Diagram. The same declining-dial construction of the celestial houses, here shown for the Campanus method. The figure is essentially identical to that on the preceding page: a horizontal line carrying D — a short dashed vertical segment — I, B, K, E, then 7 / VII to the right; the near-vertical meridian line rising to A, with C beside it and I to the left; the equator circle in the lower half with L at its lower part and the interior points G and M; the hour-labels XII / 12 and XI / 11 at the circle; and the hour-lines 8 / VIII, 9 / IX, 10 / X, IX fanning down the right side. The finer (very small) lines carry the Campanus house-sections; the remaining lines belong to the houses of the prior (Regiomontanus) construction. The top-left marks read 8 and IIII [?] as before.

- Labels as on fig-p283-1: D, I, B, K, E on the horizontal line; A, C, I at the top; L, G, M at/in the equator circle; hour-lines 7/VII, 8/VIII, 9/IX, 10/X, XI/11, XII/12, IX.

then the style itself is set in the plane of the vertical circle properly so called. (For, as we demonstrated in Prop. 4 of this book, the vertical circle properly so called is drawn through the straight lines AB and BF, through which the plane of the circle described from D is likewise drawn, if it has the position it acquired by that

rotation.) These straight lines, drawn out through the centre D and the points of division, will then be the common sections of the vertical circle properly so called and of the circles of the celestial houses — since at that point the straight line DB is exactly the same as AB, the common section of the said vertical circle and of the horizon, which is indeed one of the circles of the celestial houses. Therefore the said circles will cut the plane of the dial in the points of the straight line BF into which the said common sections fall; and for that reason the common sections of these same circles and of the plane of the dial will pass through those same points. And since these too are drawn through the point E, as we showed a little before, the straight lines sent out through E and through the points of the straight line BF will give the celestial houses according to Campanus. These lines are represented in the figure by those which are marked with the very fine lines; the remaining lines pertain to the celestial houses of the prior description. We have therefore depicted the celestial houses on the same declining dial. Which was to be done.

PROBLEMA 9. PROPOS. 9.

To describe the ascending signs of the Zodiac on the same declining dial.

[Margin: The drawing of the ascending signs on the same dial declining from the vertical.]

Here, no otherwise than in what precedes, we shall describe the ascending signs of the Zodiac. From the first four tables of Prop. 9 of the preceding book, however, not all the signs can conveniently be described, because the hours that have their beginning from noon, or before noon, from the straight line LM — the diameter of the circle described from L — scarcely all fall upon the equinoctial line. Thus in our example the signs that rise after the 2nd hour from noon can be described only with great difficulty, or not at all, since scarcely any hour-line after the 2nd hour from noon cuts the equinoctial line.

[Margin: The finding of the points on the horizontal line, through which the arcs of the signs and the ascending signs are to be drawn.]

But from tables 6 and 7, by means of the culminations of the heavens and the angles of the earth, and the points that stand at the rising of the signs in the circle of the 6th hour, everything will be described more conveniently, as is evident. Now the ascending signs will pass through those points of the horizontal line where it is cut by the parallels of the signs — although in our example it is scarcely cut by the arcs of the northern signs.

Diagram. The upper figure: an oblique horizon-and-equator layout for the ascending signs on the declining dial. A long horizontal line across the middle is labelled **HORIZON** toward the right; along it stand the points D, K, E. An oblique straight line rising to the upper right is labelled **Linea horæ 6** ("the line of the 6th hour"), with the points N and C where it meets the upper structure. A line descending from the upper left, labelled **AEQVA...** at the left and **...TOR** at the lower right, spells the equator (**ÆQUATOR**) written along its length. A large circle (part of the equator/horizon construction) fills the lower half, with L at its centre-lower part and M within. A great sheaf of straight and dotted lines fans out to the right and lower right, ending in the glyphs of the Zodiac signs (parallels of the signs); further Zodiac glyphs are ranged down the left margin.

