of which the Sun necessarily is, since the beginning of Aries rises in the daytime — cast their shadows into the opposite, namely northern, parts, toward which the tropic of Cancer ♋ declines. [The two tropic-signs here read against their glyphs on the scan: southern shadows are paired with Cancer's sort and northern shadows with Capricorn's sort; I have set each to the tropic its own hemisphere requires (southern → Capricorn, northern → Cancer) and flagged both — the zodiac sorts here are worn.] That the lines of Aries ♈ and Libra ♎ are correctly described in this way will become clear as follows.

[Margin: Another description of the ascending signs on the meridian sundial, through the points of the ecliptic lying on the circles of hour 1 from noon and hour 11 from midnight, when the beginnings of the signs ascend.]

Because, when the beginning of Aries ♈ or of Libra ♎ is placed at the rising point, the style of the sundial is the common section of the plane of the ecliptic and of

the equator, each circle will meet the plane of the sundial at the point A. [Margin: (a) — from proposition 16, whence:] But because the common sections that the ecliptic and the equator make on the plane of the sundial are parallel to the common sections they make on the meridian circle, [Margin: (b) — from proposition 10, whence:] the angle contained in the plane of the sundial between the equinoctial line and the line of Aries ♈ or of Libra ♎ will be equal to the angle enclosed by the same lines on the plane of the meridian circle. Since, then, on the plane of the meridian circle the said angle comprises 23 degrees 30 minutes, the proposition is established.

Diagram. A large figure combining the eastern and western meridian sundials for the ascending signs. Two large circles overlap near the center; a horizontal line and the diagonal equator-line (labelled ÆQVATOR) run across them, and a dense fan of straight lines radiates from the crossing points — these are the hour-lines and the sign-lines, their outer ends marked with the twelve zodiac glyphs (♈ ♉ ♊ ♋ ♌ ♍ ♎ ♏ ♐ ♑ ♒ ♓). Four of the lines carry engraved captions naming their hours.

Labelled points and lines I can read:

- F (top left of the left circle)
- G (at the top, near where the two circles meet)
- P (top right of the right circle)
- O (far left, on the horizontal line)
- E (center of each circle — two instances)
- H (two instances: lower left, and center-bottom)
- Near the left circle's center, a cluster of small labels: K, I, N, M (and an L in the same cluster) [?]
- ÆQVATOR / ÆQVA= — labelling the equator (equinoctial) line
- Line captions:
- "Hora 1^a (prima) antemeridiana, quæ est post mediam noctem." ["1st hour before noon, which is after midnight"] — upper right
- "Hora 1^a (prima) pomeridiana." ["1st hour of the afternoon"] — lower left
- "Hora ij^a (secunda) antemeridiana, quæ est... post mediam noctem." ["2nd hour before noon, which is after midnight"] — lower center [Stage-5 corrected from "Hora 12 [?]" ; the reported 4th "illegible" caption does not exist — there are exactly three]

Peripheral zodiac glyphs mark the outer ends of the sign-lines around both circles; several are worn and cannot be individually resolved [?].

ALITER. The ascending signs will be laid out otherwise, in this manner. From the eighth table of proposition 9 of this book, take the declinations of all the points on the circle of hour 11 before noon — which hour is the eleventh after midnight — and, according to the doctrine of proposition 26 of this book, find on the line of hour 11 in the eastern sundial the points through which the parallels of those declinations are to be drawn. For these points, joined with the corresponding points found on the horizontal line, will give the ascending signs. Or indeed, from the ninth table of the same proposition 9 of this book, take the declinations of the points on the circle of the first hour before noon — which is the first hour after midnight — and, according to the doctrine of proposition 26 of this book, find the points on the line of hour 1 from midnight, that is, the first before noon (which is drawn above the horizontal line, distant from it by just as much as the line of hour 11 is distant below it), through which the parallels of those declinations are to be drawn. For these, joined with the corresponding points found at hour 11, will give the ascending signs, as before, which will necessarily pass through the points of the horizontal line.

Again, from the ninth table of the same proposition 9 of this book, take the declinations of the points on the circle of hour 1 after noon, and, according to the doctrine of proposition 26 of this book, investigate on the line of hour 1 in the western sundial the points through which the parallels of those declinations are to be drawn. For these points, [joined] by straight

joined by straight lines to the corresponding points of the horizontal line, will give the ascending signs.

Or else, from the eighth table of proposition 9 of this book, take the declinations of the points on the circle of hour 11 after noon, and, by the doctrine of proposition 26 of this book, find the points on the line of hour 11 after noon — which line is described above the horizontal line, at just the distance from it that the line of hour 1 from noon is distant from the same line — through which the parallels of those declinations are to be drawn. For these points, joined by straight lines to the corresponding points found at hour 1 from noon, will give the ascending signs, as before; and they will necessarily pass through the points found on the horizontal line.

[Margin: Another description of the ascending signs, from the doctrine of the conics of Apollonius.]

And if from the seventh table of proposition 9 of this book one finds on the line of hour 6 the points through which the parallels of the declinations of the points of

the ecliptic existing at hour 6 pass, and if through these one draws — by the doctrine of the corollary of proposition 37 of Book 1 of Apollonius — the straight lines tangent to the tropics, the signs will be obtained as before, as is clear from what we demonstrated in proposition 9 of this book. We have therefore described the ascending signs of the zodiac on the same meridian dial. Which was to be done.

SCHOLIUM.

[Margin: Yet another description of the ascending signs, according to the practice of Andreas Schöner.]

By the doctrine of Andreas Schöner [Andreas Schöner] the ascending signs may be described as follows. In the first figure of the scholium of proposition 9 of this book, cut off from the straight line EC the straight line E a, equal to the gnomon of the dial, and through a draw a line parallel to BD — so that, with the center E placed at the center E of the dial and the point a at the point A, the parallel drawn through a coincides with the equinoctial line. The parallel drawn through a will then cut the lines of the signs issuing from E in points; and if the distances of these points from a are taken with the compass and transferred onto the equinoctial line of the dial, beginning from A, both above the horizontal line and below it, then through the points marked on the equinoctial line let there be drawn hidden straight lines parallel to the horizontal line itself, cutting both tropics — including the one described above the horizontal line — in the points through which the ascending signs are to be laid out; observing, however, this order.

[Margin: The order of the ascending signs on the tropics.]

In the eastern dial, the point of the tropic of Cancer [♋], where it cuts the horizontal line, belongs to Cancer [♋]; the point next below it, to Leo [♌]; the one following, to Virgo [♍]; while the nearest point above the horizontal line looks to Gemini [♊], and the one following, to Taurus [♉]. Likewise the point of the tropic of Capricorn [♏], where it cuts the horizontal line, looks to Capricorn [♏]; the point next below, to Aquarius [♑]; the one following, to Pisces [♓]; while the nearest point above the horizontal line belongs to Sagittarius [♐], and the one following, to Scorpio [♏ — glyph worn; pinned by the zodiacal sequence] [?]. But in the western dial, the point of the tropic of Cancer, where it intersects the horizontal line, belongs to Capricorn [♏]; the point next below, to Sagittarius [♐]; the one following, to Scorpio [♏] [?]; while the nearest point above the horizontal line looks to Aquarius [♑], and the one following, to Pisces [♓]. Likewise the point

of the tropic of Capricorn, where it intersects the horizontal line, looks to Cancer [♋]; the point next below, to Gemini [♊]; the one following, to Taurus [♉]; while the nearest point above the horizontal line belongs to Leo [♌], and the one following, to Virgo [♍].

[Margin: Another description of the same, by the equinoctial line.]

Again, in the second figure of the scholium of proposition 9 of this book, cut off from the straight line EC the segment E a, equal to the gnomon, and through a draw a line parallel to BD — so that once more, with the center E placed at E, the center of the dial, and the point a at the point A, the parallel drawn through a coincides with the equinoctial line. This parallel drawn through a will cut the lines of the signs issuing from E — including those signs which lie above the line BD, provided their line be produced below the center E — in points; and if the distances of these points from a are taken with the compass and transferred onto the equinoctial line of the dial, beginning from A, both above the horizontal line and below it, there will be obtained on the equinoctial line the points through which the lines of the ascending signs will pass, in this order. In the eastern dial the points of the equinoctial line marked below the horizontal line are owed to the signs that lie to the left of the straight line EC — counting also the signs above the line BD which lie below the center E and are produced beyond the center E, such as Taurus [♉], Gemini [♊], Cancer [♋], [?], and Scorpio [♏] [?]. The points of the equinoctial line above the horizontal line, however, are to be assigned to those signs found to the right of the straight line EC, of which sort are Pisces [♐], [?], [?], Leo [♌], and Virgo [♍]. But in the western dial, understand the whole matter reversed. For to the signs that lie to the left of the straight line EC correspond the points of the equinoctial line above the horizontal line; whereas to the signs that lie to the right of the same straight line EC belong the points of the equinoctial line below the horizontal line. When all this is duly carried out, if the points of the corresponding signs found on the equinoctial line and on the tropics are joined by straight lines, the ascending signs will be described. The lines of Aries [♈] and Libra [♎], however, we shall describe as before.

Now the lines of the ascending signs of either dial, produced beyond the horizontal line, exhibit the lines of those same signs on the opposite face of the plane of the dial, provided that the upper part cut off by the horizontal line is inverted, as we demonstrated in the scholium of proposition 14 of this book. It will therefore be enough to describe the ascending signs on the eastern dial, or on the western; for all its lineaments produced beyond the horizontal line will give the same ascending signs on the opposite dial, if that upper part be inverted, and

so on. In the figure we have here, for the most part, described the ascending signs from the eighth and ninth tables of proposition 9 of this book — namely, by the points found on the lines of hour 11 from midnight and hour 1 from midnight, and likewise hour 1 from noon and hour 11 from noon.

PROBLEMA 34. PROPOS. 34.

HOROLOGIVM Italicum Meridianum constituere. [To construct an Italian meridian sundial.]

[Margin: The description of the Italian meridian dial.]

Let the circle FGHI be cut into the diurnal and nocturnal arc of the tropic of Cancer [♋], as we taught in the scholium of proposition 1 of the preceding book, and let the diurnal arc be BGC and the nocturnal CIB; these arcs will also be found, as we wrote in proposition 10 of this book, if from the point G of noon there be reckoned on either side the semidiurnal arc of the tropic of Cancer, as far as B and C — namely 7 hours 32 minutes, where the pole has an altitude of 42 degrees, as it is at Rome. Next let the circle FGHI be divided into 24 equal hours, taking the beginning from the western terminus of the diurnal arc — which in the eastern dial is the point C, and in the western the point B, as is evident if the circle FGHI is understood to be moved to its proper position about the equinoctial line, until it is set in the plane of the Equator. Then, in the eastern dial from the hours between the points B and G, of sunrise and of noon, and in the western between the points B and G, of sunset and of noon, let there be drawn through the center of the circle FGHI straight lines which, as we showed in proposition 10 of this book, are the common sections of the Equator and of the great circles which are drawn through the poles of the world and parallel to the Italian hours of Cancer [♋], in the manner of hour-circles reckoned from noon or from midnight. These lines will cut the equinoctial line in points; and through these points, perpendicular hidden lines drawn to the equinoctial line will cut the tropic of Cancer [♋] in the Italian hours, or the hours from sunset — since these perpendiculars are the hour-lines from sunset, in the manner of the hour-lines from noon or from midnight, the Sun being at the beginning of Cancer [♋], as is clear from what we demonstrated in proposition 25 of this book. In the same way, if to the arcs IB, IC there be taken equal arcs GD, GE, so that DGE is the diurnal arc of the tropic of Capricorn [♋],

and again the circle FGHI be cut into 24 equal parts, beginning from the western terminus of the diurnal arc of the tropic of Capricorn [♋] — so that from the point E in the eastern dial, and from D in the western, we shall find the Italian

hours on the tropic of Capricorn [♊]. And so, if the mutually corresponding hours on the tropics are joined by straight lines, the Italian dial will be described. These hour-lines will necessarily pass through the points of the hours from noon, or from midnight, on the equinoctial line — as the 9th Italian hour through the 3rd from midnight, the 10th through the 4th from midnight, and the 20th through the 2nd from noon, and so on, as is clear from the table of proposition 19 of the preceding book, whose title is *ÆQVINOCTIALIS LINEA* [the Equinoctial Line]. And if some hours from sunset do not, in either of the tropics, have corresponding points on the other tropic, they must be drawn through the corresponding hours on the equinoctial line, as is gathered from the said table of proposition 19 of the preceding book. Thus in the eastern dial hour 16 and hour 17 are drawn through the points found on the tropic of Capricorn [♊], and through hour 10 and hour 11 from midnight on the equinoctial line, because on the tropic of Cancer [♋] they have no corresponding points. The line of hour 18, moreover, must be drawn through the

Diagram. A large combined construction figure spanning the width of the page, showing the eastern and western Italian meridian sundials side by side. Two large circles (each the circle FGHI, one for the eastern dial at left, one for the western at right) overlap near the center; a horizontal line runs across both through the points K...K, and a dense fan of straight and dotted lines radiates from the crossing points, forming the hour-lines and sign-lines. The circumference and interior carry numeric hour-labels 1–24.

Labelled points and lines I can read:

- Left circle: M (upper left), D, L, F, B ranged down the upper-left; K on the horizontal line at left; G near the upper center; H and C toward the lower center; E near the center; I on the lower left.
- Right circle (mirror image): L, D, M (upper right), F, B ranged down the upper-right; K on the horizontal line at right; G near the upper center; H and C toward the lower center; E near the center; I on the lower right.
- "12" appears near the top of each circle; "6" near the upper center between the circles.
- Numeric hour-labels around the lower portions: on the left circle 24, 23, 22, 21, 20, 18, 16, 10, 8, 7, 5, 4, 3, and "12" at the very bottom of a long line descending below the circle; on the right circle 24, 18, 17, 16, 6, 5, 4, 3, and "12" at the foot of a descending line. Several of the interior numerals are faint or crossed by other lines and cannot be individually resolved [?].

- Dotted lines mark the nocturnal-arc constructions descending below each circle to the "12" termini.

hour...

point found on the tropic of Capricorn [γ], parallel to the equinoctial line, as is evident. For since the circles of hour 6 and hour 18 from sunrise, or from sunset, have with the Equator one and the same common section (by proposition 16 of the preceding book), and likewise one and the same with the Meridian (by proposition 17 of the same preceding book), and since those two circles have but one common section, it follows that those two circles, together with the Equator and the Meridian, have one and the same common section — namely that which is also the common section of the Meridian and the Equator. Since, then, the plane of the meridian dial is equidistant from this common section — that is, from the Meridian circle itself — the sections of the remaining circles with the plane of the dial (such as the line of hour 6, the line of hour 18 from sunrise or from sunset, and the equinoctial line) will, by proposition 18 of the preceding book, be parallel to one another.

[Margin: Another description of the same Italian meridian dial, by the diurnal and nocturnal arcs of the hours of 14 and 10; likewise of 24.]

By the two diurnal and nocturnal arcs of the hours of 14 and 10, the same Italian dial will be described, as we explained in the horizontal and vertical dial. The same will be done by means of two parallels, one of which is always the greatest of the ever-apparent — that is, the diurnal arc of 24 hours — while the other is the greatest of the ever-hidden — that is, the nocturnal arc of 24 hours — if their hyperbolas be described on the dial. For the hour-lines from sunset or from sunrise touch the said hyperbolas at those points where the same are cut by the hour-lines from noon or from midnight, by proposition 14 of the preceding book — excepting the lines of hours 12 and 24, for these do not meet the said hyperbolas, as is clear from the corollary of proposition 15 of the same preceding book.

Furthermore, for the eastern Italian dial there are to be taken, out of the diurnal and nocturnal arcs, only those hours from sunset which have corresponding hours from midnight, since the hours from noon are not contained in it. For the western dial, however, there are to be taken those hours to which the hours from noon correspond, because these alone are found described in it. Let the same be observed in the diurnal and nocturnal arc of 24 hours. Thus we shall describe these hours 9, 10, 11, 12, 13, 14 from sunset on the eastern dial by the hours 2, 3,

4, 5, 6, 7 from midnight in the nocturnal arc of 14 hours. Likewise these hours 9, 10, 11, 12 from sunset by the hours 3, 4, 5, 6 from midnight in the nocturnal arc of 12 hours. But these 13, 14, 15, 16, 17 from sunset by 7, 8, 9, 10, 11 from midnight in the diurnal arc of 12 hours. Moreover hours 9, 10 from sunset by the hours 4, 5 from midnight in the nocturnal arc of 10 hours. And these 10, 11, 12, 13, 14, 15, 16 from sunset by 5, 6, 7,

8, 9, 10, 11 from midnight in the diurnal arc of 14 hours. And these 14, 15, 16, 17, 18 from sunset by the hours 7, 8, 9, 10, 11 from midnight in the diurnal arc of 10 hours. By the same reasoning, in the western dial, from the said tables we shall find the hours from noon by which the hours from sunset are to be drawn. But since hour 18 from sunset has only a single point in each dial — namely in the eastern hour 11 from midnight in the diurnal arc of 10 hours, and in the western hour 1 from noon in the diurnal arc of 14 hours — we shall draw it in the eastern dial through hour 11 from midnight in the diurnal arc of 10 hours, and through hour 6 from midnight in the nocturnal arc of 24 hours; but in the western dial through hour 1 from noon in the diurnal arc of 14 hours, and through hour 6 from noon in the diurnal arc of 24 hours. In each dial, however, the line of hour 18 from sunset is parallel to the equinoctial line, as is clear from the scholium of proposition 22 of the preceding book.

[Margin: Another description of the Italian meridian dial by the line of hour 12 from sunrise and sunset, and by the line of hour 24 from sunrise or sunset.]

Finally, the same Italian dial will be completed by means of the line of hour 12 from sunrise and from sunset, as is evident from the second table of proposition 20 of the preceding book, whose title is LINEA HORAE XII. AB ORTV, VEL OCCASV [the Line of Hour 12 from Sunrise or Sunset]. Likewise by means of the line of hour 24 from sunrise or from sunset (which is the same as the horizontal line), as is gathered from the first table of the same proposition, whose title is LINEA HORAE XXIII. AB ORTV, VEL OCCASV [the Line of Hour 24 from Sunrise or Sunset]. Indeed it will be described more accurately by means of the line of hour 12 from sunrise or sunset, and the line of hour 24 from sunrise or sunset, together with the equinoctial line — because in the eastern dial the hour-lines from sunset which are but little distant from the line of hour 12 from sunrise or sunset barely intersect the line of hour 12 itself (the same being seen in the hour-lines from sunset which are but little distant from the horizontal line in the western dial, if they be compared with the horizontal line, for it is scarcely cut by them). Hence in describing the former we shall use the horizontal line and the

equinoctial line; but in the latter, the line of hour 12 from sunrise or sunset and the equinoctial line.

[Margin: The description of the line of hour 12 from sunrise or sunset on the meridian dial.]

Furthermore, we shall trace the line of hour 12 from sunrise or sunset by this method. From the point A we shall describe a circle KL of any magnitude whatever, which cuts the line of hour 6 from noon, or from midnight, produced, in M; and the arc KM (if no error has been made in the description of the line of hour 6) will be the altitude of the pole above the Horizon, on account of the angle KAM — because the angle contained by the line of hour 6 and the equinoctial line is right, by construction, and the remaining angle out of this right angle, which the equinoctial line makes below the horizontal with the horizontal line at A, is the angle of the altitude of the Equator above the Horizon, by construction, as was said in proposition 25 of this book. Then to the arc KM we shall take an equal arc ML, and through L and A we shall produce the straight line LA. This, I say, is the line of hour 12 from sunrise or sunset.

[Margin: a — 16, hence.] For since the common sections of the circle of hour 12 from sunrise or sunset, made in parallel planes — namely in the plane of the Meridian and in the plane of the dial — are parallel; and likewise the common sections of the Horizon made in the same planes; [Margin: b — 10, hence.] the angle contained beneath those sections in the plane of the Meridian will be equal to the angle contained beneath the same sections in the plane of the dial. Since, then, AK is the common section of the Horizon and of the plane of the dial, and the angle KAL is equal to that which the common sections made by the circle of hour 12 from sunrise or sunset and by the Horizon constitute in the plane of the Meridian — because the arc KL is similar to the arc of the Meridian intercepted between the Horizon and the circle of hour 12, as is evident from the figure of proposition 9 of the preceding book, since the diameter of the parallel of the ever-apparent, the greatest of all, is bounded by the points K, L — the straight line LA will be the common section of the circle of hour 12 from sunrise or sunset and of the plane of the dial; which was proposed. Moreover, the equinoctial line will always bisect the angle contained beneath the line of hour 12 from sunrise or sunset and the horizontal line, in each dial. For since the angle MAL is equal to the altitude of the pole above the Horizon, the remaining angle out of the right angle, contained beneath the line LA and the equinoctial line, will be equal to the altitude of the Equator above the Horizon. Wherefore, since the acute angle contained beneath the horizontal line and the equinoctial line is also equal, by

construction, to the same altitude of the Equator, the angles which the equinoctial line makes with the line of hour 12 and with the horizontal line will be equal to one another. Hence the line of hour 12 will also be easily drawn, if at the equinoctial line there be constituted an angle equal to the altitude of the Equator, toward the obtuse angle which the equinoctial line makes with the horizontal line.

[Margin: When the line of hour 12 from sunrise or sunset is right, and when acute or obtuse.]

It is also manifest that the line of hour 12 from sunrise or sunset makes with the horizontal line a right angle KAL when the altitude of the pole KM contains 45 degrees, because then the whole arc KL is a quadrant; an acute angle when the altitude of the pole is less than 45 degrees, as in our example, since then the whole arc KL is less than a quadrant; and finally an obtuse angle when the altitude of the pole exceeds 45 degrees, because then the whole arc KL is greater than a quadrant. This is clearly gathered from the description of the line of hour 12 from sunrise or sunset here given.

For the rest, neither the horizontal line nor the line of hour 12 from sunrise or sunset can here be described in the manner which we prescribed for the vertical dial in proposition 22 of this book — namely by the arcs of the parallels of the ever-apparent and of the greatest of the ever-hidden cutting the meridian line — because in this dial the meridian line cannot be drawn, as we showed in proposition 25 of this book; and the aforesaid lines, namely the horizontal line and the line of hour 12 from sunrise or sunset, neither cut nor touch the arcs of the said parallels, but never meet them, as was demonstrated by us in proposition 15 of the preceding book. And so we have constructed the Italian meridian dial. Which was to be done.

PROBLEMA 35. PROPOS. 35.

HOROLOGIVM Babylonicum Meridianum constituere. [To construct a Babylonian meridian sundial.]

[Margin: The description of the Babylonian meridian dial.]

We shall describe the Babylonian dial by nearly the same methods by which we constructed the Italian — provided that, in the first method, with the circle FGHI divided into 24 equal hours, the beginning is taken from the eastern terminus of the diurnal arc, both of the tropic of Cancer [♋] and of the tropic of Capricorn [♐] — that is, both from the point B and from the point D in the eastern dial, and in

the western both from the point C and from the point E. The line of hour 6 from sunrise, moreover, must be drawn parallel to the equinoctial line, as we showed in the preceding proposition: in the eastern dial through the point of the said hour found on the tropic of Cancer [☿], and in the western through the same point found on the tropic of Capricorn [♊].

[Margin: Another description of the Babylonian meridian dial by the diurnal and nocturnal arcs.]

In the second method, which is accomplished by the diurnal and nocturnal arcs, the same is to be observed here as we observed in the Italian dial: that is, for the eastern Babylonian dial there are to be taken, out of the diurnal and nocturnal arcs, those hours from sunrise to which the hours from midnight correspond; while for the western, those to which the hours
the hours from noon [correspond].

Now the line of hour 6 from sunrise — which is also parallel to the equinoctial line in both dials, as was shown in the scholium of proposition 22 of the preceding book — must likewise be drawn: in the eastern dial through hour 6 from midnight in the diurnal arc of 24 hours, and in the western through hour 6 from noon in the nocturnal arc of 24 hours.

[Margin: Another description of the Babylonian meridian dial by the lines of hours 12 and 24 from sunrise or sunset.]

The third method, drawn from the table LINE OF HOUR XII FROM SUNRISE OR SUNSET and from the table LINE OF HOUR XXIII FROM SUNRISE OR SUNSET, presents no difficulty, provided only this is noted: in the western dial the hours from sunrise are more easily drawn by the horizontal line (that is, the line of hour 24) and by the equinoctial line than by the line of hour 12 from sunrise or sunset, because that line scarcely, or only with difficulty, cuts the line of hour 12 from sunrise or sunset in the western dial. In the eastern dial, by contrast, these same hours are more easily drawn by the line of hour 12 from sunrise or sunset together with the equinoctial line, because they scarcely, or only with difficulty, intersect the horizontal line, as is clear from the figure.

[Margin: Which line in the figure indicates the hours from noon or midnight, and which the hours from sunset or from sunrise.]

An example of the Babylonian dial is set out in the figure of the preceding proposition, for it contains the hours from noon and midnight as well as those from sunrise and sunset. The lines that are parallel to one another and

perpendicular to the equinoctial line — beside which, along the equinoctial line, the hour-numbers are placed — pertain to the hours from noon and midnight. The other lines, which in the eastern dial cut the horizontal line and in the western the line of hour 12 from sunrise or sunset, show the hours from sunset. Finally, the lines which in the eastern dial cut the line of hour 12 from sunrise or sunset, and in the western the horizontal line, signify the hours from sunrise. And so we have described the Babylonian meridian dial. Which was to be done.

SCHOLIVM.

[Margin: The Italian eastern dial, drawn on the opposite face, gives the Babylonian western; and the Italian western dial drawn on the opposite face exhibits the Babylonian eastern, and vice versa — provided that the hour-numbers are changed into their complements up to 24.]

From the figure of the preceding proposition it is clear that the hour-lines from sunset in the eastern dial have exactly the same position that the hour-lines from sunrise keep in the western dial. The same holds of the hours from sunrise in the eastern dial and of the hours from sunset in the western. Hence the Italian eastern dial, drawn on the opposite face of the dial's plane so that line answers to line, will be the Babylonian western; and likewise the Italian western will be the Babylonian eastern, and conversely — provided only that each hour-number is changed into its complement up to 24: thus 9 into 15, and 3 into 21, and so on.

PROBLEMA 36. PROPOS. 36.

HOROLOGIVM Antiquum Meridianum constituere. [To construct an ancient meridian dial.]

[Margin: Description of the ancient meridian dial.]

Let the diurnal arc both of the tropic of Cancer [♋], BGC, and of the tropic of Capricorn [♐], DGE, in the circle FGHI, be divided into 12 equal parts. For by their aid we shall find, in each tropic, the points through which the unequal hours are to be drawn — in the same manner in which, in the two preceding propositions, we investigated the points of the hours from sunrise and sunset in these same tropics.

Diagram. Two large circles set side by side, representing the eastern and western ancient (unequal-hour) meridian dials, drawn for Problema 36. Each circle carries a network of straight and dotted construction lines radiating from a dense cluster of small numerals near its center, together with the two divided tropic

arcs and the hour-lines. Because the interior of each circle is crowded with small hour-numerals that do not resolve cleanly even under magnification, the numeric labels near the centers are given as read where legible and flagged elsewhere.

Left (eastern) circle:

- D (top): circle point
- F (upper left, on circumference): circle point
- G (near top, short dashed segment): circle point
- B (left): circle point
- A (center): stylus foot / center of the hour-line pencil
- E (center-right, where the two circles meet): common point
- C (bottom): circle point
- H (lower right): circle point
- I (lower left): circle point
- Peripheral hour-numerals read: 10 (right), 8 and 9 (upper middle), 8 and 2 (lower middle), 7 (far lower left, outside the circle)
- interior numeral cluster around A: [numeral: ?]

Right (western) circle:

- D (top): circle point
- G (upper left, dashed): circle point
- F (upper right, on circumference): circle point
- B (right): circle point
- E (center-left, where the two circles meet): common point
- C (bottom): circle point
- H (lower left): circle point
- I (lower right): circle point
- Peripheral hour-numerals read: 2 (upper left), 3 and 4 (center), 13 (center), 10 (lower middle), 11 (bottom), S (lower right, outside the circle)
- interior numeral cluster: [numeral: ?]

The unequal hours, moreover, will pass through the hours from noon or midnight on the equinoctial line, as we taught in the horizontal and vertical dials, and as is clear from the tables of proposition 33 of the preceding book. If again two diurnal arcs are drawn, one comprising 18 hours and the other 6, we shall describe the same dial — just as was done in the horizontal and vertical dials —

from the tables of the scholium of proposition 33 of the preceding book, which are devoted to the unequal hours.

[Margin: Another description of the ancient meridian dial by the diurnal arcs of hours 6 and 18.]

An example of each description appears in the figure set before us. We have therefore constructed the ancient meridian dial. Which was to be done.

SCHOLIVM.

From the figure and description of each dial it appears that the lines of the unequal hours have the same position and situation in both dials. Therefore, once one dial has been drawn, if on the opposite face the same lines are laid down, corresponding in every way to the earlier ones, the other dial too will be obtained. The hour-numbers, however, must be changed into their complements up to 12: thus 1 into 11, and 2 into 10, and so on.

[Margin: The ancient eastern dial, on the opposite face of the plane, gives the ancient western, and conversely.]

DE HOROLOGIIS POLARIBVS. [ON POLAR DIALS.]

PROBLEMA 37. PROPOS. 37.

HOROLOGIVM Astronomicum polare delineare. [To delineate an astronomical polar dial.]

That is: to describe the lines of the hours from noon or midnight on a plane that is parallel to the circle of the sixth hour from noon or midnight — the circle which is drawn through the poles of the world and stands perpendicular to the meridian.

[Margin: How the astronomical polar dial differs from the meridian dial.]

This dial does not differ from the meridian dial except in the number of the hours and their order. For here, on each side of the straight line DE, all the hours are to be taken that can fall upon the plane of the dial; and the straight line DE no longer shows hour 6 from noon or midnight, as it did there, but hour 12. The lines that recede from it toward the east indicate the hours from noon, while those

placed toward the west show the hours from midnight, as appears in the opposite dial.

For suppose the dial is so placed that the straight line CS is parallel to the horizon, the straight line DE lies in the plane of the meridian circle, the point E inclines toward the south and D toward the north, and finally the point D is raised on the northern side by the altitude of the pole — that is, so that the straight line DE, together with the meridian line in a plane parallel to the horizon, makes on the side of point D an angle equal to the altitude of the pole. Then the stylus AE, standing at right angles to the plane of the dial at A (so as to be the common section of the equator and meridian, or at any rate the straight line OP, as we taught in the scholium of proposition 25 of this book), will indicate the hours from noon and midnight — such that the lines more toward the east than DE, of the sort that run toward the point S, give the hours from noon, while those more toward the west, such as the lines running toward the point C, pertain to the hours from midnight, as appears in the figure.

Diagram. The astronomical polar dial of Problema 37, drawn in the manner of an analemma. A horizontal straight line CS (the equinoctial line, parallel to the horizon) runs across the figure; a vertical straight line DE (the meridian line, the line of hour 12) crosses it, with D toward the top (north) and E toward the bottom (south). At the foot lies a circle (described from E and divided into 24 equal parts) carrying the numeral 12 within it; from its divisions the dashed hour-lines and sign-arcs radiate outward to left and right, ending at the symbols of the zodiacal signs ranged down both margins of the figure. Two arcs cross in an X above the center.

- C (left end of the horizontal line): equinoctial-line terminus toward the west
- S (right end of the horizontal line): equinoctial-line terminus toward the east
- D (upper center): meridian-line terminus toward the north
- E (lower center): stylus vertex and center of the divided circle
- 12: numeral within the lower circle
- interior points near the center (labels resembling N, O, P, S): not legibly resolved — [?]
- zodiacal sign-symbols down the left and right margins: mostly worn / not legibly resolved — [?]

Therefore, if an astronomical polar dial is to be drawn, two straight lines CS and DE must be laid down on some plane, cutting one another at right angles at A; and on the straight line DE the segment AE, equal to the proposed stylus, must be taken. Then, describing from E a circle of any size and dividing it into 24 equal parts, the rest is to be completed as in the meridian dial, and so on.

That the meridian dial becomes polar if that exchange of the hour-numbers is made, as we said, can easily be understood in this way. Both the circle of hour 6 from noon or midnight — to which the plane of the polar dial is parallel — and the meridian — to which the meridian dial is parallel — are drawn through the poles of the world. It therefore comes about that the circles of the hours from noon or midnight cut the plane of each dial in the same way, since they stand in the same relation to each, only the order and number of the hours being changed.

For as the circle of hour 6 stands to the meridian — cutting it, namely, at right angles — so in turn the meridian stands to the circle of hour 6; and therefore the line which in the meridian dial gives hour 6 will give hour 12 in the polar dial, and so on. But we shall also demonstrate geometrically the construction of the polar dial which we have just now set out. Since the planes of the meridian and of the circle of hour 6 are perpendicular to the plane of the equator (by proposition 15 of Book 1 of Theodosius [Theodosius, *Sphaerica* I.15]), inasmuch as they pass through its poles, [a] their common section will be perpendicular to that same plane of the equator. [b] Since, then, the section which the meridian makes in the plane of the polar dial — namely the meridian line — is parallel to this common section, [c] the meridian line of the dial will also be perpendicular to the plane of the equator; and therefore, by definition 3 of Book 11 of Euclid, it will also be perpendicular to the common section of the plane of the dial and of the equator — namely to the equinoctial line of the dial, which lies in the plane of the equator.

[Margin: Demonstration of the construction of the astronomical polar dial. a: Euclid XI.19; b: Euclid XI.16; c: Euclid XI.8.]

Wherefore, if the straight line CS is set as the equinoctial line, the straight line DE will be the meridian line in the polar dial, since DE is by construction perpendicular to CS. Therefore, if the plane of the circle described from E is imagined to turn about the stationary line CS until it coincides with the plane of the equator, and E, the vertex of the assumed stylus AE, is joined to the center of the world, then that circle will be concentric with the equator; and the straight lines drawn out through E and the points of the circle's divisions will be the common sections of the hour-circles from noon or midnight with the equator. For

the equator and the circle described from E, being described about the same center E, are cut into similar arcs by the said straight lines, as we demonstrated at the end of chapter 1 on the sphere — that is, the diameter of the circle described from E, perpendicular to CS, is the common section of the equator and of the circle of hour [12]...

of hour 12, or of the meridian, and so on — as is evident if one rightly considers the proper position of the circle described from E (or of the equator) in the plane of the polar dial, namely such that it stands perpendicular to the plane of the dial. Therefore the hour-circles from noon or midnight cut the equinoctial line CS, in the plane of the dial, at the points where the straight lines drawn through the center E and through the points of the divisions of the circle described from E meet it. Accordingly, through these points must be drawn the common sections of those circles and of the plane of the dial, which are indeed the hour-lines from noon or midnight.

[Margin: The line of hour 6 from noon or midnight cannot be described in the polar dial.]

Wherefore, since by the corollary of proposition 22 of the preceding book these hour-lines are parallel in the polar dial, it is clearly established that the straight lines drawn through the points of the line CS parallel to DE — the meridian line, or line of hour 12 — are the hour-lines from noon or midnight, in the order stated above. The line of hour 6 alone cannot be described, but vanishes, as we demonstrated in the scholium of proposition 11 of the preceding book. And thus far we have constructed the upper polar dial, which faces the zenith.

[Margin: The upper polar dial, drawn on the opposite face so that each line corresponds to each line, gives the lower polar dial, provided the hour-numbers are changed into their complements up to 12.]

Now these same hour-lines, drawn on the opposite face of the dial's plane (which the sun illuminates before hour 6 from midnight and after hour 6 from noon, as is clear) so that each line answers in every respect to each line, will also give the hours in the lower polar dial — provided, however, that the number of each hour is changed into its complement up to 12, so that the line of hour 7 from midnight in the upper dial is the line of hour 5 from midnight in the lower, and so on. We call the dial that faces the zenith the Upper, and that which faces the nadir the Lower. The demonstration is entirely the same as before, if the circle described from E is understood to be moved downward about CS until E is joined with the center of the world, and so on. For the diameter of that circle, cutting CS at right

angles, will be the common section of the equator and of the circle of hour 12 of midnight, and so on — as can easily be understood if the said circle is conceived in its proper position in the plane of the lower dial. We have therefore delineated the astronomical polar dial. Which was to be done.

SCHOLIUM.

[Margin: How the astronomical polar dial is constructed on a fixed plane. When the place of the stylus and its length are given, by what method the astronomical polar dial is described.]

If a dial is to be described on a fixed plane that is parallel to the circle of hour 6, and not on some arbitrary plane to be set afterward in its proper position (as we have done up to now), then, with the aid of the level and the plumb-line, one must draw on the given plane the straight line CS parallel to the horizon for the equinoctial line, and erect DE perpendicular to it for the meridian line. Then, taking on the straight line DE the length of the stylus AE, and describing from E a circle of any size, the rest is to be completed as in the meridian dial, as we also taught before.

But if the place of the stylus is given, as at A, together with its length, then CS must be drawn through A, the place of the stylus, parallel to the horizon, and DE erected perpendicular to CS from that same place of the stylus A, and so on.

PROBLEMA 38. PROPOS. 38.

PARALLELOS, siue arcus signorum Zodiaci in prædicto horologio polari describere. [To describe the parallels, or arcs of the signs of the zodiac, in the aforesaid polar dial.]

[Margin: Description of the arcs of the signs of the zodiac in the polar dial.]

The arcs of the signs of the zodiac will be described in the polar dial just as they were described in the meridian dial. For the same demonstrations can be transferred here, only this being observed: in the first figure of proposition 26 of this book, the circle of the analemma ABCD is not to be taken, as it was there, for the circle of hour 6 from noon or midnight, but for the meridian itself; and so the axis FG is the common section of the meridian and of the circle of hour 6, while the straight line LM is the common section of that same meridian and of the plane of the polar dial — that is, the meridian line of the dial, or the line of hour 12, and not of hour 6 as there.

Diagram. The polar dial of Problema 38, again in analemma form, showing the arcs of the zodiacal signs superimposed on the hour-lines. A vertical meridian line runs through the center with D toward the top and E below; at the foot lies the circle divided into parts, carrying the numeral 12. A horizontal line crosses it, and dashed sign-arcs radiate to left and right, ending at the zodiacal symbols ranged down both margins. Two arcs cross in an X above the center.

- D (upper center): meridian-line point (north)
- E (lower center): stylus vertex / center of the divided circle
- 12: numeral within the lower circle
- N (on the meridian line, toward the south): shadow point at noon when the sun is in Cancer
- interior points near the center (labels resembling F, S, D): not legibly resolved — [?]
- axis FG, line LM, points B and Q, and line $\alpha\beta$ referred to in the text: not legibly resolved on the figure — [?]
- zodiacal sign-symbols down the left and right margins: mostly worn / not legibly resolved — [?]

[Margin: In the polar dial, both upper and lower, the northern signs lie below the equinoctial line and the southern signs above it. How the horizontal line in the polar dial is described.]

By the same reasoning, in the third figure of that same proposition 26, the line $\alpha\beta$, which in the meridian dial belonged to hour 6 from noon, is the meridian line — that is, the line of hour 12 — in the polar dial; while the parallel next to it belongs to hours 1 and 11 from noon and midnight, and so on. Furthermore, in each polar dial the northern signs are contained below the equinoctial line, toward the south, and the southern signs above that line, toward the north, as can be gathered from the analemma, or first figure of proposition 26 of this book. For when the sun is in Cancer [♋], the shadow of the stylus is cast into the lower parts of the meridian line in each dial — namely to the point N, toward the south, at the time of noon; but when the sun is in Capricorn [♐], into the upper parts, as to the point Q, toward the north.

But since the plane of the polar dial is cut by the horizon (not being parallel to it) — just as the circle of hour 6 from noon or midnight, to which the dial is parallel, is likewise cut by the same horizon — we shall describe the common section of the horizon and of the plane of the dial, namely the horizontal line, upon which the shadow of the stylus is cast when the sun rises or sets, as is established from

proposition 11 of the preceding book, in the following way. At the point B, where the hour 3 or 9...

cuts the equinoctial line, let the angle ABD be made equal to the complement of the pole's elevation, and let the line BD cut the meridian line at D — above the position of the stylus in the upper dial, but below it in the lower. This is easily done: from B describe an arc of a circle beyond the meridian line, on which the complement of the pole's elevation is laid off starting from the line CS, and from the end of that measured arc draw a straight line to B, and so on. For if through D a line is drawn parallel to the equinoctial line CS, this will be the horizontal line. Since the line AB is equal to the length of the stylus AE — as we showed in the scholium of proposition 25 of this book — then, if the triangle DBA is imagined to be rotated about the line AD until it stands perpendicular to the plane of the dial and lies in the plane of the meridian circle, the horizon will pass through the point B, that is, through the vertex of the stylus, or the center of the world. For the line AB, in the position it acquired during that rotation, is perpendicular to the plane of the dial and lies in the plane of the equator; hence B will be the vertex of the stylus, or the center of the world.

[Margin: Another way of describing the horizontal line in the same polar dial.]

Now the angle DBA has been made equal to the complement of the pole's elevation — which is precisely the angle the horizon makes with the plane of the equator — and so the remaining angle BDA is equal to the pole's elevation, that is, to the inclination of the dial's plane to the horizon. The horizon will therefore pass through the line BD and will meet the plane of the dial at D. For in this way, in the plane of the meridian circle, it makes with AB — the common section of the equator and the meridian — an angle equal to the complement of the pole's elevation, and with the line AD — the common section of the dial's plane and the meridian — an angle equal to the pole's elevation, as the case requires. Therefore the horizontal line must be drawn through D. And since the equator, the horizon, and the circle of the sixth hour have one common section, and the plane of the dial is parallel to one of these (namely the circle of the sixth hour), the common sections which the plane of the dial makes upon the other two circles — that is, the equinoctial line and the horizontal line — will be parallel to each other, as was demonstrated in the scholium of proposition 22 of the preceding book. Therefore a line drawn through D parallel to the equinoctial line is the horizontal line, which was what was proposed.

We shall likewise find the point D through which the horizontal line must be drawn, in the following way. In the analemma from which the arcs of the signs

were described, let the points l, m be marked, where the diameter of the horizon BD intersects the parallels LM, LM through which the planes of the dials are drawn; and let the line Kl or Km be transferred onto the meridian line from the position of the stylus A — upward as far as D in the upper dial, but downward in the lower. For the horizontal line must be drawn through D, as before, since at the points l and m the plane of the horizon (drawn through BD) meets the planes of the dials (drawn through LM, LM), with lines drawn above K for the position of the stylus in the upper dial and below it in the lower, and so on. And since the line Kl is equal to the line Km — for in the triangles EKl, EKm the angles at K are right, [a] and the angles at the vertex E are equal, and likewise the sides EK, EK are equal, [b] so the sides Kl, Km will also be equal — for this reason we said that this same Kl or Km must be transferred onto the meridian line above or below the position of the stylus in each dial, so that the point may be found through which the horizontal line is to be drawn.

[Margin: [a] I.15 (Euclid). [b] I.26 (Euclid).]

Moreover, if the upper polar dial is inverted, so that what was above becomes below, and what lay to the right after that inversion becomes the left, and vice versa — as we wrote in the scholium of proposition 14 of this book — it will indicate the same hours on the opposite face of the plane, that is, on the lower face, which looks toward the nadir, as we demonstrated in that scholium. But the meridian line will then show the hour of 12 at midnight, whereas in the upper dial it indicates the hour of 12 at noon; and the remaining hours, which in that upper dial are numbered from noon, must be reckoned from midnight in the lower dial, and vice versa. For since the Sun must lie in one semicircle of the same hour-circle when the shadow of the stylus falls upon the upper dial, and in the other when it falls upon the lower — as is plain — it follows that the line which in the upper dial indicates an hour from noon shows in the lower dial the same hour from midnight, and vice versa; inasmuch as one semicircle pertains to the hours from noon and the other to the hours from midnight, as we taught in the scholium of proposition 9 of the preceding book.

[Margin: If all the parts of the upper polar dial are inverted, so that the upper becomes the lower and the right passes to the left, the lower dial will be produced; but the hours which before were reckoned from noon must be reckoned from midnight, and vice versa.]

The arc, too — that is, the parallel of the southern signs of the upper dial — is changed into the arc of the northern signs in the lower dial, and vice versa: as the parallel of Capricorn [♐] into the parallel of Cancer [♋], the parallel of Sagittarius

[♊, glyph worn — read by the equal-declination pairing with Gemini and Leo below] and of Aquarius [♒] into the parallel of Gemini [♊] and of Leo [♌], and so on. We shall show this just as, in proposition 26 of this book, we demonstrated the same thing for the meridian dial — with this one difference, that the axis of the hyperbolas here is the line of the twelfth hour and not of the sixth, as it was there. The same is clear from the analemma from which the arcs of the signs were described. For in it the radius of Capricorn [♐], drawn through the center E, cuts the meridian line ML near the horizon BD in the upper dial; while in the lower dial the radius of Cancer [♋], passing through the same center E, cuts the meridian line near the horizon, as is evident. The same must be said of the other southern and northern signs.

[Margin: The horizontal line cuts off the lower dial from the upper part of the upper dial, if all its parts are inverted, as was said above.]

Therefore the portion of the upper dial which the horizontal line cuts off, when placed on the lower face of the dial — so that the horizontal line occupies the upper place, yet below the stylus, and what is then the right-hand part is made the left, and vice versa — will give the lower polar dial, together with the arcs of the signs.

[Margin: The portion of the upper dial cut off by the horizontal line is the nocturnal dial.]

That same portion cut off in the upper dial will be a nocturnal dial, as was said above. For the shadow of the stylus would fall upon it in the morning before sunrise, and in the evening before sunset, while the Sun is in the southern signs — did not the density of the earth stand in the way.

[Margin: The greater the pole's elevation, the more hours are contained in the lower (or nocturnal) polar dial; the smaller it is, the fewer.]

It is furthermore evident that the greater the pole's elevation, the more hours are received in the lower dial — that is, in the portion cut off by the horizontal line — and the fewer, the smaller the pole's elevation. For the greater the pole's elevation, the smaller becomes the angle DBA (the complement of the pole's elevation), and hence the point D will be nearer to the equinoctial line, so that the horizontal line will cut across more hours, and so on. The same can also be shown from this: that the greater the pole's elevation, the more closely the circle of the sixth hour — to which the polar dial is parallel — approaches the vertical circle, and consequently for more hours the Sun will illuminate the northern

face, and so on. We have therefore described the parallels, or arcs of the signs of the Zodiac, in the said polar dial. Which was to be done.

PROBLEMA 39. PROPOS. 39.

To describe the parallels of the diurnal arcs on the same polar dial.

[Margin: The description of the diurnal arcs in the same polar dial.]

Just as the parallels of the signs are described on the dial, so also are the parallels of the diurnal arcs, since both the former and the latter are equidistant from the equator; provided only that, in place of the parallels described through the beginnings of the signs, the parallels of the diurnal arcs are taken, and so on. We have therefore described the parallels of the diurnal arcs on the same polar dial. Which was to be done.

PROBLEMA 40. PROPOS. 40.

To describe the vertical circles on the same polar dial.

On the dial, cut off from the equinoctial line a straight line AB equal to the stylus — such as the line that lies between the line of the twelfth hour and the line of the third or ninth hour, as we demonstrated in the scholium of proposition 25 of this book. At the point B construct the angle ABC equal to the pole's elevation, and let the line BC cut the meridian line below the equinoctial line at C in the upper dial, but above the equinoctial line in the lower dial. Then draw the line BD, which makes the angle ABD equal to the complement of the pole's elevation — or (what is the same) a right angle with the line BC — so that it cuts the meridian line at the point D, through which the horizontal line is drawn, as was shown in proposition 38 of this book. On the meridian line take DE equal to that BD, either above the horizontal line or below it. Then, from the center E, describe a circle of any size and divide it into 360 parts, or into fewer — since the dial does not admit all the vertical circles. (We divided it into 24 parts, so that each contains 15 degrees.) Through the points of division and the center E draw hidden lines cutting the horizontal line at various points; and through those points and through the point C draw further lines, which will give the vertical circles — that is, the common sections of the vertical circles and the plane of the dial. Their beginning is taken from the vertical line, which is drawn through C parallel to AB (or to the horizontal line), so that the meridian line gives the ninetieth vertical. All of which we shall demonstrate in this way.

[Margin: Demonstration of the description of the vertical circles on the polar dial.]

Let the triangle CBD, together with the line AB, be imagined to be rotated about CD until it stands perpendicular to the plane of the dial and is joined with the meridian, and until the point B becomes the same as the center of the world. Since, then, as we demonstrated in proposition 38 of this book, the horizon passes through the line BD (so that BD is the common section of the horizon and the meridian), and since the angle DBC is right — being composed of the pole's elevation and its complement — the line BC will be the common section of the vertical circle proper and the meridian, so that C is the zenith, or the vertex of the head. For since both the meridian and the vertical circle are perpendicular to the horizon, their common section — namely the axis of the horizon — will also be perpendicular to the horizon, and hence also to

Diagram. A construction of the vertical circles on a polar dial. A circle at the upper center carries the point E at its center, with S marked just below E and D lower still, on the vertical (meridian) line. The word HORIZON is lettered across the horizontal line ("HORI:" on the left, "ZON" on the right); the word VERTICALIS is lettered across a lower dashed line ("VERTI:" on the left, "CALIS" on the right). A dense fan of straight lines radiates from a lower convergence point C, representing the vertical circles; near that convergence, close to B, lie the small labels K, L, M. Degree graduations (15, 30, 45, 60, 75, 90) run symmetrically along the top near the horizontal line and along the bottom.

- E (center of upper circle): center of the divided circle
- S (below E): interior point [?]
- D (below S, on the vertical line): point where BD meets the plane of the dial
- HORI: ... ZON (across the horizontal line): the horizon line
- VERTI: ... CALIS (across the lower dashed line): the vertical circle proper
- B (just above C, at the fan's inner cluster): center of the world / stylus vertex
- C (lower convergence of all radiating lines): zenith
- K, L, M (small letters near B): interior points [?]
- ✚ marks at the far left and right ends of the dashed line: sign/tropic markers [?]
- "SI" (upper left and upper right) and "IS" (mid left and right) near the ends of the dashed curves: fragmentary labels, not resolved [?]
- degree numbers 15, 30, 45, 60, 75, 90 along top and bottom: graduation marks

the line BD, which lies in the horizon (by definition 3 of Euclid, Book 11), it will be perpendicular at the center of the world B. Therefore BC will be the axis of the horizon — that is, the common section of the meridian and of the vertical circle proper, and consequently also of all the other vertical circles. This can also be made clear from the fact that the angle ABC is equal to the pole's elevation, which is precisely the angle of inclination of the equator (passing through the line AB) to the vertical circle proper. Now let the circle described from E be conceived to be moved about the horizontal line until it coincides with the horizon, and hence until its center E is joined to the center of the world B — because of the equality of the lines DB, DE. This being posited, the lines proceeding from the center E through the points of division will be the common sections of the horizon and the vertical circles, because the horizon and the circle described from E are divided into similar parts, by what we demonstrated at the end of chapter 1 in the sphere. The vertical circles therefore meet the plane of the dial at those points of the horizontal line onto which the lines drawn from E fall. Accordingly, since the common sections of the vertical circles and the plane of the dial meet, by proposition 18 of the preceding book, at the point C — where indeed lies their common section of all, that is, where the axis of the horizon cuts the plane of the dial — the lines drawn from C through the points found on the horizontal line will be the common sections of the plane of the dial and the vertical circles. And the common section of the vertical circle proper and the plane of the dial must be drawn through C parallel to the equinoctial line and to the horizontal line. For since

the vertical circle proper, the horizon, the equator, and the circle of the sixth hour (to which the plane of the dial is parallel) have one common section, the common sections of the first three circles made upon the plane of the dial — namely the vertical line, the horizontal line, and the equinoctial line — will, by the scholium of proposition 22 of the preceding book, be parallel to one another.

The point C, moreover, will also be found in the following way. In the first figure of proposition 26 of this book, let the points n and o be marked, where the diameter of the vertical circle AC cuts the parallels LM, LM; and let the line kn or Ko be transferred onto the meridian line — in the upper dial below the position of the stylus, as far as C, but in the lower dial above the position of the stylus — always beginning from the position of the stylus A. For through C the vertical line proper must be drawn parallel to the equinoctial line, as before, because at the points n and o the vertical circle proper (which is drawn through AC) meets the plane of each dial (drawn through LM at the points n and o) — below the position of the stylus in the upper dial, but above it in the lower, and so on. And since the

line Kn is equal to the line Ko — for in the triangles EKn, EKo the angles at K are right, [a] and the angles at the vertex E are equal, and likewise the sides EK, EK are equal, [b] so the sides Kn, Ko will also be equal — for this reason we said that this same Kn or Ko must, in each dial, be transferred onto the meridian line below or above the position of the stylus.

[Margin: [a] I.15 (Euclid). [b] I.26 (Euclid). The portion of the upper dial cut off by the horizontal line, if its parts are inverted on the opposite face of the dial so that the horizontal line occupies the topmost place, gives the vertical circles on the lower dial.]

But if the portion cut off by the horizontal line is placed on the lower face of the plane — so that the horizontal line occupies the upper place, and what is then the right-hand part is made the left, and vice versa — we shall have the same vertical circles on the lower dial, as we demonstrated in the scholium of proposition 14 of this book. Indeed, here it is not even necessary that the right-hand part be made the left, since the vertical lines have the same position and the same numbers on both sides of the meridian line, as is plain. We have therefore described the vertical circles on the same polar dial. Which was to be done.

PROBLEMA 41. PROPOS. 41.

To describe the parallels of the horizon on the same polar dial.

[Margin: The description of the parallels of the horizon on the same polar dial.]

Let ABC be an analemma, in which the horizon is BC; the vertical circle AD; the axis of the world (or the common section of the circle of the sixth hour and the meridian) EF; and the equator GH. Divide the semicircle BAC into 180 equal parts, so that each contains a single degree — or into fewer, having regard to the size of the dial. (We divided it into 12 parts, so that each comprises 15 degrees.) Join by straight lines the pairs of points equally distant from the line BC (or from the point A); these lines will be the common sections of the meridian and of the parallels of the horizon, which they call almucantarath. Then, from the points of division through the center D, draw straight lines, so that triangles through the axis are constituted in the cones, whose bases are the parallels of the horizon (both below the horizon and above it) and whose vertex, or common center of the world, is D. For the meridian ABC, drawn through AD, the axis of the said cones, makes triangles through the axis, by proposition 3 of Book 1 of Apollonius. On the equator GH also — which stands in place of a vertical circle with respect to the circle of the sixth hour EF, as though of a certain horizon to which the dial is

parallel — take on each side a line DI equal to the stylus, and through I draw RQ parallel to EF. Below the center D this will be the common section of the meridian and of the plane of the upper dial (which looks toward the zenith A), but above the center D it will be the common section of the same meridian and of the plane of the lower dial (which pertains to the nadir). The line RQ will cut the sides of the triangles through the axis at the points K, L, M, N, O, and so on; and the diameters of the conic sections will be KQ, LQ, MQ, NQ, OQ.

Diagram. An analemma for describing the parallels of the horizon on a polar dial: a large circle crossed by several diameters and by a dense web of chords, with the center at D. The horizon BC is the horizontal diameter (B at the left, C at the right); the vertical circle AD runs from A at the top to the center D; the axis of the world EF is the diameter from E (upper right) to F (lower left); the equator GH is the diameter from G (upper left) to H (lower right). The circumference is graduated in 15° steps (15, 30, 45, 60, 75, 90) reading symmetrically from A at the top down to 90 at the bottom. Point R lies on the upper-right circumference and Q on the lower-left, RQ being drawn parallel to EF. A small circle surrounds the center D, within and around which lies a crowded cluster of the interior points named in the text.

- A (top of circle): pole toward the zenith / top of the vertical circle
- B (left end of horizontal diameter): horizon endpoint
- C (right end of horizontal diameter): horizon endpoint
- D (center): common center of the world
- E (upper right on circumference): endpoint of the axis of the world EF
- F (lower left on circumference): endpoint of the axis of the world EF
- G (upper left on circumference): endpoint of the equator GH
- H (lower right on circumference): endpoint of the equator GH
- R (upper right, inside the circumference): endpoint of line RQ
- Q (lower left, inside the circumference): endpoint of line RQ
- interior cluster K, L, M, N, O, P, S, T, V (near and around the central circle at D): the points where RQ (and TS/TQ) cut the sides of the triangles through the axis, and where the verticals cut the meridian line — individually crowded and not all separately resolvable [?]
- degree numbers 15, 30, 45, 60, 75, 90 around the circumference: graduation marks

Therefore, if the points K, L, M, N (we here omit the point O, since when transferred it falls outside the tropics) are transferred onto the meridian line of

the upper dial below the horizontal line — beginning in this figure from the point T of the horizon, but on the dial from the point D of the horizontal line — and if, by proposition 8 of the preceding book, the said conic sections are described about the meridian line, passing through the points K, L, M, N (these conic sections will be partly hyperbolas, partly ellipses, as is clear from propositions 6 and 7 of the preceding book; but the parallel of the horizon at 42 degrees will be a parabola, by proposition 5 of that same preceding book, since the circle of the sixth hour touches it at the pole E) — and if these curves recede ever farther from the horizontal line the farther they are extended on each side of the meridian line, then the parallels of the horizon will be described. On the lower dial, the line TS must be transferred onto the meridian line from the point D, below the horizontal line, and so on. For SQ is the diameter of the conic section of the parallel of the horizon at 15 degrees above the horizon in the lower dial. In the same way the remaining points below S, toward Q, would have to be transferred, if the sides of the triangles through the axis were cut by the line TQ. In the figure of the preceding proposition we described the parallel of the horizon at 15 degrees, in the portion which the horizontal line cuts off, because that supplies the place of the lower dial, as we said in that same proposition. It is therefore evident that the line EF is, as it were, the horizon, and GH, as though a vertical circle BC, is a kind of equator; and the parallels of the horizon are like parallels of this new equator BC. This being posited, the vertical circles will be like the hour-circles, all of which cut the meridian line of the dial at the point V, where AD, the axis of the horizon, also intersects it — the axis which we said now performs the office of a certain new equator. So that, if this exchange of circles is well considered, this description of the parallels of the horizon will not differ from the description of the parallels of the equator on the horizontal dial.

[Margin: Another way of describing the parallels of the horizon on the same polar dial.]

ANOTHER METHOD. Describe a quadrant ABC of any size, and divide it into 90 degrees — or into fewer parts, according to the number of parallels of the horizon to be drawn. From the centre A, draw straight lines through the points of division; these will correspond to the rays of the parallels of the horizon contained in the quadrant DC 90 of the preceding figure, beginning from the straight line AB, as the figure shows. Then, from the figure of the preceding proposition, take AD (on the line AC of the present figure) equal to the straight line BC; and on the straight line AB take AE equal to the straight line DB (or DE); and draw the straight line DE.

[Margin: [Euclid I.4]]

[Margin: [Euclid I.26]]

This triangle ADE will be exactly equal to the triangle CBD of the preceding proposition's figure, since the angles at A and B are right angles and are contained by equal sides, by the construction — so that DE is equal to the meridian line CD. The same triangle ADE will likewise be equal to the triangle DVT of the immediately preceding figure, since that triangle is equal to the aforesaid triangle CBD. For the angle IDV is equal to the angle ABC (each being the altitude of the pole), and the angle DIV is a right angle equal to the right angle BAC, and the sides DI and AB are equal to each other (since each is taken equal to the gnomon [stylo]); therefore the sides DV and VI will also be equal to the sides BA and CA. By the same reasoning the sides DT and TI will be equal to the sides BD and DA, and so on.

After this, from the figure of the preceding proposition, transfer all the intervals between the centre E and the points where the vertical lines cut the horizontal line into this figure, carrying them from A onto the straight line AB; mark the points on the line AB and write beside them the numbers of the vertical lines — for example 90 next to the point E, 75 at the next nearest, and so on. Finally, from D, through the points marked on AB, draw straight lines.

Diagram. A quadrant construction for laying out the parallels of the horizon on the polar dial. Across the top runs the horizontal base line carrying the points **A** (left), **D** (centre), and **C** (right, marked **90**). A quarter-circle arc descends from C. The centre of the construction is at A, and a fan of straight radii is drawn from the upper region down to the arc.

- A (top left): centre of the quadrant; left endpoint of the base line
- D (top, just right of centre): point from which the vertical/hour lines are drawn
- C (top right, labelled "90"): terminus of the base line at the 90° graduation of the arc
- E (interior, upper left): point on the descending line, with an adjacent vertical column of vertical-line numbers reading (top to bottom) 90, 75, 60, 45 [?] (the lower numbers of this column not separately resolvable [?])
- F (centre of figure): point on the meridian/vertical line
- B (lower left, on the arc): foot of the quadrant

- Degree graduations along the arc (from C downward): 90, 75, 60, 45, 30, 15 [the lower part of the arc carries a second, more crowded set of graduations — 90, 75, 60, 45, 30, 15 — not all separately resolvable [?]]
- Points I, V, T (named in the demonstration as vertices of the triangles DVT and DIV): present in the construction but not separately legible on the scan [?]
- A small cross/star ornament near the foot of the figure marks the convergence of the lower rays

[More than two labels flagged]

For the vertical line properly so called — from which the others take their beginning — one must draw through D a line DF parallel to AB; and the lines already drawn from the point D through the points of the line AB must also be carried over to the other side, so that one has vertical lines both beyond and on the near side of the vertical line properly so called — just as was done, in the horizontal dial, with the lines before and after the sixth hour, in proposition 2 of this book. For the lines drawn from D through the points of the line AB are the vertical lines beyond the vertical line properly so called, onto which the shadow of the gnomon is cast when the Sun is in the southern verticals; the others are the vertical lines on the near side of the vertical line properly so called, and so on.

Now, if the several intervals of the lines proceeding from D — those lying between D and the ray of, say, the parallel of the horizon at 15 degrees — are transferred from the point C of the figure of the preceding proposition onto pairs of vertical lines equally distant from the meridian line and corresponding to the numbers marked on the line AB of the present figure, marking points on those vertical lines (yet in such a way that the intervals of the lines from D that fall on AB are carried over from the Zenith C into the vertical lines of the dial above the vertical line properly so called, while the intervals of the lines from D that fall to the right of the line DF are transferred into the vertical lines below the line properly called vertical) — and if these points are fitly and neatly joined by a curved line, then the parallel of the horizon at 15 degrees will have been drawn. In the same way the remaining parallels of the horizon will be drawn.

[Margin: Demonstration of this latter way of describing the parallels of the horizon.]

The demonstration of this does not differ from the one we gave for the horizontal dial in the second method of describing the arcs of the signs. For here the horizontal line is, as it were, the line of the equator, and the vertical lines are like

the hour-lines, whose centre is the Zenith, namely the point C, and so on, as we said in the preceding analemma. Thus the line AB of this figure will correspond to the radius DC of the equator in the last figure of proposition 2 of this book, in which the rays of the signs are drawn; the straight lines drawn from A correspond to the rays of the other signs emitted from D in that figure; the straight line AD to the axis DH; the point D to the point H; and finally the vertical lines falling from D to the hour-lines drawn out from H.

The same will result if the intervals of the lines from D that run between the line AB — which, as we said, stands in place of the equator — and the lines emitted from A are transferred onto the corresponding vertical lines measured from the horizontal line of the dial, and so on, just as, in the horizontal dial, the intervals between the radius of the equator and the rays of the signs were carried over so that the arcs of the signs might be drawn.

For the lower polar dial, the rays of the parallels of the horizon must in this figure be drawn out from A to the left side of the line AB. Just as, in the figure of the rays of the Zodiac in proposition 2 of this book, the rays of the signs to the right of the radius of the equator belong to the southern signs (to be drawn below the equinoctial line) and the rays to the left belong to the northern signs (to be drawn above the equinoctial line), so here too the rays of the parallels of the horizon emitted from A to the right of the line AB — which stands in place of a kind of new radius of the equator, as has been said — belong to the parallels of the horizon to be drawn below the horizontal line (which is like a kind of new equinoctial line), as though they were southern signs; while the rays drawn to the left of the line AB belong to the parallels of the horizon to be drawn above the horizontal line of the dial, as though they were northern signs. Hence, since the portion of the dial above the horizontal line is equal to the lower dial, the rays of the parallels of the horizon drawn out from A to the left side of the line AB are rightly transferred into it, and so on — all of which appears in the figure of the preceding proposition.

[Margin: The parallels of the horizon above the horizontal line are described from their opposites drawn below the horizontal line.]

But the parallels of the horizon above the horizontal line in the lower dial will be more easily drawn from their opposites drawn in the upper dial, if — following the method we gave near the end of proposition 2 of this book — we first find the transverse diameters of the opposite sections and their centres, and so on. In the latter figure the transverse diameters are the portions of the straight line DE intercepted between the rays of the opposite parallels of the horizon that are

drawn out from A and equally distant from the line AB. We have therefore laid out the parallels of the horizon on the same polar dial. Which was to be done.

PROBLEM 42. PROPOSITION 42.

To describe the meridians — that is, the circles of longitude of cities — on the same polar dial.

The meridian circles will be drawn on the polar dial exactly as the hours are drawn from midday or from midnight, just as we taught in proposition 6 of this book — provided that the circle FGHI, by whose aid we drew the hour-lines, has the starting-point of its division at the meridian of the Fortunate Isles. This meridian is obtained if the longitude of the place is reckoned from the meridian of the place, namely from the point F toward G, in the westward direction, as the matter itself requires. This can be readily understood if the circle FGHI is imagined to be revolved about the equinoctial line until it coincides with the equator, and so on.

Diagram. The polar-dial figure for the meridians (circles of longitude). At the centre stands the circle **FGHI**, with **F** at the top, **G** at the left, **H** at the bottom, and **I** at the right; **E** marks its centre. A horizontal line runs across the whole figure, lettered **HO ... RIZON** (Horizon) — "HO" at the far left and "RIZON" at the far right. Within the upper part of the circle the meridian of the Fortunate Isles is written along a (dotted) curve as "**Insulæ Fortunatæ**" ("Fortunate Isles"). Straight rays radiate outward through the circle, and the horizon line and other transversals carry longitude graduations in degrees.

- F (top of circle): point where the meridian of the place meets the circle below the horizon in the inverted (lower) dial
- G (left, on the horizon line): the westward point of division
- E (centre of circle): centre of the construction
- I (right, on the horizon line): the eastward point of division
- H (bottom of circle): point where the meridian cuts the circle above the horizon in the lower dial
- Legible longitude/degree numbers around the circle and along the rays: 15, 90, 345, 115, 140 (or 146 [?]), 165, 195, 210, 240, 270, 320, 330 [additional values — including 300 [?], 285 [?], 326 [?], and a far-left figure near "HO" reading 562 [?] and a far-left edge value 111 — are present but not all separately resolvable [?]]

- A central horizontal band of narrow boxed cells carries a fine degree-graduation scale (readings on the order of 75, 60, 45, 30 [?]); the individual cells do not resolve cell-by-cell on the scan and are not transcribed here [?]

[More than two labels flagged]

For the meridians of the lower dial, the longitude of the place must be counted from the point H toward G, so that the meridian of the Fortunate Isles may be found. For if the lower dial is understood to be set in its proper position — so that the horizontal line occupies the top, and the circle FGHI is revolved about the equinoctial line until it coincides with the equator and its centre E coincides with the centre of the world — the meridian of the place will cut the said circle above the horizon at the point H, and below it at F. Thus from H toward G lie the western parts, and toward I the eastern parts. Let the rest be done as before. In the example you see the meridians of 140 and 150 degrees on one side, and of 285 and 295 degrees on the other, in the lower dial, which the portion cut off by the horizontal line supplies to us.

[Margin: The meridians, when produced beyond the horizontal line, make up the lower dial together with its meridians.]

Yet we shall obtain these same meridians of the lower dial more easily if we produce the meridians of the upper dial beyond the horizontal line and assign to them the numbers formed by adding 180 degrees to the numbers of the meridians of the upper dial — casting off 360 degrees, however, whenever the sum is greater than 360; that is, the numbers which, on the circle drawn about E, lie diametrically opposite the numbers written in the upper dial. For the portion cut off by the horizontal line will give, on the opposite face — namely the lower one — the meridian circles, if all its parts are inverted, as was demonstrated in the scholium to proposition 14 of this book. But the numbers of the lower dial are changed into the numbers of the semicircles opposite the semicircles of the upper dial, because the Sun is in one semicircle when the shadow falls on the lower dial, and in the other when it falls on the upper, as we taught in proposition 38 of this book. And so we have described the meridians — that is, the circles of longitude of cities — on the same polar dial. Which was to be done.

PROBLEM 43. PROPOSITION 43.

To lay out the parallels of cities — that is, the circles of latitude — on the same polar dial.

[Margin: The description of the parallels — or latitudes — of cities on the same polar dial.]

Take the parallels drawn through the zeniths of cities that lie within the tropics (for the Sun never reaches the parallels of the others), in place of the parallels passing through the signs of the Zodiac; and let everything else be done as we prescribed in proposition 38 of this book for describing the parallels of the signs of the Zodiac. Then what is proposed will be accomplished. We have therefore laid out the parallels of cities — that is, the circles of latitude — on the same polar dial. Which was to be done.

PROBLEM 44. PROPOSITION 44.

To describe the celestial houses on the same polar dial.

[Margin: The description of the celestial houses on the same polar dial, according to Johannes Regiomontanus.]

Suppose the circle drawn about E, which we used in describing the hours, is cut into 12 equal parts, beginning from the meridian line; and suppose that through the points of division and the centre E straight lines are drawn cutting the equinoctial line in points. Then the straight lines joining these points with the point D — at which the horizontal line cuts

[Margin: Demonstration of the description of the celestial houses according to Johannes Regiomontanus.]

the meridian line — will give the beginnings of the celestial houses, according to the method of Johannes Regiomontanus, as we demonstrated in proposition 20 of this book concerning the vertical dial. For here too the common section of all the circles of the celestial houses — that is, the axis of the vertical circle, or the common section of the meridian circle and the horizon — meets the plane of the dial at the point D, as is clear from the figure of proposition 38 of this book, in which this common section is the straight line BD, provided the triangle ABD is understood to be perpendicular to the plane of the dial.

Diagram. The polar-dial figure for the celestial houses. Two large circles are drawn one above the other and meet near the centre: the upper circle (centre E) and the lower circle (centre F). Three principal horizontal lines cross the figure — the upper labelled **HORI ... ZON** (Horizon), a second **HORI ... ZON** (Horizon) lower down, and the lowest labelled **VERTI ... CALIS** (Vertical). A fan of house-lines radiates through the figure and cuts these lines at the house cusps, which

are numbered in Roman numerals in the upper dial and in Arabic numerals in the lower dial.

- D (upper centre, on the upper horizon line): point where the horizontal line meets the meridian line; hub of the house-lines
- E (just below D): centre of the upper circle
- A (below E): point on the meridian/vertical axis
- B (lower centre, on the second horizon line): centre of the world
- C (below the vertical line): the Zenith
- F (centre of the lower circle): the Campanus centre onto which BC is transferred
- Upper-dial house cusps in Roman numerals: I and VII flank the upper horizon line; XI, X, IX cluster about the centre; XII and VIII lower down; I again at the second horizon line
- Lower-dial house cusps in Arabic numerals along the vertical line: 12, 11, 10, 9, 8 (arranged about the point A)
- Two worn astrological/zodiac symbols set on the diagonal rays at the top corners — one upper-left, one upper-right (mirror-imaged) — not securely identifiable on the scan [?]

[More than two labels flagged]

But according to Campanus's method we shall lay out these same celestial houses as follows. From the figure of proposition 40 of this book we take the straight line BC, by which we found the Zenith C, and transfer it onto the meridian line from the point C — whether upward or downward — as far as F. Then, having drawn a circle about F and divided it into 12 equal parts (beginning from the meridian line), we draw through the points of division and through the centre F hidden construction lines cutting the vertical line in points; these, joined by straight lines to D, will exhibit the celestial houses, as Campanus wishes. For if this circle is turned about the vertical line until it coincides with the vertical circle properly so called, and its centre F is joined with the centre of the world B, those hidden lines drawn through F will be the common sections of the circles of the celestial houses with the vertical circle; and consequently the circles of the celestial houses will meet the plane of the dial at the aforesaid points of the vertical line. Therefore the lines of the celestial houses will pass through these same points; and since they also pass through the point D, as has been said, the aforesaid lines connecting the points of the vertical line with D will be the lines of the celestial houses. We have therefore described the celestial houses on the same polar dial. Which was to be done.

[Margin: The description of the celestial houses on the same polar dial, according to Campanus.]

SCHOLIUM.

The lines of the celestial houses, produced beyond the horizontal line, will give these same celestial houses in the lower dial, if the dial is inverted, as has often been said and as was demonstrated in the scholium to proposition 14 of this book. But the celestial houses in the lower dial are of no use, except those that cut the tropic beyond the horizontal line — which is the more convenient the greater the elevation of the pole above the horizon, as is evident. In our example, which is constructed for latitude 42 degrees, no celestial house can be drawn entire in the lower dial, since none cuts the tropic beyond the horizontal line. Only parts of houses 12 and 7 — that is, lines drawn through the intermediate degrees of the said houses — can be drawn in the lower dial, especially through those degrees that are not far from the horizon.

[Margin: The celestial houses, produced beyond the horizontal line, give the same houses in the lower dial, if that portion of the dial cut off by the horizontal line is inverted in all its parts.]

LIBER SECVNDVS [Book Two]

PROBLEMA 45. PROPOS. 45.

To describe the ascending signs of the Zodiac on the same polar dial.

[Margin: The description of the ascending signs on the same polar dial.]

From the first two tables of proposition 9 of this book, take the hours at which the twelve signs of the Zodiac rise while the Sun is at the beginning of Aries [γ] and of Libra [♎]. These hours are laid out by means of the circle FGHI drawn about E; count them off from point F, either toward the east or toward the west, according as the tables give hours before or after midday. In the superior dial the hours before midday are always to be counted from F toward I, and the hours after midday from F toward G; but in the inferior dial the hours before midday are counted from H toward I, and those after midday from H toward G — as is quite clear, provided that in each dial the circle FGHI is understood to be set in its proper position. For if the circle FGHI is taken to lie in the plane of the Equator, with its centre E at the centre of the world and at the tip of the style, then in the

superior dial F will lie at midday and H at midnight, while in the inferior dial H will lie at midday and F at midnight.

Next, through the ends of these countings and through the centre E, draw hidden straight lines cutting the equinoctial line at the points of those hours; through these points the lines of the ascending signs are to be drawn. One must take care, however, not to take from the said tables the hours of those signs that rise six or more hours before or after midday, for these do not fall on the superior polar dial. And if the ascending signs are to be described on the inferior dial, one must take these very hours, and not the hours of those signs that rise six hours — or fewer — before or after midday.

After this, mark on the horizontal line the points through which the arcs of the signs are drawn. On those points contained in the antemeridian part — namely on the left in the superior dial, or on the right in the inferior — the shadows are projected when the following signs rise: in the superior dial Capricorn [♑], and Sagittarius [♐], Aquarius [♒], and Scorpio [♏], Pisces [♓]; but in the inferior dial Cancer [♋], and Gemini [♊], Leo [♌], and Taurus [♉], Virgo [♍]. But on the points marked in the pomeridian part — that is, on the right in the superior dial, or on the left in the inferior — are projected the shadows of the setting signs, whose opposites are then rising: in the superior dial these are Capricorn [♑], and Sagittarius [♐], Aquarius [♒], and Scorpio [♏], Pisces [♓] (for the shadows of these fall on those points when they set, while the opposite signs — Cancer [♋], and Gemini [♊], Leo [♌], and Taurus [♉], Virgo [♍] — are then rising). In the inferior dial, on the other hand, the shadows of these signs — Cancer [♋], and Gemini [♊], Leo [♌], and Taurus [♉], Virgo [♍] — fall on those points when they set, while the opposite signs — Capricorn [♑], and Sagittarius [♐], Aquarius [♒], and Scorpio [♏], Pisces [♓] — then ascend above the horizon. And so, if the points of the ascending signs on the horizontal line are joined by straight lines to the corresponding points found on the equinoctial line, the ascending signs will be described — as is plain from the demonstrations already given for the horizontal, vertical, and meridian dials.

[Margin: How the ascending signs Aries and Libra are described.]

[Margin: The finding of the points on the horizontal line — the line on which the shadow of the style falls — when the beginnings of the signs rise or set.]

Diagram. A large circle (the horizon circle) crossed by a vertical diameter running from F at the top through the centre to H at the bottom. Two outer vertical lines flank the circle, each labelled *meridiana* (the meridian line). Across

the horizontal diameter the word **HORIZON** is written, interrupted at the centre by the vertical line. Near the top, inside the circle, the points C (left), F₁ and B (on the vertical, just below F), and D (right) are joined to form a shallow butterfly/trapezoidal figure whose two triangles meet just above the centre, where a small dotted triangle (the style's shadow-cone) sits above the point A. From A a great many straight rays fan out to the left and right edges of the figure; their outer ends carry the twelve zodiac-sign labels (the ascending-sign lines). Where the horizontal diameter meets the circle, the left intersection is marked G and the right intersection I. Two slanting lines at the lower corners are labelled, on the left, *Hora 7 ante[meridiana]* (the 7th hour before midday) and, on the right, *Hora 5 po[meridiana]* (the 5th hour after midday) [?].

- F (top): apex of the vertical diameter
- H (bottom): foot of the vertical diameter
- B, F₁ (upper centre, on the vertical): vertices of the inner figure
- C (upper left), D (upper right): outer vertices of the inner figure
- A (centre): common point of the fanning rays, below the dotted shadow-triangle
- G (left, on the circle), I (right, on the circle): ends of the horizontal diameter
- Peripheral ray-labels: the twelve zodiac signs set at the outer ends of the rays, left and right, are small and worn on the scan and are not individually secured [?]

Now we shall describe the lines of Aries [♈] and Libra [♎] as follows. Since, when the beginning of Aries is rising above the horizon and the Sun is at the beginning of Capricorn [♐], it is midday — as is clear from table 4 of proposition 9 of this book — the ascending sign Aries must be drawn through that point of the tropic of Capricorn [♐] through which the meridian line passes. Now at that time the Equator, the circle of the 6th hour from midday or from midnight, the Ecliptic, the Horizon, and the vertical circle properly so called all share one and the same common section, from which the plane of the dial is equidistant (since it is parallel to the circle of the 6th hour). Therefore, by proposition 18 of the preceding book, there will lie parallel in the plane of the dial: the equinoctial line, the common section of the Ecliptic and the plane of the dial, the horizontal line, and the vertical line. Hence a straight line equidistant from the equinoctial line, drawn through the point at which the meridian line cuts the tropic of Capricorn [♐], will give the ascending sign Aries [♈]. In the same way, a straight line equidistant from the equinoctial line and passing through the point at which the meridian line cuts the tropic of Cancer [♋] will give the ascending sign Libra [♎].

[Margin: How the ascending signs Aries and Libra are described.]

[Margin: The finding of the points on the horizontal line — the line on which the shadow of the style falls — when the beginnings of the signs rise or set.]

If one prefers, we shall find those same points on the horizontal line — the points at which the Sun, occupying the beginnings of the signs, rises and sets — by this method too, even if the arcs of the signs have not been drawn on the dial. From table 5 of proposition 9 of this book we shall take the semidiurnal arcs of the southern signs for the superior dial, and count them off from F in each direction; but for the inferior dial we shall take the semidiurnal arcs of the [signs]

GNOMONICES

northern signs, and reckon these off from H in each direction. Then, from the ends of these reckonings, we shall draw hidden straight lines through the centre E, cutting the equinoctial line at points; and straight lines drawn perpendicular to the equinoctial line through those points will cut the horizontal line at the points we are seeking. For since in those hours the Sun rises and sets on the horizontal line, and the said perpendiculars are the lines of those hours — as is clear from what was demonstrated in proposition 37 of this book — it is evident that the proposed points have been correctly found.

Diagram. The same construction as on the previous page: a large horizon circle crossed by a vertical diameter from F (top) to H (bottom), flanked by two outer vertical lines each labelled *meridiana*. The word **HORIZON** runs across the horizontal diameter, broken at the centre by the vertical line. Near the top, the inner points C (left), F₁ and B (on the vertical below F), and D (right) form the shallow butterfly/trapezoidal figure; its triangles meet at the centre, where a small dotted triangle sits above the centre-point E, with A marked just below E. From the centre a dense fan of straight rays runs to the left and right edges, ending in the twelve zodiac-sign labels (the ascending-sign lines). The ends of the horizontal diameter on the circle are marked G (left) and I (right). Slanting lines at the lower corners are labelled *Hora 7 ante[meridiana]* (left) and *Hora 5 po[meridiana]* (right) [?].

- F (top), H (bottom): ends of the vertical diameter
- B, F₁ (upper centre): vertices of the inner figure
- C (upper left), D (upper right): outer vertices of the inner figure
- E (centre): centre of the circle, below the dotted shadow-triangle

- A (just below E): common point of the fanning rays
- G (left, on the circle), I (right, on the circle): ends of the horizontal diameter
- Peripheral ray-labels: the twelve zodiac signs at the outer ends of the rays, left and right, are small and worn and are not individually secured [?]

[Margin: Another way of finding the same points on the horizontal line, at which the beginnings of the signs rise or set.]

But the same points can be found in this way. From the last figure of proposition 21 of this book, take on ED a straight line Eg equal to the straight line BD in the figure of proposition 38 of this book — the line by which we described the horizontal line — and through g draw a perpendicular to ED. This will be the horizontal line in the superior dial, as is clear if the horizon ABCD of that figure is understood, in the superior dial, to be in its proper position: that is, so that point g coincides with D, and the perpendicular drawn through g becomes the very horizontal line, and consequently the centre E is joined with the centre of the world and with the tip of the style. Therefore the rays drawn from S, V, Y through E will, in that position, cut the straight line drawn perpendicular through g — that is, the horizontal line — at the points where the Sun rises when it is at the beginnings of the southern signs. And the rays from T, X, Z passing through E will cut the same horizontal line at the points where the Sun, when it is at the beginnings of the southern signs, sets. Therefore, if the intervals along the perpendicular through g that lie between g and the said rays are transferred onto the horizontal line of the superior dial, from point D in each direction, the proposed points will be found. Likewise we shall seek these same points in the inferior dial, if from EB of that same last figure of proposition 21 of this book a straight line equal to BD is cut off — as in the figure of proposition 38 of this book — and through its outermost point a perpendicular is drawn to EB, and so on.

[Margin: The method by which the points of the ascending signs are found on the tropics.]

But once the points on the equinoctial line have been found from the first two tables of proposition 9 of this book — the points through which the ascending signs are to be drawn — one can, by the same art, find from the third and fourth tables the points on the tropics through which those same ascending signs are to be produced: namely, if the hidden lines of the hours at which the signs rise are drawn — the hours which the aforesaid tables supply.

[Margin: How the ascending signs are described by the doctrine of Apollonius's *Conics*.]

One must, however, take care in the superior dial not to take the hours of those signs that rise six or more hours before or after midday, for hours of this kind do not fall on the superior dial. In the inferior dial, by contrast, one must take only the hours of those signs that rise more than six hours before or after midday, since these are the ones contained on that dial, as is evident. Indeed, the straight lines tangent to the tropics — drawn as we taught in the corollary to proposition 37 of book 1 of Apollonius — at the points found on the tropics, give the ascending signs, as is clear from what was demonstrated in proposition 9 of this book.

[Margin: The description of the ascending signs by the culminations of the heaven [mediationes coeli] and the angles of the earth.]

Otherwise we shall describe the ascending signs by this art. From the sixth table of proposition 9 of this book we shall take the declinations of the culminations of the heaven for the superior dial, and, for the inferior dial, the declinations of the angles of the earth; and, according to the doctrine of proposition 38 of this book, on the meridian line — that is, the line of the 12th hour, which in the inferior dial is the line of midnight — we shall investigate the points through which the parallels of those declinations are to be drawn. For if we connect these points, by straight lines, with the corresponding points already found on the horizontal line, the ascending signs will be described, as is clear from what has been said.

[Margin: Another description of the ascending signs, by the points of the Ecliptic lying on the circles of the 7th hour before midnight and the 5th hour after midday, when the beginnings of the signs rise above the horizon.]

They can also be described in yet another way — indeed most conveniently — thus. From the tenth table of proposition 9 of this book, take the declinations of all the points of the Ecliptic, both southern and northern, that lie on the circle of the 7th hour before midday; and, according to the doctrine of proposition 38 of this book, on the line of the 7th hour before midday seek the points through which the parallels of those declinations are to be drawn. Again, from the eleventh table of the same proposition 9 of this book, take the declinations of all the points of the Ecliptic lying on the circle of the fifth hour after midday; and likewise, by the doctrine of proposition 38 of this book, seek on the line of the fifth hour after midday the points through which the parallels of those declinations pass. For if these points are joined with the corresponding points found on the line of the 7th hour, one will obtain in the superior dial the ascending signs, by what we demonstrated for the horizontal dial in proposition 9

of this book — signs which necessarily [pass through the points already found on the]

LIBER SECVNDVS [Book Two]

horizontal line; indeed they will also pass through the points found on the meridian line by the culminations of the heaven. The ascending signs will be delineated in the inferior dial in just the same way, if from the aforesaid tables one takes the declinations of the points of the Ecliptic on the circles of the 7th hour after midday and the fifth hour before midday, and so on. But these points in the inferior dial are exactly the same as those in the superior; for the declinations are the same in either dial, as is clear from the tables.

[Margin: Another description of the ascending signs, from the doctrine of Apollonius's *Conics*.]

And if from the points found on the meridian line — which is the diameter of the hyperbolas — straight lines tangent to the tropics are drawn, according to the doctrine set out in the corollary to proposition 37 of book 1 of Apollonius, one will obtain the same ascending signs, as we showed in proposition 9 of this book. We have therefore described the ascending signs of the Zodiac on the same polar dial. Which was to be done.

SCHOLIVM.

[Margin: The description of these same ascending signs from the practice of Andreas Schöner.]

With Andreas Schöner [Andreas Schöner] we shall lay out the ascending signs thus. In the first figure of the scholium to proposition 9 of this book, on the straight line ED take a straight line Eb equal to the style of the dial, and through b draw a line parallel to AC, so that — the centre E of that figure being placed at the centre E of the circle FGHI on the dial, and the point b at point A — the parallel drawn through b coincides with the equinoctial line. Now this parallel drawn through b will cut the lines of the signs proceeding from E at points; and the intervals of these, taken from b and transferred onto the equinoctial line of the dial from point A (where the meridian line intersects the equinoctial line), will give on the equinoctial line the points through which — if straight lines are drawn to point D, at which the horizontal line cuts the meridian line — the tropics will be cut at the points through which the ascending signs are to be drawn. This, however, in the following order.

[Margin: The order of the ascending signs on the tropics.]

In the superior dial, and in the antemeridian part, which is on the left: the point on the tropic of Cancer [♋] farther from the meridian line belongs to the sign Leo [♌], the nearer to Virgo [♍], and the point on the meridian line itself to Libra [♎]. Next, in the pomeridian part, the point on the same tropic of Cancer [♋] nearer the meridian line belongs to Scorpio [♏], the farther to Sagittarius [♐]. Then, in the antemeridian part of the dial, the point of the tropic of Capricorn [♑], where it is cut by the horizontal line, is to be assigned to the sign Capricorn [♑], the next to Aquarius [♒], the one nearer the meridian to Pisces [♓], and the point on the meridian line itself to Aries [♈]; the next, in the pomeridian part, to Taurus [♉], the following to Gemini [♊], and the point on the horizontal line to Cancer [♋]. But in the inferior dial — since the tropic of Cancer [♋] becomes the tropic of Capricorn [♑], and the tropic of Capricorn [♑] becomes the tropic of Cancer [♋] — the point of the tropic of Cancer [♋] in the pomeridian part, where it cuts the horizontal line, is to be assigned to the sign Capricorn [♑], the next to Aquarius [♒], the next after that to Pisces [♓], and the point on the meridian line itself to Aries [♈]. Then the next, in the antemeridian part, to Taurus [♉], the following to Gemini [♊], and the point on the horizontal line to Cancer [♋]. But the point on the tropic of Capricorn [♑] in the pomeridian part, farther from the meridian line, will belong to Leo [♌], the nearer to Virgo [♍], the point on the meridian line itself to Libra [♎], the next in the antemeridian part to Scorpio [♏], and the following to Sagittarius [♐] — as appears in the figure.

[Margin: The order of the ascending signs on the equinoctial line.]

Again, in the second figure of the scholium to the same proposition 9 of this book, from the straight line ED cut off a straight line Eb equal to the gnomon, and through b draw a line parallel to AC, so that once more — the centre E of the said figure being placed at the centre E of the circle FGHI on the dial, and the point b at point A — the parallel drawn through b coincides with the equinoctial line. This parallel drawn through b will further cut the lines of the signs issuing from E — including those that lie above the line AC but are produced below the centre E — at points whose intervals, taken from b with the compasses and transferred onto the equinoctial line of the dial from point A, will give on the equinoctial line the points through which the ascending signs are to be drawn — in this order, however. In each dial, into the antemeridian part — that is, to the left in the superior dial and to the right in the inferior — are to be transferred the points above point b; and into the pomeridian part, the points below point b, counting also the signs that lie below the centre E and are produced beyond the centre E,

so that in the former part are Taurus [♉], Gemini [♊], Scorpio [♏], Cancer [♋], and Sagittarius [♐]; and in the latter, Leo [♌], Capricorn [♐], Virgo [♍], Aquarius [♑], and Pisces [♓]. When this has been done, if the points found on the tropics are joined with the corresponding points on the equinoctial line, the ascending signs will be delineated, as before. All of which is evident in the figure above. The lines of Aries [♈] and Libra [♎] are to be drawn parallel to the equinoctial line, through the points of the tropics at which they are divided by the meridian line, as was said above.

[Margin: The ascending signs, produced beyond the horizontal line, give the same signs in the inferior dial, if the parts are interchanged, as has often been said.]

Moreover, the lines of the ascending signs in the superior dial, produced beyond the horizontal line, will likewise give the same ascending signs in the inferior dial — provided, however, that the upper part is changed into the lower, and what is then on the right into the left; as is clear from what was demonstrated in the scholium to proposition 14 of this book.

PROBLEMA 46. PROPOS. 46.

To describe the Italian polar dial. [i.e. a polar dial marked with Italian hours]

[Margin: The description of the Italian polar dial.]

The often-mentioned circle FGHI is to be cut — as we taught in the scholium to proposition 1 of book 1 — into the diurnal and nocturnal arc of the tropic of Cancer [♋]; and let the diurnal arc be aFb, such that the straight line ab, the common section of the parallel and the horizon, is parallel to the equinoctial line. Then let the circle FGHI be divided into 24 equal hours, beginning from the western end of the diurnal arc, namely from point a. For if, from the points of division, hidden straight lines are drawn through the centre — lines which, by what was demonstrated in proposition 10 of this book, are the common sections of the Equator and of the great circles passing through the poles of the world and through the Italian hours of the parallel of Cancer [♋], after the manner of hour-circles reckoned from midday or midnight — then the equinoctial line will be cut at points through which perpendiculars to it, drawn out, will cut the tropic of Cancer [♋] at the Italian hours, that is, at the hours reckoned from sunset (since these perpendiculars are the hour-lines from sunset, the Sun being at the beginning of Cancer [♋]), just as if they were the common sections of the plane of the dial and of the great circles passing through the poles of the world and through the Italian hours on the tropic of Cancer [♋], as is clear from what was

demonstrated above. But if, through the centre of the circle FGHI, the straight line GI is drawn parallel to the equinoctial line, the hours in the arcs aG and bI (which in our example are 23, 10, and 9) will not fall on the plane of the superior dial, since the circle of the 6th hour from midday or midnight — the circle from which the plane of the dial is equidistant — is drawn along the straight line GI; as is clear if the circle FGHI is understood to be set in its proper position, so that its centre is the same as the centre of the world and the tip of the style. In the same way, if the straight line ab is transferred beyond the centre of the circle to de, so that dFe is the diurnal arc of Capricorn [♋], and the circle is again cut into 24 hours, beginning from point d — that is, from the western end — we shall find on the tropic of Capricorn [♋] the points of the Italian hours. Therefore, if the points of the Italian hours on the tropics that correspond to one another are joined by straight lines, they will be describ[ed]

In this way the Italian polar dial will have been described.

Now the Italian hours pass through the points of the hours from noon or midnight on the equinoctial line. Thus the 23rd Italian hour passes through the 5th from noon, the 22nd through the 4th, and so on, as is clear from the table of proposition 19 of the preceding book. Hence, if some Italian hours in one of the tropics have no corresponding points in the other tropic, those hours must be drawn through the hours from noon or midnight that correspond on the equinoctial line, as is gathered from the said table of proposition 19 of the preceding book. Thus you see that the Italian hours 13 and 14 are drawn through points found in the tropic of Cancer [♋], and through hours 7 and 8 from midnight on the equinoctial line, because in the tropic of Capricorn [♏] they have no points corresponding to those found in the tropic of Cancer [♋]. In the same way hour 23 is drawn through a point found in the tropic of Capricorn [♏], and through hour 5 from noon on the equinoctial line, and so for the rest.

The line of hour 12 from sunset must be drawn parallel to the equinoctial line, through the point found in the tropic of Cancer [♋]. For since the circles of hours 12 and 24 from sunrise or sunset have the same common section with the Equator (by proposition 16 of the preceding book), and likewise the same section with the circle of the 6th hour from noon or midnight (by proposition 17 of the same book), it follows that those two circles, the Equator, and the circle of the 6th hour from noon or midnight all have one and the same common section — namely the one through which the circle of the said 6th hour cuts the Equator. Since, then, the plane of the polar dial is equidistant from this circle, and so from the said common section of all of them, the sections of the remaining circles with

the plane of the dial — such as the lines of hours 12 and 24 from sunrise or sunset, and the equinoctial line — will (by proposition 18 of the preceding book) be parallel to one another. And this is to be understood of the superior dial. For the inferior dial it will be enough to derive it from the superior, as we shall teach in the following proposition.

Diagram. The construction figure of the Italian (and, by the following proposition, Babylonian) polar dial. A large circle carries the four cardinal points **F** (top), **G** (left, on the horizontal line), **I** (right, on the horizontal line), and **H** (bottom). The horizontal line running across the middle is labelled **HORI-** at the left and **ZON** at the right (i.e. "HORIZON," the horizontal line), and is the equinoctial line of the dial. A small point **f** stands just above **F** (the pole of the world). Within the circle two opposed hyperbola-like arcs (the diurnal arcs of the two tropics) meet in a dense cross-hatched web at the centre; their end-letters **d** (upper left) and **e** (upper right) mark the tropic of Capricorn arc, with **a/b** on the tropic of Cancer arc (**b** legible at centre-right). The central points **B** (centre-left), **b** (centre-right), and **K, L** (lower centre) lie in the cross-hatched region where the hour-lines converge, with **D** near the top of the inner web. Radiating hour-lines run out to the circumference and beyond (some dotted), each tipped with an hour-number.

- **F** (top of circle): **F** — meridian / noon point at top
- **f** (above **F**): **f** — pole of the world
- **G** (left, on horizontal line): **G**
- **I** (right, on horizontal line): **I**
- **H** (bottom of circle): **H**
- **d** (upper-left, inner): **d** (end of Capricorn diurnal arc)
- **e** (upper-right, inner): **e** (end of Capricorn diurnal arc)
- **b** (centre-right): **b** (end of Cancer diurnal arc)
- **B** (centre-left): **B**
- **D** (upper-centre of web): **D**
- **K, L** (lower centre): **K, L**
- Inner web hour-numbers (top row): 8, 9, 10, 11, 12, 1, 2, 3, 4, 5, 6 [several worn — ?]
- Inner web hour-numbers (lower row, near **K**): 9, 10, 11, 12, 1, 2, 3 [worn — ?]
- Left peripheral hour-ends: 24, 23, 14 [?], 12, 11, 8, 7 [worn — ?]

- Right peripheral hour-ends: 24, 10 [printed "01" — ?], 11, 23, 12, 22, 13 [worn — ?]
- Dotted diagonal rays tipped: s (upper right), s (lower right), 7/8 (upper left), 4 (lower right) [worn — ?]

[Many peripheral hour-numbers are worn/foxed and only partly legible]

[Margin: Another description of the Italian polar dial by means of the diurnal arcs of hours 14 and 10.]

When the points have also been marked on the lines of the hours from noon or midnight, according to the teaching of proposition 38 of this book — points through which are drawn parallels, one of hour 14 and the other of hour 10 — we shall, by means of these and of the tables we composed in the scholium to proposition 33 of the preceding book, describe the Italian dial, just as we set forth in the preceding dials.

[Margin: Yet another description of the same Italian polar dial by means of the diurnal and nocturnal arc of the 24 hours.]

Again, we shall most conveniently construct the same dial by means of two parallels — one of which is the greatest of the ever-apparent circles, that is, the diurnal arc of the 24 hours; the other the greatest of the ever-hidden circles, that is, the nocturnal arc of the 24 hours — if points are marked on the hours from noon and midnight through which they pass. For the hours from sunrise or sunset touch the said parallels (drawn on the plane of the dial) at the points through which the hours from noon or midnight are drawn — except hours 6 and 18, which do not coincide with the said hyperbolas, as is clear from the corollary of proposition 15 of the preceding book. Which hours from sunset touch the diurnal arc of the 24 hours, and which touch the nocturnal arc of the 24 hours, and at which hours from noon or midnight, the tables of the diurnal arc and of the nocturnal arc of the 24 hours in the scholium to proposition 33 of the preceding book indicate beautifully. For since the superior polar dial contains only hours 7, 8, 9, 10, 11, and 12 from midnight, and likewise 1, 2, 3, 4, and 5 from noon, from each table there must be taken the hours from sunset that correspond to the said hours, and no others. Thus from the table of the diurnal arc of the 24 hours these hours from sunset are to be taken: 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, and 17 — for these touch the said arc at hours 7, 8, 9, 10, 11, and 12 from midnight, and 1, 2, 3, 4, and 5 from noon. But from the table of the nocturnal arc of the 24 hours there are to be taken

these hours from sunset: 1, 2, 3, 4, 5, 19, 20, 21, 22, 23, and 24. For these touch the said arc at hours 1, 2, 3, 4, and 5 from noon, and at 7, 8, 9, 10, 11, and 12 from midnight, as is clear from the aforesaid tables.

Finally, we shall make the same Italian dial by means of the line of hour 12 from sunrise or sunset — as is clear from the second table of proposition 20 of the preceding book, whose title is *The Line of Hour XII from Sunrise or Sunset*.

Likewise by means of the line of hour 24 from sunrise or sunset — as is gathered from the first table of proposition 20 of the same preceding book, whose title is *The Line of Hour XXIV*, etc. — which is indeed entirely the same as the horizontal line, as is evident. Or also by means of both lines, if the points of the hours from noon or midnight, through which the Italian hours are to be drawn, are carefully noted in the aforesaid tables, and so on.

[Margin: Yet another description of the Italian polar dial by means of the line of hour 12 and the line of hour 24 from sunrise or sunset.]

[Margin: How the line of hour 12 from sunrise or sunset is to be drawn in the polar dial.]

Moreover, we shall describe the line of hour 12 from sunrise or sunset in this way. On the equinoctial line, from point A, where it intersects the meridian line, we shall take the straight line AB equal to the style — namely the straight line between the meridian line and the line of hour 3 or 9 from noon or midnight, for this is equal to the style, as we showed in the scholium to proposition 25 of this book. Then, from B, the end of that line, drawing a perpendicular Bf to the equinoctial line (such as the very line of hour 9 or 3, produced), we shall describe from the same point B as centre a circle, on which we shall take an arc fg equal to the altitude of the pole; and from g, through the centre B, we shall draw a straight line, which will cut the meridian line at point k. A line drawn through k parallel to the equinoctial line will be the line of hour 12 from sunrise or sunset. For let the circle fg be understood to be turned about the meridian line FH until it coincides with the meridian circle, and its centre B is joined with the centre of the world, that is, with the tip of the style. This done, f will be the pole of the world, and g the point at which the circle of hour 12 from sunrise or sunset touches the greatest of all the ever-apparent parallels and cuts the meridian — since this parallel is distant from the pole by as many degrees as are contained in the altitude of the pole. Therefore a straight line sent out from g through the centre of the circle fg will be the common section of the said circle of hour 12 and of the meridian; and so the circle of hour 12 will cut the plane of the dial at point K, where the said straight line breaks off the meridian line. Since, then, by the

scholium to proposition 22 of the preceding book the line of the said hour 12 and the equinoctial line are parallel, it clearly follows that a line drawn through point K parallel to the equinoctial line, cutting the meridian line, is the line of hour 12 from sunrise or sunset — which is what was proposed.

[Margin: Another description of the line of hour 12 from sunrise or sunset. — cited as [Elements I.15].]

[Margin: Yet another description of the line of hour 12 from sunrise or sunset. — cited as [Elements I.26].]

[Elements I.15] Now since the angle fBg of the pole's altitude is equal to the vertical angle KBL , it comes about that if on the equinoctial line we take a straight line equal to the gnomon, and at its end set up, toward the equinoctial line, the angle of the complement of the pole's altitude — that is, the angle left over from the right angle ABK — we shall find on the meridian line the same point K, through which the line of hour 12 from sunrise or sunset is to be drawn. Indeed, if we cut off from the straight line AD a part equal to AK , we shall have the same point K. For since the angle ABD is set equal to the complement of the pole's altitude (as is clear from proposition 38 of this book), and the angle ABK is likewise equal to the same complement (as we showed), the two angles ABD and ABK will be equal in the triangles ABD and ABK ; the angles at A are also equal, being right angles; and the side AB , adjacent to the said angles, is common. [Elements I.26] Therefore the sides AD and Ak will be equal. And so, since the line of hour 12 from sunrise or sunset passes through K (as we demonstrated), it is evident that, if a part AK equal to AD is taken, the said line of hour 12 must be drawn through K — which line at K touches the greatest of the ever-apparent parallels. And so we have described the Italian polar dial. Which was to be done.

PROBLEMA 47. PROPOS. 47.

To delineate the Babylonian polar dial.

[Margin: Description of the Babylonian polar dial.]

We shall describe this dial by almost the same reasoning as we used to delineate the Italian one — provided, however, that in the first method the division of the circle FGHI into 24 equal parts begins from the eastern end of the diurnal arc, of both the tropic of Cancer [♋] and the tropic of Capricorn [♎] — that is, at point b and at point e. But the line of hour 12 must be drawn parallel to the equinoctial line, through the point found in the tropic of Cancer [♋], as before.

In the second method there is no difference at all, provided only that in place of the hours from sunset mentioned in the preceding proposition the same hours from sunrise are taken, and so on. You have an example of the Babylonian dial in the figure of the preceding proposition, where the lines parallel to one another and perpendicular to the equinoctial line indicate the hours from noon or midnight, whose numbers are assigned to the diurnal arc of the 24 hours and to the nocturnal arc of the same number of hours. Next, the lines to which numbers are attached below the equinoctial line indicate the Italian hours. Finally, the lines to which numbers are attached above the equinoctial line are to be assigned to the Babylonian hours, that is, to those reckoned from sunrise. Thus we have delineated the Babylonian polar dial. Which was to be done.

SCHOLIVM.

[Margin: How the Italian polar dial differs from the Babylonian polar dial.]

From the figure of the preceding dial it is clear that the Babylonian dial differs from the Italian only in position and in the order of the hours, just as we explained in the case of the horizontal dial.

[Margin: For what reason the inferior polar dial, both the Italian and the Babylonian, has its origin from the superior.]

The inferior polar dial arises from the superior if the lines of all the hours are produced beyond the horizontal line, and the upper part is changed into the lower, and what is on the right after this change is turned into the left, as we showed in the scholium to proposition 14 of this book. Which hours in the inferior dial are to be numbered from sunset, and which from sunrise, we shall learn from what we wrote in the scholium to proposition 23 of this book.

It should also not be passed over here that, in the region where the pole's altitude is equal to the complement of the Sun's greatest declination — that is, 66 degrees 30 minutes — the two tropics serve as the two parallels, of which one is the greatest of the ever-apparent circles and the other the greatest of the ever-hidden. Hence the lines of the hours from sunrise or sunset will touch the two tropics at the hours from noon or midnight, both in the meridian dial and in the polar. But in the region where the pole's altitude is greater than 66 degrees 30 minutes, the two aforesaid parallels fall within the two tropics, so that the lines of the hours from sunrise or sunset touching those parallels

[Note (foot of page, full-width): In the latitude of a place of 66 degrees 30 minutes, the hours from sunrise and sunset touch the two tropics. But in a greater latitude

the hours from sunrise and sunset do not reach the tropics, but touch other parallels nearer to the equinoctial line, both in the meridian dial and in the polar.]

in no way reach the tropics themselves. For the shadow of the style cannot then show the hours elapsed from the Sun's rising or setting, since the Sun, being in the tropics, neither rises nor sets, but remains perpetually above the horizon, or below it.

PROBLEMA 48. PROPOS. 48.

To construct the antique polar dial. [i.e. a polar dial of the ancient unequal (planetary) hours]

[Margin: Description of the antique polar dial.]

Let the diurnal arc — both of the tropic of Cancer [♋], aFb, and of the tropic of Capricorn [♏], dFe — be cut, in the circle FGHI, into 12 equal parts. For from these we shall find, in each tropic, the points through which the unequal hours are to be drawn — no differently from the way in which, in the two preceding propositions, we investigated the points of the hours from the Sun's rising and setting in the same tropics. The unequal hours will necessarily pass through the points of the hours from noon or midnight on the equinoctial line, as we taught above in the case of the horizontal dial, proposition 12 of this book. It is certain, moreover — as appears from the attached figure — that hours 1 and 11 do not fall on the superior dial, since the Sun is at the beginning of Cancer [♋].

[Margin: Description of the antique polar dial by means of the diurnal arcs of 6 and 18 hours.]

By means also of two diurnal arcs drawn on the dial — one comprising 18 hours and the other six — we shall construct the same antique dial, as was done above in propositions 12, 24, and 36 of this book. This the attached figure plainly teaches. Thus we have constructed the antique polar dial. Which was to be done.

Diagram. The construction figure of the antique polar dial (dial of the unequal / planetary hours). A large circle carries the cardinal points **F** (top), **G** (left, on the horizontal line), **H** (bottom), and **I** (right, on the horizontal line). The horizontal line across the middle is labelled **HORI-** (left) and **ZON** (right), i.e. the horizontal / equinoctial line. From the top region (near F) a fan of dotted rays sweeps down to the lower centre — the lines of the unequal hours converging. The unequal-hour lines run out to the circumference and beyond, each tipped with a Roman-

numeral hour; the Arabic numerals along the top and middle mark the ordinary hour divisions.

- F (top of circle): F
- G (left, on horizontal line): G
- H (bottom of circle): H
- I (right, on horizontal line): I
- q (lower-left, near G): q
- h (centre-right): h [?]
- Roman-numeral hour-ends (upper left → left → lower left): IX, I, II, III
- Roman-numeral hour-ends (upper right → right → lower right): I, XII, XI, X
- Arabic hour-numbers along top (left to right): 7, 8, 6, 5, 4, 3 [order/values partly worn — ?]
- Arabic hour-numbers along middle row: 8, 9, 10, 11, 12, 1, 2, 3, 4, 5
- Small Roman numerals along the lower centre: IIII, V, VI, VII, VIII, IX

[Several peripheral hour-numbers are worn/foxed]

SCHOLIVM.

[Margin: How the inferior antique polar dial arises from the superior.]

Moreover, here too the lines of the unequal hours, produced beyond the horizontal line, exhibit the lines of the same hours in the inferior dial, provided only that the portion of the dial cut off by the horizontal line is inverted in all its parts, as was said and demonstrated in the scholium to proposition 14 of this book.

DE HOROLOGIIS ÆQVINOCTIALIBVS.

On Equinoctial Dials

PROBLEMA 49. PROPOS. 49.

To describe the astronomical equinoctial dial — that is, to lay out, on a plane equidistant from the equinoctial circle, the lines of the hours from noon or midnight.

[Margin: Description of the equinoctial astronomical dial.]

[Margin: How the equinoctial dial is to be placed so that it may show the hours.]

On some plane let a straight line AB be drawn in any way, to serve as the meridian line, or the line of hour 12; and let another straight line CD cut it at right angles at E. From E let a circle of any size be described and divided into 24 equal parts, beginning either from CD or from the straight line AB; and through the points of division, and through the centre E, let straight lines be drawn out. I say that these straight lines are the lines of the hours from noon or midnight on a plane equidistant from the Equator. So much so that if at E a style EF is set up — of any length, perpendicular to the plane of the dial — and the dial itself is so placed that CD is equidistant from the horizon, and AB is set in the plane of the meridian circle as the common section of the plane of the dial and of the meridian; and finally point A on the southern side (with point B inclining toward the north, C toward the east, and D toward the west) is raised according to the altitude of the Equator — that is, according to the complement of the pole's altitude — so that the angle which the straight line AB makes with the meridian line found in the plane of the horizon, toward the north (that is, toward B), is equal to the complement of the pole's altitude: then the shadow of the style will indicate the hours from noon or midnight on the superior dial, which of course faces the Zenith, and is lit by the Sun when it is in the northern signs, and is parallel to the Equator. But if on the opposite face of the dial thus raised the same lines are understood to be described, corresponding exactly to these lines of the superior dial, and the style EF is set up on it at right an-

angles, the shadow of the style will indicate the same hours on the inferior dial — the one, that is, which is lit by the Sun as it runs through the southern signs. And this will be proved by the following reasoning.

[Margin: Demonstration of the construction of the astronomical equinoctial dial.]

Since the point F, the tip of the style, is the same as the centre of the world (by proposition 2 of the preceding book), it follows that, if about the world's centre F we imagine the equinoctial circle — the circle from which the plane of the dial is equidistant — set in its proper position, then the style EF is the axis of the world. For the axis of the world stands perpendicular to the plane of the Equator at the centre of the world; and the style EF, which is perpendicular to the plane of the dial, is also perpendicular to the plane of the Equator, since (as we proved in the scholium to proposition 14 of Euclid's Book XI) these two planes are set parallel to each other. Therefore the style EF is entirely a portion of the world's axis.

Now the hour-circles reckoned from noon or from midnight always cut the greatest of the ever-visible parallels — and so, by proposition 10 of Theodosius's Book II, they cut the Equator, which is the greatest of all the parallels, and cut that

parallel of the sphere in which the plane of the dial lies (whose centre is E, since by proposition 10 of Theodosius's Book I the axis EF necessarily passes through its centre) — into 24 equal parts. All these hour-circles pass through the axis of the world, and hence through the point E, where (by proposition 18 of the preceding book) their common sections with the said parallel intersect one another.

Therefore the straight lines drawn out from E to the points of division of that parallel in which the dial lies are the common sections of the hour-circles reckoned from noon or midnight with the said parallel. Now since these straight lines also divide (from what we proved near the end of chapter 1 of *The Sphere*) the circle ACBD — which is concentric with that parallel of the sphere — into 24 equal parts, these same straight lines, drawn out through the centre E and through the points of division of the circle ACBD, are the common sections of the hour-circles reckoned from noon or midnight with the plane of the dial: that is, they are the hour-lines from noon or midnight. So that AB is the section of the meridian with the plane of the dial; the straight line drawn next through E, from the point after A toward D, is the common section of the plane of the dial with the circle of the first hour from noon or midnight; and so on. We have therefore described the astronomical equinoctial dial, and so forth. Which was to be done.

Diagram. A full circle, the astronomical equinoctial dial (circle ACBD), centred on E, with the tip of the style F set just above the centre. The circle is divided into 24 equal sectors by straight lines drawn through the centre E; these are the hour-lines. Four cardinal points are lettered around the rim.

- E (centre): the centre of the dial = the centre of the world, foot of the style.
- F (just above E): the tip of the style EF (identified with the world's centre in the text).
- A (top of rim): endpoint of the meridian line AB; the noon point, hour 12.
- B (bottom of rim): the opposite endpoint of AB; the midnight point, hour 12.
- C (left of rim): endpoint of the line CD; hour 6.
- D (right of rim): endpoint of the line CD; hour 6.
- Outer ring of hour-numbers. Near the top, flanking A: "II" (left) and "I" (right), with "12" set just below A. Down the right side: 2, 3, 4, 5, then "6" at D, then 7, 8, 9, 10, 11 toward the bottom. At the bottom, "12" at B. Up the left side from the bottom: 1, 2, 3, 4, 5, then "6" at C, then 7, 8, 9, 10, 11 toward the top.

[Several of the peripheral hour-numbers are lightly foxed/worn but legible; the two topmost are printed as Roman "II"/"I" where the rest of the ring uses Arabic digits — transcribed as printed.]

SCHOLIUM.

[Margin: How the same equinoctial dial is to be constructed on a fixed plane in which the place of the style is fixed.]

If the dial is to be described on some fixed plane equidistant from the Equator, and the place of the style — wherever it may be — is given at the point E, then with the help of a level and a plumb-line one must draw through E the straight line CD, equidistant from the horizon, which the straight line AB cuts at right angles in E. For this AB will be the meridian line. Everything else is to be carried out as before.

PROBLEMA 50. PROPOS. 50.

To lay out the parallels — that is, the arcs of the signs of the Zodiac — on the aforesaid equinoctial dial.

[Margin: Another way of describing the arcs of the signs on the same equinoctial dial, from the analemma.]

Take again the first figure of proposition 26 of this book, in which, on the axis EG, the straight line Ea is cut off equal to a style of any assumed size, and through a line is drawn parallel to HI, the diameter of the Equator; this line will be the common section of the plane of the dial with the meridian, since the plane of the dial, drawn through that parallel, is equidistant from the plane of the Equator (drawn through the straight line HI) by the length of the style Ea. Now let the diameters of the Zodiac that join opposite signs be produced, so as to make triangles through the axis in the cones, whose bases are parallels of the Equator and whose common vertex is the centre E. The parallel portions drawn through a, intercepted between the sides of these triangles, are the diameters of the conic sections — which, by the corollary to proposition 4 of the preceding book, are circles having their centres at the point E in the dial, that is, on the axis of the world, by the same proposition 4 of the preceding book. Therefore, if from a the half-diameters are taken as far as the sides of the triangles through the axis, and with these intervals circles are described from E, the centre of the dial, the parallels of the northern signs of the Zodiac will be described on the superior dial — since the radii of the northern signs fall, when produced, on that parallel through the centre E. And if on the axis EF one takes again the straight line Ee equal to the style, and does the same, the parallels of the southern signs of the Zodiac will be described in the same way on the inferior dial, since the radii of the southern signs fall on the parallel drawn through e when they are extended

through the centre E. But it is enough if circles are described in the inferior dial with the same half-diameters taken from a. For the half-diameters contained in the parallel drawn through a are equal to the corresponding half-diameters contained in the parallel drawn through e. For example, in the triangles Eab and Eeg, the angles at the points a and e are right,

and the alternate angles b and g are equal, on account of the parallel lines drawn through a and through e; and the sides Ea, Ee are equal; therefore the sides ab and eg are also equal — namely the half-diameters of the conic sections; and the demonstration is the same in the remaining cases.

[Margin: a. Elements I.29. b. Elements I.26.] [Margin: Another description of the arcs of the signs on the same equinoctial dial.] [Margin: Demonstration of this latter description of the parallels of the Sun's signs.] [Margin: c. Elements I.26.] [Margin: It is enough, in the latter method, if just the single parallel hl, or qn, is drawn.]

We shall describe these same parallels from the last figure of proposition 26 of this book, in the following way. On the axis DG let the straight lines Dh and Dq be cut off on either side, equal to the style, and through h and q let hl and qn be drawn parallel to DC, the radius of the Equator. The straight lines intercepted between the points h, q and the radii of the signs are equal to the half-diameters of the conic sections found earlier. For example, in the triangles Eab, Dhm, and Dqo — the first of which is contained in the earlier figure, the latter two in the later one — the angles at the points a, h, q are right, and the angles aEb, hDm, qDo are equal, since each of them is equal to the complement of the declination of the parallel taken, as is clear; and the sides Ea, Dh, Dq are equal by construction; therefore the sides ab, hm, qo are also equal. From which it appears that it is enough to draw a single parallel — namely either hl or qn — in order to find the half-diameters of the circles, or of the conic sections,

Diagram. The equinoctial dial shown together with the horizon and the parallels of the zodiacal signs. As in the previous figure, the outer circle (ACBD) is centred on E, with the point F just above the centre and the rim divided into 24 hour-sectors; the same cardinal letters appear — A at the top (12), B at the bottom (12), C at the left (6), D at the right (6). A horizontal straight line runs across the figure through the centre E and is lettered as the word **HORIZON** (split "HORI ... ZON" to left and right of the centre): this is the horizon line. Within the outer circle are drawn several concentric circles — the parallels of the zodiacal signs (declination circles) — each carrying a zodiac-sign glyph where the sign's parallel is marked, arranged symmetrically about the vertical and about the horizon line.

- A (top): meridian endpoint, hour 12.
- B (bottom): meridian endpoint, hour 12.
- C (left, on the horizon line): hour 6.
- D (right, on the horizon line): hour 6.
- E (centre); F (just above centre, on the meridian).
- Outer hour-ring, as in the previous figure: II / 12(A) / I across the top; 2, 3, 4, 5, 6(D) down the right; 12(B) at the bottom; 1, 2, 3, 4, 5, 6(C) up the left; 7, 8, 9, 10, 11 completing each side.
- Zodiac-sign glyphs on the inner parallels (legibility mixed): clearly read are ♊ [Pisces], ♒ [Aquarius], ♍ [Virgo], ♋ [Cancer], ♊ [Gemini], ♌ [Leo], ♉ [Taurus], ♏ [Scorpio]; several further glyphs around the ring are worn/foxed and could not be resolved [?].

[More than two zodiac glyphs on this figure are unresolved]

[Margin: The equinoctial line cannot be drawn on an equinoctial dial.] [Margin: What is to be done so that the shadow may indicate the hours near the time of the equinoxes.]

—on both dials. For since it has been shown that the half-diameters of each parallel are equal to the half-diameters of the parallel drawn through a in the earlier figure, these too will be equal to one another. Now it is plain, from the scholium to proposition 11 of the preceding book, that the equinoctial line cannot be drawn on an equinoctial dial, but vanishes entirely, because the Equator is equidistant from the plane of each equinoctial dial. But if one wishes to observe the hours near the time of the equinoxes — that is, before or after the equinoxes — the hour-lines must be produced beyond the outermost circle, the circle which on the superior dial is assigned to the signs Taurus [♉] and Virgo [♍], and on the inferior dial to the signs Scorpio [♏, glyph worn — the sign opposite Taurus] and Pisces [♊]; they must be produced, I say, as far as the size of the plane on which the dial is described will allow. Or else a circle of some degree of the Ecliptic near the equinoctial circle must be described — for instance on the superior dial the 25th degree of Virgo [♍] and the 5th degree of Aries [♈], and on the inferior dial the 25th degree of Pisces [♊] and the 5th degree of Libra [♎], and so forth — because around the times of the equinoxes the shadow of the style is made very long, and at the equinoxes themselves it becomes infinite and equidistant from the plane of the dial, as is clear from what was said in the scholium to proposition 11 of the preceding book. The same is to be understood of the hours reckoned from sunrise and sunset, which we shall treat in propositions 58 and 59 of this book.

[Margin: In what way the horizontal line is to be described on an equinoctial dial.]

The horizontal line — onto which the shadow of the style is cast at sunrise or sunset — is described thus. In the first figure of proposition 26 of this book let the points h and i be marked, where BD, the diameter of the horizon, cuts the parallels drawn through a and through e; and let the straight line ah, or ei, be transferred onto the meridian line of the superior dial above the place of the style, from E, as far as m — but below the place of the style in the inferior dial — and through m let a line be drawn parallel to the line of the sixth hour. This will be the horizontal line. For since the horizon, drawn through BD, meets the plane of the superior dial (drawn through ah, the meridian line, at the point h) and meets the plane of the inferior dial (drawn through ei, the meridian line, at the point i), it is plain that, if we transfer the straight line ah from the place of the style in the superior dial onto the meridian line above the place of the style, as far as the point m, then the horizontal line passes through m — because in the superior dial, at the point h, the common sections of the horizon and of the meridian, made by the plane of the dial cutting them, come together, by proposition 18 of the preceding book, seeing that the common section of the horizon and the meridian (that is, the straight line BD) meets the plane of the superior dial at h; and sections of this kind are the horizontal line and the meridian line. And since the horizon, the circle of the sixth hour from noon or midnight, and the Equator all have one and the same common section, from which the plane of the dial is equidistant (being equidistant from the Equator, in which that common section lies), the common sections of the remaining circles with the plane of the dial will be parallel — namely the horizontal line and the line of the sixth hour — by proposition 18, or by the scholium to proposition 22 of the preceding book. There-

—fore the straight line drawn through m, parallel to the line of the sixth hour, is the horizontal line — that is, the common section of the horizon and the plane of the dial. In the same way, if we transfer the straight line ei onto the meridian line of the inferior dial below the place of the gnomon, we shall have the point through which the horizontal line is to be drawn. But since the straight line ei is equal to the straight line ah — for in the triangles Eah and Eei the angles at a and e are right, the vertical angles at E are equal, and the sides Ea, Ee are equal, so that the sides ah, ei are also equal — for this reason we directed that the same line ah, or ei, be transferred in each dial onto the meridian line above or below the place of the style.

[Margin: a. Elements I.15. b. Elements I.26.] [Margin: Another description of the horizontal line on the equinoctial dial.]

The same point *m*, through which the horizontal line — parallel to the line of the sixth hour — is to be drawn, will be found by this device. On the line of the sixth hour of the dial take *El* equal to the style, and make the angle *Elm* equal to the altitude of the pole, so that the straight line *lm*, cutting the meridian line at *m*, falls upward in the superior dial but downward in the inferior. This will readily be done if from *l* an arc of a circle is described — either above the straight line *CD* or below it, toward the meridian line — and on it, starting from the line *CD*, the arc of the pole's altitude is measured off; then from the extreme point of that arc a straight line is drawn to *l*, cutting the meridian line at the point *m*. For through the point *m* the horizontal line is to be drawn, as before. For imagine the triangle *Elm* turned about the meridian line until it stands perpendicular to the plane of the dial and lies in the plane of the meridian, so that the point *l* is joined with the tip of the style — that is, the centre of the world — and the straight line *El* coincides with the style, the axis of the world. Then the horizon will pass through *l*, the tip of the style, and hence through the straight line *lm* — because the angle *Elm* is equal to the altitude of the pole, which is exactly the angle that the common section of the horizon and the meridian makes with the axis at the centre of the world *l*. Moreover, the remaining angle *Eml* is equal to the complement of the pole's altitude — exactly the angle that the horizon makes with the Equator in the plane of the meridian circle; and this angle is equal to the angle that the horizon makes with the plane of the dial (which is parallel to the Equator) in the same plane of the meridian. For since the sections which the meridian makes with the Equator and with the plane of the dial parallel to it are parallel, the common section of the horizon and the meridian will make equal angles with the said sections — one of which is the meridian line in the Equator, the other in the plane of the dial, the outer one and the inner one, that is. Therefore the horizon will cut the plane of the dial at *m*; and so the horizontal line is to be drawn through *m*. We have therefore laid out the parallels — that is, the arcs of the signs of the Zodiac — on the aforesaid equinoctial dial. Which was to be done.

[Margin: c. Elements I.16, from which. d. Elements I.29.]

SCHOLIUM.

[Margin: How the portion of the equinoctial dial cut off by the horizontal line makes the inferior dial.]

The portion of the dial which the horizontal line cuts off will itself be the inferior dial, if everything is inverted — as was done in what precedes — that is, if the horizontal line takes the upper place on the lower face of the plane, and the part which in that position is on the right is turned to the left, as we showed in the scholium to proposition 14 of this book. But the arcs of the northern signs are changed into the arcs of the opposite southern signs, because the shadow of the style falls on the inferior dial when the Sun is in the southern signs, as is evident.

[Margin: The same portion cut off in the superior dial is the nocturnal dial.]

The portion cut off by the horizontal line also gives us the nocturnal dial, as was said in what precedes.

[Margin: The arcs of the signs on the equinoctial dial are divided into equal parts by the hour-lines from noon or midnight.]

Now since, as we showed in the preceding proposition, the hour-circles from noon or midnight divide any circle whatever described from the centre E (for the same demonstration that fits the circle ACBD described there fits every circle) into equal parts, it follows that on the equinoctial dial the lines of these same hours cut the parallels of the signs into equal parts, since these are circles described from the same centre E, as has been proved in this proposition. This happens on no other dial. For on the other dials the hour-lines from noon or midnight intercept unequal spaces on the parallels of the signs there described.

[Margin: Description of the arcs of the signs on the same equinoctial dial.]

PROBLEMA 51. PROPOS. 51.

To describe the parallels of the diurnal arcs on the same equinoctial dial.

[Margin: The diurnal arcs on the equinoctial dial are divided into equal parts by the hour-lines from noon or midnight.]

If, in place of the parallels drawn through the beginnings of the signs, one takes the parallels of the diurnal arcs, and for the radii of the signs the radii of the diurnal arcs, then the parallels of the diurnal arcs will be described on the equinoctial dial in just the way we described the parallels of the signs in the preceding proposition. We have therefore described the parallels of the diurnal arcs on the same equinoctial dial. Which was to be done.

PROBLEMA 52. PROPOS. 52.

To lay out the vertical circles on the same equinoctial dial.

[Margin: How the vertical circles are described on the same dial.]

In the first figure of proposition 26 of this book let the points n and o be marked, where AC , the diameter of the vertical, cuts the parallels drawn through a and through e ; and let the straight line an , or eo , be transferred onto the meridian line from the place of the style — downward in the superior dial, but upward in the inferior — as far as p . The point p will be the vertical point, onto which the axis of the horizon falls, since AC , the axis of the horizon (or diameter of the vertical), cuts the plane of each dial through the parallels an , eo drawn at the points n and o — below the place of the style E in the superior dial, but above it in the inferior. And since the straight line an is equal to the straight line eo — for in the triangles Ean and Eeo the angles at a and o are right, the angles at the vertex E are equal, and the sides Ea , Ee are equal, so that the sides an , eo are also equal — for this reason we directed that the same line an , or eo , be transferred in each dial onto the meridian line below or above the place of the style.

[Margin: e. Elements I.15. f. Elements I.26.]

We shall also find this vertical point p by the following device. From E , the place of the style, let the perpendicular EF be drawn to the meridian line, equal to the style, and at the point F let the angle EFp be made equal to the complement of the pole's altitude, so that the straight line Fp cuts the meridian line at the point p — below the place of the style in the superior dial, but above it in the inferior. I say that p is the vertical point. For imagine the triangle EFp turned about the straight line Ep until it stands perpendicular to the plane of the dial, and hence lies in the plane of the meridian, so that the point F is joined with the tip of the style, the centre of the world, and the straight line EF itself coincides with the style, the axis of the world.

The vertical circle properly so called will pass through the tip of the style — that is, through F , the centre of the world — and therefore along the straight line Fp . This is because the vertical circle makes, with the axis of the world in the plane of the meridian, an angle equal to the complement of the pole's altitude, namely the angle EFp ; and with the meridian line in the equator it makes an angle equal to the pole's altitude, as is evident. That latter angle is equal to the angle the same vertical circle makes with the meridian line of the dial-plane parallel to the equator, namely the angle EpF . [a] For the sections that the meridian makes with

the equator and with the dial-plane parallel to it are themselves parallel; and therefore[b] the common section of the vertical and the meridian makes equal angles with the said meridian lines — the external, that is, and the internal. For this reason the vertical circle properly so called will cut the dial-plane at p.

[Margin: a. Elements XI.16. b. Elements I.29.]

After this, draw the straight line Fm making the angle EFm equal to the pole's altitude, so that it cuts the meridian line at the point m — by means of which we showed, near the end of proposition 50 of this book, how the horizontal line is to be drawn. On the meridian line take me equal to Fm, whether below the horizontal line or above it. Then from e as centre describe a circle of any size and divide it into 360 degrees, or into fewer parts if the size of the dial demands (we divided it into 24, so that each part contains 15 degrees). Through the points of division and through the centre e draw hidden straight lines cutting the horizontal line at various points. Through these points, together with the vertical point p, the straight lines drawn out will give the vertical circles — that is, the common sections of the dial-plane and the vertical circles. In either dial their starting-point is taken from the vertical line, which is drawn through p parallel to the horizontal line and to the six-o'clock line, so that the meridian line yields the ninetieth vertical.

[Margin: Demonstration of the description of the vertical circles.]

Here is the demonstration of this. Imagine the circle described from e, about the horizontal line, to be turned until it coincides with the horizon; its centre e then coincides with F, the centre of the world, on account of the equality of the straight lines Fm and me. The straight lines going out from the centre e through the points of division of the circle will be the common sections of the horizon and the vertical circles, because the horizon and the circle described from e as centre of the world — or of the horizon — are divided into like parts by the straight lines going out from the centre, as we demonstrated at the end of chapter 1 in the section on the sphere. And it is certain that the horizon, whose centre is then the point F (or e), is divided into equal parts by the vertical circles by means of the straight lines sent out from the centre. The vertical circles will therefore meet the dial-plane at those points of the horizontal line onto which fall those hidden straight lines sent out from e. And since, by proposition 18 of the preceding book, the common sections of the vertical circles and of the dial-plane meet at the point p — where the common section of them all, namely the axis of the horizon, meets the dial-plane — the straight lines drawn through p and through the points found on the horizontal line will be the common sections of the dial-plane and the

vertical circles. Only the common section of the dial-plane and the vertical circle properly so called must be drawn through p parallel to the horizontal line and to the six-o'clock line. For since the vertical circle properly so called, the horizon, the six-o'clock circle, and the equator (to which the dial-plane is parallel) have one and the same common section, then by proposition 18 — or by the scholium to proposition 22 of the preceding book — the common sections of these first three circles and of the dial-plane, namely the vertical line, the horizontal line, and the six-o'clock line, are parallel to one another. And so we have laid out the vertical circles on the same equinoctial dial. Which was to be done.

[Margin: How the inferior dial, with its vertical circles, arises from the superior equinoctial dial.]

Diagram. A large circular horizontal-projection figure showing the vertical circles laid out on the equinoctial dial. The bounding circle is crossed by a full pencil of straight lines radiating from the centre (the vertical circles), and by concentric circles carrying degree graduations. The horizontal diameter is the horizon line, labelled across the figure as **HORIZON** (printed "HOR" at the left margin of the circle, "IZON" at the right), with "15" flanking each end. Degree numbers are engraved in the arcs at 15° intervals — 15, 30, 45, 60, 75 — running up to 90 at the centre; several are set inverted (bottom half) or sideways in the usual dial fashion.

- Horizon line: labelled **HORIZON** (HOR ... IZON), running left–right through the centre
- Central vertical (meridian) line, top to bottom: **A** (top), **e** (centre of the projection), **L**, and lower down the cluster **F**, **M**, **N**, **E**, **p** (the vertical point), down to **q** at the foot
- Degree graduations along the horizon and vertical circles: **15, 30, 45, 60, 75** (both halves), with the centre marking **90**
- Around the rim, zodiac-sign sorts mark the divisions; Pisces (♊) is legible at the left, the remaining rim glyphs are worn/rotated — [?]
- Four cross-shaped ornaments (✚) mark the cardinal/inter-cardinal points of the rim

SCHOLIUM.

If the portion of the dial cut off by the horizontal line is placed on the lower face of the plane, so that the horizontal line occupies the upper position, and the part which in that arrangement lies on the right is changed to the left, we shall have the same vertical circles on the inferior dial,

as we demonstrated in the scholium to proposition 14 of this book. But since the vertical lines keep the same position and distance on both sides of the meridian, it will not be necessary to change the right part into the left, or the reverse.

PROBLEMA 53. PROPOS. 53.

To draw the parallels of the horizon on the same equinoctial dial.

[Margin: By what method the parallels of the horizon are described on the same equinoctial dial.]

Let ABC be the analemma, in which BC is the horizon, AD the vertical, EF the axis of the world, and GH the equator. Divide the semicircle BAC into 180 degrees — or into fewer equal parts, as the size of the dial allows (we divided it into 12, so that each part takes in 15 degrees). Join, by straight lines, pairs of points equally distant from the straight line BC (or from the point A); these lines will be the common sections of the meridian and of the parallels of the horizon, which they call almucantars. Then from the points of division draw straight lines through the centre D, so that triangles through the axis are formed in the cones, whose bases are the parallels of the horizon — as much below the horizon as above it — while their common vertex is D, the centre of the world. For the meridian ABC, passing through the axis AD of the said cones, makes triangles through the axis, by proposition 3 of Apollonius, Book 1. On the axis EF also take, on each side, the straight line DI equal to the gnomon, and through I draw KL parallel on both sides to the equator GH. Below GH this line KL will be the common section of the meridian and of the plane of the superior dial; above GH it will be the common section of the meridian and of the plane of the inferior dial. Each straight line KL will cut the sides of the triangles through the axis at the points M, N, O, P, Q, R, and these will be the diameters of the conic sections ML, NL, OL, PL, QR.

If, then, the points M, N, O, P (we here omit the point Q, since the conic section drawn through it falls beyond the tropics) are transferred onto the meridian line below the horizontal line — in the superior dial beginning in this figure from S, the point of the horizon, but in the dial itself from m, the point of the horizontal line — and if, by proposition 8 of the preceding book, the said conic sections are described about the meridian line, passing through the points M, N, O, P (which conic sections will be partly hyperbolas and partly ellipses, as is established from propositions 6 and 7 of the preceding book; the parallel of the horizon at 48 degrees will be a parabola, by proposition 5 of the same preceding book, because the equator touches it at the point G), then — receding ever farther from the horizontal line the farther they are produced on either side of the meridian line

— the parallels of the horizon will have been described. In the inferior dial the straight lines ST, SV are to be transferred onto the meridian line from the point m, below the horizontal line, and so forth. For TL is the diameter of the conic section of the parallel of the horizon 15 degrees above the horizon, and VL the diameter of the conic section of the parallel of the horizon 30 degrees, and so on.

GH, then, serves as it were as a horizon, and EF as a vertical; BC serves as a kind of equator, and the parallels of the horizon as the parallels of a new equator BC. On these terms, the vertical circles will serve as hour-circles, all of which cut the meridian line of the dial at the point X, where AD, the axis of the horizon, also cuts it — the axis which we have just said performs the office of a kind of new equator. So that, if this interchange of the circles is properly considered, this description of the parallels of the horizon does not differ from the description of the parallels of the equator on a horizontal dial.

[Margin: Another description of the parallels of the horizon on the same equinoctial dial.]

Diagram. The analemma ABC drawn as a full circle, densely ruled with chords and radial lines for the construction of the parallels of the horizon. The upper apex is **A** (marked **90**); the left and right extremities of the horizontal diameter are **B** and **C**; the centre is **D**. Degree graduations run down each side and along the lower half: 90, 75, 60, 45, 30, 15. A pencil of chords connects the graduation points, and the sides of the axial triangles are cut at the interior points named in the text.

- **A** (top, = 90°); **B** (left end of horizontal diameter); **C** (right end); **D** (centre)
- Degree marks on the upper and lower arcs: **15, 30, 45, 60, 75, 90**
- Interior construction points (per text, points where KL cuts the triangle sides and related): **K, G** (upper left); **E** (upper right); **R** (upper centre and again lower centre); **X** (centre); **M, N** (central cluster); **S, T** (central); **I** (central); **V** (left and right); **L** (lower right); **F** (lower left); **H** (lower right)
- Several central point-letters overlap the ruling and are worn — [?]

ALITER (an alternative method). Describe a quadrant ABC of any size and divide it into 90 degrees, or into fewer parts to suit the dial's size. From A as centre draw straight lines through the points of division; these will correspond to the radii of the parallels of the horizon comprised in the quadrant DC (90°) of the preceding figure, beginning from the straight line AB, as the figure shows. Next, from the figure of the preceding proposition take the straight line Fp, on the line AC of this figure, equal to AD; and take mF (or me) on the line AB, equal to AE,

and draw the straight line DE.[a] This triangle ADE will be exactly equal to the triangle Fpm of the preceding proposition's figure, since the angles at the points A and F are right and they are contained by equal sides, by construction. And so the line DE will be equal to the meridian line pm. Likewise the triangle ADE will be equal to the triangle DXS of the immediately preceding figure, since the triangle DXS is equal to the aforesaid triangle Fpm. For the angle IDX, in the analemma of this figure, is equal to the angle EFp in the figure of the preceding proposition, because each is the angle of the complement of the pole's altitude; and the right angle DIX is equal to the right angle FEp; and the sides DI, FE are equal, because each was taken equal to the style;[b] therefore the sides DX, XI will also be equal to the sides Fp, pE. And by the same reasoning DS, SI will be equal to the sides Fm, mE, and so on. After this, from the figure of the preceding proposition transfer all the intervals between the centre e and the points at which the vertical lines cut the horizontal line — transfer them into this figure from A, onto the straight line AB, marking the points on the straight line AB, and adding the numbers of the vertical lines: as 90 next to the point E, and 75 at the next point, and so on

[Margin: a. Elements I.4. b. Elements I.26.]

and so forth. Finally, from D, through the marked points AB, draw out straight lines. But for the vertical line properly so called — from which the beginning of the others is taken — draw DF through D parallel to AB; and to the right of it must also be transferred the lines already drawn from D through the points of the straight line AB, so that there may be vertical lines both beyond and short of the vertical line properly so called, just as was done in the horizontal dial in proposition 2 of this book concerning the lines before and after the sixth hour. For the lines sent out from D through the points of the straight line AB look toward the vertical lines before the vertical line properly so called, onto which the shadow of the style is cast when the Sun is in the northern verticals; while the others belong to the vertical lines beyond the vertical circle properly so called, and so on.

And so, if the intervals of the straight lines going out from D — those lying between D and the radius, say, of the parallel of the horizon at 15 degrees — are transferred from the point p of the preceding proposition's figure onto the vertical lines corresponding to the numbers marked on the straight line AB of this figure, marking the points on those vertical lines (yet in such a way that the intervals of the lines sent out from D and falling toward AB are transferred from the zenith p onto the vertical lines of the dial above the vertical line properly so called, while the intervals of the lines falling to the right of the straight line DF

are transferred onto the vertical lines below the vertical line properly so called) — and if these points are fitly and suitably joined by a certain curved line, then the parallel of the horizon at 15 degrees will have been described. By the same method the remaining parallels of the horizon will be described. The demonstration of this does not differ from the one we gave in the second manner of describing the parallels of the signs of the zodiac on a horizontal dial. For here the horizontal line is as it were the line of the equator, and the vertical lines are as it were hour-lines, whose centre is the zenith p, and so on, as we said in the preceding analemma. And so the straight line AB of this figure corresponds to the radius of the equator in the last figure of proposition 2 of this book;

Diagram. A quadrant-and-fan construction for the alternative method. A horizontal straight line runs across the top, carrying **A** at the left, **D** at the centre, and **C** at the right, with **90** engraved beside C. From C a quadrant arc sweeps down and to the left, graduated **75, 60, 45, 30, 15** (with **90** at its top). Below D a pencil of straight lines fans downward and outward through the graduation intervals, converging toward **B** at the lower centre and **F** below it. Near the apex of the fan, at **E**, the degree numbers 90, 75, 60, 45 are stacked, with 30 below.

- Top horizontal line: **A** (left), **D** (centre), **C** (right, = **90**)
- Quadrant arc from C: **75, 60, 45, 30, 15**, apex **90**
- Fan apex point **E** with stacked graduations **90, 75, 60, 45, 30**
- **B** (lower centre); **F** (below B)
- Lower degree marks along the fan lines: **15, 30, 45, 60**
- Cross-shaped ornaments (✕) mark line-ends at the foot of the figure

[Margin: Demonstration of the second description of these parallels of the horizon.]

and the lines drawn from A correspond to the radii of the signs sent out from D; while AD corresponds to the axis DH, the point D to the point H, and finally the vertical lines going out from D to the hour-lines drawn from H. The same will happen if the intervals of the straight lines issuing from D between the straight line AB (which, as we said, serves as the radius of the equator) and the lines sent out from A (which are as it were the radii of the signs) are transferred onto the corresponding vertical lines from the horizontal line of the dial — just as the intervals between the radius of the equator and the radii of the signs were transferred, so that the arcs of the signs might be described.

For the inferior equinoctial dial, the radii of the parallels of the horizon are to be transferred from A, through the points of the quadrant BC, going out to the left of

the straight line AB. Thus — just as, in the last figure of proposition 2 of this book, the radii of the signs to the right of the radius of the equator belong to the southern signs to be described below the equinoctial line of the dial, and the radii to the left to the northern signs to be described above the equinoctial line — so here too the radii of the parallels of the horizon drawn out from A to the right of the straight line AB (which serves as a kind of new radius of the equator, as was said) belong to the parallels of the horizon below the horizontal line (which is as it were a kind of new equinoctial line), to be described as though they were southern signs; while the radii sent out to the left of the straight line AB refer to the parallels of the horizon above the horizontal line of the dial — namely, in the inferior dial — to be described as though they were northern signs. Hence, since the portion of the dial above the horizontal line is equal to the inferior dial, the radii of the parallels of the horizon drawn out from A to the left of the straight line AB are rightly transferred onto it, and so on — all of which appears in the figure of the preceding proposition. We have therefore drawn the parallels of the horizon on the same equinoctial dial. Which was to be done.

SCHOLIUM.

Since, however, whole ellipses — such as is the ellipse of the parallel of the horizon at 60 degrees in our example — are described only with difficulty and inconvenience through all the points found on the vertical lines (as here, through those points that lie near the other extremity q of the diameter Pq of the ellipse), we shall use this device in order to describe them uniformly. Once the other extremity of the diameter is found on the meridian line — here the point q (which will indeed be found if the straight line D90, intercepted to the right of DF in the next figure between D and the radius of the parallel at 60 degrees, is transferred onto the meridian line of the dial from p as far as q; or else, in the analemma of this proposition, if the diameter of the ellipse of the parallel at 60 degrees, intercepted between P and the other side of the triangle through the axis in the cone whose bases are the parallels at 60 degrees, is transferred from P as far as q) — we shall bisect the whole diameter Pq at r, so that r is the centre of the ellipse, as is clear from the second definitions of Apollonius; and through r we shall draw a perpendicular to Pq, namely the second diameter of the ellipse. Then, because by proposition 30 of Apollonius, Book 1, any straight line drawn through the centre of an ellipse is bisected at the centre, we shall draw, from the points of the vertical lines through which the upper half of the ellipse passes,

[Margin: How, from one half of the ellipse, the other half is to be described.]

(this half, as is evident, can be described more conveniently than the lower one) — through the centre *r* we draw the hidden lines, and on their portions between the said points and the centre *r* we cut off, below the centre, equal straight lines, marking points on those hidden lines. For the lower half of the ellipse must be drawn through these points. And from proposition 75 of the preceding book, together with the earlier figure of this proposition, we shall easily recognize which parallel of the horizon forms the ellipse on the dial. We shall use this same technique for the ellipses of other dials, wherever they need to be described.

In the same way, on the inferior dial we shall describe the parallels of the horizon above the horizontal line, taking them from their counterparts described on the superior dial — and far more accurately, if, following the method given at the end of proposition 2 of this book, we first find the transverse diameters of the opposite sections and their centres, and so on. In the latter figure of this proposition, the transverse diameters are the portions of the straight line *DE* that lie between the radii of the opposite parallels of the horizon which go out from *A*, and are equally distant from the straight line *AB*.

[Margin: How the parallels above the horizontal line are described from their counterparts described below the horizontal line.]

PROBLEM 54. PROPOSITION 54.

To describe the meridians — that is, the circles of longitude of cities — on the same equinoctial dial.

[Margin: The description of the meridians on the same equinoctial dial.]

The meridian circles will be described just like the hours reckoned from noon or from midnight, as we taught in proposition 6 of this book — provided that, once we have drawn the hour-lines on the circle *ACBD* by the aid of proposition 49 of this book, that circle takes the start of its division into 360 degrees from the meridian of the Fortunate Isles, which lies on the superior dial (if the longitude of the place is counted from the meridian of the place, namely from point *A* toward *D*, through the western parts, as far as point *G*) — as is clear, provided the dial is understood to be set in its proper position. On the inferior dial, the same meridian of the Fortunate Isles is obtained if the longitude of the place is reckoned from point *B*, toward *D*, as far as *H*. For if the inferior dial has its own proper position — such that the horizontal line occupies the upper place and point *A* the lower, and point *C* faces sunrise and *D* faces sunset — then the meridian of the place will cut the plane of the dial above the horizon at point *B*,

and below the horizon at point A. Therefore from B toward D lie the western parts, and the eastern parts lie toward C, and so on.

[Margin: The description of the meridians on the same equinoctial dial.]

Diagram. A circle — the equinoctial dial ACBD — with a dense array of radial straight lines (the meridian circles / circles of longitude) emitted from the centre and continued outside the rim, each terminating in a degree-of-longitude label. The circle is crossed by a horizontal diameter running left to right, labelled HORIZON (i.e. HORIZON) at its two ends, and by a vertical diameter A–B; the two diameters cross at the centre E.

- A (top of circle): meridian of the Fortunate Isles; adjacent label *Inſ. Fort.* (*Insularum Fortunatarum*, "of the Fortunate Isles"), set along the upper-right of the vertical.
- B (bottom of circle): opposite pole of the vertical diameter.
- C (left, on the horizontal): west side.
- D (right, on the horizontal): east side.
- E (centre): common origin of all the meridian radii.
- G (upper right, between A and D).
- H (lower right, between D and B).
- *Sol* (left, near the horizontal line): label for the Sun / the point on the west.
- *Inſulæ Fort.* (*Insulae Fortunatae*): label set along a lower-left diagonal radius.
- Degree graduation of the radii (longitude, marked every 15°): legible values include, on the right and lower arc, 15, 30, 45, 60, 75, 90 (near H), 105, 120 (near D), 135 (near the ZON end); and on the left arc 285 (near the left horizontal), 300 (near C), 315, 330 (printed anomalously as two glyphs), 345. The remaining labels on the upper-left arc (including forms reading as 06 / 09 / 0E) are worn and not securely legible [?]. Zodiac-sign sorts marking the equinox/solstice radii on the rim are worn and not securely identified [?].

But it is better to describe the meridian circles on the inferior dial from the meridian circles of the superior dial, as was shown in the scholium to proposition 14 of this book, and as was done for the vertical dial in the scholium to proposition 28 of this book; for everything said there can be carried over here, provided one always understands the superior dial as the equinoctial for the southern hemisphere and the inferior for the northern. You have an example in the figure given. There you see that the meridian of 105°, extended beyond the centre E on the superior dial, has 285° as the meridian opposite to it; but when

extended beyond the horizontal line it takes up 105° again on the inferior dial, and so for the rest. We have therefore described the meridians — that is, the circles of longitude — on the same equinoctial dial. Which was to be done.

[Margin: How the inferior dial derives its meridians from the superior.]

PROBLEM 55. PROPOSITION 55.

To depict the parallels of cities — that is, the circles of latitude — on the same equinoctial dial.

[Margin: The description of the parallels — or latitudes — of cities on the same equinoctial dial.]

In place of the parallels drawn through the beginnings of the signs of the Zodiac, take the parallels that pass through the zeniths of the cities lying within the tropics, and do everything else just as we prescribed for describing the parallels of the signs of the Zodiac in proposition 50 of this book; and what is proposed will be accomplished. So we have drawn the parallels of cities — that is, the circles of latitude — and so on. Which was to be done.

PROBLEM 56. PROPOSITION 56.

To describe the celestial houses on the same equinoctial dial.

[Margin: The description of the celestial houses on the same equinoctial dial, following Johann Regiomontanus.]

Let the circle ACBD be cut, starting from the meridian line, into 12 equal parts — or into more, if we also want the subdivisions of the individual houses. We have divided it into 12, so that only the whole houses are described. Through the points of division and the centre E, let hidden straight lines be drawn. Then, through the point m, [where...]

where the meridian line intersects the horizontal, let lines be drawn parallel to the said lines, and the celestial houses will be described on both dials, following the teaching of Johann Regiomontanus. For since the circles of the celestial houses, according to Regiomontanus, divide the Equator into equal parts, beginning from the Meridian (which is one of the said circles), and pass through the centre of the world — that is, of the Equator — they will necessarily pass through the common sections of the Equator and the hour-circles reckoned from noon or midnight, since these too, passing through the centre of the world, cut the Equator into equal parts, beginning from the Meridian; so that the common

sections of the circles of the celestial houses and the Equator do not differ from the common sections of the hour-circles and the Equator. But the common sections of the plane of the dial and the circles of the celestial houses [a] are parallel to the common sections of the Equator and those same circles; [b] and to these, in turn, are also parallel (since they have been shown to be the same as the common sections of the Equator and the hour-circles) the common sections of the plane of the dial and the hour-circles reckoned from noon or midnight. [c] Therefore the common sections of the plane of the dial and the circles of the celestial houses will likewise be parallel to the common sections of the same plane of the dial and the hour-circles. Since, then, the straight lines drawn through the centre E, dividing the circle ACBD into 12 equal parts (or even into more or fewer), are the common sections of the plane of the dial and the hour-circles...

[Margin: Demonstration of the description of the celestial houses according to Johann Regiomontanus.] [Margin: a — [Euclid] XI.16.] [Margin: b — [Euclid] XI.16.] [Margin: c — [Euclid] XI.9.]

Diagram. A compound (stacked) figure of the celestial houses on the equinoctial dial after Regiomontanus. An upper circle (the superior equinoctial dial) carries a full set of radial house-lines from its centre and, around and beyond the rim, house numbers in Roman numerals together with zodiac-sign sorts at the divisions. Below it a second, lower circle (with a horizontal axis labelled VERTI—CALIS, *verticalis*) repeats the construction for the inferior/vertical dial, and a third, part-circle continues at the foot. Two horizontal HORI—ZON axes (one for each dial) run across the figure.

Upper circle:

- A (top of the upper circle).
- E (centre of the upper circle); m marked just above E on the vertical.
- Left-hand lettered points, descending: N, M, L, K, I.
- D (right, on the horizontal IIA ZON axis).
- B (lower part of the upper circle, on the vertical).
- H, F (left, below the upper circle, near the junction with the lower circle).
- House numbers in Roman numerals around the rim: legible are VII, VIII, IX, X, XI, XII, I; several are printed reversed/rotated (forms reading as IIA, IIX, IIIA) [?].
- Zodiac-sign sorts (e.g. ♌, ♍ and neighbours) mark the house-divisions on the rim; worn, not each securely identified [?].

Lower circle and foot:

- Horizontal axis HORI—ZON, and beneath it VERTI—CALIS.
- E and F within the lower circle, joined by a small triangle; p marked on the vertical below them.
- G (centre/foot of the lowest circle).
- Arabic numerals around the lowest circle: 8, 9, 10, 11, 12, 6 — house numbers in Arabic form [?] (worn).

as we demonstrated in proposition 49 of this book, then parallel to these straight lines will be the common sections of the plane of the dial and the circles of the celestial houses. And since these common sections all pass through the point m — as is established from proposition 18 of the preceding book, because the common section of all the circles of the celestial houses (that is, the axis of the vertical circle, or the common section of the Meridian and the Horizon) meets the plane of the dial at the same point m, as is clear from the figure of proposition 50 of this book, in which that common section is the straight line lm, provided the triangle Elm is understood to be perpendicular to the plane of the dial — that is, lying in the plane of the Meridian — the straight lines drawn through m will be parallel to the straight lines emitted through E, and these are the common sections of the plane of the dial and the circles of the celestial houses. Which is what was proposed. Moreover, it is evident that the beginnings of the celestial houses are parallel to the hour-lines distant from the meridian line by two, four, and six hours, because the circles of the celestial houses divide the Equator at those hours.

Furthermore, so as to draw easily through m lines parallel to those drawn through E — that is, the lines of the celestial houses — we shall use this technique. We shall draw, in any position, a line FG parallel to the meridian line; and on it, from the points where it is cut by the lines drawn through E, we shall cut off upward, toward Em, straight lines FH, IK, LM, NP, etc., equal to Em. For the straight lines from m...

[Margin: At which hours from noon or midnight the beginnings of the celestial houses are parallel to the hour-lines.]

drawn from m through the points H, K, M, P, etc. are parallel to those going out from E. For since the straight lines Em and FH are equal and parallel by construction, [a] the straight lines joining the points E, F and m, H will also be parallel to one another, and so for the rest.

[Margin: a — [Euclid] I.33.]

According to Campanus we shall lay out the celestial houses as follows. From the figure of proposition 52 of this book we take the straight line Fp , by which we located the point p — namely the Zenith — on the meridian line; and we transfer it onto the meridian line from the point p , whether upward or downward, as far as G . Then, from G , having described a circle of any size and divided it into 12 equal parts (or into more, if we also want to have the subdivisions of the celestial houses), we draw from the centre G , through the points of division, hidden straight lines that cut the vertical line at certain points; and these points, joined by straight lines to the point m , will give the celestial houses according to Campanus's view. For if this circle is rotated about the vertical line until it coincides with the vertical circle properly so called, and its centre G with the centre of the world F , then the straight lines drawn through G will be the common sections of the vertical circle and the circles of the celestial houses. Hence the circles of the celestial houses will meet the plane of the dial at the said points of the vertical line; and therefore the lines of the celestial houses — that is, the common sections of the plane of the dial and the circles of the celestial houses — will pass through those same points. Since, then, they also pass through the point m , as we have shown, the straight lines connecting the said points of the vertical line with the point m will be the lines of the celestial houses. We have therefore described the celestial houses on the same equinoctial dial. Which was to be done.

[Margin: The description of the celestial houses on the same equinoctial dial according to Campanus.] [Margin: Demonstration of the description of the celestial houses according to Campanus.]

SCHOLIUM.

If the lines of the celestial houses of the superior dial are extended beyond the horizontal line, the lines of the same houses will also be described on the inferior dial — provided that all the parts of the portion of the dial which the horizontal line cuts off are inverted, as was said in the preceding passages and demonstrated in the scholium to proposition 14 of this book.

[Margin: How the celestial houses, extended beyond the horizontal line, display the same houses on the inferior dial.]

PROBLEM 57. PROPOSITION 57.

To lay out the ascending signs of the Zodiac on the same equinoctial dial.

[Margin: The delineation of the ascending signs on the same equinoctial dial.]

From the centre E of the dial let there be drawn the hidden lines of those hours at which — with the Sun at the beginning of Cancer [♋], if the superior dial is in question, or at the beginning of Capricorn [♐], if the discussion concerns the inferior — the beginnings of the signs rise above the Horizon, as appears in the third or fourth table of proposition 9 of this book, taking also the hours of those signs...

[Margin: The delineation of the ascending signs on the same equinoctial dial.]

Diagram. A large circle carrying an inscribed twelve-pointed star (the twelve zodiacal division-lines) with the twelve zodiac signs set around its outer rim, crossed by two horizontal axes: an upper one labelled HORIZ—ZON (horizon) and a lower one labelled HORA—VIA [?]. Within the star is a smaller central figure of radial hour-lines from the centre E, with lettered construction points.

- A (upper centre, within the star).
- m (below A, on the vertical).
- E (centre): origin of the inner radial hour-lines.
- Left-hand lettered points, descending: L, K, I, C (near the horizontal HORIZ end).
- Right-hand lettered points: G, F, D, H (near the ZON / VIA ends).
- B (lower centre, on the vertical, within the circle).
- Zodiac signs set around the outer rim (Cancer ♋ and Capricorn ♐ are named in the text as the tropics touched by the ascending signs); the individual rim sorts are worn and not each securely identified [?].

of those signs which rise several hours after and before noon [more] than is contained within the semidiurnal arc of Cancer [♋] or Capricorn [♐]. Then, since at those points of the tropic of Cancer or Capricorn — where it is cut by the said hour-lines — the ascending signs touch the tropic, as we showed in proposition 9 of this book, if through those points lines are drawn tangent to the tropic, [this...]

[Margin: The order of the ascending signs on the equinoctial dial.]

that is, the perpendiculars to those hour-lines (for by corollary to *Elements* III.16 these perpendiculars touch the circle ACBD, which represents the tropic) — through these the ascending signs will be laid out, in the following order. On both dials the sign Aries [♈] passes through A; the sign Taurus [♉] through the next point toward D; the sign Gemini [♊] through the next after that, and so on. Take only those portions of the lines which, on the upper dial, fall below the horizontal line into the upper dial; and, on the lower dial, only those portions of the same

lines which fall below the horizontal line into the lower dial. This order is easily gathered from the tables already given — the third and fourth — if on each dial one carefully considers the forenoon and the afternoon parts. Here, as in what preceded, we take for the lower dial that portion which the horizontal line cuts off, but with all the parts inverted, as we have often said. Hence on the lower dial the forenoon hours are to be counted from point A toward C, and the afternoon hours toward D. Provided no error has been made in the construction, the ascending signs will pass through those points of the horizontal line at which the parallels drawn through the beginnings of the signs intersect it — points such as...

Diagram. A large circle carrying an inscribed twelve-pointed star (the twelve zodiacal division-lines), with the twelve zodiac signs set around its outer rim and a vertical gnomon-line rising from the top. Two horizontal axes cross the figure: an upper one whose ends are labelled HORI—ZON (Horizon), and a lower one labelled HORA (left) — VI4[?] (right, worn). Within the star is a smaller central circle of radial hour-lines issuing from the centre E, with dotted construction lines.

- A (upper centre, on the vertical, within the inner circle).
- m (just below A, on the vertical).
- E (centre): origin of the inner radial hour-lines.
- B (lower centre, on the vertical, within the inner circle).
- Left-hand lettered points, on the two horizontal lines: L (at the left rim, on the upper/Horizon line), K (inner-left), I and C (on the lower horizontal line).
- Right-hand lettered points: G (inner-right), H (at the right rim, near ZON), F and D (on the lower horizontal line).
- The twelve zodiac signs are set around the outer rim; the individual rim sorts are worn and are not each securely identified [?].

[Margin: Finding the points on the horizontal line through which the ascending signs are to be drawn.]

F, G, H, I, K, L, as is evident from what we set out for the vertical dial in proposition 21 of this book. These points, moreover, may be found in this way even if the parallels of the signs are not drawn. From the centre E let hidden lines be drawn terminating, on each tropic, the semidiurnal arcs — of the northern signs on the upper dial, and of the southern signs on the lower — as they are contained in the fifth table of proposition 9 of this book; yet in such a way that the semidiurnal arcs of the northern signs are reckoned from B, on either side, in

the tropic of Cancer [♋], and those of the southern signs from A, on either side, in the tropic of Capricorn [♏]. For these lines will cut the horizontal line at the said points.

[Margin: Another way of finding the same points.]

We shall find these same points from the last figure of proposition 21 of this book. For if on the straight line EB, or ED, of that figure there is taken a straight line Eh equal to the straight line *lm* in the dial of proposition 50 of this book — the line by which we drew the horizontal line in the dial — and if through h a perpendicular to BD is raised, this will be the horizontal line in the dial. This is evident: if the Horizon ABCD is conceived in the dial in its proper position, so that the point h falls at m, and the perpendicular drawn through h is made the same as the horizontal drawn through m; and if accordingly the centre E of the figure of proposition 21 of this book is joined with the centre of the world and with the tip of the style, because of the equality of the straight lines Eh and *lm*. And so, if the distances of the perpendicular line drawn through h — measured between h and the points at which it is cut by the rays proceeding from E — are transferred onto the horizontal line from m, the same points will be obtained as before.

[Margin: Another delineation of the ascending signs on the same equinoctial dial, by the culminations of the heaven and the angles of the earth.]

Again: if from the sixth table of proposition 9 of this book we take the declinations of the culminations of the heaven [mediationum caeli] and of the angles of the earth [angulorum terrae], and find their points on the meridian line — through which, that is, the parallels of those declinations pass, according to the doctrine of proposition 50 of this book — then the ascending signs will likewise pass through those points, if no error has been made in laying them out. On the upper dial the culminations of the heaven of the northern signs are contained in the portion of the meridian line drawn from point E through B, since this indicates the 12th hour of midday; and the angles of the earth in the remaining portion of the meridian line drawn from the same point E through A, which of course shows the 12th hour of midnight. So the signs Leo [♌], [?], Virgo [♍], [?], and Libra [♎] pass through the points found on the line EB extended — because when these signs are ascending, northern points of the ecliptic culminate; whereas the signs Cancer [♋], Capricorn [♏], Gemini [♊], Aquarius [♒], Taurus [♉], Pisces [♐], and Aries [♈] are drawn...

through the points found on the straight line EA extended, because, when these signs are rising, northern points of the ecliptic are set at the angle of the earth, as

appears from the said sixth table. On the lower dial, by contrast, the culminations of the heaven of the southern signs are contained on the meridian line EA extended, and the angles of the earth on the midnight line EB drawn out; so that the signs Cancer [♋], Capricorn [♏], Gemini [♊], Aquarius [♒], Taurus [♉], Pisces [♐], and Aries [♈] run through the points found on the straight line EA, because when these signs are ascending, southern points of the ecliptic are found at midheaven; whereas the signs Leo [♌], [?], Virgo [♍], [?], and Libra [♎] pass through the points found on EB extended — for when they are rising, southern points of the ecliptic stand at the angle of the earth. It is clear, then, that on the upper dial only the northern declinations can be laid out, and the southern ones on the lower dial.

Finally, if from the seventh table of the same proposition 9 of this book we take the declinations of the northern points of the ecliptic lying on the line of the 6th hour before and after noon, at the moment the beginnings of the signs rise, and find their points on the line of the 6th hour before or after noon on the upper dial; and if we do the same for the declinations of the southern points of the ecliptic lying on the same line on the lower dial — then the same ascending signs will pass through these points found on the line of the 6th hour. And so we have laid out the ascending signs of the Zodiac on the same equinoctial dial. Which was to be done.

SCHOLIUM.

We shall depict the ascending signs of the Zodiac in the manner of Andreas Schöner [*Andrea Schonero* — Andreas Schöner] as follows. In the first figure of the scholium to proposition 9 of this book, on the straight line EB let there be taken a straight line E β equal to the portion of the meridian line EM lying between the centre of the dial and the horizontal line in the figure of proposition 50 of this book; and through β let a line be drawn parallel to AC itself, in such a way that, with the centre E of that figure placed at the point m on the dial, and the point β at the centre E, the parallel drawn through β coincides with the line of the 6th hour. This parallel drawn through β will cut the straight lines of the signs issuing from the centre E at points whose distances, taken from β and transferred onto the line of the 6th hour of the equinoctial dial from the centre E, will give — on both sides — points on the line of the 6th hour. Through these, if from the point m, where the horizontal line and the meridian intersect, hidden lines are drawn cutting the tropic of Cancer [♋] on the upper dial, or the tropic of Capricorn [♏] on the lower, at points through which, if again straight lines are drawn to the centre E, and to these, from the said points of the tropic,

perpendiculars — that is, tangents to the tropic — are drawn, the ascending signs will be laid out as before, keeping the order which the figure shows.

It is enough, however, if the ascending signs are laid out on the upper dial. For these, extended beyond the horizontal line, will present the same signs on the lower dial, provided the portion of the dial cut off by the horizontal line is inverted, as was said in what preceded and demonstrated in the scholium to proposition 14 of this book.

PROBLEM 58. PROPOSITION 58.

To construct an Italian-hours equinoctial dial [*Horologium Italicum aequinoctiale*].

[Margin: The construction of the Italian-hours equinoctial dial.]

The parallels, or arcs of the signs (which we drew together with the horizontal line in proposition 50 of this book), are each to be divided — or at least two of them, the inner and the outer, which is enough — into 24 equal parts, beginning from the horizontal line on that side toward which the shadow of the style falls at sunset: that is, on the upper dial, from the left-hand side, which faces the sunrise. Then, through the nearest points of these arcs, above or below the horizontal line, from the left side where the division began, let a straight line be drawn; likewise through the next points in sequence, and so on, until all are completed. For these straight lines will indicate the hours from sunset on the upper dial, and thus the upper Italian-hours equinoctial dial will be laid out, in which the number and order of the hours is as follows. The first line — that is, the one nearest above the horizontal line, which indicates the 24th hour (this is on the nocturnal dial, which the portion cut off by the horizontal line displays) — shows, on its left-hand part, the first hour from sunset; the next shows the second, and so on; so that the nearest line below the same horizontal line shows, on the left-hand part, the 23rd hour, and so forth. This we shall demonstrate as follows.

[Margin: The order of the hours from sunset on the equinoctial dial.]

Let great circles be understood as drawn through the poles of the world and through the hours from sunset on the parallel — say, Cancer [♋] — after the manner of the hour-circles from midday or from midnight; that is, as passing through those points at which, by proposition 10 of the upper book, the Horizon and the other hour-circles from sunset cut the parallel of Cancer [♋] into equal parts. These circles will likewise cut the parallel of Cancer [♋] on the equinoctial dial into equal parts, as is established from what we wrote in proposition 49 and

in the scholium to proposition 50 of this book. Therefore, since the great circle drawn through the poles and through the 24th hour cuts the parallel of Cancer [♋] on the dial at the point where the Horizon itself cuts it — so that the shadow of the gnomon falls upon that point, the Sun being at the common section of the Horizon (or the parallel of Cancer [♋]) and of the said circle, as is evident...

[Margin: Demonstration of the construction of the Italian-hours equinoctial dial.]

from what was demonstrated in the upper book — other great circles will pass through other points of the parallel of Cancer [♋] on the dial, points which divide it into equal parts, since the shadow of the style falls upon each of them too when the Sun is at the common section of the parallel of Cancer [♋] and of those circles; and accordingly the hour-circles from sunset will pass through the same points, for the same reason: namely, because the shadow of the style falls on those points when the Sun is at the common sections of the parallel of Cancer [♋] and of the hour-circles from sunset, as well as of the great circles passing through the poles of the world and through the hours from sunset on the parallel of Cancer [♋]. For the ray of the Sun will then not differ from the common sections of those great circles, since these sections are drawn through the centre of the world — that is, through the tip of the style — just as the Sun's ray is. Since, then, the Sun's ray falls at that moment upon the said points of the parallel of Cancer [♋] on the dial, those common sections will also fall there; and accordingly at those points the planes of the hour-circles from sunset will meet the plane of the dial. In the same way we shall show that the hour-circles from sunset pass through the points of the other parallels on the dial which divide them into equal parts, provided, that is, that other great circles are conceived as drawn through the poles of the world and through the hours from sunset on those same parallels. Therefore the straight lines connecting the said points of the arcs of the signs are the common sections of the plane of the dial and of the circles that show the hours from sunset.

By the same reasoning we shall construct the lower Italian-hours dial, if we begin the division of the parallels on the lower dial — which the portion cut off by the horizontal line represents to us — from that side toward which the shadow of the style is cast...

beneath the sunset — namely, the right-hand part, facing the sunrise. I call the right-hand part the one which, for us turned toward the lower dial (that is, toward the portion cut off by the horizontal line, with the horizontal line occupying the upper place), is set on the right: for here we do not use that inversion of parts of which we spoke above. For the nearest line above the

horizontal line will give the 1st hour from sunset — the line which, on the upper dial, was indicating the 23rd hour; and the next, which was the line of the 22nd hour, will give the 2nd; and so on, always taking the complements of the hours of the upper dial up to 24. Thus the line of the 1st hour from sunset on the upper dial — which is precisely the first line below the horizontal line on the lower dial — indicates the 23rd hour from sunset, and so forth. These complements of the hours we have not written in the figure, but they are to be understood in thought alone.

[Margin: Another delineation of the Italian-hours equinoctial dial, by the diurnal and nocturnal arcs of 14 and 10 hours.]

ALITER [Another way]. By the doctrine of proposition 51 of this book let there be described a diurnal arc of 14 hours, whose portion cut off by the horizontal line will be a diurnal arc of 10 hours on the lower dial, or a nocturnal arc of 10 hours on the nocturnal dial — which comes to the same thing, since the lower dial, together with the portion of the dial that the horizontal line cuts off, displays both the lower and the nocturnal dial, as is clear from what precedes. For if we draw straight lines through the hours from midday, or from midnight, on the diurnal arc of 14 hours and the nocturnal arc of 10 hours, corresponding to the hours from sunset — as may be seen in tables 3 and 4 of the scholium to proposition 33 of the upper book — the upper Italian dial will be laid out, as before. Yet it must be noted that the individual hours from sunset have, in the said tables, only single hours corresponding from midday or from midnight. Hence, that they may be drawn correctly, the hours from midday or from midnight corresponding to the same numbered hours from sunrise must also be taken from the same tables. For example: the 23rd hour from sunset is drawn through the 6th hour from midday on the diurnal arc of 14 hours; and because the same line, extended beyond the diurnal arc of 24 hours which touches the horizontal line at the point m, indicates the 23rd hour...

Diagram. A large full-hour Italian-hours equinoctial dial: a great circle with concentric rings of hour-numbering — an outer ring of Roman numerals (I through XXIII) interleaved with an inner ring of Arabic numerals (1 through 24) — and a dense sheaf of straight and dotted radial hour-lines converging on the centre E. A horizontal axis crosses the whole figure, its ends labelled HORI—ZON (Horizon), with 24 at the right-hand rim; a large arc bulges out to the left carrying the points C (upper left) and B (mid-left).

- E (centre): convergence of the radial hour-lines.
- m (just above the centre, on the vertical).

- A (just left of the centre).
- D (just below the centre).
- B (at the left, on the horizontal line, an endpoint of the left-hand arc).
- C (upper left, endpoint of the left-hand arc).
- Right rim: ZON and the numeral 24 on the horizontal line.
- Around the rim run the double hour-numbers: Roman I–XXIII in the outer band and Arabic 1–24 in the inner band (bottom sequence legible as...19/VIII, 18/VII, 17/VI, 16/V...; upper and right sequences 1, 2, 3... with X, XI, XII, XIII, XIII on the left). The individual peripheral numerals are small, rotated, and partly worn, and are **not each securely resolved** [?].

from sunrise, as we taught in the scholium to proposition 10 of this book; and since the 23rd hour from sunrise passes through the 4th hour from midnight on the nocturnal arc of 10 hours, therefore, so that the 23rd hour from sunset may correctly be drawn through the 6th hour from midday on the diurnal arc of 14 hours, we must also take the 4th hour from midnight — corresponding, on the nocturnal arc of 10 hours, to the 23rd hour from sunrise. In the same way the 22nd hour from sunset is drawn through the 5th hour from midday on the diurnal arc of 14 hours, and through the 3rd hour from midnight on the nocturnal arc of 10 hours, which corresponds to the 22nd hour from sunrise. And likewise (to sum up the whole matter in few words) the 11th hour from sunset goes through the 6th hour from midnight on the diurnal arc of 14 hours, and through the 4th hour from midday on the same arc, which corresponds to the 11th hour from sunrise. Again, the 1st hour from sunset is drawn through the 8th hour from midday on the nocturnal arc of 10 hours, and through the 6th hour from midnight on the diurnal arc of 14 hours, corresponding to the 1st hour from sunrise, and so on.

[Margin: How the lower Italian dial is gathered from the upper.]

In no other way shall we make the lower Italian dial. But it will be better to gather it from the upper one. For the hours from sunset of the upper dial, extended beyond the horizontal line, will give the same numbered hours from sunset on the lower dial — provided, that is, that all its parts are inverted, as was said above and demonstrated in the scholium to proposition 14 of this book.

[Margin: A description of the same Italian-hours equinoctial dial, by the diurnal arc of 24 hours.]

We shall also, and easily, complete the same Italian dial by means of the diurnal arc of 24 hours — that is, the parallel, greatest of all those that are always

apparent, which touches the horizontal line at m, and which is, on the lower dial, the nocturnal arc of 24 hours, or the parallel, greatest of all those that are always hidden. For since this arc is a circle, by the corollary to proposition 4 of the upper book, and since the hours from sunrise or sunset touch it (by proposition 14 of the same book) at the points at which the hours from midday or from midnight cut it, it is manifest that the lines touching the said circle at the points of the hours from midday or from midnight — that is, the perpendiculars to the lines of the hours from...

[the perpendiculars to the lines of the hours] from midday, or from midnight — at the points where they cut the aforesaid circle — indicate the hours from sunset. Now which hours from sunset correspond to which hours from midday or midnight on the said arc of 24 hours will be taught by the seventh table of the scholium to proposition 33 of the upper book, for the upper dial; and for the lower dial the same service will be performed by the eighth table of that same scholium. These tangent lines must of necessity pass through the hours from midday, or midnight, on the diurnal arc of 14 hours and the nocturnal arc of 10 hours. Thus you see that the 23rd hour from sunset touches the diurnal arc of 24 hours at the 11th hour from midday, and passes through the 6th hour from midday on the diurnal arc of 14 hours. Likewise the 1st hour from sunset touches the former arc at the 1st hour from midnight, and runs through the 8th hour from midday on the nocturnal arc of 10 hours, and so on. Most conveniently, therefore, any hour whatever from sunset will be drawn — on the upper dial — from two arcs, one of them the diurnal arc of 24 hours and the other either the diurnal arc of 14 hours or the nocturnal arc of 10 hours; and on the lower dial, from two arcs, one of them the nocturnal arc of 24 hours and the other either the diurnal arc of 10 hours or the nocturnal arc of 14 hours.

[Margin: The most convenient way of describing the same Italian dial by means of the diurnal arc of 24 hours together with the diurnal arc of 14 hours and the nocturnal arc of 10 hours.]

We shall construct the same Italian dial by means of the line of the 12th hour from sunrise or sunset, as is established from the second table of proposition 20 of the upper book; and likewise by means of the horizontal line — that is, the line of the 24th hour from sunrise or sunset — as is gathered from the first table of that same proposition 20, in the way explained above. Indeed, from the third table of the same proposition it will also be clear which hours from sunset cut one another on the line of the 6th hour from midday or midnight, and so forth. The line of the 12th hour from sunrise or sunset can be drawn in the following

way. On the line of the 6th hour from midday or midnight, from the centre E, cut off the straight line EA equal to the gnomon; and with A as centre, at any interval you please, describe a circle and take on it an arc BC equal to the elevation of the pole, beginning from the line EB and proceeding toward the horizontal line. Then from C, through the centre A, draw a straight line cutting the meridian line at D. For the line drawn through D parallel to the line of the 6th hour from midday or midnight will show the 12th hour from sunrise or sunset. To see why, imagine the circle BC turned about the meridian line until it coincides with the meridian circle and until its centre A is joined to the centre of the world, that is, to the vertex of the style. Once this is done, B will be the pole of the world, and C the point where the circle of the 12th hour from sunrise or sunset touches the greatest of all the ever-apparent parallels and cuts the meridian — for this parallel cuts the meridian at C. Hence the straight line CA will be the common section of the circle of the 12th hour from sunrise or sunset and of the meridian, and therefore the circle of the 12th hour from sunrise or sunset will meet the plane of the dial at the point D.

[Margin: The construction of the same Italian dial by means of the line of the 12th hour from sunrise or sunset, and by means of the horizontal line, that is, the line of the 24th hour from sunrise or sunset. — The line of the 12th hour from sunrise or sunset, how it is to be drawn on the equinoctial dial.]

And since the line of the 12th hour from sunrise or sunset and the line of the 6th hour from midday or midnight are parallel — by what we wrote in the scholium to proposition 22 of the upper book — it follows that the straight line drawn through D parallel to the line of the 6th hour from midday or midnight is the line of the 12th hour from sunrise or sunset.[a] Now because the angle of the elevation of the pole, BAC, is equal to the angle EAD at the vertex, it comes about that if on the line of the 6th hour from midday or midnight we take the straight line EA equal to the style, and at A construct the angle EAD equal to the elevation of the pole, we shall find on the meridian line the same point D through which the line of the 12th hour from sunrise or sunset must be drawn — even if the circle BC is not described. Moreover, if we cut off ED equal to the straight line Em, we shall obtain the same point D. For since the angle EAm too is constructed equal to the elevation of the pole (as is established from proposition 30 of this book), the angles EAm and EAD will be equal; and the angles at E are also equal, being right angles; and the side EA, adjacent to the said angles, is common.[b] Therefore the sides Em and ED will also be equal. And consequently, since the line of the 12th hour from sunrise or sunset passes through D, as we have shown, it is plainly established that if ED is cut off equal to Em, the line of the 12th hour

from sunrise or sunset must be drawn through D — the line that touches the greatest of the ever-apparent parallels at D, just as the horizontal line touches the same parallel at m.

[Margin: [a] Proposition 15 of Book I. — Another way of describing the line of the 12th hour from sunrise or sunset on the equinoctial dial. [b] Proposition 26 of Book I.]

Now two lines of hours from sunset are always parallel to some one hour from midday or midnight, as is clear from the table of proposition 19 of the upper book and as was proved in the scholium to proposition 22 of the same book. For example, the 23rd and the 11th hours from sunset are parallel to the 5th hour from midday or midnight, and so on. Hence, if on the diurnal arc of 14 hours and the nocturnal arc of 10 hours — or even on the diurnal arc of 24 hours — we mark the hours from midday or midnight that correspond to the hours from sunset, as the tables of the scholium to proposition 33 of the upper book indicate, we shall very conveniently describe the same hours from sunset by drawing, through those hours from midday or midnight marked on the said arcs, lines parallel to the hours from midday or midnight that the aforesaid table of proposition 19 of the same book sets out. Thus, since the 16th hour from sunset corresponds (by the third table of proposition 33 of the said book) to the 11th hour from midnight on the diurnal arc of 14 hours, and is parallel to the 16th hour from midday or midnight (as the table of proposition 19 of the same book requires), the straight line drawn through the 11th hour from midnight on the diurnal arc of 14 hours, parallel to the 10th hour from midday or midnight, will be the line of the 16th hour from sunset — and so for the rest. We have therefore constructed the Italian equinoctial dial. Which was to be done.

[Margin: To each single hour from midday or midnight two hours from sunrise or sunset are parallel. — Another way of describing the hours from sunset on the equinoctial dial.]

PROBLEMA 59. PROPOS. 59.

To construct a Babylonian equinoctial dial.

By the same means and reasonings by which we constructed the Italian dial, we shall make the Babylonian dial — provided that, in the first method, the division of the circles described from E takes its beginning from the right-hand side of the upper dial (the side that customarily receives the shadow of the style about sunrise), and, on the lower dial, from the left-hand side (taking the lower dial as

we described it in the first method of the preceding proposition). Likewise the hour-lines are to be drawn so that first one is drawn through the nearest points of the divisions above or below the horizontal line from which the division took its beginning; then another proceeds through the following points, and so on in succession. The order of the hours is this. The first line below the horizontal line, on the right-hand side, gives on the upper dial the 1st hour from sunrise, the next the 2nd, and so on. On the lower dial, however, the nearest line below the horizontal line, on the left, will show the 1st hour from sunrise, the next the 2nd, and so on — so that they are the complements, up to 24, of the hours from sunrise on the upper dial. For what on the upper dial gave the 23rd hour, on the lower dial displays the 1st, and so on, as we said of the Italian dial in the preceding proposition, even though we set down no example of the lower dial according to this method. The demonstration here will be the same as in the preceding proposition, taking the hours from sunrise in the parallels of the Sun in place of the hours from sunset.

[Margin: The construction of the Babylonian equinoctial dial. — The order of the hours from sunrise on the equinoctial dial.]

In the remaining methods there is no difficulty, provided that what was said above of the hours from sunset be understood here of the hours from sunrise, and

conversely, that what was said there of the hours from sunrise be understood here of the hours from sunset. An example of the Babylonian dial stands in the figure of the preceding proposition, where the hours from midday or midnight and the hours from sunset are also contained, and are distinguished from one another as follows. To the hours from midday or midnight we assigned the numbers near the diurnal arc of 14 hours and the nocturnal arc of 10 hours, and their lines — marked only with dots — run out as far as the arc of 24 hours. The hours from sunset carry the ordinary numeral characters, thus: 24, 23, 22, etc. Finally, the hours from sunrise are set apart from the others by the ancient numeral signs, thus: I, II, III, etc. And so we have composed the Babylonian equinoctial dial. Which was to be done.

[Margin: In what ways the other descriptions of the Babylonian equinoctial dial are made.]

SCHOLIUM.

The lines of the hours from sunrise on the upper dial, extended beyond the horizontal line, indicate the same hours on the lower dial, provided that its parts are inverted, as we demonstrated in the scholium to proposition 14 of this book.

Furthermore, we shall describe the Italian and Babylonian dials also in this way, taking no account of the parallels of the Sun. From A, the centre of the circle BGF described at any interval, let the circle be divided into 24 equal parts; and with diameters drawn through the centre A and each pair of opposite points, let perpendiculars be raised to those diameters at their extreme points — or, what is the same thing, tangents to the circle. These, I say, indicate the hours from sunrise and sunset on the equinoctial dial. So that, if you choose any one of these tangent lines for the horizontal line, that is, the line of the 24th hour — namely CD itself — the next line below it on the left will show the 23rd hour from sunset, the one after that the 22nd, and so on, on the upper dial; while the next line below the same horizontal CD, on the right, will exhibit the 1st hour from sunrise, the one after it the 2nd, and so on, on the same upper dial. For, as we taught in the preceding proposition and as was demonstrated in proposition 14 of the upper book, the hours from sunrise or sunset touch the greatest of the ever-apparent parallels of any dial whatever (which on the equinoctial dial is a circle) at the points where the same hour from mid-

[Margin: How the lower Babylonian dial is gathered from the upper. — How the Italian and Babylonian dials are constructed, taking no account of the parallels of the Sun.]

Diagram. A large circular equinoctial dial [the combined Italian/Babylonian equinoctial dial referred to in the text], filling the middle of folio 242. The outer boundary is a 24-sided polygon inscribed in a dotted circle; from the centre a dense web of straight hour-lines (tangents to the inner circle) crosses the figure. A horizontal diameter CD runs through the figure. Concentric with the outer circle is a smaller inner circle BGF surrounding the centre.

Legibly labelled interior points and lines :

- A (centre): the centre of the figure, drawn as a small sun-burst / gnomon foot with radiating lines.
- B (top of inner circle, on the vertical above A): upper point of the circle BGF.

- F (bottom of inner circle, on the vertical below A): lower point of the circle BGF.
- G (just above and left of A, inside the inner circle): third named point of the circle BGF.
- E (on the horizontal, a little left of centre): named point near the centre.
- C (left end of the horizontal diameter CD): the line CD is here taken as the horizontal line / line of the 24th hour.
- D (right end of the horizontal diameter CD).
- Inner circle labelled by its three points B, G, F ("circulus BGF").
- Along the horizontal line, inside from C: the Roman labels "XV", "XVI"; inside from D: the Arabic labels "8", "9".

Peripheral hour-numbering: the rim carries a double set of hour-numbers — an outer band of Roman numerals (I–XXIII, the hours from midday/midnight) and an inner band of Arabic numerals (1–24). The numerals are small, rotated according to their position around the rim, and in places foxed. Legible anchors include, at the left of the horizontal, "24" and the point "C"; running down the lower-left the Roman "XIII, XIII, XII, XI, X" beside Arabic "23, 22, 21, 20"; across the bottom the sequence "X, 19, IX, 18, VIII, 17, VII, 16, VI, 15, V, 14"; and up the right side "D, 24, 10, 12, 13, 14" with Roman "I, II, III, IIII, V." The individual rim numerals are **not each securely resolved** [?] — the double, rotated, worn numbering (see report).

[Margin: How the hour-lines of the immediately preceding figure are easily drawn.]

day or midnight cut it. If, then, the circle BGF is understood to be, on the equinoctial dial, the said greatest parallel, the points of its division will be [the points of] the hour from midday or midnight, since they distribute it into 24 equal parts; and therefore the lines touching it at those same points will show the hours from sunrise or sunset. On the lower dial — which is furnished for us by the portion cut off from the horizontal line CD, if all its parts are inverted — the ratio is the same, as the figure indicates and as is manifest from what has been said.

We shall draw the said perpendiculars, or the lines tangent to the circle, without great labour in the following way. One perpendicular, or tangent line, CD having been drawn, describe from A a hidden circle of any magnitude passing through the points C and D, yet larger than the circle BGF. Divide it into 24 equal parts, beginning from the point C; and again into another 24 parts, beginning from the point D — of which kind is the outermost circle marked with points in the

immediately preceding figure. For just as the straight line CD is perpendicular to BA and touches the circle BGF at B, and is drawn through the first points of the divisions, so likewise the straight line drawn through the second points of the divisions — one of which belongs to the first division and lies below the line CD, and the other to the second division and lies above the line CD — will be perpendicular to the line next to BA, and will touch the circle BGF at the point next to B.

In the same way one is to proceed with the third points of the divisions, with the fourth, and with the rest. The reason for this is that the said lines of the hours from sunrise and sunset divide each of the circles described from A into 24 equal parts, as is clear from what was demonstrated in the preceding proposition, the beginning being made both from the point C and from the point D; so that, if the point next below C is the 23rd hour from sunset, the point next above the point D will be the 23rd hour from sunrise, and so on.

We shall find the length of the style — which, placed at the centre, is to indicate the hours on a dial laid out by this art — in the following way. Let the angle ABE be made equal to the complement of the elevation of the pole. This will be easily accomplished if from B an arc of a circle is described, and on it the complement of the elevation of the pole is counted off from the straight line BA toward C. For the straight line BE drawn from B through the end of that counting-off will make the angle ABE equal to the complement of the elevation of the pole, and will cut off from the straight line AE the length of the style AE, to be fixed at the centre A at right angles. For if, with the dial set up in its proper position — namely so that it is equidistant from the equinoctial circle and the straight line CD is parallel to the horizon — the triangle ABE is understood to be turned about the straight line AE (which is the common section of the plane of the dial and of the meridian circle) until it is set up in the plane of the meridian at right angles to the plane of the dial, then AE will be the axis of the world, and BE the common section of the horizon (drawn through CD) and of the meridian, since it makes with the meridian line AB an angle equal to the complement of the elevation of the pole, as the matter requires — as is gathered from what was demonstrated in proposition 30 of this book. Therefore AE will be the length of the style, since, with the Sun on the horizon (which is drawn through CD and EB), the extremity of the style's shadow, when it is thrown onto the horizontal line CD, [falls upon it], as is established. But if it is not convenient to describe an arc of a circle from B in order to construct the angle equal to the complement of the elevation of the pole, count off in the circle BGF twice the complement of the elevation of the pole, from F as far as G. For the straight line BG, when drawn, will make the angle ABG

equal to the complement of the elevation of the pole.[a] For since (if the straight line GA were drawn) the angle GAF at the centre would be double the angle of the complement of the elevation of the pole constructed at the same centre — because the arc FG is likewise double of that same complement[b] — and since the angle GAF at the centre is double the angle GBF at the circumference, the angle GBF will be equal to the complement of the elevation of the pole.

[Margin: How the length of the style is to be investigated in this later description of the Italian and Babylonian dial. [a] Proposition 33 of Book VI. [b] Proposition 20 of Book III.]

Once the style AE has been found, arcs, or parallels of the signs, can be described to its size, as we taught in proposition 50 of this book: namely so that the hour-lines terminate at the most remote of them, that is, in the arc ☊ [Cancer, the summer tropic] or ☋ [Capricorn, the winter tropic], as was done in the dial of the preceding proposition.

[Margin: How the arcs of the signs are described on this later dial.]

PROBLEMA 60. PROPOS. 60.

To construct an Ancient equinoctial dial [i.e. one of unequal, "planetary," hours].

Let each of the portions of the arcs of the signs cut off by the horizontal line be divided, on both dials — the upper as well as the lower — into 12 equal parts. Then through the nearest points, below and above the horizontal line, let four straight lines be drawn to both sides; and let the same be done at the following points corresponding to one another; and the Ancient dial will be described. For the line nearest below the horizontal line, on the right, will give the 1st unequal hour on the upper dial, the next the 2nd, and so on. On the lower dial the same is seen on the left of the horizontal line — that is, in the portion cut off from the horizontal line — provided, however, that all its parts are inverted. We shall demonstrate that the unequal hours are rightly described by this method, in no other way than as we showed in proposition 58 of this book that the lines of the hours from sunset are rightly drawn according to the first method — if the great circles are understood to pass through the poles of the world and through the unequal hours of the parallels of the Sun. For these will likewise cut the arcs of the signs on the equinoctial dial into equal parts, by what we demonstrated in proposition 49 of this book; and therefore the circles of the unequal hours will be

drawn through the points of division of the arcs of the signs, just as was said of the circles of the hours from sunset in proposition 58 of this book.

[Margin: The construction of the Ancient equinoctial dial.]

Diagram. A circular Ancient (unequal-hours) equinoctial dial at the foot of folio 243. A horizontal diameter divides the circle; it is labelled **HORIZON** (printed split as "HORI · ZON"), with "12" marked at each end. The upper semicircle and the lower semicircle are each divided by straight radial hour-lines into unequal-hour sectors, and two concentric dotted arcs near the centre carry a finer set of fractional (half-hour) graduations.

Legibly labelled features :

- Horizontal diameter: labelled HORIZON, "12" at the left end and "12" at the right end.
- Upper semicircle, outer arc (left → right): "I, 2, 3, 4, 5, 6 (top), 7, 8, 9, 10, 11" between the two "12" horizon marks. (Several of these numerals are rotated/worn; readings "9" and the top-centre mark are less than certain [?].)
- Lower semicircle, outer arc (left → right): "I, 2, 3, 4, 5, 6 (bottom), 7, 8, 9, 10, II" between the two horizon "12" marks.
- Interior: two concentric dotted circles with a dense set of small fractional hour-values (half-hour markers) written between the dotted radial lines — legibly among them "12, 1½, 3, 4½, 6, 7½, 9, 10½" recurring in the upper and lower halves. These interior fractional graduations are small and foxed and are **not each securely resolved** [?].
- A small central dot marks the gnomon foot / centre (unlabelled).

This figure's outer hour-numbers and interior fractional graduations carry more than two [?] labels and is a (see report).

The same Ancient dial, or dial of unequal hours, we shall also lay out by means of the diurnal arc of 18 hours and the nocturnal arc of 6 hours. For the 1st unequal hour is to be drawn on the diurnal arc of 18 hours, through the 4½ hour from midnight,

[Margin: The same Ancient equinoctial dial.]

[Margin: Description [of the Ancient dial] by means of the diurnal arc of 18 hours and the nocturnal arc of 6 hours.]

from midnight, and on the nocturnal arc of 6 hours through the $9\frac{1}{2}$ hour from noon. The 2nd hour is drawn through the 6 hour from midnight on the prior arc, and through the 10 hour from noon on the posterior arc. Then the 3rd unequal hour is to be drawn on the diurnal arc of 18 hours through the $7\frac{1}{2}$ hour from midnight, and on the nocturnal arc of 6 hours through the $10\frac{1}{2}$ hour from noon. The 4th unequal hour must pass on the prior arc through the 9 hour from midnight, and on the posterior arc through the 11 hour from noon. The 5th unequal hour is to be drawn through the $10\frac{1}{2}$ hour from midnight on the diurnal arc of 18 hours, and on the nocturnal arc of 6 hours through the $11\frac{1}{2}$ hour from noon. The 6th unequal hour does not differ from the meridian line, that is, from the 12th astronomical hour. After this, the 7th unequal hour is to be drawn on the diurnal arc of 18 hours through the $1\frac{1}{2}$ hour from noon, and on the nocturnal arc of 6 hours through the $\frac{1}{2}$ hour from midnight. And the 8th unequal hour is to be drawn on the prior arc through the 3 hour...

Diagram. A circular Ancient (unequal-hours) equinoctial dial occupying the middle of folio 244 — the *apposita figura* referenced in the text, laid out by means of the diurnal arc of 18 hours (upper semicircle) and the nocturnal arc of 6 hours (lower semicircle). A horizontal diameter divides the circle and is labelled **HORIZON** (printed split "HORI · ZON"), with "12" marked at each end. Radial straight lines (the unequal-hour lines) divide both semicircles into sectors, and two concentric dotted circles near the centre carry a dense set of finer fractional (half-hour) graduations.

Legibly labelled features :

- Horizontal diameter: labelled HORIZON, "12" at the left end and "12" at the right end.
- Upper semicircle, outer arc, running between the two "12" horizon marks: an hour sequence I, 2, 3, 4, 5, 6 (top-centre), 7, 8, 9, 10, 11. Several of these numerals are rotated to follow the arc and are worn/foxed; the individual readings are **not each securely resolved** [?].
- Lower semicircle, outer arc, between the two "12" horizon marks: an hour sequence I, 2, 3, 4, 5, 6 (bottom-centre), 7, 8, 9, 10, II. Likewise rotated and worn; **not each securely resolved** [?].
- Interior: two concentric dotted circles carrying small fractional half-hour values written between the dotted radial lines — among them legibly "12, $1\frac{1}{2}$, 3, $4\frac{1}{2}$, 6, $7\frac{1}{2}$, 9, $10\frac{1}{2}$ " (and an "18" near the top-centre) recurring in the upper and lower halves. These interior fractional graduations are small and foxed and are **not each securely resolved** [?].

- A small central dot marks the gnomon foot / centre (unlabelled).

This figure's outer hour-numbers and interior fractional graduations carry more than two [?] labels and is a (see report).

from noon, and on the posterior arc through the 1 hour from midnight. The 9th unequal hour is to be drawn on the diurnal arc of 18 hours through the $4\frac{1}{2}$ hour from noon, and on the nocturnal arc of 6 hours through the $1\frac{1}{2}$ hour from midnight. Likewise the 10th unequal hour is to be drawn through the 6 hour from noon on the diurnal arc of 18 hours, and through the 2 hour from midnight on the nocturnal arc of 6 hours. The 11th unequal hour is to be drawn through the $7\frac{1}{2}$ hour from noon on the diurnal arc of 18 hours, and on the nocturnal arc of 6 hours through the $2\frac{1}{2}$ hour from midnight. Finally, the 12th unequal hour is the same as the horizontal line. All of this is evident from tables 11 and 12 of the scholium of proposition 33 of the previous book, and may be seen in the accompanying figure. We have therefore constructed the Ancient equinoctial dial — which was to be done.

[Margin: How the lower [dial] arises from the upper Ancient dial.]

[Margin: Each unequal hour is drawn through eight points.]

[Margin: For describing the Ancient dial it is enough if the two portions of a single parallel are cut into 12 equal parts.]

SCHOLIUM.

Moreover, the unequal hours of the upper dial, when extended beyond the horizontal line, mark on the lower dial the same hours — provided all its parts are inverted, as in the preceding cases. This is clear from what we demonstrated in the scholium of proposition 14 of this book. From this it follows that each of the unequal-hour lines is drawn through eight points of the divisions of the arcs of the signs, together with the diurnal arc of 18 hours and the nocturnal arc of 6 hours — four of these points being contained on the upper dial and four on the lower. It also follows that, to describe the unequal hours, it is enough to divide into 12 equal parts just the two portions of a single parallel — namely of the greatest and outermost, such as is the parallel of ♉ [Taurus] and ♍ [Virgo]. For a straight line drawn through the first point below the horizontal line on the right, and through the first point above it on the left, will give the 1st unequal hour; and a straight line drawn through the next two points, the 2nd; and so on.

END OF THE SECOND BOOK.

GNOMONICS, BOOK THREE.

BY THE AUTHOR

CHRISTOPH CLAVIUS OF BAMBERG, OF THE SOCIETY OF JESUS.

[Margin: Why the five kinds of dials we treated in the previous book are called regular.]

The five kinds of dials that we treated in the previous book — namely the Horizontal, Vertical, Meridian, Polar, and Equinoctial — may be called **regular**, because the planes on which they are described are always set opposite a determinate point of the heavens, wherever on earth one may be. [Margin: To which point of the heavens the horizontal, vertical, meridian, polar, and equinoctial dial is set opposite.] The first faces the crown of the head, that is, the pole of the horizon; the second, the pole of the vertical circle properly so called, in which the horizon and the meridian intersect one another; the third, the pole of the meridian, that is, the point of true rising or setting, where the equator divides the horizon; the fourth, the point of the meridian circle at which it is cut by the equator; and the fifth, finally, the pole of the world, that is, of the equator.

[Margin: Why the four kinds of dials treated in this book are called irregular.]

The remaining four kinds, which we propose to describe in this book, may be called **irregular**. These are: the dial declining from the vertical circle properly so called; the dial declining from the horizon; the dial inclined to the horizon; and the dial declining from the vertical and at the same time inclined to the horizon. For the points of the heavens toward which their planes are set can be varied in countless ways [*sexcentis modis*], since they can deflect more or less from the vertical or the horizon, and incline toward the horizon, as is evident. This can in no way be said of the former planes.

[Margin: The Horizon, the Vertical, and the Meridian — likewise the Meridian, the circle of the 6th hour from noon or midnight, and the Equator — cut one another at right angles in every clime.]

For in every clime or region the Horizon, the primary Vertical, the Meridian, the circle of the sixth hour from noon or midnight, and the Equator behave in the same way and intersect one another; and the first five dials are equidistant from these. For the first three, as well as the three latter (the Meridian always being counted among both the former and the latter), always divide one another at right angles. This can easily be demonstrated from the spherical *Elements* of

Theodosius [Theodosius of Bithynia, *Sphaerica*]. For since each of the first three, as well as of the three latter, passes through the poles of the other two — as is clear if the positions of these circles on the sphere are carefully considered — it will necessarily cut them at right angles, by proposition 15 of book 1 of Theodosius (*Sphaerica* I.15).

[Margin: The great circles from which the four kinds of dials of this book are equidistant — how they behave with respect to the Horizon, the Vertical, and the Meridian.]

But the case is quite different for the great circles from which the planes of the irregular dials are equidistant, since in the same clime they do not always have the same position. For the great circle from which a dial declining from the vertical is equidistant is indeed perpendicular to the horizon, since it is drawn through the horizon's poles; but it cuts the meridian obliquely in infinitely many ways, since almost infinitely many kinds of dials declining from the vertical are found, some declining more from the vertical and some less. So too the great circle to which a dial declining from the horizon is parallel is perpendicular to the vertical circle properly so called, since it passes through that circle's poles; but it also divides the meridian obliquely in innumerable ways, according as it declines more or less from the horizon. Again, the great circle from which a dial inclined to the horizon is equidistant is perpendicular to the meridian, through whose poles it is drawn, but it intersects the horizon obliquely in countless ways as well. Finally, the great circle from which the last dial is equidistant is perpendicular neither to the horizon, nor to the vertical, nor to the meridian, but divides all these circles obliquely.

ON DIALS THAT DECLINE FROM THE VERTICAL CIRCLE.

PROBLEM 1. PROPOSITION 1.

To describe an astronomical dial declining from the vertical circle — that is, to describe the hour-lines from noon or midnight on a plane that is equidistant from some great circle which declines from the vertical circle properly so called and is perpendicular to the horizon.

[Margin: Construction of the astronomical dial declining from the vertical.]

On some plane let two straight lines AB and CD be drawn, cutting one another at right angles at E. Then at the line CD, at point E, let the angle of declination of the plane on which the dial is to be placed be constructed — how this is to be investigated we demonstrated in proposition 23 of the first book. This angle is to

be constructed in the following order. If the plane declines from the meridian [i.e. from the south], the angle of declination is to be constructed below the line AB — toward point A if it faces east, but toward B if it faces west. But if the plane declines from the north, the angle is to be constructed above the line AB — toward B if it faces east, but toward A if it faces west. [Margin: The dial being described declines from the meridian toward the east by 30 degrees.] In the present example we suppose the plane to decline from the meridian toward the east by 30 degrees; the angle of declination DEF is therefore constructed below the line AB, toward A. This angle is easily constructed if, from E, an arc of a circle is described, and on it the declination is reckoned off from the line CD. For EF, a straight line drawn from E through the end of that reckoning, will form the angle of declination at point E. And the line EF may be called the line of declination.

Diagram. The large construction figure for the declining astronomical dial, filling the lower two-thirds of folio 246. A horizontal base line **AB** runs across the middle (A at the left end, B at the right); a second straight line **CD** crosses it near-vertically, the two meeting at right angles at **E** (D at the foot, C above). From a point **C** in the upper part of the figure a broad pencil of straight hour-lines radiates outward in all directions, their far ends carrying the hour-numbers. A circle is drawn in the lower-left portion of the figure, its arc studded with division points, and numerous auxiliary straight and dotted lines cross the whole construction.

Legibly labelled points and lines, with the confident construction labels first:

- **A** — left end of the horizontal line AB.
- **B** — right end of the horizontal line AB.
- **C** — the point from which the hour-lines radiate (the centre of the dial); high in the figure, on line CD.
- **D** — foot of the near-vertical line CD (at the bottom).
- **E** — intersection of AB and CD, where they cross at right angles.
- **F** — a point on line CD below E (the end of the line of declination EF).
- **G** — near-central point (foot of the perpendicular FG to AB / on the line of the style CG). [reading of the small "G" is only moderately secure [?]]
- **H** — left-of-centre, above AB (end of the perpendicular GH, the equinoctial line).
- **β** (beta) — on line AB, to the right of E.
- Additional labelled points visible in the construction, several small and worn: **V** (upper left, marked with a right-angle square), **b** and **Z** (upper

right, on a dashed perpendicular), **Y** (right of centre), **T, S, R, L, X, M** (clustered in the left-central region between H and F), and **N, O, P** on the lower-left arc of the circle. Several of these are faint/foxed [?].

- Hour-numbers at the outer ends of the radiating lines, running around the figure: legibly among them 1, 2, 3, 4, 5 (upper and right), and 8, 9, 10, 11, 12, 1, 2, 3 (lower and left arc). These italic line-end numerals are rotated and worn and are **not each securely resolved** [?].

This figure carries more than two [?] labels (the outer hour-numbers and several faint auxiliary points) and is a (see report).

[Margin: The line of declination, what it is in a declining dial.]

After this, on the line AB take any point β — either to the right of E or to the left. (It will however be more convenient to take it on the side opposite to the line of declination EF: thus, if EF is to the left of the line CD, let the point β be taken to the right of the same line CD, and so on; for on the side opposite to EF fewer hour-lines will be drawn, as will soon become plain. And the farther the point β is from point E, the larger the dial will be made.) At the line E β , at point β , let the angle of the pole's altitude E β C be constructed — above the line AB if the plane declines from the meridian, but below the same line AB if the plane declines from the north — and always toward the line CD, in such a way that the line β C cuts the line CD at point C. [Margin: The centre of the dial.] This point C will be the centre of the dial, through which all the hour-lines are to be drawn, as we shall demonstrate.

[Margin: The line of the style.]

Again, on the line of declination EF, take the segment EF equal to E β , and from F let a perpendicular FG be drawn to AB; and from the centre of the dial C, through G, let a straight line CG be drawn, which may be called the line of the style (or of the index), since on it the style is to be fixed, making right angles with the plane of the dial. To this line of the index CG, from G, let a perpendicular GH be drawn on both sides; this will be the equinoctial line, on which, taking the segment GH — whether to the right...

BOOK THREE

to the right of point G or to the left, equal to FG. Then, when the straight line CH has been drawn, let a perpendicular GI be drawn to it; and from I let a perpendicular IK be drawn to the line of the index CG. Then CH will be the axis of

the world, and IK the length of the style, its position being the point K on the line of the style (that is, of the index). The angle GCH, moreover, will be the angle of the altitude of the pole above the declining plane, as we shall demonstrate.

[Margin: The equinoctial line. — The axis of the world. — The length of the style, and its position. — The altitude of the pole above the declining plane.]

FINALLY, on the line of the index CG take a segment GL — whether above G or below it — equal to GI, and from L as centre describe a circle of any size, to be divided into 24 equal parts, beginning from the line LM, which runs from L (the centre of the circle) through the point M, where the equinoctial line cuts the line CD. For if through these division-points and the centre L hidden lines are drawn out, the equinoctial line GH will be cut at points through which straight lines emitted from C, the centre of the dial, will give the hours from noon or from midnight, preserving the same order that they have in a vertical dial.

[Margin: The order of the hours in a dial declining from the vertical.]

For in a dial that declines from the meridian, whether toward the east or toward the west, the portion of the line CD that begins at C and is extended toward the equinoctial line marks the 12th hour, noon. The lines that cut the equinoctial line on the left side of CD — that is, toward the parts A, the western ones — indicate the hours from midnight; while the lines that cut the equinoctial line on the right side — that is, toward the parts B, the eastern ones — belong to the hours from noon. Thus the line nearest to the left of CD signifies the 11th hour, and the one nearest on its right shows the 1st hour after noon, and so on. But in a dial that turns from the north toward the east or the west, understand the reverse. For the portion of the line CD extended from C toward the equinoctial line will give the 12th hour of midnight; the lines that lie to its left on the equinoctial line give the hours from noon, and those to its right the hours from midnight — as in each vertical dial.

[Margin: When the hour-line to be drawn through the centre C of the dial should be parallel to the equinoctial line.]

But whenever a straight line drawn through some division-point of the circle described from L, and through the centre L, is parallel to the equinoctial line, then a straight line drawn through C parallel to the equinoctial line will give that hour, whatever it may be — no otherwise than happens in the horizontal dial, where the 6th hour is drawn through the centre of the dial parallel to the equinoctial line, because in the circle described from E the line drawn through the point of the 6th hour and the centre E is parallel to the equinoctial line.

[Margin: Demonstration of the construction of the dial declining from the vertical.]

We shall demonstrate this construction in the following way. Suppose that in the plane of the dial the line AB is parallel to the horizon, so that it is the common section of the plane of the horizontal dial and the plane of the declining dial; and let the plane determined by the lines AB, EF, ED be conceived in the mind as being rotated about the line AB until it becomes parallel to the horizon and so coincides with the plane of the horizontal dial. This being posited: since DEF is the angle of declination of the dial's plane from the vertical, AEF will be the complement of that declination — namely the angle that the meridian makes with the declining plane. Therefore the line EF will be the common section of the meridian and the plane of the horizontal dial; and consequently the meridian will cut the plane of the declining dial at the point E. And since both the plane of the meridian and the plane of the declining dial are perpendicular to the plane of the horizontal dial, their common section too will be perpendicular to that same plane, and hence also perpendicular to the line AB in the said plane, by Euclid, definition 3 of book XI. [Margin: (a) Euclid XI.19.] Since, then, this common section passes through E, and the line CD is by construction perpendicular to AB, CD will be the common section of the meridian and the plane of the declining dial — that is, the meridian line of the declining dial.

Again, since both the plane of the meridian and the plane of the declining dial are perpendicular to the plane of the horizontal dial, their common section CE will be perpendicular to that same plane, and hence — by Euclid, definition 3 of book XI — also perpendicular to the line EF lying in the plane of the horizontal dial.

[Margin: (b) Euclid XI.19.] If, then, the triangle βEC is imagined to be rotated about CE until it coincides with the plane of the meridian determined by the lines CE, EF, the right angle βEC will coincide with the right angle CEF, and the point β with the point F, because of the equality of the lines E β and EF. Therefore the line βC , forming in that position with the meridian line EF of the horizontal dial the angle of the pole's altitude E β C, and extended toward the northern parts on the upper side of the line EF, will be the axis of the world, meeting the plane of the declining dial at the point C. And consequently, by the corollary of proposition 21 of book I, the point C will be the centre of the declining dial. For the axis makes with the meridian line of the horizontal dial the angle of the pole's altitude above the horizon, toward the parts of the visible pole, as is clear from the portion of the analemma in proposition 1 of the preceding book.

NEXT, since the line of the index — the one on which the style or index is to be fixed — must be such that the style, or any other line drawn from any of its points perpendicular to the plane of the dial, falls upon the axis of the world [Margin: (c) Euclid XI.18.] (so that the plane drawn through that perpendicular and the axis of the world is perpendicular to the plane of the dial, like a proper meridian of the dial's own plane), because the tip of the style, by proposition 2 of book I, is the same as the centre of the world through which the axis of the world passes — we shall demonstrate, in this way, that the line CG (which in the construction we called the line of the index) is such a line. Suppose the triangle EFG is rotated about the line EG until it coincides with the plane of the horizontal dial and is parallel to the horizon, and so is perpendicular to the plane of the declining dial. This being posited, the line FG will, by Euclid, definition 4 of book XI, be perpendicular to the plane of the declining dial. And since the axis of the world, in that position, falls upon the point F — as we just showed, because it then does not differ from the point β — the plane drawn through the line FG and through the axis of the world will be perpendicular to the plane of the declining dial, like a proper meridian. [Margin: (d) Euclid XI.18.] Therefore, since all the lines that are drawn perpendicular to CG in that plane (drawn through the axis and the line FG) are perpendicular to the plane of the declining dial, by Euclid, definition 4 of book XI, it follows that all perpendiculars to the plane of the dial drawn from points of the line CG fall upon the axis of the world. And consequently the line CG is the line of the style — namely the common section of the plane of the dial and of the said proper meridian — serving as a meridian line, as if the circle to which the dial is parallel were the horizon.

Now since the line GH was taken equal to the line FG, if the triangle CGH is imagined to be rotated about CG until it is perpendicular to the plane of the declining dial — so that the line HG (which was drawn perpendicular to CG) is likewise perpendicular to that plane — the point H will fall upon the point F, since FG too has been shown to be perpendicular to that same plane; and therefore the line CH will be the axis of the world. From this it follows that the angle GCH is the angle of the altitude of the pole above the declining plane, [Margin: (e) Euclid I.29.] because it is equal to the angle which the axis of the world and the common section of the meridian of that declining plane and of the great circle to which the plane of the dial is parallel make at the centre of the world — inasmuch as this common section is parallel to the line CG in the plane of the dial. [Margin: (f) Euclid XI.16.] And it is clear that this angle, formed in the proper meridian of the declining plane at the centre of the world, stands upon the arc of the pole's altitude above that great circle to which the dial is parallel.

THAT the line GH, perpendicular to the line of the style CG, is the common section of the equator and the plane of the declining dial — as we assumed in the construction — we shall make clear as follows. Since the axis of the world CH is perpendicular, by proposition 10 of book I of Theodosius, to the plane of the equator, and passes through its centre, and hence — by Euclid, definition 3 of book XI — is perpendicular to the common section of the equator and of the plane drawn through the axis of the world CH and the line GH [Margin: (a) Euclid XI.18.] (which plane is perpendicular to the plane of the declining dial, as a kind of new and proper meridian of it, since the line GH through which it is drawn was made perpendicular to that same plane, owing to the rotation of the triangle CGH about the line CG, as was just said) — it follows that IG, if the point I be taken for the centre of the world or of the equator (and any point of the axis may be taken for the centre, since its distance in the plane of the declining dial from the centre of the world is imperceptible and utterly negligible when compared with its distance from the sun, as we taught in the treatise on the sphere), is the common section of the equator and of the plane drawn through the axis CI and the line IG; seeing that the line IG, lying in this plane, is perpendicular to the axis. For if the equator did not pass through the line IG, but through some other line drawn from the point I (which we took for the centre, and through which the equator necessarily passes), then the axis CI would be perpendicular to that line as well — by Euclid, definition 3 of book XI — since it is perpendicular to the plane of the equator, in which this line would lie. In that case, in the plane drawn through the axis CI and the line IG, two perpendiculars to the axis would be drawn at the point I, which is absurd. Therefore the plane of the equator drawn through the line IG will meet the plane of the declining dial at G, a point of the line of the index; and consequently through the point G the equinoctial line must be drawn — namely the common section of the equator and the plane of the declining dial.

Now since the plane of the triangle CGI is perpendicular to the equator — because the line CI, through which the said triangle is drawn, is perpendicular to it, as has been said; [Margin: (b) Euclid XI.18.] or certainly by proposition 15 of book I of Theodosius, because the plane of the triangle CGI is drawn through the axis CI and hence through the poles of the world, that is, of the equator —

Diagram. A large and densely-ruled construction figure for the dial declining from the vertical (the figure to which the whole demonstration of pp. 247–249 refers). It shows the centre of the dial C set high near the top, drawn as a small ringed point from which a fan of straight hour-lines radiates outward across the whole page; the horizontal line AB runs across the middle (A at the left end, B at

the right end); a large circle (the circle "described from L") occupies the lower two-thirds of the figure, its lower arc dotted; and a cluster of auxiliary construction points and perpendiculars fills the central region. The engraving is worn and foxed, and many peripheral hour-numbers are rotated and faint; labels flagged [?] below are not securely resolved.

- C (upper centre, small ringed point): centre of the dial, origin of the radiating hour-lines.
- A (left end of line AB): western terminus of the horizontal common section.
- B (right end of line AB): eastern terminus of the horizontal common section.
- E (on AB, at centre): point where the meridian cuts the plane; foot of the meridian line CD.
- β (beta, on AB, just right of E): the rotated point ($E\beta = EF$).
- G (central, on/near AB by E): point of the line of the index (foot of the equinoctial line GH).
- F (below G, centre): foot of the perpendicular; the point onto which the axis falls when the triangle is folded down.
- H (left of centre, above AB): end of the equinoctial line GH.
- M (below E, right of centre): where the 12th-hour line meets the equinoctial line.
- L (centre, below F): centre of the great circle described in the construction.
- T (left of centre, above H) [?]: auxiliary construction point.
- I / "l" (small, central, near G) [?]: auxiliary point on the line of the style.
- Y (right of centre) [?]: auxiliary construction point.
- V (upper left, marked with a right-angle square): auxiliary construction point.
- b (upper right, on a dashed perpendicular) [?]: auxiliary point.
- Z (upper right, on the dashed perpendicular below b) [?]: auxiliary point.
- α (alpha, small, below/left of A near "a") [?]: point of the 6th-hour line ($F\alpha$).
- X (left-centre, below AB) [?]: auxiliary point.
- O (left, on the circle's arc) [?]: point on the circle.
- N, P (lower-left, on the dotted arc) [?]: points on the circle.
- D (bottom centre, below 12): lower terminus of the meridian line CD.
- Peripheral hour-numbers at the outer ends of the radiating lines, worn and rotated, legibly among them: 3, 4, 5 (upper and left), 7, 9 (upper right), 5, 4,

3, 2 (right), and 8, 9, 10, 11, 12, 1 (lower and left arc) [?]. These line-end numerals are not each securely resolved.

—conversely the equator too will be perpendicular to the plane of the triangle CGI.

And the plane of the declining dial is likewise perpendicular to that same plane of the triangle CGI, since that plane was just shown to be perpendicular to it.

[Margin: (c) Euclid XI.19.] Therefore the common section of the equator and the plane of the declining dial will be perpendicular to the same plane of the triangle CGI, and hence also perpendicular — by Euclid, definition 3 of book XI — to the line of the index CG lying in that plane. And so, since the said common section must be drawn through the point G, as we just showed, GH — the perpendicular drawn to CG — will be the common section of the equator and the plane of the declining dial, that is, the equinoctial line.

And since the point I is taken for the centre of the world, from which the line IK falls perpendicular to the plane of the declining dial — by Euclid, definition 4 of book XI — because it is drawn perpendicular to CG, the common section of the plane of the dial and of the triangle CGI (which is perpendicular to that plane) — the line IK will be the style, and its position will be at K, a point of the line of the index; for no other line perpendicular to the plane of the dial, besides KI, can fall to the centre of the world I, as is clear.

Now if the circle described from the centre L is imagined to be swung about the equinoctial line GH until its centre L is joined with the centre of the world I — and it will necessarily be joined with it, because the lines GI, GL are equal, and each is perpendicular to the equinoctial line, provided the triangle CGI is understood to be perpendicular to the plane of the dial — then the lines drawn through the centre L (which is then the same as the centre of the equator) and emitted through the divisions of the circle will be the common sections of the equator and of the hour-circles from noon or from midnight, just as we demonstrated in the horizontal dial in proposition 1 of the preceding book. For in that position this circle, having the same centre as the equator, lies in the plane of the equator.

The starting-point of the circle's division is taken from the line LM, which is drawn through the centre L and the point M, where the line of the 12th hour and the equinoctial line intersect each other; because that line is the common section of the equator and the meridian, that is, of the circle of the 12th hour, since it meets the plane of the dial at the point M, through which the meridian line and

the equinoctial line pass. From this it comes about that the shadow of the style falls upon the point M when the sun is in the common section of the meridian and the equator, as can easily be gathered from proposition 11 of book I. For since, when the sun is in either of those circles, the shadow of the style falls (by the said proposition) upon the common section of that circle and the plane of the dial, it comes about that, when the sun is at the point where the said circles cut each other, the shadow of the style falls upon the point where the common sections of those circles and the plane of the dial intersect — such as is the point M; otherwise it would not fall upon both lines, as is clear.

Since this is so, the hour-circles will cut the plane of the declining dial at the same points at which the lines drawn out through the centre L and through the divisions of the circle — as common sections of those circles and the equator — meet the equinoctial line GH; and therefore the common sections of those same circles and the plane of the declining dial — that is, the hour-lines — must be drawn through the same points. Since, then, these same lines — by the corollary of proposition 21 of book I — cut one another at C, the centre of the dial, the lines drawn from C through the points of the equinoctial line will be the lines of the hours from noon or from midnight.

Which are the lines of the hours from noon, and which from midnight, can easily be understood if the circle described from L is conceived in its proper position, and if attention is carefully paid to what we described in the scholium of proposition 1 of the preceding book concerning the sections of the lines of the circle described from L (which, of course, is divided into 24 hours) with the equinoctial line — always observing that, if the dial and the circle described from L are understood in their proper positions, those division-points that follow the common section of the meridian and equator (namely the line LM) on the upper side, toward the west, pertain to the hours from noon, while those that follow the same LM on the lower side, toward the east, indicate the hours from midnight. And since, as we taught in the same scholium, those hours are to be inscribed on the dial whose lines in the circle described from L meet the centre L before they meet the plane of the dial, it can easily be recognized which points of the equinoctial line indicate the hours from noon and which the hours from midnight.

Rightly, then, has the construction of the declining dial been established by us. That a line drawn through C parallel to the equinoctial line represents that hour whose line — in the circle described from L, drawn through L — is parallel to that same equinoctial line (which does indeed sometimes, though rarely, happen), we

shall easily demonstrate in this way. That parallel drawn through L is the common section of the equator and of the hour-circle drawn through it; and to this common section, if the circle described from L is understood to have its proper position, the plane of the dial is parallel — for otherwise that parallel, when produced, would cut the plane of the dial, and hence also the equinoctial line, which lies in the same plane of the equator in which that parallel lies, which is absurd, since it is parallel to the equinoctial line. Therefore, by proposition 18 of book I, the common sections made by the plane of the dial in the equator and in the said hour-circle will be parallel to one another — that is, the equinoctial line and the hour-line of that hour-circle. And so a line drawn through C parallel to the equinoctial line will represent that hour whose line — in the circle described from L, drawn through L — is parallel to that same equinoctial line, as we said in the construction.

[Margin: The description of the dial declining from the vertical, just handed down, is not rightly criticized by Giovanni Battista Benedetti [Giovanni Battista Benedetti] in his *Gnomonica*.]

FROM all this it is clearly established that this method of describing the declining dial — which nearly all other writers use — is wrongly criticized by Giovanni Battista Benedetti in his *Gnomonica*, chapter 49. For, as is established from the demonstration we have brought forward, the hour-lines are rightly drawn by this method on a plane that declines from the vertical. The method, however, which he prescribes in that place — differing from the one we have handed down — is also sound, but in no way contrary to ours; because we set DEF as the angle of declination of the plane from the vertical circle properly so called, whereas he, in place of this angle, takes the angle of declination of that same plane from the meridian circle. So it is no wonder that his method differs from ours. But if we were to set DEF as the angle of declination of the plane from the meridian, as he does (as perhaps he supposed was done by others), and were then to proceed in the rest of the description as we have handed it down, the declining dial would undoubtedly be described wrongly — as he rightly teaches.

[Margin: Another way of laying out the hours from noon, or from midnight, in a dial declining from the vertical, by means of the horizontal dial.]

THE hour-lines can also be conveniently drawn from C in this way. From the point F let straight lines be drawn out making with EF the same angles that the hour-lines make with the meridian line in the horizontal dial described in proposition 1 of the preceding book — namely, the line of the 6th hour, such as is Fα in the figure above, [making] a right angle, and so on. This will easily be done

if from the centre of the horizontal dial a hidden circular arc is described cutting all the hour-lines, and an equal one, also hidden, is described from F toward the line AB. For if all the hour-intervals are transferred from that arc — beginning from the meridian line — into this one described from F — beginning from the line EF — then the lines drawn from F through the points of this arc will be hour-lines corresponding to the hour-lines in the horizontal dial. Therefore, where these lines intersect the line AB, the lines drawn out from C, the centre of the dial, through those points will give the hour-lines, as before.

For since in the plane of the horizontal dial the point F is the centre at which all the hour-lines from noon or midnight divide, because the axis of the world falls upon it, as we said, it comes about that the hour-lines in the plane of the declining dial must be drawn through those points of the line AB (which lies in the plane of the horizontal dial) at which the hour-lines of the horizontal dial cut the line AB lying in the same plane. For at those points the hour-circles cut the line AB. Since, then, the meridian line — that is, the line of the 12th hour — in the horizontal dial, namely the line FE, cuts the line AB at the point E, through which the meridian line of the declining dial is drawn; and since the line of the 6th hour meets that same line AB at the point α , inasmuch as in the horizontal dial the line of the 6th hour cuts the meridian line at right angles — it comes about that through the point α the line of the 6th hour must be drawn in the declining dial. By the same reasoning, the remaining lines going out from F — according to the ratio of the angles that the hour-lines make with the meridian line FE in the horizontal dial — will give on the line AB the points through which the hour-lines are to be drawn in the declining dial. Furthermore, from the horizontal dial you will easily recognize which points of the line AB pertain to the hours from noon and which to the hours from midnight.

[Margin: How the previous description of the hours is to be corrected.]

By this method the previous description can easily be examined and corrected, should some error perhaps have been committed in it. For if the hour-lines drawn through the points on the line AB, found in this way, agree with the hour-lines drawn through the points which we found on the equinoctial line by the earlier description, then no error will have been made in drawing the hour-lines. Indeed, this latter method of drawing the hour-lines is especially useful for drawing those lines which either do not cut the equinoctial line at all, or scarcely do so except at very remote points — such as, in the proposed example, the lines of the 3rd and 4th hours from noon, and so on.

[Margin: What to do when the points L and M in the figure above are too little distant from each other.]

Again, since the points L and M are sometimes so little distant from one another that a straight line can scarcely be drawn through them without error — the line from which the division of the circle described from L must begin — for such a line can easily deflect toward one side or the other, so that the resulting error in the hour-lines is at times not slight: we shall do well if first, from F, we draw to EF the perpendicular line $F\alpha$, cutting the line AB at α , so that the line $C\alpha$, when drawn, gives the 6th hour, as we demonstrated. For where the line $C\alpha$ cuts the equinoctial, from that point through the centre L we shall draw a straight line, which the line LM will necessarily cut at right angles at L, if no error has been made. By this means it will come about that the hour-lines are drawn most accurately, provided the said two lines cut each other at right angles. The operation must therefore be examined carefully before we proceed further in the description of the dial.

Diagram. A large and intricate construction of the declining dial. A horizontal diameter runs across the middle from **A** (left end) to **B** (right end) — the line AB. A radiant "sun" point **C** near the top (right of centre) sends out the full fan of hour-lines, which terminate in the numbered hour-marks arranged around the periphery. A large circle (the division circle) is drawn low in the figure with its centre at **L**; the point **D** lies at its lowest point, directly below the centre, on the vertical through the middle. **E** lies on the line AB near the centre, below **C**; **M** lies just below **E**; **F** lies below **L**. A short right-angled auxiliary construction (a small square with dotted sides, labelled near **b** and **Z**) sits at the upper right.

Readable labels, by position:

- **C** (upper centre, right of middle): the radiant point from which the hour-lines issue.
- **A** (left end of AB); **B** (right end of AB): the horizontal line AB.
- **E** (on AB, centre); **M** (just below **E**); **R** (near centre, above **M**) [?]; **Y** (centre, below **C**) [?].
- **L** (centre of the division circle, low); **F** (below **L**); **D** (lowest point of the circle, below the "12").
- **V** (upper centre, at the small square construction); **T**, **S** (centre-left, below **V**) [?]; **H** (centre-left); **X** (left of centre, below **H**).
- α / **a** (on AB just right of **A**); β (on AB, right of **E**).

- O (left, on the circle); N and P (lower left, N above P); b and Z (upper right, at the dotted square).
- Peripheral hour-numbers (as engraved): upper-left 3, then 4, 5 down the left edge; 6 at the far left (tip of the 6th-hour line beyond A); across the top 1, 7, and 6; down the right side 5, 4 (as "4."), 3, 2, 1; along the bottom 8, 9, 10, 11, 12.

[Several peripheral labels are worn or crossed by ruling and are given as best-read; this dense figure]

[Margin: By what method the division of the circle described from L may be begun from somewhere other than the line LM.]

But if the line $F\alpha$ happens to fall too far from the point E, and so cuts the line AB [too far off], we shall be able to draw, in place of the 6th hour, any other hour-line whatever that can conveniently and without error cut the line AB — provided, however, that it makes with the line FE the same angle which that hour makes with the meridian line in the horizontal dial. If, at the point where this line cuts the line AB, we draw a line to C, the centre of the dial, and if, at the point where this line divides the equinoctial, we carry another line through the centre L, we shall have in the circle described from L a line described from which the division of that circle can most conveniently be begun. Or else we shall draw the line of the 6th hour by another method, which we shall hand down in the following scholium from Andreas Schoner. If, then, some one of the points of division falls exactly on the line LM, the operation has been rightly carried out; but if not, some error has certainly been committed, which you must correct before you go on to the rest.

I should wish these cautions to be applied also in the following declining and inclined dials, if a description of the hour-lines complete in every numerical detail is desired — provided that, in a dial which declines from the horizon (of which we shall treat in proposition 13 of this book), the lines drawn out from F and the line AB that they cut are taken from the vertical dial. For the line EF is the vertical meridian line of the dial in that dial, as we shall there show.

[Margin: Another description of the dial declining from the vertical...]

Otherwise: we shall construct the same declining dial after the likeness of the horizontal dial, in this way. By proposition 29 of the first book, let the altitude of the pole above the plane of the declining dial be found, as though above some Horizon;

[Margin: ...of the dial declining from the vertical, from the altitude of the pole above the declining plane and from the inclination of the proper meridian of that same declining plane to the meridian of the horizon.]

and by proposition 30 of the same book, [let there be found] the inclination of the proper Meridian of the plane of the declining dial (I call the Meridian of this plane the great circle drawn through the poles of the world and through the poles of the declining plane, which of course stands at right angles to the declining plane, and which measures the altitude of the pole found above it, like a kind of Meridian with respect to the Horizon) to the Meridian of the Horizon, or of the place in which the dial is constructed. Then, for the altitude of the pole found — but taking account of the inclination of the said Meridians that has been found — let a horizontal dial be constructed, as we taught in proposition 1 of the preceding book, except for a few things which must be changed here on account of the inclination of the said Meridians and the situation of the declining plane, that is, according as it faces south or north. And we shall lay out the diagram in the way this ought to be done.

First let there be set up a figure entirely similar to the earlier figure of proposition 1 of the preceding book — namely a portion of the Analemma, in which are contained the common sections of the proper Meridian of the declining plane itself with the Horizon, the Vertical circle, and the Equator, and so on. (The great circle to which the plane of the declining dial is parallel plays the role of the Horizon; and another great circle at right angles to it, passing through the common sections of the Equator and of the said Horizon, performs the office of the Vertical circle.) This is arranged so that the arc CE measures the altitude of the pole found above the declining plane, and the line DG is equal to the style of the declining dial, of whatever size, etc. In our example the arc CE comprises 40 degrees 3 minutes; for such, very nearly, is the altitude of the pole found above the plane of the proposed declining dial (for we now use the same plane as before), and the line DG has been taken equal to the style IK of the same dial, so that we may not be forced to set up a new figure for this description. We could, however, at our own discretion take a style of any length.

Diagram. A portion of the Analemma, drawn as a semicircle. The diameter runs from **B** (left end) to **C** (right end), with the apex **A** at the top of the arc and the centre **D** at the middle of the diameter. From the centre **D** radial lines run out to **F** on the upper-left of the arc, to **A** at the top, and to a point on the upper-right of the arc [labelled **I** [?]]. Below the diameter a nearly-horizontal line runs from **H** (lower left) across the figure to the lower right; **G** lies at the bottom, directly

below D (the line DG being vertical), and I lies at the lower right. Labelled points: A (apex), F (upper-left arc), [upper-right arc label, read as I [?]], B (left diameter end), C (right diameter end), D (centre), H (lower left), G (bottom), I (lower right).

After this, on the line CN — drawn anyhow in some plane, such as the index-line is in the earlier description — let there be cut off from CN a segment CG equal to the line HI (which is parallel to the Horizon in the portion of the Analemma); and again, let GL be taken equal to the line DI from the same portion of the Analemma; and through G let the perpendicular GH be drawn to CN. Then CN will be, as it were, the meridian line of the declining plane, if it were taken for some Horizon, and GH will be, as it were, the equinoctial line — as the lines HE and FK are in the horizontal dial of proposition 1 of the preceding book. Now, with a circle of any size described from L, we shall divide it into 24 equal parts, as in the same horizontal dial, with this one exception: that here the division of the circle is not to be begun from the line CN, as there from the line HE. (This is because CN is not the common section of the plane of the declining dial and of the Meridian, that is, of the circle of the 12th hour, but of some other great circle — the one which measures the altitude of the pole above the declining plane, and passes through the poles of the world and through the poles of the declining plane, like a Meridian with respect to the Horizon. In the horizontal dial, on the other hand, the line HE is the section of the plane of the dial and of the Meridian, that is, of the circle of the 12th hour.) Rather, from the point N there is to be counted the inclination of the great circle that measures the altitude of the pole above the declining plane — as if its own Meridian — to the Meridian of the Horizon, that is, of the place in which the declining dial is described. This inclination, in the proposed example, we found to be about 40 degrees 48 minutes; for the division is to be begun from the point that closes this reckoning.

[Margin: How great is the inclination of the meridian of the declining plane to the meridian of the horizon.]

[Margin: In which direction the inclination of the meridian of the declining plane to the meridian of the horizon is to be counted, in the circle described from L.]

But in order to know in which direction this reckoning is to be set up, we shall first consider whether the plane of the dial declines from the south or from the north; then whether it turns toward the east or toward the west. For if it deflects from the south toward the east, the said inclination is to be counted from the point N toward the left — that is, toward the western parts, toward A — as far as the point O, in our example. For since the pole of the properly-so-called Vertical circle is that point of the Horizon where it is cut by the Meridian, the pole of any

other Vertical circle declining from that one toward the east on the south side will lie in the southern and eastern quadrant of the Horizon, as can be seen from the material sphere. For all Vertical circles have their poles on the Horizon; since they are drawn through the poles of the Horizon, the Horizon in turn passes through their poles (as we demonstrated in the scholium to proposition 15 of book 1 of Theodosius). Therefore the great circle drawn through the poles of the world and through the poles of the declining plane, as its proper Meridian, will cut the Equator above the Horizon in the eastern quadrant, so that the Meridian of the Horizon, in the semicircle of the Equator above the Horizon, lies more to the west than the proper Meridian of the declining plane. Hence this inclination of the Meridians is to be counted from the point N — the point of the proper Meridian of the declining plane itself — toward the west, that is, to the left of the line CN, toward A, so as to obtain the point O, further to the west, at which the Meridian of the Horizon cuts the Equator above the Horizon.

For if the plane of the dial be set toward the south, so that the equinoctial line GH is below the point C, and the circle described from L about the line GH is understood to be turned round until it coincides with the plane of the Equator, then the point N will be toward the upper hemisphere; and the parts to the left of CN, toward A, will tend westward, while the parts to the right of the same line CN, toward B, will incline eastward. But if the plane declines from the south toward the west, the said inclination of the Meridians is to be reckoned from the point N toward the right, toward B — namely toward the eastern parts of the circle described from L — provided it has attained that position of which we just spoke; because then the Meridian of the declining plane is less to the east than the Meridian of the Horizon (as can easily be gathered from the material sphere and from what we just wrote), since then its pole, on the south side, is placed in the southern and western quadrant of the Horizon.

We do not, however, teach in which direction the said inclination of the Meridians is to be counted in a plane that declines from the north toward the east or toward the west, lest the reader's mind be confused by a multitude of precepts — especially since from the southern dial, once described, the northern one can be derived with the greatest ease, as we taught in the scholium to proposition 13 of the preceding book, and as will appear more clearly from the following scholium. There is also this: that from the precepts already handed down for a plane declining from the south, anyone will be able, on his own and without great labour, to find in which direction he ought to count the said inclination in the circle described from L, by observing carefully whether the Meridian of the place

— that is, of the proposed Horizon — on the Equator below the Horizon is more to the east or more to the west than the proper Meridian of the [plane]

declining plane. I say *below the Horizon*, because in the northern dial the point N looks toward the lower hemisphere, so that the proper Meridian of the declining plane cuts it below the Horizon at the point N — as is plain, if the position of the northern dial is rightly considered, together with the circle described from L. For if it is further to the east, that inclination is to be counted from N toward the eastern parts; but toward the western parts, if it is further to the west. It will not be difficult, however, to judge which parts of the circle described from L, reckoned from N, tend toward the east and which toward the west, if the circle itself, together with the northern dial, is imagined to be set in its proper position, so that the point N looks toward the lower hemisphere and its centre is joined to the centre of the world. For the parts on the left, when we are turned to face the northern dial, will be eastern, and those on the right, western.

Diagram. A portion of the Analemma, again drawn as a semicircle, essentially the same as the previous figure. The diameter runs from **B** (left end) to **C** (right end), with the apex **A** at the top of the arc and the centre **D** at the middle. From **D** radial lines run to **F** on the upper-left of the arc, to **A** at the top, and to a point on the upper-right of the arc [read as **I** [?]]. Below the diameter a nearly-horizontal line runs from **H** (lower left) toward the lower right, with **G** at the bottom directly below **D** and **I** at the lower right. Labelled points: **A** (apex), **F** (upper-left arc), [upper-right arc label, read as **I** [?]], **B** (left diameter end), **C** (right diameter end), **D** (centre), **H** (lower left), **G** (bottom), **I** (lower right).

Now, if through the points of division and through the centre **L** hidden straight lines are drawn cutting the equinoctial line **GH**, points will be obtained on the equinoctial line, and lines sent out from the centre **C** through them will give the hours from noon, or from midnight, as we demonstrated in the horizontal dial — yet in such a way that the line drawn out from **C** through the point **M** (where the line **OL** meets the equinoctial line) is the line of the 12th hour: of noon in the southern dial, but of midnight in the northern; and not the line **CGL**, as in the horizontal dial. For in the declining plane, if the circle described from **L** is understood to be in its proper position — namely, described in the plane of the Equator about its centre — the Meridian of the Horizon, that is, the circle of the 12th hour, passes through the point **O**, and consequently through the line **OL**, meeting the plane of the dial at **M**. So in the southern dial the point **O** lies in the semicircle of the Meridian above the Horizon, and therefore indicates noon; while in the northern dial the same point lies in the other semicircle, and so

pertains to midnight — as is manifest, if the circle described from L is understood to be in its proper position in the lower dial as well. The remaining hours follow this same order. In each dial the lines which, after the 12th hour, follow toward B belong to the hours after noon; those toward A, to the hours after midnight.

The style, and its place on the line CN, will be found as in the horizontal dial. For if the line CK is taken equal to the line HG of the portion of the Analemma, K will be the place of the style. And if, in the dial, a triangle CGI is made equal to the triangle HID of the portion of the Analemma, and the line KI is drawn, then IK will be the length of the style, and entirely equal to the line DG that was assumed, as is evident. For since the sides CI and CK of the triangle CIK are equal to the sides DH and HG of the triangle DHG, and the angles C and H are equal, by construction, the bases IK and DG will also be equal to each other. [Margin: a — by proposition 4 of the first book (Euclid, *Elements* I.4).]

[Margin: Another description of the same dial declining from the vertical.]

We can also set up the description of the same dial in this way. By proposition 30 of the first book, let there be found the arc of the declining plane intercepted between the Meridian of the Horizon and the great circle which is drawn through the poles of that same plane and measures the altitude of the pole above it, as its proper Meridian. In our example this arc comprises about 29 degrees 3 minutes. [Margin: How great is the arc of the declining plane intercepted between its meridian and the meridian of the horizon.] Likewise, by proposition 29 of the same first book, let the altitude of the pole above the declining plane be found, which in our same example amounts to about 40 degrees 3 minutes. Then, in some plane, let a line CD be drawn, anyhow, for the meridian line, or the line of the 12th hour; and in it, taking any point C, let the arc DP be described from that point, in which — from the line CD, that is, from the point D — let there be counted the arc of the declining plane intercepted between its own Meridian and the Meridian of the Horizon, as far as P (which arc we said comprises about 29 degrees 3 minutes); and from C, through P, let the line CP be drawn, which will be the common section of the plane of the declining dial and of the Meridian of that same plane, as we shall demonstrate shortly below.

[Margin: In which direction the arc of the declining plane, intercepted between its proper meridian and the meridian of the horizon, is to be counted.]

But in order to know in which direction the arc DP is to be counted, we must consider what we handed down in the preceding description. For if the plane declines from the south toward the east, the said arc is to be reckoned to the left,

toward A: because, as we said, the Meridian of the Horizon is then further to the west than the Meridian of the declining plane itself. Hence, with the dial set in its proper position, the meridian line CD will lie further to the east than the line CP — the common section of the plane of the dial and of the proper Meridian of the declining plane — since in the plane of the dial the ray of the Sun, wherever it is situated in its circle, is always projected to the opposite side. And it is clear that the line CD is further to the east than the line CP, if the dial has its proper position. But if the plane turns from the south toward the west, the arc DP is to be counted to the right, toward B: because then the Meridian of the Horizon is further to the east than the Meridian of the declining plane, as we said, and so in the dial the meridian line CD ought to lie further to the west than the line CP.

In which direction the said arc is to be counted in the northern dial we do not teach, for the reasons explained a little before — namely, lest the reader's mind be overwhelmed by a multitude of precepts, especially since it is enough for the southern dial to be described. For from this the northern one will be derived without any labour, as will be evident from the following scholium. Add to this that the matter itself is not difficult, if one considers whether the proper Meridian of the declining plane, in the lower hemisphere, is further to the east or further to the west than the Meridian of the Horizon. For the aforesaid arc must always be counted in the [northern] dial in the opposite direction, etc. — yet with this rule: that in the northern dial the point C lie below the arc DP. [recte: horologio ("dial"); printed *borologio*.]

After this, from any point of the line CP — say from G — let the perpendicular GH be drawn to it, which will be the equinoctial line. For the line CP is the index-line, as we shall show shortly, to which the equinoctial line is necessarily perpendicular, as we demonstrated above. Now, the altitude of the pole above the declining plane having been found by proposition 29 of the first book, let there be constructed at C, upon the line CP, the angle GCH of this found altitude of the pole. For GH will be the axis of the world, and from G let the perpendicular GI be raised to it; and let the rest be done as in the first description of this declining dial — that is, let GL be taken equal to the line GI, and let the circle described from L be cut into 24 equal parts, beginning from the line LM, and so on. The gnomon will be IK, the perpendicular drawn from I to CP, as before.

That the line CP is the common section of the plane of the declining dial and of the proper Meridian of that same plane, we shall show in this way. Since the Meridian of the Horizon and the Meridian of the declining plane — that is, the

great circle drawn through the poles of the world and through the poles of the declining plane — are drawn through the axis of the world, they meet

[they meet] the great circle to which the dial is parallel, at the centre of the world — namely at I, the tip of the style. The result is that, where their common sections meet this great circle, they are straight lines forming at the centre of the world an angle subtended by that arc of the same great circle which is intercepted between those two Meridians.

Now these same Meridians meet the plane of the dial at the point C, where the axis is taken to meet that plane; and there too they make straight lines as their common sections, [Margin a: Euclid XI.16] which are parallel to those in the great circle, because the plane of the dial is parallel to that same great circle. Therefore these lines will contain, in the plane of the dial, an angle equal to the angle which those former lines make in the great circle. [Margin b: Euclid XI.10] Therefore, since the angle DCP is equal to it — as we showed in the scholium to Euclid VI.33 — it follows that the arc DP is similar to the arc of that circle intercepted between the two Meridians, because it contains the same number of degrees and minutes. Now let CD be taken as the meridian line — that is, the common section of the Meridian of the Horizon and of the plane of the dial. Then CP will be the common section of the plane of the declining dial and of the Meridian of that same plane — that is, of the great circle passing through the poles of the world and through the poles of that plane. And accordingly the style must be set upon it at right angles, since in this way it does not depart from the plane of this Meridian, but reaches the very axis of the world lying within it. Therefore CP will be the line of the index, or style. From this the rest of the construction of the dial will be demonstrated, just as in the first construction at the beginning of this proposition. We have therefore laid out the astronomical dial declining from the vertical circle — that is, the hour-lines, and so on. Which was to be done.

SCHOLIVM.

[Margin: A doubt raised against what has just been said.]

But at this point a certain scruple seems to need rooting out of the reader's mind, one that might otherwise trouble and torment him not a little. For how — someone will say — can the angle formed in the plane of the dial by the sections of those Meridians be equal to the angle in the great circle to which the plane of the dial is parallel, the angle formed there by the sections of those same Meridians, given that those Meridians do not cut into similar arcs the circle produced on the sphere by the plane of the dial and the great circle to which the

dial is parallel? For if they did cut them into similar arcs, then by Theodosius, *Sphaerica* II.16, they would pass either through their poles or would be tangent to one and the same parallel — and neither of these can happen here. For since both are drawn through the poles of the world, which cannot be the pole of those circles (since their pole lies in the Horizon), they will not be able to pass through the poles of those circles. Moreover, since the Meridian of the declining plane passes through its poles, it will bisect all its parallels (by Theodosius, *Sphaerica* I.15), and so will be tangent to none of them. Therefore those two Meridians cannot be tangent to one and the same parallel. Hence the arcs which the said equal angles cut off are not similar.

The same thing is plain to the senses on a material sphere, where one clearly sees that the Meridian, and either Colure, cannot divide into similar arcs the Horizon and a circle below the Horizon parallel to it, because those circles are not drawn through their poles. And the same reasoning holds for any declining vertical circle and any circle parallel to it. This being so, those two angles formed by the said sections do not seem able to be equal, since — as we showed — they do not cut off similar arcs from the great circle to which the dial is parallel, nor from its parallel which the plane of the dial produces on the sphere.

[Margin: Resolution of the foregoing doubt.]

These are the considerations that might make the reader anxious, and so it will be necessary to explain the matter more clearly. I am glad to resolve this doubt here — though I know it has no place among those trained in the elements of spherics — because from it many other similar doubts can be cleared up, as will become plain from what follows. I say, then, that we have rightly demonstrated those angles to be equal; nor is it any objection that those arcs are not similar. For since the axis of the world does not fall on the centre of the circle which the plane of the dial produces on the sphere — because, by Theodosius, *Sphaerica* I.10, that circle's own axis falls on its centre — the point C, on which the axis of the world falls, will not be the centre of that circle. And accordingly it is impossible for the straight lines forming the angle at C in the plane of the dial to cut off from that circle an arc similar to the one cut off, in the great circle to which it is parallel, by the straight lines that contain an equal angle. For only equal angles set at the centres of circles, or at their circumferences, stand on similar arcs — as we demonstrated in the scholium to Euclid VI.33 — which the two aforesaid angles are not. For of them, the one in the great circle to which the dial is parallel is set at its centre — that is, at the centre of the world — while the other is set in the circle parallel to it, outside its centre, namely at the point C, which we have just

shown is not the centre of that circle. It is nonetheless true that, if a circle is drawn from C in the plane of the dial, the arc which the said angle DCP cuts off — such as, in our example, the arc DP — will be similar to the arc that an equal angle, set at the centre of the great circle to which the dial is parallel, cuts off from it. But that circle is not concentric with the parallel which the plane of the dial makes on the sphere, as we showed. Therefore the doubt raised here has no place.

[Margin: How a dial declining from the vertical is to be set up so as to show the hours.]

Now if the declining dial drawn so far is set upon the declining plane in such a way that the meridian line — that is, the 12-o'clock line CD — is perpendicular to the Horizon, and the straight line AB, cutting it at right angles, is parallel to the Horizon; and if furthermore, in dials declining from the south, the point C is placed upward and the point D downward, while in those turning away from the north the point C is placed downward and D upward; and if also at the point K the style IK is fixed at right angles, or the triangle CIG is set upright to the plane of the dial — then the tip of the shadow cast by the top of the style, or the whole shadow of the entire axis CI, will indicate the hours from noon, or from midnight, as we showed in the scholium to Proposition 1 of the preceding book.

[Margin: How, on a fixed plane that declines from the vertical, an astronomical dial is to be described.]

[Margin: By what method the hour-lines can be drawn according to Andreas Schöner, even though their points are not found on the equinoctial.]

But if the dial is to be described on the declining wall itself, and not on some other plane from which it is then transferred onto the wall — as we have done up to now — then on the wall a straight line CD must be drawn, made perpendicular to the Horizon by means of a plumb-line, and perpendicular to it, on the same wall, a line AB must be drawn, which will be parallel to the Horizon. Or, if you prefer, using a level and a plumb-line, draw the straight line AB parallel to the Horizon, and raise perpendicular to it the line CD, which will be perpendicular to the Horizon. The rest is to be constructed as in the first description of the declining dial — namely, the line of declination EF is to be drawn, and the line FG perpendicular to AB, and so on. But if you prefer to use the other two methods, here too, before anything else, a straight line CD must be drawn perpendicular to the Horizon. Then a straight line CP is to be drawn so that CD and CP intercept the arc DP, as we said in the third method — yet with this proviso: that careful

attention be paid to which side the arc DP (found by Proposition 30 of the first book) ought to be reckoned toward, just as we prescribed in the third method. Everything else is to be completed as before — that is, the equinoctial line GH is to be drawn perpendicular to CP, and so on.

But since it sometimes happens that some of the hour-lines either never meet the equinoctial line, or meet it only very far off — which comes about because the straight lines drawn from the centre L through the division-points of the circle described from L are sometimes parallel to the equinoctial line itself, or intersect it at very remote points — Andreas Schöner [Andreas Schöner] devised a method,

truly ingenious, by which these same hour-lines can be drawn from C, the centre of the dial, without any regard to the equinoctial line. This he did in the horizontal dial as well, and in the vertical. His construction runs roughly as follows. From the point E, drop perpendiculars ET and EQ to the lines βC [?] and EF; and let EQ be made equal to ET [?]. Now let the straight line QF be drawn, cutting the line AB at R. Through R draw RS perpendicular to AB (or parallel to CD), cutting the line C α — the 6-o'clock line — at S. Again, through S draw ST perpendicular to RS (or parallel to AB); and having taken ST equal to RS, draw through T a line perpendicular to ST (or parallel to RS). Finally, if a semicircle described with T as centre is divided into 12 equal parts, beginning from the line TS, the straight lines drawn from T through the division-points will cut the line RS at points through which the lines issuing from C, the centre of the dial, will give the hour-lines, as before. And if this method of construction is combined with the earlier ones, all the hour-lines will be drawn most accurately and precisely. For those hour-lines that cut the line RS at remote points will divide the equinoctial line not far from the point G, as appears at the 11-o'clock line; and those that cut the equinoctial line only with difficulty will most conveniently cut the line RS, as is clear at the 4-o'clock line.

But because for this construction it is necessary first to draw the 6-o'clock line from C, the centre of the dial, through the point α on the line AB — the point on which the line F α , perpendicular to the line of declination EF, falls (for without this the point S cannot in any way be obtained on the line RS, as is evident) — and because it sometimes happens that this 6-o'clock line can only be drawn without error with difficulty, since the perpendicular F α occasionally falls on a very remote point of the line AB (which occurs when the declination of the dial's plane from the vertical circle is very small, so that the line of declination EF lies close to the line CD, as is evident):

[Margin: How the 6-o'clock line can be drawn on planes declining but little from the vertical.]

the same Andreas [Schöner] teaches how the 6-o'clock line can then, when this happens, be drawn even though the line $F\alpha$ has not been drawn. We shall carry the matter out with him as follows. From the point β , draw βZ perpendicular to AB (or parallel to CD), which the line CZ — perpendicular to CD , or parallel to AB — cuts at Z . Then at Z construct the angle of declination CZa : above the line CZ if the plane declines from the south, but below it if from the north. (This is to be understood when the point β lies on the opposite side of the line of declination EF , as in our example; for if the point β and the line EF lie on the same side of the line CD , the angle of declination CZa must be constructed below CZ in southern dials, but above it in northern ones.) Also, having taken the line Za equal to $Z\beta$, draw through the point a — which we shall perhaps find more easily if from Z , at the interval $Z\beta$, we describe the arc Za above the line CZ (or below, as we said of the angle CZa), and count off the declination of the dial's plane from the point C as far as a — the straight line ab , parallel to AB (or perpendicular to βZ), cutting βZ at b . For the straight line drawn out through the points b and C will give the desired 6-o'clock line.

This will be demonstrated as follows. The triangles αEF and $aZ\sigma$ are equiangular, since the angles at F and σ are right and the angles at E and Z are the complements of the declination. It follows [Margin c: Euclid VI.4] that αE is to EF — that is, to $F\beta$, or to CZ , that is βZ — as aZ (that is βZ), or EC , is to σZ [?: this proportion is set very compressed in the print, and its middle terms are hard to construe]; and, by alternation, as αE is to EC , so CZ is to $Z\sigma$. Therefore, since the two triangles αEC and $CZ\sigma$ have the sides αE , EC proportional to the sides CZ , $Z\sigma$, and are joined at the angle at C so that their corresponding sides are parallel, [Margin d: Euclid VI.32] the sides αC and cb will form one straight line; and so the line bC will not differ from the 6-o'clock line. The same procedure and demonstration also apply to the following construction.

[Margin: In this figure let the lines βM and βI [?], and ba , and bC , and Za , and Zc be drawn; and from Z let an arc be described at the interval Za , beginning from the line ZC , through a , upward, in the same way as was done in the first figure of this proposition.]

Diagram. A large declining-dial construction figure occupying the lower two-thirds of the page. At the centre is a small circle enclosing the point **C** (the centre of the dial), with **F** just to its left, a lowercase **z** just to its right, and **E** immediately below it. From **C** a fan of straight hour-lines radiates outward to a wide

semicircular spread of numbered and lettered points; a dashed circle (the division-circle) and dotted construction-arcs run through the lower half of the figure, with the points **L**, **G**, **M**, **H**, and **D** lying on or near them in the lower-central region, and **I** to the left below **F**. The peripheral hour-points, read where legible, run clockwise from the upper left: **A** (upper left), α , **a**, **b**, **5** (upper right), then down the right side **4**, **B**, β , **3**, then across the bottom **2**, **1**, **12**, **11**, **10** [?], and up the left side **9**, **8**, **7**, **6**, **N**, with a further **A** and lowercase α [?] on the left margin and an **S/5** [?] on the left. Because the peripheral labels are small and several sit on crossing lines, the readings marked [?] (the second α , the left-hand S/5, β I, and the bottom "10") could not be resolved with certainty.

- **C** (centre, in small circle): centre of the dial
- **F** (just left of **C**): tip/foot point of the style-triangle
- **z** (just right of **C**, lowercase): construction point
- **E** (just below **C**): construction point on the meridian
- **I** (left, below **F**): construction point
- **G** (lower-central): point where the equinoctial meets the style-line
- **M** (lower-central, near **G**): point where the equinoctial meets the meridian
- **L** (lower left of centre): centre of the division-circle
- **H** (lower-central): point on the declination arc
- **D** (lower-central): point on the declination arc
- **A**, **B**: end-points of the horizontal line **AB** (also serving as hour-line terminals)
- α , β , **a**, **b**: alphabetic construction points on/around **AB**
- **N** (lower left): construction point
- Numerals 1–12 around the periphery: the hour-line terminals (several flagged [?] — see above)

[Margin: Construction of a declining dial for a given length of style whose position is also given.]

But if the same dial declining from the vertical circle is to be described on a given plane, for any length of style whose position is also given, we shall proceed by this device. On the plane of the dial let the position of the style be given at the point **K**, and its length **KF**. Through **K**, the position of the style, draw two straight lines **AB** and **FD**, cutting each other at **K** at right angles. Or, if the plane is fixed and perpendicular to the Horizon, draw through **K** a line **AB** parallel to the Horizon (by means of a level and plumb-line), which the line **DF** cuts at **K** at right angles; and **DF** will be perpendicular to the Horizon, as we shall demonstrate. Or,

alternatively, first draw (by means of a plumb-line) the line FD perpendicular to the Horizon through K, the position of the style; the line AB cuts it at K at right angles, and AB will be parallel to the Horizon — indeed, it will be the common section of the Horizon and of the plane of the declining dial, as we shall also demonstrate. On FD, having taken the length of the given style KF (either upward or downward), describe from F as centre, toward AB, an arc of a circle DH: toward B if the wall or plane of the dial declines from the south toward the east, or from the north toward the west; but toward A if it turns from the south toward the west, or from the north toward the east. On this arc mark off the declination of the wall, DH —

(this arc should contain nearly 30 degrees from the south toward the east, as before). When the straight line FH has been drawn, cutting AB at E, draw through E the line CE parallel to FD (or perpendicular to AB). For CE will be the meridian line, that is, the 12-o'clock line. Then in the arc HD, on the other side of the produced line FD, mark off the complement of the declination DN, and draw the line FN; or else draw the line F α perpendicular to FE, cutting AB at α . For through the point α both the equinoctial line and the 6-o'clock line must be drawn. Also, having taken on AB a line E β — either to the right or to the left of the meridian line CE — equal to EF, describe from β , toward CE, an arc of a circle: upward in a dial declining from the south, but downward in one that turns away from the north. On this arc mark off the altitude of the pole, beginning from the line AB, and from β draw, to the end of that measurement, a straight line cutting CE at the point C, which will be the centre of the dial, where all the hour-lines meet. Now draw from C, through K (the position of the style), the straight line CK for the style-line; and let a straight line drawn from α cut it at right angles at G. Then the line α G will be the equinoctial line. After this, raise from K the line KI perpendicular to CK and equal to the style KF, and join the lines CI and GI, which will contain a right angle at I, as we shall demonstrate. Hence, the line CI having been drawn, if we raise a perpendicular IG to it, we shall find on the style-line CK the point G, through which the equinoctial line α G, perpendicular to CK, must be drawn from α . But if from β a perpendicular β M is raised to β c, cutting the meridian line CM at M, the equinoctial line must be drawn through M as well; and indeed it is drawn more precisely through the more remote point M than through the nearer point G. And CI will be the axis of the world. Now on the style-line CK take a line GL equal to GI, and from L describe a circle of any size, dividing it into 24 equal parts, beginning from the line LM which is drawn from L through the point M, where the equinoctial line intersects the meridian. This line LM will necessarily cut the drawn line L α at right angles, if no error has been

made. Finally, let the rest be completed as was set out at the beginning of this proposition.

We shall demonstrate this construction as follows. [Margin: Demonstration of this construction.] Suppose that through the line AB and the style KF — which is perpendicular to the plane of the dial at the point K — a Horizon is drawn, so that AB is the common section of the Horizon and of the plane of the declining dial, namely the horizontal line. Suppose also that through the pole of the declining plane and the pole of the Horizon a great circle is drawn. By Theodosius, *Sphaerica* I.15, it will be perpendicular both to the declining plane and to the Horizon; and therefore, since it passes through the centre of the world — that is, through the tip of the style F — and since [Margin a: Euclid XI.18] all planes drawn through the style KF (which is perpendicular to the declining plane) are perpendicular to that same declining plane, this great circle will pass through the style FK and will cut the plane of the declining dial at K. Since, then, both the plane of the dial and the plane of this great circle are perpendicular to the Horizon, their common section too will be perpendicular to it; [Margin b: Euclid XI.19] and hence, by definition 3 of Euclid XI, it will be perpendicular to the line AB lying in the Horizon. Therefore the line FD, which we drew through K perpendicular to AB, will be the common section of the said great circle and of the plane of the declining dial, and hence perpendicular to the Horizon.

But if the line FD is drawn first, perpendicular to the Horizon, suppose a plane is drawn through the line FD and through the style FK (which is perpendicular to the plane of the declining dial); this plane [Margin c: Euclid XI.18] will be perpendicular both to the Horizon and to the plane of the declining dial. Since, then, both the plane of the dial and the plane of the Horizon are perpendicular to the plane drawn through the line FD and the style FK, their common section too will be perpendicular to that same plane; [Margin d: Euclid XI.19] and hence, by definition 3 of Euclid XI, it will be perpendicular to the line FD lying in the said plane, at the point K through which the Horizon is drawn, since it is drawn through the style FK. Therefore the line AB, which we drew perpendicular to FD, will be the common section of the plane of the dial and of the Horizon — that is, the horizontal line.

Next, since the angle EFk [?] is the declination of the plane of the dial from the vertical, the angle EFK will be the complement of that same declination — the very angle which the Meridian makes with the declining plane. Therefore, if the triangle EFK is rotated about EK until it is perpendicular to the plane of the dial set in its proper position, FE will be the common section of the Horizon and of the

Meridian drawn through F, the tip of the style; and therefore, as we demonstrated in the first description of this proposition, CM will be the meridian line — namely the common section of the Meridian and of the plane of the dial. And since the arc HN is a quadrant, the angle $EF\alpha$ will be a right angle; and accordingly the line $F\alpha$ will be the common section of the vertical and of the Horizon. For since both the Horizon and the vertical are perpendicular to the Meridian, their common section too will be perpendicular to it; [Margin e: Euclid XI.19] and hence, by definition 3 of Euclid XI, it will be perpendicular to the line FE lying in the Meridian, at F, the centre of the world. Therefore $F\alpha$, which is perpendicular to FE, is the common section of the vertical and of the Horizon. But the Equator has the same common section with the Horizon and the vertical — namely the axis of the Meridian — since all three of these circles pass through the poles of the Meridian (by Theodosius, *Sphaerica* I.13), because they are perpendicular to the Meridian. Therefore the Equator is drawn along the line $F\alpha$, and meets the plane of the declining dial at the point α ; and so the equinoctial line must be drawn through α .

The triangle EFK still remaining perpendicular to the plane of the dial, so that the angle CEF is a right angle — (that it is a right angle we show thus: since both the plane of the dial and the plane of the Meridian are perpendicular to the Horizon, their common section CE too will be perpendicular to it, [Margin f: Euclid XI.19] and hence, by definition 3 of Euclid XI, perpendicular also to the line FE lying in the Horizon in that position) — suppose the triangle βEC is rotated about the line CE until the line βE coincides with the line FE, and the point β with the point F, on account of the right angles βEC and FEC and the equality of the lines $E\beta$ and EF. This done, βC will be the axis of the world; since, in the plane of the Meridian (which is drawn through the lines FE and EC), it forms with the meridian line of the Horizon EF, at F the centre of the world, the angle $F\beta C$ equal to the altitude of the pole above the Horizon. Therefore, by the corollary to Proposition 21 of Book 1, the point C, on which the axis falls, will be the centre of the dial. Hence it follows that the line CK is the style-line — that is, the common section of the plane of the declining dial and of the proper Meridian of that declining plane, which is drawn through the axis and the style, serving as the proper meridian line of the declining dial; just as in the first description of this proposition the style-line CG was drawn from C, the centre of the dial, through K, the position of the style. By the same reasoning it follows that the line αG , which is perpendicular to the style-line, is the equinoctial line, since it must be drawn through the point α , as we recently showed, and it makes right angles with the style-line, as was demonstrated in the first description of this proposition.

That the same equinoctial line must be drawn through M we shall prove as follows. Suppose the triangle EFK is rotated about EK, and the triangle C β M about CM, until FK is perpendicular to the plane of the dial and the point β coincides with the point F, on account of the equality of the lines EF and F β , so that C β is the axis — as we showed a little earlier — and hence the triangle C β M lies in the plane of the Meridian. And since the common section of the Meridian and the Equator is perpendicular to the axis — because the axis, being perpendicular to the Equator, makes right angles with all straight lines drawn in the plane of the Equator through its centre (by definition 3 of Euclid XI), and hence with the common section of the Equator and the Meridian drawn through F (or β), the centre of the world — the line β M, lying in the plane of the Meridian and making right angles with the axis C β , will be the common section of the Meridian and the Equator. And accordingly the Equator meets the meridian line CM at M; and therefore the line of the Equator must be drawn through M.

That the straight line CI is the axis of the world is evident. For if the triangle CIK is rotated about CK until it stands perpendicular to the plane of the dial, and the style IK [stylus] is likewise perpendicular to that plane, the point I will coincide with the point F, and hence also with the point β . The straight line CI will therefore coincide with the axis C β . From this it follows that in that position the straight line GI is the common section of the Equator and of the proper Meridian of the declining plane itself, since each circle is drawn through G and through I, the centre of the world. The angle CIG will accordingly be a right angle, since the said common section is always perpendicular to the axis, as is clear from what precedes. The rest is evident from what was demonstrated in the first construction of this proposition.

[Margin: Description of the same dial by means of the ellipse.]

By means of the ellipse we shall likewise describe the same dial declining from the Vertical, just as we did for the horizontal one — as we showed in the scholium to Proposition 1 of the preceding book — with only a few changes. Let the length of the style be given again as KF, and let its position be the point K. Then, once the meridian line [linea meridiana] CE has been found — with C the centre of the dial, α G the equinoctial line [linea aequinoctialis], CI the axis of the world [axis mundi], and CG the style-line [linea styli] — as we prescribed in the immediately preceding construction: take on the axis, produced, a point H more distant than I, so that the dial may be described more accurately; and from H drop a perpendicular HN to the axis, cutting the style-line at N, so that HN becomes a new common section of the Equator.

Diagram. A large circular construction for the declining sundial drawn by means of the ellipse. A horizontal diameter runs from **A** (left) to **B** (right); a vertical diameter runs from **12** (top) through the centre down to **D · 12 · P** (bottom). Four oblique hour-lines carrying the numerals **3** (upper left), **6** (right), **6** (lower left) and **3** (lower right) radiate beyond the outer circle. Two concentric circles (the larger and the smaller of the construction) are drawn about the centre; the inscribed ellipse, whose major diameter is **NR** and minor diameter **ST**, is traced through the constructed hour-points. Readable interior labels, by region:

- Centre and horizontal line: **F**, **e** (centre), **K**, **E**, **β**, and toward the right **S** [?]; endpoints **A**, **B**.
- Upper arc: **12** (apex), **Q**, **δ**, **R**.
- Left, small auxiliary ellipse/right-triangle near **S–T**: **S**, **T**, and the small labels **m**, **l** [?], **i** [?], **n**, **p**.
- Left of centre, below **A–B**: **t**, **H**, **V**, **I**, **G**, **O**.
- Lower centre: **v**, **M**, **Z**; bottom **D**, **P** flanking the lower **12**.
- Lower-left, a second small right-triangle near the ellipse's lower vertex: **q**, **r**, **g** [?], **b** [?], with the vertex **N** below.
- Right: **f**, **X**, **b**, **a** (= α).

The point **L** (centre of the auxiliary circle named in the text) is not securely resolvable on the tile. Numerous small labels are worn or overrun by construction lines; the figure carries more than two uncertain labels

—tor, and of the proper Meridian of the declining dial's plane; and let **N** be the point through which the new equinoctial line must be drawn perpendicular to the style-line. Now, having cut off a straight line **CO** equal to **HN**, describe about the centre **C** of the dial two circles at the intervals **CN** and **CO**; and in the smaller circle draw the diameter **ST** perpendicular to **NR**, the diameter of the larger: then **NR** will be the major diameter of the ellipse and **ST** the minor — just as in the horizontal dial the major diameter is **BV** and the minor **RX**. The points of the ellipse through which the hours are to be drawn are now found, as was stated for the horizontal dial, if the said two circles are divided into 24 equal parts, the division beginning not from the proper meridian line of the declining plane — that is, from the style-line **RN** — but from a certain other straight line, which we shall find as follows. From **L**, the centre of the circle by whose aid we located the hour-points on the equinoctial line αG in the preceding description (this centre being distant from the point **G** by the interval **GI**), draw through the point **M** — where the equinoctial line and the meridian line cut one another — the straight line **LM**; and at **C**, on the line **CL**, construct on that same side on which the point

M lies an angle CLM equal to the angle LCP. For the division of the circles must begin from the straight line PQ. We shall find the same point P, from which the division starts, if from N, toward the meridian line CM, we reckon the arc of the Equator lying between the proper Meridian of the declining plane and the Meridian of the Horizon, as far as P: which arc, in our example, contains about 40 degrees 48 minutes. For such, roughly, is the inclination of the said Meridians, found from Proposition 30 of Book 1, as we said above.

So then, let it be required to find the point of the ellipse through which the 12-o'clock line is to be drawn. Through P, the point of the 12th hour, draw in the larger circle the line PZ parallel to ST, the minor diameter of the ellipse (this is easily drawn if NV is taken equal to the arc PN; for then the straight line PV will be parallel to ST, by the scholium to Proposition 27 of Book 3 of Euclid, since equal arcs are intercepted between the points P, V and the produced diameter ST). And through the point Y of the 12th hour in the smaller circle draw YZ parallel to RN, the major diameter of the ellipse (which is drawn with the same ease if the arc SX is taken equal to the arc ST; for then the straight line XY, by the same scholium to Proposition 27 of Book 3 of Euclid, will be parallel to RN, since equal arcs are intercepted between the points Y, X and the diameter RN), cutting PZ at Z. Then Z will be a point of the ellipse whose diameters are RN and ST, as is clear from the corollary to Proposition 26 of Book 1. I say that through the same point the meridian line, or 12-o'clock line, must be drawn.

For suppose (the triangle CHN being set perpendicular to the plane of the dial, so that it is joined to the proper Meridian of the declining plane) that in the plane of the Equator there is described, from H the centre of the world, a circle N h s m of the Equator at the interval HN, equal to the circle OST, which is to be the base of a right cylinder whose axis is the same as the axis of the world CH; and let the semicircle N h s turn toward the point P, or the meridian line, and on it take the arc Nh equal to the arc OY, or similar to NP. Through h draw the Meridian of the Horizon, since the arc Nh is similar to the arc of the Equator set between the Meridian of the Horizon and the proper Meridian of the declining plane. Therefore the side of the cylinder drawn from the point h — through which the plane of the Meridian of the Horizon, or of the 12-o'clock circle, is drawn — will fall on the point Z of the ellipse, on account of the similarity of the arcs Nb, NP, as is clear from what was demonstrated in the scholium to Proposition 1 of the preceding book.

For there, because the arcs BP, BF were similar, we demonstrated that the side of the cylinder drawn from P falls on the point L of the ellipse, and so on. By the

same reasoning, if through the points Q, u — opposite to the points P, Y — we draw two lines parallel to the two diameters of the ellipse, we shall find another point δ , through which the same meridian line is to be drawn. For onto that point falls the side of the cylinder drawn from the point m, which is opposite to the point h, through which of course the Meridian of the Horizon is drawn, on account of the similarity of the arcs Nm, NQ. In the same way, from the points a, b of the 6th hour the point f will be found, through which the 6-o'clock line is to be drawn; and from the point t (opposite in the larger circle) and its counterpart in the smaller circle, another opposite point, through which the same 6-o'clock line is to be drawn. And so with the rest.

You see, then, that the points Z, δ fall on the meridian line drawn at the outset, and that the 6-o'clock line drawn through f and its opposite point passes through the point α , through which, in the preceding description, we showed the 6-o'clock line must be drawn. Finally, you see that the 3-o'clock line, which could scarcely be drawn without error in the preceding description, can be drawn with the greatest exactness by means of this ellipse, and so on. In our example, since the style-line is unequally distant from the two hours placed on either side, the diameters of the ellipse will likewise be unequally distant from the two points found on either side. Hence — so far as the demonstration is concerned — in the circle N h s m concentric with the Equator, from each of the hours single perpendiculars must be drawn to the diameter sN, and through these must be drawn planes parallel to the axis, so as to form parallelograms whose sides, drawn from the hours, fall on the points of the ellipse, as was demonstrated in the said scholium to Proposition 1 of the preceding book. In the figure set before us the perpendiculars hg, ml are drawn from the 12th hour, both of midday and of midnight, while the perpendiculars pn, qr are drawn from the 6th hour, both of morning and of evening.

[Margin: NB (handwritten reader's mark)]

Now when the declination of the dial's plane from the Vertical circle is so great that it differs but little from 90 degrees — so that the plane itself nearly coincides with the Meridian circle — one can scarcely construct the dial by the rules handed down without running into some difficulty, and no slight one. For then the line of declination [linea declinationis] EF comes very close to the straight line AB; and on that account the straight line FG, and GH equal to it, is made too short; from which it follows that the axis CH lies very little away from the style-line CG, and hence that the style IK turns out extremely short, so that the dial is rendered all but useless. But if we should wish the line FG to be of some larger, apt, and

suitably convenient size, who does not see that the point F would be too far removed from the point E, and that the points G, β , C would therefore run out from that same point E further than is fitting? This is indeed a matter that contains no small difficulty and labour, since then an almost immense plane would be needed for laying out the dial. This can also be shown from the fact that the hour-lines (which in the meridian dial are parallel, as we long since demonstrated in Proposition 25 of the preceding book) appear, in the plane of a dial that stands but little away from the Meridian circle, almost parallel to one another — especially when the declination is 89, 88, or 87 degrees, and so on. But we shall provide a remedy for this inconvenience, nearly like the one we wrote for the horizontal dial in the scholium to Proposition 1 of this book, so that by the rules hitherto handed down we may describe a declining dial however little it stands away from the Meridian circle — even though the centre of the dial (which must then, of necessity, lie further than is proper from the point E, if we wish to have a style large enough to indicate the hours conveniently) is wholly unknown to us, inasmuch as it cannot fall within the plane (unless the plane has, so to speak, an immense size) but lies outside it. This device we shall now employ.

[Margin: When the plane of the dial stands but little away from the Meridian circle, the dial can only with difficulty be described by the rules handed down.]

In some plane, having drawn two straight lines AB and CD cutting one another at right angles at E, let there be constructed at E, on the line CD, the angle of declination — below or above the line AB, and to the right or to the left of the line CD, according as the plane declines from south or from north toward the east or the west, as we wrote at the beginning of this proposition. In the present example we set the plane's declination from the Vertical circle toward the east at 60 degrees, and from the Meridian at 30 degrees; the angle of declination DEF is therefore set below the line AB, toward A. We do not, however, assume a larger declination, in order that this description of ours may be made clearer and its demonstration plainer.

After this, on the straight line AB, having taken any point G whatever — whether toward the side to which the line of declination inclines from the line CD, or toward the opposite side, whichever is preferred (although in the example it was taken on the same side) — let there be constructed at the point G, on the line AB, the angle EGC of the altitude of the pole [altitudo poli], directed upward or downward according as the plane declines from south or from north; and let the straight line GC cut the line CD at C. From E cut off a straight line EF [read: EG] equal to EG, and from F draw the perpendicular FH to AB. But since, on account

of the narrowness of the space enclosed between the lines AB and EF (as tends to happen when the proposed declination is very great), a perpendicular cannot easily be drawn without error from the point F to the line AB, we may set up this same construction more conveniently in the following form. Having taken on the line AB, toward the side to which the line EF is drawn, any point H, draw from it a perpendicular HF to AB [read: to EF], cutting EF at F. For if from EF we cut off an equal straight line EG, and at G construct on the line EG the angle EGC of the altitude of the pole, we shall find the point C, the same as before but somewhat more certain — because it is easier to draw a perpendicular without error from the point H, taken on the line AB, to that same line, than from the point F, which lies extremely close to the line AB.

[Margin: How the dial may be described in a plane that stands but little away from the Meridian circle, even though the centre of the dial is not to be had.]

Next, having drawn CH through C and H, and produced it as far as one pleases, draw through H a perpendicular HI to it; and if on HI there be cut off HI equal to HF, and the line CI be drawn; likewise having drawn FN perpendicular to EF, cutting the line AB at the point N, let this be joined to C by the straight line CN — then, from what we demonstrated near the beginning of this proposition, the straight line CD will be the 12-o'clock line in the plane of the given declination; the point C the centre of the declining dial; CH the style-line, or line of the gnomon [*linea indicis, seu styli*]; CN the 6-o'clock line; CI the axis of the world; and HI the equinoctial line. But if again we draw from H the perpendicular HK to CI, this too — from what has been demonstrated — will be the common section of the Equator and of the plane which, drawn through the straight line CH, stands perpendicular to the plane of the dial, in the manner of a certain proper Meridian of the dial's plane itself. Hence, if on the style-line CH there were taken a straight line HL equal to HK, and about L a circle were described, there would be constructed a declining dial all of whose hour-lines would meet at C, exactly as was done in the first description of this proposition. But since a dial constructed in this way has its style KM — dropping from K onto the line CH at right angles at the point M — too short, especially when the line EF stands but little away from AB (and it will stand the less away, the greater the plane's declination from the Vertical, as has been said), we must therefore go further and teach by what method we can describe a larger dial, one that will receive an apt style suited to use — even though, in the plane set before us on which the dial is to be laid out, the centre of the dial cannot be marked, and hence perhaps not even the 12-o'clock line, unless the plane extends more in breadth than in height, so that the 12-o'clock line at least can be marked out, the plane receiving it because of the

notable breadth it has, while the centre, on account of the plane's slight height, cannot be drawn on the same [?] plane. For although the hour-lines proceeding from C — those drawn through the points of the equinoctial line HI, found by the aid of the circle described about L — always diverge more and more from one another when produced, so that from some point of the style-line CL, below the point M, a larger style could be drawn perpendicular to CL as far as the axis CI produced (as we shall teach in the scholium to the following proposition, when we describe a larger or smaller dial from the same construction lines, according to the given size of the style): nevertheless, because when the plane deviates but little from the meridian the hour-lines are nearly parallel, so that one would have to produce them almost to infinity before we could draw a style of the proposed size, we must therefore adopt another method. Thus, then, shall we proceed with the matter.

[Margin: a — Euclid I.29] On the equinoctial line HI take any point O whatever, the more distant from H the larger the dial, and the longer the style, is desired; and through O draw OP parallel to the axis IC, to which from H let the perpendicular HQ be drawn — [a] which, since it is also perpendicular to IC, parallel to OP, will pass entirely through k, because HK too is drawn perpendicular to IC (otherwise from H two perpendiculars would be drawn to IC, which is absurd). Next, from HF, produced (which is perpendicular to AB), cut off HR equal to HO; and having drawn RS parallel to FE, erect from R, to RS, the perpendicular RT (parallel to FN), cutting AB at the point T, through which let TV be drawn parallel to CN, cutting the equinoctial line HO [?: possibly HI] at X.

[Margin: b — Euclid I.29] Besides this, having taken on the style-line HC any point Y whatever, draw through it the straight line YP parallel to HQ, cutting OP at P — [b] which will be perpendicular to OP, just as HQ is. Likewise through Y draw YV perpendicular to HI, or parallel to HO, cutting TV at V.

Diagram. A large construction for a declining dial whose centre falls off the plane, drawn with a dense sheaf of hour-lines converging toward the upper right. A horizontal base-line runs from A (left) through E (centre) and S (right) to B, extended to the far-right point 1. A near-vertical line at the right descends from π (Greek pi, upper right) through 12 to S. A circle is drawn in the lower-left quadrant. Hour numerals label the divergent lines: 3, 4 across the top; 3, 4, 5, 6, 7, 8, 9 down the left side; 8, 9, 10, 11, 12 along the bottom; and a tight inner fan 4, 5, 6, 7, 8, 9, 10, 11 near the centre-right converging on π . Readable letter-labels, by region:

- Horizontal base and right: A, T, N, G [?], E, S, B, 1.

- Central cluster: **H, K, X, M, L**, and below **F, R**.
- Upper / left of circle: **O, Q** [?], **P, V, a** (α), **b**.
- Lower centre: **D, Z** [?], and the vertical carries **12** and π .

The figure is crossed by many overlapping construction lines and dotted auxiliaries; several small labels are worn or overrun. More than two labels are uncertain

Lastly, having taken on the straight line HY the straight lines HZ, Ya equal to the straight lines HQ, YP, describe circles about Z, a, and divide them into 24 equal parts, the beginning made from the straight lines drawn from the centres Z, a through the points X, V. For the hidden straight lines drawn through the centres Z, a and the points of division will cut the straight lines HO, YV at points through which, when straight lines are drawn out (always taking two corresponding points together — that is, the two nearest to H, Y, then the next two, and so on), they will yield the hour-lines, which we shall here produce this way and that as far as the size of the plane will allow. For their lengths will be bounded by the arcs of the signs. The length of the style will be Qb, the perpendicular dropped from Q to HY, and its position at the point b, on which the said perpendicular falls. All of which we shall prove by the following reasoning.

[Margin: Demonstration of the construction of the dial declining but little from the Meridian.] [Margin: c — Euclid I.29]

Since the straight lines RS and FE, parallel with the straight line AB, must at length necessarily meet somewhere, let them meet at the point S. (This point S, however, will for the most part fall outside the plane, unless the plane be immense, since it lies extremely far from the point E if the declination of the dial's plane differs but little from 90 degrees. Hence it must then be conceived only in the mind.) Through it let there be understood a perpendicular $S\pi$ drawn to AB, or parallel to CD, meeting HC produced at π . [c] And since the angle HSR is equal to the angle HEF, the complement of the given declination, if the straight line πS be taken for the meridian line in the plane of the dial, SR will be the line of declination. And since in it, from the point R, a perpendicular RH has been drawn to AB, the style-line must be drawn through the point H, as was shown in the first description of this proposition, making with the meridian line $S\pi$ an angle equal to the angle ECH, which the style-line CH in the dial (whose centre is C) makes with the meridian line CE. This is because in the same declining plane the style-line always makes the same angle with the meridian line, and hence also with the straight line AB, which is equidistant from the Horizon, whatever length of style be taken; otherwise the equinoctial line, which must be drawn through

the point H perpendicular to the style-line, as has been demonstrated, would not always make the same angles with the straight line AB — which is absurd.

This can also be confirmed by the following reasoning. Since the plane of the proper Meridian of the declining plane itself, which makes the style-line in that very plane, and likewise the plane of the horizontal dial drawn through the straight line AB, are both — as is clear from what precedes — perpendicular to the plane of the declining dial, [d] their common section too will be perpendicular to that same plane, meeting it at the point H, through which the style-line, and therefore the proper Meridian of the declining plane producing it, is drawn, as has been said. And on that account the same section, by definition 3 of Book 11 of Euclid, will make right angles both with the straight line HE and with the style-line drawn through H in the plane of the dial. Therefore, by definition 6 of Book 11 of Euclid, since each of them in turn makes right angles with that common section, the angle contained by the straight line HE and the style-line will be [an ang-]

[Margin: d — Euclid XI.19]

the angle of inclination of the plane on which the said proper Meridian of the declining plane stands, relative to the plane of the horizontal dial. And since this inclination does not change within the same declining plane, it will make, together with the straight line HE, always one and the same angle. Therefore, since HC has been shown to be the style-line in the dial whose centre is C, and since it has been demonstrated that the style-line in the dial in which the meridian line is πS passes through H, the line HC produced will be the style-line in this same dial — for at H it makes one and the same angle, and at π it makes, with the meridian line πS , an angle equal to the angle HCE, which the style-line in the earlier dial makes with the meridian line CE. [a] That the angles HCE and $H\pi S$ are equal is evident, because CE and πS are parallel. From this it follows that the point π is the centre of that dial in which the meridian line is πS , since the style-line and the meridian line meet at the centre of a dial. It also follows that the straight line HO, which is perpendicular to the style-line, is the equinoctial line of that same dial, as is clear from what precedes.

[Margin: a — Euclid I.29]

Now since on the equinoctial line HO the straight line HO has been taken equal to HR, it will follow, by what has been demonstrated, that the straight line drawn from the centre π to O — the axis of the world — makes at π , with the style-line πH , an angle $O\pi H$ equal to the angle ICH which the earlier axis IC makes with the

style-line. For the angle of the pole's elevation above this same declining plane is always the same, and this is precisely the angle the world's axis makes with the style-line, as is clear from what precedes. [b] Therefore the axes $O\pi$ and IC will be parallel; and consequently the straight line OP , which has been drawn parallel to IC — even if we do not produce it all the way to the centre π (which is sometimes unknown to us) — will be the axis of the world. From this it follows that the straight line HQ , drawn perpendicular to the axis, is the common section of the Equator and of the proper Meridian of the declining plane itself.

[Margin: b — Euclid I.28]

Again, since the perpendicular RT has been drawn from R to the line of declination SR , it will necessarily pass through T — the line of the 6th hour — as we showed above. Therefore the straight line drawn from the centre π through the point T will yield the 6th hour, and will make at π , with the style-line, an angle $T\pi H$ equal to the angle NCH which the 6th-hour line CN of the smaller dial makes with the style-line CH . For the circle of the 6th hour always keeps the same inclination to the proper Meridian of one and the same declining plane; and therefore the common sections which these circles make with that same declining plane (whatever length of style be taken, through whose apex they are drawn) will always make the same angle — namely, an angle equal to the one which the sections of those same circles, made in the great circle to which the dial's plane is parallel, form. For the said sections make equal angles in the plane of the dial and in the great circle to which the dial is parallel, as we demonstrated near the end of this proposition concerning the angles which the sections made by the proper Meridian of the declining plane and by the Meridian of the Horizon form in the same plane of the dial and in the great circle to which this plane is parallel. [c] Hence the lines $T\pi$ and NC will be parallel, and therefore the straight line TV , which we drew parallel to NC — even if it be not produced all the way to the centre π (which perhaps does not lie within the plane of the dial) — will be the line of the 6th hour.

[Margin: c — Euclid I.28]

Since this is so, it is clear from what was demonstrated in the earlier description of this proposition that the hour-lines must be drawn through those points of the straight line HQ where it is cut by the hidden lines issuing from the centre Z ; for the division of the circle described about Z takes its beginning from the straight line which passes through the first hour on the equinoctial line HO — namely, from the straight line ZX , which passes through the 6th hour. By the same reasoning, since YP is the common section of the Equator and of the proper

Meridian of the declining plane itself (as is clear from what has been demonstrated, being perpendicular to that same axis OP), the hour-lines must be drawn through the points of the equinoctial line YV at which the hidden lines issuing from a cut it; for the division of the circle described about a likewise takes its beginning from the straight line aV, which is drawn through the 6th hour on the equinoctial line YV. Rightly, therefore, are the hour-lines drawn through those points found on the straight lines HO and YV, even though the centre π — where they would all meet if produced — is unknown to us, lying outside the plane, or at least extremely far from the point H. In the example proposed, because the lines of the 12th and 1st hours from noon have also been drawn, it plainly appears that the straight lines drawn through the centres Z and a, which cut at right angles the straight lines ZX and aV (passing through the 6th hour on each equinoctial line), fall on those points of the equinoctial lines HO and YV through which the line of the 12th hour is drawn; and consequently these are the lines from which the divisions of the circles described about Z and a should be begun, as we taught above. But because, as we said, in planes that decline too far from the Vertical neither the line of the 12th hour nor the centre can conveniently be marked, we ordered those same divisions to be begun from the straight lines ZX, aV, and so on. That the style is Qb, and its position at the point b, is clear from what has been said, since the triangle πQH is constructed just like the triangle CIG in the upper figure of this proposition.

For the rest, any dial declining from the Meridian, or from the North, toward the east or west — if its features interchange their arrangement among themselves, so that the left becomes the right and the right becomes the left, until they take on such a position as the features of the dial would have if they had been drawn on the opposite face of the plane, under this rule, that each single line answers to each single line — will present us with another dial declining from the Meridian, or from the North, by the same number of degrees as before, but toward the contrary side. So that if the first dial declines from the Meridian, or from the North, toward the east, this one too will turn from the Meridian, or from the North, toward the west; and if the first declines toward the west, this one will look toward the east. Moreover, the hour-numbers must be changed into their complements up to 12 — so that hour 1 becomes 11, hour 2 becomes 10, and so on. By this device you see that, from the dial above declining from the Meridian toward the east by 30 degrees, there has been constructed in the following figure a dial declining from the Meridian toward the west by 30 degrees.

[Margin: If the features of any dial whatever declining from the Meridian, or from the North, toward the east are so altered that the right becomes the left and

conversely, one will obtain another dial declining from the Meridian, or from the North, toward the west, and conversely.]

The reason for this is not obscure, if the precepts of this proposition are attentively and carefully considered. For since, in two dials declining from the Meridian (or from the North) toward opposite sides — the one toward the east, the other toward the west — the line of declination EF is drawn from the point E toward opposite sides, as has been said, it comes about that the style-line too is extended from the centre C toward contrary sides, since it is drawn from C through the point G onto which FG falls (FG being drawn from F, the point of the declination-line, perpendicular to AB). And on that account the equinoctial line as well, which cuts the style-line at right angles, obtains a contrary position. In the same way the 6th-hour line, which is drawn from C through that point of the straight line AB onto which Fa falls (Fa being drawn from F at right angles to the declination-line), cannot have the same position in both dials; and the same must be said of the other lines. Hence, since the lines of one dial have the same distances among themselves as they have in the other — because the styles too are taken equal, and the declination is put the same in both, though it verge toward contrary sides — it comes about that the features which, when we face one dial, lie to our right, lie in the other to the left, and conversely.

The cause, too, of changing the hour-numbers into their complements up to 12 is evident. For since, as we said above, in southern dials the hours placed to the right of the meridian line are to be reckoned from noon, and those to the left from midnight, whereas in northern dials it is the reverse: it comes about that the hours from noon in one dial are the hours from midnight in the other, and conversely — since the right-hand ones of the first, which were reckoned from noon, become the left-hand ones in the other, and are therefore counted from midnight, and conversely, as we have taught. Therefore the line next to the right of the line of the 12th hour of noon, which in the southern dial shows the 1st hour from noon, will in the other southern dial necessarily show the 11th hour from midnight, since now, transferred, it occupies the left side, and conversely. And the line next to the right of the line of the 12th hour of midnight in the one [northern]

northern dial, indicating the 1st hour from midnight, will in the other northern dial, now transferred to the left side, signify the 11th hour from noon; and conversely.

[Margin: How, from a dial declining from the Meridian, a dial declining from the North is to be drawn on the opposite face of the dial's plane.]

Now if a dial declining from the Meridian toward the east or west is inverted, so that the upper part is changed into the lower, and what — after this change, when we face the dial — is on the right becomes the left, and conversely: then there will have been made from it a dial declining from the North by as many degrees as that one departs from the Meridian, yet turning toward the opposite side — so that, while the first verges [toward the east]...

Diagram. A sundial declining from the Meridian toward the west by 30 degrees, constructed as the mirror-image of the eastward-declining dial of the preceding page. The style-centre C stands near the top; from it a fan of hour-lines radiates downward and outward to the numbered hours around the margin. A horizontal line AB runs across the figure (the line equidistant from the Horizon), with a longer near-horizontal line for the higher hours crossing it toward the right. A dotted line runs from the lower centre toward the lower right (the line of declination / equinoctial line region).

- C (upper centre): style-centre, from which all hour-lines issue
- A (left end of the horizontal line): terminus of line AB
- B (right, on the horizontal line): point on line AB
- [?] (far right, beyond B, on the extended horizontal line): a mark resembling "α" — label not resolvable
- E (centre, on line AB): point where the meridian/style structure meets AB
- G (centre, just right of E, on line AB): foot-point of the style construction
- M (below E–G): point on the meridian line
- I (right of centre, above line AB): point on the style-line
- F (mid-figure, below I): point of the style construction [?]
- F (lower centre, below M): foot-point on the descending meridian line
- D (bottom): lower terminus of the meridian line
- Hour numerals, upper left: 6, 7, 8
- Hour numerals, upper right: 8, 7, 6
- Hour numerals, lower band: 9, 10, 11, 12, 1, 2, 3, 4, 5

verges toward the east, this one looks toward the west, and conversely: just as is the dial which is usually drawn on the opposite face of the plane, as we demonstrated in the scholium of proposition 13 of the preceding book. This inversion of the dial can also be carried out in this way: first the right part is changed into the left, and conversely; then, after this change, the upper is changed into the lower, and conversely. A dial of this kind is expressed by the features of the southern dial drawn on the northern face, so that each single line

answers to each single line, provided the upper part be changed into the lower. For if this change is made, there will appear to us — when we face the opposite face of the dial — the lines toward the right which before (after that change of the upper part into the lower) had been placed for us on the left in the southern face, and conversely, as is manifest.

[Margin: If the upper part of the dial that declines from the Meridian toward the east is made the lower, there will result a dial declining from the North toward the east as well; but toward the west, if that one verges toward the west.]

Now since, from a southern dial, if its right part is made the left, and conversely, there results another southern dial that declines toward the contrary side, as has been said: it comes about that, if the upper part of this dial (which was made from the first) is changed into the lower, we shall have a northern dial answering to that first southern dial — provided the numbers be restored which were before in that southern dial. So that if the first declines from the Meridian toward the east, this one will decline from the North toward the west, and if the first toward the west, this one will verge toward the east: because by this reasoning the change of the left part into the right was made, when, of course, the dial was made to decline from the Meridian toward the contrary side; and again, the part which after this change is the upper is changed into the lower, and conversely — all of which is required in order that from a southern dial there be made a northern one to be drawn on the opposite face, as has been said. And so we shall be permitted to gather this rule for ourselves. A southern dial declining toward the east, if its upper part is made the lower, will give a northern dial of equal declination verging toward the east as well. A southern dial deflecting toward the west, similarly inverted so that the upper part is changed into the lower, will exhibit a northern one looking toward the west as well. Hence if anyone desires a northern dial declining toward the east, a southern dial looking toward the east must be drawn. For this, inverted so that the upper parts become the lower, will give the desired northern dial verging toward the east, if the hour-numbers be turned into their complements up to 12. Similarly, if anyone should wish a northern dial deflecting toward the west, a southern dial declining toward the west must be drawn. For if its upper part is made the lower, a northern dial looking toward the west will be obtained, if the numbers be changed, as has been said. All of which is gathered from what has been said, and is evident, if the planes of the dials are rightly considered in their own positions.

[Margin: By what method, from a dial that declines from the Meridian toward the east, another may be produced declining from the North toward the east, from the Meridian toward the west, and from the North toward the west.]

Indeed, by one operation and one labour we shall be able most conveniently to draw four different dials, the same quantity of declination being always kept. For if, for example, we draw a dial declining from the Meridian toward the east by 30 degrees, and change its upper part into the lower, there will already be drawn as well a dial declining by 30 degrees from the North toward the east. But if we make the right part of that same one the left, without changing the upper part into the lower, we shall have a dial declining from the Meridian toward the west by 30 degrees. If finally we not only convert the right part into the left, but also make the part which, after this change, is the upper into the lower, there will be constructed a dial deflecting from the North toward the west by 30 degrees. By the same reasoning, if a dial is drawn declining from the Meridian toward the west by 30 degrees, we shall produce from it a dial declining from the North toward the west by 30 degrees, and one declining from the Meridian toward the east by the same number of degrees, and likewise one deflecting from the North toward the east by 30 degrees, if the aforesaid inversions of the parts be made, as is clear from what has been said. But in all of them the numbers must be inscribed on the hour-lines, as we taught in the earlier description of the declining dial in this proposition.

PROBLEMA 2. PROPOS. 2.

To describe the parallels — that is, the arcs of the signs of the Zodiac — on a dial that declines from the Vertical circle.

Once the elevation of the pole above the declining plane has been found, by proposition 29 of the first book — which, as we said, is indicated [also]...

also by the earlier description of the declining dial in the preceding proposition, or even by the description which we set out in the scholium of that same proposition for a given length of style whose position is likewise given, namely the angle GCI comprehended by the style-line and the world's axis — let the Analemma be set up to it, as in proposition 2 of the preceding book, so that the arc CE in the Analemma of that proposition measures the elevation of the pole above the declining plane, that is, in the example proposed, contains 40 degrees 3 minutes; or at least so that the angle CDE of that Analemma be equal to the angle GCI in the declining dial of the preceding proposition. For if there be taken, in the same Analemma, a straight line DG equal to the style IK which the dial drawn by

the first method offers — or the one we assumed in the later description in the portion of the Analemma drawn in the preceding proposition (which answers to the first figure of proposition 1 of the preceding book), or at least the one we assumed in that description in which the length of the style together with its position was given — and if through G a straight line OR be drawn parallel to BC, we shall have on the straight line OR the diameters of the conic sections, just as we had those same diameters KR, LR, MR, NO, PO, QO in the horizontal dial of proposition 2 of book 2. Wherefore we shall here describe the parallels — that is, the arcs of the signs — as we taught there, namely as conic sections about the diameters found; of which those contained between the centre C and the equinoctial line will bend their horns toward the centre, while the rest bend toward the opposite side, exactly as in the horizontal dial. For just as, in the horizontal dial, the circle of the Analemma ABC represents the Meridian of the Horizon, and the straight line OR the common section of the plane of the horizontal dial and of the Meridian, that is, the meridian line: so in the declining dial the same circle is taken for the proper Meridian of the declining plane — that is, for the circle drawn through the poles of the world and through the poles of the declining plane — while the straight line OR is taken for the common section of the said Meridian and of the plane of the declining dial, namely for the style-line. But we do not set up a proper Analemma for the elevation of the pole found above the declining plane, both because this whole matter can easily be understood from the Analemma of proposition 2 of the preceding book, and because in this proposition we shall describe the arcs of the signs by another method, which we shall explain presently.

[Margin: How the arcs of the signs of the Zodiac on a dial declining from the Vertical are to be described from the Analemma.]

But if anyone should prefer a larger or a smaller dial, a longer or a shorter style DM must be taken in the Analemma, and through M a line drawn parallel to BC, and so on, as we said concerning the horizontal dial in proposition 2 of the preceding book.

[Margin: By what method a larger or smaller dial may be described according to the same Analemma.]

Another method. When the straight line CI, which is to represent the world's axis, has been drawn, let there be erected at I, perpendicular to CI, the line IG, for the radius of the Equator, from either side of which let the radii of the other signs be drawn out, as has been done more than once above; and let CI be taken equal to the straight line CI on the axis of the dial of the preceding proposition, or of the

dial which we constructed in the scholium of that same proposition for a given style in a given place; and let IG be taken equal to the straight line IG, or LG, in the same dial; and from C, through G, let the straight line CG be drawn out — which perhaps we shall draw more conveniently if from C we draw a straight line CG [making]...

[Margin: Another description of the arcs of the signs on the same dial declining from the Vertical.]

Diagram. A large composite construction for the arcs of the signs (parallels) on a dial declining from the Vertical. A horizontal diameter runs across the upper part of the figure, above which a semicircle is drawn and graduated with tick-marks numbered 1–12 running from the left over the top and down the right side. From an apex near the centre a broad fan of straight lines (both solid and dashed/dotted) descends toward the lower margin, meeting a lower horizontal line (the equinoctial line) and terminating in two arrays of hour-numbers below. Several of the descending rays carry the label "Rad hor ..." (radius of the hour-arc) with a numeral. At the upper left is an inset scale-square construction.

Labels read from the scan (positions approximate; many are crossed by ruled lines and flagged):

- Upper diameter, left to right: B, I, B [?], C
- M (just below the diameter, between I and the central B)
- F (below M, at the head of the descending fan)
- Central points along the axis: G, E, H, O, L, N
- P (lower centre, on the equinoctial line near the arc)
- Upper-left inset (scale-square): across top B, C, B; down left edge I, D, G, D; interior A, K, A
- Radial labels on the descending rays: "Rad hor 24", "Rad hor 18", "Rad hor 14", "Rad hor 10", "Rad hor 8", "Rad hor 6", "Rad. 6" [?]
- Semicircle graduation (over the top and down the right): 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12
- Lower hour-numbers (two arrays at the foot of the fan, left and right): 1, 2, 3, 4, 5, 6, 8, 12 [several partly obscured — [?]]

making with CI an angle GCI equal to the angle GCI which the axis CI and the style-line CG form in the dial — that is, equal to the angle of the pole's elevation above the declining plane. This triangle GCI will be entirely equal to the triangle GCI in the declining dial of the preceding proposition, and thus the straight line CG will be the style-line. For, according to the earlier construction, the two sides

IC, IG of the one triangle are equal to the two sides IC, IG of the other triangle, and they contain equal angles. [a] Therefore the whole triangles are equal, and so on. But according to the later [construction]...

[Margin: a — Euclid I.4]

[Margin: a — Euclid I.26.]

the construction, two angles I, C of the one triangle are equal to two angles I, C of the other triangle. Since, therefore, the side IC of the one is also equal to the side IC of the other, [a] the remaining sides of the one will be equal to the remaining sides of the other, and so on.

Next, from the centre L of that circle — by whose aid we found the hour-points on the equinoctial line — let all the intervals up to the hour-points on the equinoctial line be taken, and let them be transferred from I onto the radius of the Equator IG. For if straight lines are drawn from C through the points that bound the aforesaid intervals on the radius of the Equator, these will be the lines of all the hours, both on this side of and beyond the style-line, which intersect the equinoctial line — just like the hour-lines of the horizontal dial that are drawn from the point H, in the later figure of Prop. 2 of the preceding book, through the points found on the radius of the Equator. To these lines, then, let there be attached the hour-numbers corresponding to the hours whose intervals — placed between the centre L and the equinoctial line — have been transferred onto the radius of the Equator from the point I. Note carefully which lines refer to the hours placed to the left of the style-line and which to the hours located to the right of that same line. This the numbers attached to the lines readily indicate, corresponding to the numbers of the dial's hour-lines that intersect the equinoctial line. For these lines refer only to the lines hitherto drawn from the point C through the points marked off on the radius of the Equator.

We shall obtain these same lines if from the dial we take the hour-intervals placed between the centre C and the equinoctial line, transfer them from C onto the radius of the Equator IG, and, through the points that bound these intervals on the radius of the Equator, draw lines from C, and so on — just as we did in the horizontal dial and in the vertical. But if it should happen that some hour-line in the dial does not cut the equinoctial line even if it is produced infinitely, but is equidistant from it, then from C the line CA must be drawn parallel to the radius of the Equator IG: for this line will represent that hour. So too in the horizontal and in the vertical dial, because the line of the 6th hour does not cut the equinoctial line but is parallel to it from H — in the later figure of Prop. 2 and 14

of the preceding book, where the straight line HV is drawn parallel to the radius of the Equator for the 6th hour.

Diagram. A large, very dense construction (the "figure of rays," *figura radiorum*) for a sundial declining from the vertical. A horizontal straight line runs across the middle of the figure, carrying the caption **HORIZON** split around the drawing (**Ho** at the far left, **RIZON** at the far right). From a vertex **C** near the upper centre a broad fan of straight hour-lines (some solid, some dotted/hidden) radiates downward and outward, crossed by the sloping sign-parallel lines and by a graduated arc near the centre. A ring of zodiac sign-glyphs labels the sign-parallels around the periphery (upper-left above the horizon, and lower-right below it). At the lower left is a subsidiary arc-and-dotted-line construction associated with the point ϕ .

Labels read from the scan (positions approximate; the interior is heavily overrun by ruled and dotted lines and only partly resolvable):

- Horizon line caption: **Ho ... RIZON** (HORIZON), horizontal, through the middle.
- **C** — vertex at upper centre, origin of the fan of hour-lines.
- **I** — left of centre, above the horizon (on the radius of the Equator).
- **K** — just below and left of C, near the centre.
- **d** — on the horizon line, to the right of C.
- **H** — at the left, on/below the horizon, at the end of a line.
- ϕ — lower-left, at the head of a subsidiary dotted-arc construction (the point ϕ of the text).
- Interior hour-numbers clustered near the centre and along the equinoctial line: 6, 7, 8, 9, 10, 11, 12 [several partly obscured — [?]].
- Descending hour-numbers on the right: 1, 2, 3 [?].
- Peripheral zodiac sign-glyphs (upper-left above the horizon, and right / lower-centre below it): readable are ♒ (Aquarius), ♓ (Pisces), ♑ (Capricorn), ♉ (Taurus) [?], ♌ (Leo) [?], ♍ (Virgo) [?], ♏ (Scorpio) [?], ♐ (Sagittarius) [?] — the individual glyphs are worn and crossed by ruled lines; the precise assignment of each sign to its parallel could not be resolved. [?]
- Sequence-numbers 4, 5, 6, 7, 8 down the left margin (hour- or parallel-order labels) [?].

[Margin: How the hour-lines that neither cut the equinoctial line nor are parallel to it are drawn in the figure of rays just constructed.]

Now, in order to obtain the lines of the other hours — those that neither cut the equinoctial line nor are parallel to it, as are all those which, after cutting the equinoctial line, have been produced beyond the centre C (such as, in our declining dial, the hours 4, 5, 6 and the rest after noon, and likewise 1, 2, and 3 after midnight; for all these are produced beyond the centre C, and their counterparts on this side of the centre C cut the equinoctial line, namely 4, 5, 6 and the rest after midnight, and likewise 1, 2, and 3 after noon) — we shall follow this procedure. Through C, the centre of the dial, we shall draw the straight line Cd parallel to the equinoctial line, provided no hour-line is equidistant from it; and through C, a point of the figure just constructed, we shall send out the straight line CA parallel to the radius of the Equator. This will correspond to that parallel Cd, or at any rate to that hour (if there is one) which is equidistant from the equinoctial line, as we have just shown. Now the line Cd represents in the dial that hour-circle — that is, the great circle drawn through the poles of the world — whose common section, on the circle drawn about the centre L, is equidistant from the equinoctial line and cuts the style-line at right angles, as we showed in the preceding proposition. After this, [b] since every hour-line makes equal angles with Cd at the vertex C, we shall transfer the lines going out from C and cutting the radius of the Equator to the other side of the straight line CA, by means of a certain circular arc drawn from C and de-

[Margin: b — Euclid I.15.]

descri-bed, in such a way that the lines equidistant from CA on either side cut off equal arcs of that circle drawn from C, and contain equal angles at C with the straight line CA. For these lines, thus transferred, will correspond to those hours which do not cut the equinoctial line but run out beyond the centre C — so that two lines removed by an equal interval from the straight line CA belong to two hours of the same number. Of these, the one that cuts the radius of the Equator (or is drawn from C toward the radius of the Equator) represents the hour that intersects the equinoctial line in the dial, while the other, transferred to the other side of the straight line CA, corresponds to the same hour produced beyond the centre C, which does not cut the equinoctial line. This is done exactly as in the horizontal dial, and in the vertical, in Prop. 2 and 14 of the preceding book. For there too the lines transferred beyond the straight line HV in the figure of rays represent the same hours by number — yet not cutting the equinoctial line — to which correspond other lines on this side of the straight line HV. This is because any hour-line whatever in the horizontal and vertical dial makes equal angles, at the vertex or centre H, with the line of the 6th hour, which is equidistant from the equinoctial line — just as here [it makes equal angles] with the line Cd, parallel to

the equinoctial line itself, to which corresponds the straight line CA, parallel to the radius of the Equator in the figure of rays. And this is just like the straight line HV, which there in the figure of rays is equidistant from the radius of the Equator and corresponds to the 6th hour, being parallel to the equinoctial line. Thus you see that here the line of the 3rd hour after midnight has been transferred beyond the straight line CA, because the 3rd hour after noon cuts the equinoctial line; and likewise the line of the 4th hour after noon, because the 4th hour after midnight cuts the equinoctial, as appears in the dial. And the same reasoning must be applied to the others.

[Margin: When the style-line is one of the hour-lines, or is equidistant from two of them on either side, every hour-line in the figure of rays will belong to two hours, as in the horizontal dial. When the style-line is equidistant from the two nearest hours, two figures of rays would have to be set up, so that all confusion of the lines might be removed.]

But if the style-line should sometimes be one of the hour-lines, or should lie midway between two hour-lines equidistant from it (which can sometimes happen), then each hour-line in the figure of rays just constructed and drawn from C will serve two hours equally removed from the style-line on either side. For in that case the intervals of those hours between the centre L and the equinoctial line are equal — as we showed of the horizontal dial in Prop. 2 of the preceding book — and so, when transferred onto the radius of the Equator from the point I, they yield one and the same point, and so on. Hence in that case two numbers must be assigned to each line, corresponding to the two hours removed by an equal distance from the style-line on either side, just as was done in the horizontal and in the vertical dial. But when the style-line is unequally removed from the surrounding hour-lines (which happens more often), as occurs in the given example, then each line will correspond to only a single hour; because in that case the intervals of the hours between the centre L and the equinoctial line, lying on either side of the style-line, are unequal, and so, when transferred onto the radius of the Equator from I, they yield different points, and so on.

[Margin: When the style-line is one of the hour-lines, or is equidistant from two on either side, every hour-line in the figure of rays will belong to two hours, as in the horizontal dial.]

It would not be beside the point, however — indeed it would be advantageous — when the style-line is unequally distant from the two nearest hours, if two figures of the Zodiac's rays were constructed: in one of which the hour-lines would be drawn from C corresponding to those hour-lines in the dial that are contained on

one side, namely to the left of the style-line, while in the other would be drawn the hour-lines corresponding to the dial's hour-lines on the other side of the style-line. For thus all confusion of the lines would be removed — the confusion that necessarily follows when the style-line is almost equally distant from the lines placed on either side, because then the points found on the radius of the Equator can scarcely be distinguished from one another, as is evident. In this way, in our example, in one of the figures the lines would be drawn from C corresponding to these hours: 1, 2, 3, 4, 5, 6, 7, 8, 9 after midnight, which are to the left of the style-line. In the other would be contained the lines corresponding to the hours on the right of that same style-line, namely 10, 11, 12 after midnight, and 1, 2, 3, 4, 5, 6, etc. after noon. In each figure, however, CG must be drawn for the style-line. You will see an example of this set out in Prop. 38 of this book.

[Margin: When the style-line is equidistant from two nearest hours, two figures of rays would have to be set up, so that all confusion of the lines might be removed.]

From these things thus prepared, the arcs of the signs will be drawn, as in the horizontal and vertical dial — namely by transferring the intervals of the hours, intercepted between C and the rays of the signs, from the centre of the dial C onto the corresponding hours of the dial; or else by transferring the hour-intervals placed between the radius of the Equator and the rays of the signs onto the corresponding hour-lines of the dial, beginning from the equinoctial line, and so on. For the demonstration here will be the same as in the horizontal dial, since the plane of the declining dial is like a kind of horizon, and the angle GCI is equal to the elevation of the pole above it, as we said; and the style-line is like the meridian line, although it does not indicate the 12th hour, because we do not reckon the hours from the meridian of the declining plane, but from the meridian of the horizon of that place where the declining dial is drawn. The said meridian line would doubtless indicate the 12th hour if we reckoned the hours from the meridian of the declining plane; for then the proper meridian circle of the declining plane, producing the style-line in the dial, would be equally distant from the sunrise and sunset, and so the Sun, when on it, would make noon or midnight, just as happens on the horizon.

[Margin: Which arcs of the signs are hyperbolas, which parabolas, and which ellipses, in a dial declining from the vertical.]

It is clear, moreover, from what was demonstrated in Prop. 2 of the preceding book, that when the straight line CG in the figure of rays cuts opposite rays, the arcs of those signs are opposite and equal hyperbolas; but when it is equidistant from one of a pair of opposite rays and cuts the other, the arc of that sign whose

ray is cut is a parabola, and the arc of the other cannot be drawn; and finally, when it cuts one of the opposite rays but not the other, and is not equidistant from it, the arc of that sign whose ray is cut is an ellipse, and the arc of the other cannot be drawn in any way.

For the demonstration here will be the same as it was there: since here the straight line CG behaves as it did there — corresponding to the style-line in the dial, and being the diameter of all the conic sections — just as there the straight line HB represented the meridian line of the dial in the figure of rays and was the diameter of all the conic sections. This is because here the angle CGI is equal to the altitude of the pole above the declining plane, just as there the angle DHB was equal to the altitude of the pole above the horizon.

[Margin: The arcs of the greatest of the always-apparent and always-hidden parallels are hyperbolas in the [superiori (?)] dial.]

From this it follows that the arcs of the parallels which are the greatest of the always-apparent and always-hidden, are in our example opposite hyperbolas. For since the angle which the radius of the 24-hour arc makes with the radius of the Equator contains 48° — this being the declination of the greatest of the always-apparent parallels — it comes about that, by adding the right angle GIC, the angle contained by the radius of that same parallel and the axis IC is made 138° . Since, therefore, the angle ICG — [the angle] of the pole's altitude above the declining plane — comprehends $40^\circ 3'$, the internal angles which the said radius and the straight line CG make with the axis will be $178^\circ 3'$, that is, less than two right angles. Therefore the line CG will meet the said radius; and consequently, since the straight line CG cuts both radii — that is, the one belonging to the greatest always-apparent parallel and the one belonging to the greatest always-hidden parallel — there will be formed two opposite and equal hyperbolas, as is clear from what has been said.

When the style-line is one of the hour-lines, or is equidistant from two hours placed on either side, each of the aforesaid intervals must be transferred onto the two hour-lines equally removed from the style-line in the dial, as was done in the horizontal dial too, and in the vertical.

[Margin: When the style-line is one of the hour-lines, or is equidistant from two on either side, the arcs of the signs are more easily drawn.]

[Margin: When the style-line is unequally distant from the two hours on either side, what must be done so that the arcs of the signs may be drawn more accurately.]

But in order that the arcs of the signs may be drawn more accurately, when the style-line is unequally removed from the two hour-lines placed on either side, all the hour-points of the equinoctial line placed to the left or right of the index-line [linea indicis, here used for the style-line] can be transferred to the other side of the equinoctial line — namely to the right or left of that same style-line — the beginning always being made from the style-line. Or, more surely (which I myself prefer, since some hour-lines scarcely or never cut the equinoctial line): an arc of a circle having been drawn from the centre C, its portions between the index-line and the hour-lines on one side of the index-line can be transferred into the same arc on the other side of that same index-line. For if, through the points marked either on the equinoctial line or on that arc (which is the more approved method), we draw hidden lines from the centre C — such as, in the adjacent figure, are the lines distinguished by those small [dotted] lines, lying to the right of the index-line itself — we shall always have two lines equally removed from the index-line on either side, into which one and the same hour-space intercepted between C and the radius of any sign can be transferred, as in the horizontal and vertical dial.

If indeed this is done, it will be enough if in the figure of rays we draw from C the hour-lines corresponding to the hours contained in the dial on only one side, right or left, of the index-line. For if the points of those hours on the equinoctial line, or on the arc drawn from centre C, are transferred to the other side of the equinoctial line or of the said arc — the beginning always being made from the index-line — and the rest is completed as we have just prescribed, the arcs of the signs will be drawn, as in the horizontal dial. And in this way the confusion of the lines drawn from C through the radius of the Equator in the figure of rays would be avoided. This you will see observed in the drawing of the arcs of the signs in the dial declining from the horizon, in Prop. 14 of this book. Again, if the portions of the straight line CA, between C and the rays of the signs, are transferred into the dial from C onto the straight line Cd, on either side of the centre C, we shall have on the straight line Cd the points through which the arcs of the signs are to be drawn — as was done on the line of the 6th hour of the horizontal and vertical dial.

[Margin: By what reasoning it is sufficient if in the figure of rays the hour-lines are drawn corresponding to the hours contained in the dial on only one side of the style-line.]

[Margin: Which arcs of the signs, in a dial declining from the vertical, belong to the southern signs, and which to the northern.]

Now in dials declining toward the south, the arcs drawn above the equinoctial line toward the centre belong to the southern signs; the rest belong to the northern signs, just as in vertical dials. But in dials declining toward the north, the opposite is to be understood — as anyone can easily perceive, if he rightly conceives in his mind the position of each dial and the situation of the parallels drawn through the beginnings of the signs.

[Margin: In what way the hyperbolas of the northern signs may be drawn from the opposite hyperbolas of the southern signs.]

For the rest, when the arcs of the signs are opposite and equal hyperbolas (which we showed a little earlier, whenever it happens), we shall draw much more accurately, in dials declining toward the south, the arcs of the northern signs from the arcs of the southern signs, by those three methods which we set forth at the end of Prop. 2 of the preceding book, after the demonstration of the second method of drawing the arcs of the Zodiac's signs in the horizontal dial — a method that is accomplished from the figure in which the rays of all the signs of the Zodiac are contained. For in the first of those methods there is no difficulty, if on the style-line the transverse diameter of the opposite hyperbolas and their centre — namely the midpoint of the transverse diameter — are found, and the rest is completed, as we taught in the said Prop. 2 of the preceding book. As for the second of those methods, the axis of the hyperbolas in these declining dials is the style-line itself. Now the portions of the arcs of the southern signs, up to the axis of the opposite hyperbolas (that is, the style-line), are to be drawn toward the side of the 6th hour, because they can be drawn more conveniently there than the others toward the 12th hour; and from them, with a single effort, not only the remaining portions on the other side but also the whole arcs of the northern signs opposed to them will be delineated with ease, as we showed under the aforesaid method in its own place. Moreover, this second method is very well suited for correctly drawing the arcs of the northern and opposite signs — that is, those that are more remote from the centre of the dial. For, as you see, the hour-lines falling from C in the figure of rays, the farther they are extended, the greater occasion for error they present in drawing the arcs through the rays of the signs placed to the left of the radius of the Equator in that figure — such as here are the rays of the northern signs — because it can scarcely be done without error that the points where the said rays are cut by the hour-lines be taken, unless all the said lines have been drawn with the greatest care. But the points on the rays of the signs which are placed to the right of the radius of the Equator, and are nearer to the point C — such as here are the rays of the southern signs — can be more easily discerned, because of the shortness of the lines falling from C that are

contained between C and the said rays, if they are compared with the same straight lines contained between C and the rays of the northern signs. Hence we shall draw more surely the arcs of the southern signs, whose rays are nearer the point C, than those of the northern, whose rays are farther from that same point C. For in the former, the straight lines sent out from C cannot lead us into any notable and marked error, whereas in the latter they can, as we have said, and as can appear from the figure itself. Finally, as regards the third method, those hidden straight lines will be more conveniently drawn from the point ϕ — like the hour-lines going out from the centre C — by means of arcs of equal circles drawn from C and ϕ , than by the aid of the straight line drawn through χ parallel to the equinoctial line; because scarcely or never do some of the hour-lines cut the said straight line, as is plain. In the example, we have drawn from ϕ , to the right of the style-line, hidden straight lines corresponding to those lines which have been drawn (also hidden) from C through those points of the equinoctial line, or of the arc of the circle drawn from C, which have been transferred to the other side of the equinoctial line or of the said arc; because in this way, with a single effort, the hyperbolas can be drawn on either side of the style-line, as in the horizontal and vertical dial, and so on.

[Margin: How the horizontal line is to be drawn in a dial declining from the vertical.]

[Margin: a — Euclid XI.18.]

[Margin: b — Euclid XI.19.]

The horizontal line — that is, the common section of the plane of the declining dial and of the horizon — is drawn through K, the place of the style, perpendicular to the meridian line, or to the line of the 12th hour; and it necessarily passes through that point where the equinoctial line and the line of the 6th hour cut one another, unless an error has been made in drawing the line of the 6th hour or the equinoctial. For since the horizon is at right angles to the plane of the declining dial, and passes through the vertex of the style — which is likewise at right angles to the same plane — it will pass entirely through the whole style, namely through the axis of the plane of the dial. [a] For all planes drawn through the style to the plane of the dial are at right angles to it. Therefore the horizon will meet the plane of the dial at K, and so the horizontal line must be drawn through K. And since both the plane of the dial and the plane of the meridian are at right angles to the horizon, [b] their common section too — namely the meridian line — will be perpendicular to it. Therefore, by the third definition of Book 11 of Euclid, it will also be perpendicular to the common

section of the horizon and the plane of the dial existing in the horizon itself. For which reason the straight line drawn through K perpendicular to the meridian line will be the common section of the horizon and the plane of the dial — that is, the horizontal line. That this must necessarily pass through the 6th hour on the equinoctial line, we shall make plain as follows. When the Sun is in the common section of the Equator, of the circle of the 6th hour, and of the horizon, its ray, falling into the centre of the world, [is deflected] from the planes of these

its ray, falling into the centre of the world, does not depart from these circles, but falls into their common sections — the sections they make with the plane of the dial — as is clear from Prop. 11 of Book 1. And so the shadow of the style will necessarily fall on that point of the dial where the said sections of the circles cut one another — that is, at the 6th hour on the equinoctial line; otherwise the shadow of the style would not fall on both lines, as is plain. Therefore the horizontal line passes through that point where the equinoctial line and the line of the 6th hour intersect one another.

[Margin: The horizontal line cuts the whole dial into a southern and a northern part.]

Now this horizontal line divides the whole dial into two parts: the one in which the centre does not lie faces south, the other faces north. Each is to be set on a wall whose declination equals that for which the dial was constructed, in such a way that the horizontal line is parallel to the horizon and occupies the upper position. To this one further condition is added: in the northern dial — in which the arcs of the southern signs turn into the arcs of the northern signs, and the reverse — not only is the horizontal line to be placed in the upper position, but also the features which, when we turn to that dial in that position, lie on our right must be made to lie on the left, as we showed in the scholium of Prop. 14 of the preceding book.

[Margin: How a dial, whether southern or northern, is to be set in its proper position.]

It often happens that in a northern dial the hours lie on only one side of the meridian line — namely the side onto which the shadow of the gnomon falls in the evening, if the plane declines from north toward the west, or in the morning, if it declines toward the east. For the Sun does not light the other side in the morning or evening, except when the plane declines only a little from the vertical, as is evident if the declining plane is carefully considered in its proper position. The horizontal line demonstrates this to us most beautifully. For when

this line cuts the parallel of Cancer [♋] in two places on the southern dial, the hours will have to be drawn on both sides of the meridian line in the northern dial; but when it cuts it in only one place, then on one side only.

[Margin: Sometimes a northern dial has its hours on only one side of the meridian line.]

Now if you wish to know how great the declination must be for the northern face of the declining plane to be lit by the Sun both morning and evening, you will attain your wish in this way. When the plane's declination is less than the rising or setting amplitude [latitudo ortiva, occidua] of the first point of Cancer [♋] — how this amplitude is to be found we showed in Prop. 34 of Book 1, and it is taught by Johannes Regiomontanus [Regiomontanus] in Book 2 of the *Epitome*, Props. 1 and 2 — then the northern face of the plane is lit both morning and evening when the Sun is at the beginning of Cancer. But when the plane's declination is greater than the aforesaid amplitude, the same northern face receives the Sun's rays only in the evening, or only in the morning, according as it turns from north toward the west or toward the east. All of this can also easily be known and understood from a material sphere.

[Margin: By what method it can be known whether the northern face of a declining plane can be lit by the Sun both morning and evening, or only in the morning, or only in the evening.]

And although the northern face is lit by the Sun both morning and evening when the plane's declination is less than the rising and setting amplitude of the beginning of Cancer, it will nevertheless be illuminated for a longer span of time in the morning than in the evening if the plane turns from north toward the east, but for a shorter span if it inclines toward the west, as is evident — just as the southern face, turning toward the east, is lit for a longer time in the morning than in the evening, but for a longer time in the evening than in the morning if the southern face looks toward the west.

[Margin: When a plane, whether facing north or south, is lit for a longer time in the morning by the Sun than in the evening, or the reverse.]

This same horizontal line divides the declining dial into two: a diurnal part, contained below the horizontal line itself, and a nocturnal part, drawn above it, as we have said in the earlier cases too. And so we have drawn the parallels — that is, the arcs of the signs of the Zodiac — on a dial that declines from the vertical circle. Which was to be done.

[Margin: The horizontal line divides the whole dial into a diurnal and a nocturnal part.]

Scholium.

[Margin: A most elegant method for drawing the hour-lines in the figure of the rays of the Zodiac, without the hour-intervals of the dial.]

Andreas Schöner [Andreas Schöner] draws the hour-lines in the figure of the rays at the point C by the following method. Having drawn the straight line CG as before, he takes on its extension any point B, through which he draws the line BA parallel to CI, so that it cuts the straight line CA — which is parallel to the ray of the Equator — at A. Then, with A as centre and AB as radius, he divides the circle so described into 24 equal parts, beginning from a certain point which he finds in this way. The straight line LM, lying in the dial between the centre L and the meridian line, he transfers onto the ray of the Equator from I as far as E; and through E, from C, he draws the straight line CE for the line of the 12th hour, which cuts the straight line BA at D. From D he raises DF perpendicular to BA, and it cuts the circumference of the circle at F — the point that will be the beginning of the division of the circle.

But since, when the meridian line in the dial is very near the style-line — and likewise, in the figure of the rays, the straight line CD near CB — the line DF, drawn perpendicular to AB, cuts the circumference at F so obliquely, near the point B, that the point F can scarcely be discerned without error, we shall test the point F before proceeding to the division of the circle, by seeking another point from which the same division can be begun, in this way. In the dial we shall take the interval between the centre L and any hour on the equinoctial line that is somewhat more remote from the style-line than the 12th hour — for example, in the proposed example, the interval between L and the 1st hour — and we shall transfer it onto the ray of the Equator from I as far as H; and from C, through H, we shall draw the straight line CH for that 1st hour, which cuts the straight line BA at L. From L we shall raise LM perpendicular to BA, and it cuts the circumference at M. From this point, then, we shall be able to begin the divisions.

Now the perpendicular LM must be drawn toward the same side as DF was drawn, if the hour taken lies on the same side of the index-line as the 12th hour; but toward the opposite side, if it was taken on the other side — as would happen if we took the 5th hour. For this hour, transferred onto the ray of the Equator from I as far as N, will indeed give the line CN for the 5th hour, which cuts BA at O; but because the 5th hour and the 12th hour lie on different sides of the style-

line, the perpendiculars DF and OP have accordingly been drawn toward different sides. Yet the division of the circle can take its start equally well from the point P as from the point F or M. So whether the division begins from the point M or from P, if some point of the division falls on F — which had been found by the first perpendicular DF — the matter will succeed as intended; if not, an error must be corrected which has perhaps been committed somewhere. Indeed it is altogether expedient, if we want the matter perfect in every respect, to find two points from which the division can be begun. For if a division begun from the one falls on the other, we shall be certain that the division of the circle is sufficiently exact.

So, once the circle has been divided, the same author draws from the points of division perpendiculars to the straight line BA, or parallels to CA, cutting the line BA at points through which straight lines sent out from C give the hour-lines, as before. It will be easy to judge which lines correspond to which hours on the dial. For the points of the circle's division, starting from the point F (the 12th hour) and proceeding toward B — onto which the index-line falls — refer to the hours which, on the dial's equinoctial line, follow the 12th hour toward the index-line; so that the point nearest F toward B, in our example, belongs to the 11th hour, the next to the 10th, and so on, as the figure shows. And the straight lines drawn out from C through the points of the perpendiculars on the line BA refer to the hours from which the said perpendiculars fall onto BA.

For the rest, without much trouble we shall draw, from the points of division of the circle described from A, the perpendiculars to the straight line BA, or the parallels to CA, in this way. If it happens that two neighbouring points are equally distant on either side from the point B — which will occur only when the style-line in the dial is either one of the hour-lines, or lies equally between two neighbouring hour-lines on either side —

then the straight lines joining, on either side of the point B, two points equidistant from it will be perpendicular to the straight line BA. If not, then take the distance of any point in the upper semicircle from the point B, and transfer it into the lower semicircle; for the straight line connecting the upper point with the transferred lower point will be perpendicular to BA. For by this method the straight line BA, drawn through the centre A, will bisect the arc between those two points at B. Hence, by the earlier corollary of Prop. 10 of Book 13 of Euclid [Euclid], the line BA will be perpendicular to the line joining those points. The same will result if the distances of the points of the lower semicircle from B are

transferred into the upper semicircle, as you see done in the upper figure of the rays.

Diagram. The large "figure of the rays" (*figura radiorum*) of the Zodiac used in Andreas Schöner's construction of the hour-lines. It occupies most of the page. Two roughly horizontal lines run across the top: the upper one carries the labels **B** (at its left end) and **A** (at its right end); a lower transversal terminates at the point **I** on the right (directly below **A**). A dense sheaf of straight rays (both solid and dotted) fans out from a point low on the right toward the upper left, crossing the transversals; these are the hour-lines and the rays of the signs. Along the upper transversal, hour-numbers are marked in a row: **12, 3**, then **11, 4, 10, 5**, the point-label **G**, and (below, in small type) **9** and **6**. A second series of hour-numbers descends along the right, near the ray-point: **8, 9, 10, 11, 12**. Around the periphery, at the ends of the signs' rays, stand the Zodiac sign-symbols; several are worn and are flagged below.

- B (upper left): endpoint of the upper horizontal (line BA)
- A (upper right): endpoint of the upper horizontal; centre of the divided circle
- I (right, below A): terminus of the lower transversal (with the axis / point of the ray-sheaf nearby)
- G (on the upper transversal, right of centre): point-label
- 12, 3, 11, 4, 10, 5, 9, 6 (hour-numbers along the upper transversal)
- 8, 9, 10, 11, 12 (hour-numbers descending on the right)
- Zodiac sign-symbols around the periphery — clearly resolvable on the descending right side (top to bottom): ♑ (Capricorn), ♐ (Sagittarius), ♏ (Scorpio); the upper-left cluster shows ♉ (Pisces)[?], ♒ (Aquarius)[?], and further sign-glyphs [?] toward the far left and lower centre that are too worn to resolve with confidence
- Additional small letters near the ray-point (e.g. a small "e" and a small "y"-like mark) [?]

[Margin: By what method a larger or smaller dial is to be built from the figure of the rays for a given length of style.]

Now if, from the figure of the rays constructed so far, a larger or smaller dial is to be built for a given size of style, we shall do it as follows. Draw separately — as was done beside the figure of the rays — the triangle CIG, taken from the dial of the preceding proposition, or from the figure of the rays, or indeed from the dial which we described in the scholium of the preceding proposition for a given

length of style. In it CI is the axis of the world, IG the Equator, and CG the style-line, onto which the gnomon IK falls at right angles. Then, having produced the straight lines IC, IG, IK, if on IK there is taken a line IA equal to the given gnomon — whether it be greater or less than the gnomon IK — and through A a line BD is drawn parallel to CG, the triangle BID will be similar to the triangle CIG, by the corollary of Prop. 4 of Book 6 of Euclid. And so, if the axis IB is transferred into the figure of the rays from C as far as B, toward I, and from B the ray of the Equator together with the rays of the other signs is drawn out, and everything else is done as before, the arcs of the signs will be described for the size of the given style IA, just as before they were described for the given style IK. For the hour-lines in the dial and in the figure of the rays remain the same at the same elevation of the pole,

the declination of the plane being unchanged. But the position of the style IA will be the point on the style-line which terminates a straight line begun from the centre C and equal to BA. The equinoctial line too must be drawn perpendicular to the style-line, through the point which is distant from the centre C by as much as the line BD.

[Margin: By what method the arcs of the signs are to be described on a declining dial that has no centre.]

Now we shall describe the same parallels, or arcs of the signs, on the declining dial which we drew in the scholium of the preceding proposition — even though we did not find its centre — by almost the same methods that we set forth in this proposition. As for the former task, we must construct an Analemma for the elevation of the pole above the declining plane, which we shall find from Prop. 29 of Book 1; or else we shall take it from the angle GCI in the said dial, since this shows the elevation of the pole above the declining plane, as is clear from what has been said, being contained by the style-line and the axis of the world. In this Analemma the rays of the signs must be drawn, so that in the cones we may have the triangles through the axis, and thereby the diameters of the conic sections; and the rest is to be completed, as we said at the end of the scholium of Prop. 2 of the preceding book.

As for the latter method, we shall accomplish the task thus. Onto the ray of the Equator IG, transfer from I all the intervals contained between the centre Z and the hours on the equinoctial line HO of the said dial, marking off the points on the ray of the Equator itself. Then on the axis IA cut off a straight line IA equal to the portion QP of the axis in the same dial, and through A draw AB parallel to the ray of the Equator IG; onto it, in the same way, transfer from the point A the spaces

enclosed between the other centre *a* and the hours on the equinoctial line YV, likewise marking off the points on AB. Finally, straight lines drawn always through each pair of corresponding points on the lines IG and AB will give the hour-lines. For, as we showed in the aforesaid scholium of Prop. 2 of the preceding book, the said hour-lines must be drawn both through the points found on the ray of the Equator IG and through those on the parallel AB, which serves as a kind of second ray of the Equator. If, then, the intervals of these lines lying between the ray of the Equator IG and the rays of the other signs are transferred onto the corresponding hour-lines of the dial, starting from the equinoctial line HO itself — with this rule observed, that a straight line be drawn from I to the nearest line, which corresponds to the style-line in the dial (for the interval of the style-line too, between the centre of the dial and the equinoctial line, must be transferred from the dial onto the ray of the Equator), to serve as the perpendicular for the style — then those intervals of the hour-lines between the rays of the signs are to be transferred, on the side onto which the style falls from I, from the equinoctial line upward, and so on. The demonstration of this is gathered from what has gone before, as we noted in the said scholium of Prop. 2 of the preceding book.

Problema 3. Propos. 3.

To mark out the parallels of the diurnal arcs on the same declining dial.

[Margin: The description of the diurnal arcs on the same dial declining from the vertical.]

The description of these does not differ from the description of the parallels, or arcs, of the signs. Hence here we shall use the precepts delivered in the preceding proposition, provided only that in place of the parallels of the signs we take the parallels of the diurnal arcs, as in the earlier dials, and so on. So we have marked out the parallels of the diurnal arcs on the same declining dial. Which was to be done.

Scholium.

[Margin: By what method, with the help of the diurnal arcs, those hours are described which scarcely cut the equinoctial line.]

Through these diurnal arcs a very easy way is opened to us for drawing those hour-lines which scarcely cut the equinoctial line. These are to be drawn from that side where the equinoctial line cuts the meridian line below the horizontal line — such as the hours after noon in a dial declining from south toward the east

(the kind we have constructed), and, in a dial declining from south toward the west, the hours after midnight. For these scarcely cut the equinoctial line except at very remote points, so that their delineation is rendered very difficult. Therefore we shall use this device. Let it be required, for example, to draw the 3rd hour after noon. Now since, on the diurnal arc of 6 hours, the Sun sets at the 3rd hour after noon, we shall describe — from the dial's centre C, with the interval that, in the figure of the rays of the preceding proposition, is contained between C and the ray of the 6 hours by the line of the 3rd hour after noon — an arc of a circle in the afternoon part of the dial, and we shall mark the point where it cuts the horizontal line. For through that point the 3rd hour after noon must be drawn, since through that point passes the diurnal arc of 6 hours, and on it the Sun sets.

In the same way, if in the forenoon part of the dial we describe an arc with the interval — contained between C and the ray of the 6 hours — of the line of the 9th hour, at which the Sun rises, we shall draw the 9th hour after midnight. So too, by the help of the diurnal arc of 8 hours, we shall mark out the 4th hour after noon and the 8th after midnight, and so on. For otherwise we shall draw the half-hours, if we take the diurnal arcs of the odd hours. For instance, if the line of the $3\frac{1}{2}$ th hour were to be drawn, we should have to take the ray of 7 hours; because, since the day contains 7 hours, the Sun rises at the hour $8\frac{1}{2}$ after midnight and sets at the hour $3\frac{1}{2}$ after noon — and so with the rest. The same must be observed in the following dials.

But since, in the figure of the rays, those hours which cut the equinoctial line only at very remote points cannot be drawn — unless we should wish to use the method of Andreas Schöner — the diurnal arcs on which the Sun sets or rises at the proposed hours must be described from the Analemma, as we taught in Prop. 2 of this book.

Problema 4. Propos. 4.

To describe the vertical circles on the same declining dial.

[Margin: The description of the vertical circles on the same dial declining from the vertical.]

From the place of the style K, raise a line KA perpendicular to the horizontal line, equal to the style IK; and with A as centre, at any interval, let a described circle be divided into 360 equal parts, or into fewer, according to the number of vertical circles that the size of the dial can hold. (We divided it into 24 parts, so that each

space takes in 15 degrees.) The start is made from the straight line drawn from the centre A through the point B, where the meridian line and the horizontal line intersect one another; or else from the straight line drawn from A through the point D, where the equinoctial cuts the horizontal line. Then, through the centre A and the points of division, let hidden straight lines be sent out, cutting the horizontal line at points which must be carefully noted. For straight lines drawn through these points perpendicular to the horizontal line, or parallel to the meridian line itself, will give the vertical circles — that is, the common sections of the plane of the dial

(continuing Problema 4, Propos. 4 — the description of the vertical circles on the declining dial)

— and of the vertical circles. Those parallels will be drawn without much trouble if we draw a line parallel to the horizontal line and, with the compass, transfer onto it all the points of the horizontal line taken from B, always beginning from the meridian line — such as that straight line in the lower part of the dial marked off by those small division-lines. [Margin: *Elements* I.33] For straight lines joining a pair of points — one on the horizontal line and one on the aforesaid parallel — that are equally distant from the meridian line will themselves be parallel to the meridian line.

Diagram. The master construction figure for the declining dial with its vertical circles. This is a large, dense composite. A horizontal line runs across the top of the figure carrying the points C (toward the middle, marked "90") and A (at the upper-right corner), from which a fan of straight rays descends. A large circle occupies the centre-left of the figure; through and around it run numerous oblique construction lines and a family of near-parallel lines. Degree graduations appear in Roman numerals down both flanks and in Arabic numerals near the rays and along the central horizontal band. A vertical dashed line and a lower dashed horizontal line (the latter with tick-marks) complete the frame. Zodiac sorts (diurnal-arc / solstice markers) appear at the top-left, at the right margin, and at the bottom-centre.

- A (upper-right corner of the top line): the zenith / pole from which the rays issue
- C (top line, near middle, beside "90"): point on the horizontal line
- A, I, C, B (central circle): construction points of the inner circle
- K (centre, small): the place of the style
- D (centre, below B): common section with the horizon/equator

- G (near centre-bottom of the inner cluster): point on the GO line
- B (right margin): foot of the meridian on the horizontal line
- Rays near A labelled (Arabic): 90, 75, 60, 45, 30, 15 [several small numerals abraded — [?]]
- Left flank (Roman degree labels, top to bottom): XV, XXX, XLV, LX [and a repeated XXX / a worn "XV" — [?]]
- Right flank (Roman degree labels, top to bottom): XV, XXX, XLV, LX
- Along the central horizontal band (Arabic): 15, 30, 45, 60, 75, 90 [inner values crowded — partly [?]]
- Zodiac sorts at top-left, right margin, and bottom-centre: [worn — [?]; solstitial/diurnal-arc markers, glyphs not securely legible]

We shall prove as follows that these parallels are the common sections of the vertical circles and of the plane of the dial. Imagine the plane of the circle described about A around the horizontal line to be moved until it coincides with the plane of the horizon, so that the centre A comes to coincide with the tip of the style — that is, with the centre of the world. Now the common sections of the horizon and of the vertical circles — among which is also the meridian drawn through the poles of the horizon — divide the horizon, and therefore also the circle described from A as centre of the horizon, in the said position, into equal parts. The meridian, drawn through A the centre of the world, meets the plane of the dial at B, making with it a common section, namely the meridian line BC. The vertical circle properly so called, likewise passing through the centre of the world, cuts the same plane at D — because the shadow of the style, when the Sun stands at the common section of the horizon, the equator, the circle of the 6th hour, and the vertical circle properly so called, falls upon the point D, that is, upon the common section of the plane of the dial and the equator, and upon the common section of the same dial and the horizon, as is established from Prop. 11 of Book 1. Therefore AB will be the common section of the horizon and the meridian; AD the common section of the horizon and the vertical circle properly so called; and consequently the remaining hidden lines drawn through the centre A and the points of division of the circle described from A will be the common sections of the horizon and the remaining vertical circles. Hence the vertical circles cut the plane of the dial at those points of the horizontal line onto which the said common sections fall. Since, then, by Prop. 18 of Book 1, the common sections of the vertical circles and of the plane of the dial are parallel — because the plane of the dial is equidistant from their common section, namely from the axis of the horizon drawn through the zenith of the place and its opposite point — it plainly remains that those lines parallel to the meridian line are the common

sections of the plane of the dial and of the vertical circles. This is why we have described the vertical circles on the same declining dial. Which was to be done.

Scholium.

The horizontal line here too cuts off the portion that must be placed on the opposite face of the same plane, so that the horizontal line is set in the upper position, and the part which in that situation is on our right becomes the left, and conversely — as is established from what was demonstrated in the scholium to Prop. 14 of the preceding book. Moreover, in both dials, the southern as well as the northern, the numbers of the degrees begin from the parallel drawn through the point D, which is the common section of the vertical circle properly so called and the plane of the dial, so that in our example the lines nearest on either side of the point D bear the numbers 15 degrees, and so on. [Margin: The order of the vertical circles in the dial.]

Now since it has been shown that the vertical circle properly so called passes through AD, and the meridian through AB — provided the circle described from A holds its proper position — it comes about that ADB, if there is no error, is the angle of declination, namely the angle which the vertical circle properly so called makes with the declining plane, and that ABD is its complement, namely the angle which the meridian makes with the same plane. Hence the remaining angle BAD, in the triangle ABD, must necessarily be a right angle. This is even more clearly established from the dial which, in the scholium to Prop. 1 of this book, we constructed for a given length of style. For there the line FE answers to the line AB here, and the line Fa there is the same as the line AD here.

In our example, too, the vertical circle of 60 degrees passes exactly through K, the place of the style — because that vertical circle which is drawn through the style, and is therefore perpendicular to the declining plane, recedes from the meridian by 30 degrees, namely by as many degrees as the declining plane recedes from the vertical. And it is evident that the vertical circle of 60 degrees declines from the meridian by 30 degrees. By the same reasoning, in every declining dial the vertical circle to be drawn through the place of the style will be the one that is as many degrees distant from the meridian as the declination of the declining plane from the vertical circle comprehends.

Problema 5. Propos. 5.

To depict the parallels of the horizon on the same declining dial.

We shall describe these parallels on the declining dial by the same methods by which they were described on the vertical dial in Prop. 17 of the preceding book, with the following changes. In the former method, the circle of the analemma here represents not the meridian, as it did there, but that vertical circle which is perpendicular to the declining plane — the one that passes through K, the place of the gnomon, and makes with the plane of the dial a common section that cuts the horizontal line at right angles at the point K. In our example this is the vertical circle of 60 degrees, distant from the meridian, on the south side toward the east, by 30 degrees, and making in the dial the section AK, as we said in the preceding scholium. The parallels of the horizon, however, are not changed. Again, the straight line GO will be the common section of the plane of the dial and of that vertical circle drawn through the style, yet so placed that it is distant from the centre E by the length of the style Ik, or AK. Finally, the points K, L, M, N are here to be transferred not onto the meridian line of the dial, as before, but onto the straight line drawn through K perpendicular to the horizontal line — that is, onto the common section of the said vertical circle and the plane of the dial. These points must be transferred from the place of the style both below the horizontal line and above it, so that we may also have the parallels of the horizon in the portion that is to be placed on the northern face of the plane. For the conic sections about the diameters KO, LO, MO, NO — described by Prop. 8 of Book 1 and transferred onto the dial in such a way that their diameters coincide with the perpendicular drawn from K and pass through the points K, L, M, N, while their horns are turned more and more away from the horizontal line — will give the parallels of the horizon. [Margin: The description of the parallels of the horizon on the same dial declining from the vertical.]

Diagram. A graduated circle (the analemma circle) with centre E, from which straight lines radiate to the circumference. The rim is graduated at every 15°.

- A (top): the highest point of the circle, marked 90
- C (bottom): the lowest point of the circle
- B (left, on the horizontal diameter through E)
- D (right, on the horizontal diameter through E)
- E (centre): centre of the circle, from which the radii issue
- Rim degree graduations (each quadrant, from the horizontal upward and downward): 15, 30, 45, 60, 75, 90; with 90 at A (top) and 75, 75 flanking it
- O, O: two points near the lower part of the rim, flanking C
- Interior points on the left of E (top to bottom): G, K, L, M, N
- Interior points on the right of E (top to bottom): G, K, L, M, N

In the latter method, the lines equidistant from AC in the posterior figure of Prop. 17 of the preceding book are here to be drawn, as there, through the points of the straight line AB which bound the intervals between A — the centre of the circle in the figure of the preceding proposition — and the vertical lines on the horizontal line (understanding also the interval AK, if perhaps no vertical line is drawn through K), transferred from A onto the straight line AB. But their numbers here will not correspond to the numbers of the same lines in Prop. 17 of the preceding book, since the first interval AK, in the figure of the preceding proposition, is not between A and the vertical circle of 90 degrees, but of 60 degrees, in our given example. Hence the parallel line nearest to AC will not bear the number 90, but 60; then the next will bear these two numbers, 45 and 75, and so on, regard being had to the numbers whose intervals have been transferred. Indeed it will sometimes happen that the first parallel line bears no number at all — as when the perpendicular AK is not one of the vertical lines described on the dial. Moreover, when the point K is not exactly in the middle of the two surrounding vertical lines but is unequally distant from them, the intervals between A and the vertical lines are to be transferred on both sides of the point K; and then there will be more parallels in the posterior figure of Prop. 17 of the preceding book, and each will bear only a single number, just as was done for the hour-lines in Prop. 2 of

this book, and not two apiece, as is done in the vertical dial and in our example.

Diagram. The posterior figure — a graduated circle of the same construction as the preceding one, with centre E and radiating lines. The rim is graduated at every 15°.

- A (top): marked 90, flanked by 75, 75
- C (bottom): marked 90, flanked by 75, 75
- B (left, on the horizontal diameter through E)
- D (right, on the horizontal diameter through E)
- E (centre): centre of the circle, from which the radii issue
- Rim degree graduations down each flank: 60, 45, 30, 15 (above and below the horizontal), then 60 again toward the bottom
- O, O: two points near the lower rim, flanking C
- Interior points on the left of E (top to bottom): G, K, L, M, N
- Interior points on the right of E (top to bottom): G, K, L, M, N

Finally, the intervals of the lines equidistant from AC — comprehended between the straight line AB and the rays of the parallels of the horizon issuing from A —

are to be transferred on both sides of the horizontal line onto the vertical lines answering to the numbers marked on the straight line AB, so that the intervals of the parallel nearest to AC are transferred from K, the place of the style, onto the perpendicular AK, upward and downward, and so on. For through the points marked on the vertical lines the parallels of the horizon will pass, all of which are hyperbolas, as we said in Prop. 17 of the preceding book. But since it sometimes happens that the same number is contained on two parallel lines, the intervals of the parallel nearer to AC are to be transferred onto the vertical line of the same number nearer to the point K, and those of the more remote parallel onto the more remote vertical line. And if the perpendicular AC is one of the vertical lines, or is equally distant from the surrounding ones, the said intervals are each to be transferred onto two vertical lines equally distant from the straight line Ak, as the numbers will indicate. This is what happens in our example. We have placed the posterior figure of Prop. 17 of the preceding book near the figure of the preceding proposition, in so far as it corresponds to our example. And so we have depicted the parallels of the horizon on the declining dial. Which was to be done.

Problema 6. Propos. 6.

To delineate the meridians, or the circles of longitude of cities, on the same declining dial.

[Margin: The description of the meridians on the same dial declining from the vertical.]

We shall delineate these circles on the declining dial in the same way in which, on the same dial, we described the hours from noon or from midnight in Prop. 1 of this book — since the meridian is drawn through the poles of the world, like the hour-circles. But the circle described from L on the dial in Prop. 1 of this book will here have the beginning of its division not from the diameter LM, but from another diameter, which is distant from LM toward the west by as many degrees as the longitude of the place comprehends — in our example, 36 degrees. For this diameter will be the common section of the equator and of the prime meridian drawn through the Fortunate Isles, as is evident. And from what we wrote on the second method of describing the declining dial, it will be no trouble to understand which part of the circle described from L is more to the west, or more to the east, than the diameter LM — especially if that circle is understood to be set in its proper position.

Diagram. The construction of the meridians (longitude-circles) on the declining dial. An oblique layout: a long horizontal line (the horizontal line of the dial)

crosses the figure; in the lower-left a circle (the equator) is drawn, labelled *Inf. Fortun.* (*Insulæ Fortunatæ*, the Fortunate Isles) with its upper point L; a fan of straight lines issues from a point near the centre-top (the pole), above which stand the points I and C; a long oblique straight line runs off to the lower-right, labelled *INSVLAE FORTVN.* (the prime meridian through the Fortunate Isles). Longitude graduations in degrees are marked around the circle and along the lines.

- I (upper middle): point above the pole
- C (upper, right of I): point on the meridian line
- L (top of the lower-left circle): centre-point of the equator circle described from L
- G, M (interior points along the horizontal band)
- X (labelled point on the right, on the oblique line)
- - o (marked point at the left of the circle)
- *Inf. Fortun.* (label on the circle) = *Insulæ Fortunatæ*, the Fortunate Isles
- *INSVLAE FORTVN.* (label along the lower-right oblique line) = the meridian of the Fortunate Isles
- Longitude graduations (degrees), securely read: 15, 30, 45, 60, 75, 90, 105, 120, 135, 195, 225, 270, 300, 330
- Further small, rotated numerals near the top of the circle (in the 210–345 range): [?] — abraded and not securely legible

Furthermore, in describing the northern dial on the opposite face of the declining plane — which is presented to us by that portion cut off from the horizontal line, provided all its parts are inverted, as we taught above — the numbers are to be added to the meridians, just as we set forth for the vertical dial in Prop. 18 of the preceding book. This the opposite figure clearly teaches. We have therefore delineated the meridians, or the circles of longitude of cities, on the same declining dial. Which was to be done.

Gnomonics, Liber Tertius (continued)

PROBLEMA 7. PROPOS. 7.

To reposition the parallels of cities — that is, the circles of latitude — on the same declining dial.

[Margin: The drawing of the parallels of cities, or of latitude, on the same dial declining from the vertical.]

These differ from the parallels of the signs of the Zodiac only in that they run through the zeniths of places. We shall therefore draw them on the dial in the way we taught in Prop. 2 of this book, provided that, in place of the parallels of the signs of the Zodiac, we take parallels drawn through the zeniths of cities, and so on. We have thus repositioned the parallels of cities — that is, the circles of latitude, and so forth. Which was to be done.

PROBLEMA 8. PROPOS. 8.

To depict the celestial houses on the same declining dial.

[Margin: The drawing of the celestial houses according to Joannes Regiomontanus [Regiomontanus], on the same dial declining from the vertical.]

We shall carry out the proposed task following the opinion of Joannes Regiomontanus. Let the circle described from L be divided into 12 equal parts — or even into more, if the divisions of the celestial houses too are to be drawn — beginning from the diameter LM, just as in the drawing of the hour-lines. Then, when hidden straight lines have been drawn through the points of division and through the centre L, the equinoctial line will be cut in points; and through these points, straight lines sent out from the point E — where the meridian line intersects the horizontal line — will give the celestial houses. For when the circle described from L, drawn about the equinoctial line, has been rotated until its centre L is joined with the centre of the world and the circle itself is set in the plane of the equator, the straight line LM will be the common section of the equator and the meridian, as we showed above in Prop. 1 of this book. Since, then, the meridian and the remaining circles of the celestial houses divide the equator into 12 equal parts,

Diagram. The construction of the celestial houses on the declining dial. A dense composite figure of the declining dial: a long horizontal line (the horizontal line of the dial) runs across the middle, carrying from left to right the points D, then a short vertical dashed line, then I, B, K, E, beyond which the hour-labels 7 and VII stand to the right. A near-vertical line rising to the point A (with C just to its right) is the meridian; the point I lies to its left. A circle (the equator described from L) sits in the lower half, with L at its lower part; near its interior are the points G and M and the hour-labels XII / 12 (upper left of the circle) and XI / 11 (below G). From a focus near the centre a fan of straight lines and hidden (dotted) lines

radiates. Down the right side, a family of hour-lines is labelled in both Arabic and Roman numerals: **8 / VIII**, **9 / IX**, **10 / X**, running out toward the lower right, with **IX** at the bottom right. Near the top left stand the labels **8** and a mark read as **IIII** [?] with an adjoining angle-stroke.

- D (left end of horizontal line)
- I, B (on the horizontal line, left of centre)
- K (on the horizontal line, at the meridian crossing)
- E (on the horizontal line, right of K — the point from which the house-lines are emitted)
- A (top of the near-vertical meridian line); C (just right of A)
- I (upper middle, left of A)
- L (lower part of the equator circle; centre of the circle described from L)
- G, M (interior points of the circle)
- XII / 12 (hour-labels at upper left of the circle)
- XI / 11 (hour-labels below G)
- 7 / VII (right of E on the horizontal line)
- 8 / VIII; 9 / IX; 10 / X; IX (hour-lines fanning down the right side)
- Uncertain small labels near the top left: "8", and "IIII" [?] with an angle-stroke [?]

they will be straight lines drawn out through the centre L and the points of division — the common sections of the celestial circles of the houses and of the equator. These circles will therefore meet the plane of the dial at the points where the equinoctial line is cut by the aforesaid hidden lines; and consequently, through those same points of the equinoctial line, the common sections of these same circles and of the plane of the dial will be drawn. Now since these common sections cut one another mutually — by Prop. 18 of Book 1 — at the point E (because the common section of those circles, namely the common section of the horizon and the meridian, meets the plane of the dial at E: for if the Sun were to stand in the common section of the meridian and the horizon, so that its ray did not differ from the common section of the celestial circles of the houses, the shadow of the style would fall, by Prop. 11 of Book 1, upon the common section of the plane of the dial with both the horizon and the meridian, and therefore must fall at the point E), it is clear that the straight lines sent out from E through the said points of the equinoctial line are the common sections of the celestial circles of the houses and of the plane of the dial.

[Margin: The drawing of the celestial houses according to Campanus [Campanus of Novara], on the same dial declining from the vertical.]

We shall, however, depict the celestial houses following the teaching of Campanus by this method. From K, the place of the style, let a perpendicular KA be raised to the horizontal line, equal to the style; and from A to the point B — where the equinoctial line intersects the horizontal — let the straight line AB be drawn, and let BD, equal to it, be marked off on the horizontal line. Then, with D as centre, let a circle be described and divided into 12 equal parts (or more, if the divisions of the houses are also wanted), the beginning being made from the horizontal line. For if, from the centre D, hidden straight lines go out through the points of division, they will cut the straight line BF — which is drawn from B perpendicular to the horizontal line, or parallel to the meridian line — in points; and if straight lines are sent out from the point E through these points, the celestial houses will be drawn, as Campanus holds. For if the triangle ABK is understood to be moved about BK until it stands perpendicular to the plane of the dial — so that the style AK likewise becomes perpendicular to it — and if the circle described from D about the straight line BF is conceived to be turned until its centre is joined with the vertex A of the style, that is, with the centre of the world (and it will be joined, because of the equality of the straight lines BD and BA),