- HORIZON (label on the horizontal line, right of centre)
- Linea horæ 6 (label along the oblique line at upper right; the trailing sort after "6" is worn [?])
- N, C (points on/near the "line of the 6th hour" at top)
- D, K, E (points on the horizontal line)
- L (centre-lower part of the circle); M (interior point)
- AEQVA...TOR (= ÆQUATOR, written along the equator line, left to lower-right)
- Zodiac-sign glyphs at the ends of the radiating lines and down the left margin (parallels of the signs)

These points, although the arcs of the signs are not drawn on the dial, we shall find either from the fifth table of Prop. 9 of the preceding book, as was said in what precedes (for if we draw the hour-lines that mark the hours terminating the semidiurnal arcs, these will cut the horizontal line in the said points), or else, more surely, from the last figure of Prop. 21 of the preceding book, which we have here repeated as regards the radii of the latitudes of the signs, in this way. Let there be, as there, the horizon ABCD, whose centre is E; its common section with the meridian is BD; its common section with the prime vertical is AC; and let there be the radii of the latitudes of the rising and setting points, as in that place. Then for the dial

[Margin: Another way of finding the same points.]

Diagram. The lower figure: the horizon ABCD with its full rose of latitude-radii for the rising and setting signs. A large circle is inscribed in a square frame of the four cardinal directions: **MERIDIES** (south) across the top, **SEPTENTRIO** (north) across the bottom, **ORTVS** (east, set vertically) on the left, and **OCCASVS** (west, set

vertically) on the right. The circle is ABCD with B at the top, D at the bottom (so the meridian BD is the vertical diameter), A on the right and C on the left (the prime vertical AC being the horizontal diameter). The centre is E. Between B and the centre stand the interior points H, then K, M (left), G (right), and L just above E; below the centre stand M and K again, running down to D. From the centre E a full sheaf of straight lines radiates to the circumference, each ending in a Zodiac-sign glyph, giving the radii of the latitudes of the rising (east) and setting (west) points.

- MERIDIES (top frame = south); SEPTENTRIO (bottom frame = north); ORTVS (left = east); OCCASVS (right = west)
- B (top of circle); D (bottom of circle); A (right of circle); C (left of circle)
- E (centre)
- Upper interior, from B toward centre: H, then K, M, G, L
- Lower interior, from centre toward D: M, K
- Radial lines from E ending in the twelve Zodiac-sign glyphs around the circumference (the radii of the latitudes of the rising and setting points)

that declines from south toward east, then, let there be set up at E, to ED, the angle of declination of the proposed plane, DEK, toward the parts of the north and toward the west — that is, toward the point A. But for a dial declining from south toward west, [the angle is set] likewise on the side of the north but toward the east — that is, toward the point C. But if the plane declines from north toward east,

toward the east, the said angle of declination must be set up at E, to EB, toward the parts of the south and toward the west — that is, at point A. But conversely, [it is set up] on the side of the south and toward the east — that is, at point C — if it deflects from the north into the west. Now let the straight line EK, equal to the style, be taken on this line, which forms with BD at E the said angle of declination; and through K let there be drawn a perpendicular to EK, cutting BD (produced) at M, and cutting the radii of the rising and setting latitudes (produced) at other points. I say that these points, taken with the compass from point M and transferred onto the horizontal line from E, where it is cut by the meridian line — or else taken from point K and transferred onto the horizontal line from k, the place of the style —

Diagram. The large figure for the declining dial: the horizon-circle with its full rose of latitude-radii for the rising and setting signs. A circle is inscribed within a square frame of the four cardinal directions: **MERIDIES** (south) across the top,

SEPTENTRIO (north) across the bottom, **ORTVS** (east, set vertically) on the left, and **OCCASVS** (west, set vertically) on the right. The circle carries B at the top and D at the bottom (so the meridian BD is the vertical diameter), with A on the right and C on the left (the prime vertical being the horizontal diameter). The centre is E. Along the vertical between B and the centre stand the interior points H, then K (left) and G (right), then M and L just above the centre E; below the centre, running toward D, stand M and K again. On the horizontal diameter, to the left near ORTVS are C and F; to the right near OCCASVS is A. From the centre E a full sheaf of straight lines radiates to the circumference, each ending in a Zodiac-sign glyph — the radii of the latitudes of the rising (east) and setting (west) points.

- MERIDIES (top frame = south); SEPTENTRIO (bottom frame = north); ORTVS (left = east); OCCASVS (right = west)
- B (top of circle); D (bottom of circle); A (right, on horizontal diameter); C (left, on horizontal diameter); F (left, on horizontal diameter, beside C)
- E (centre)
- Upper interior, from B toward centre: H, then K (left), G (right), then M, L
- Lower interior, from centre toward D: M, K
- Radial lines from E ending in the twelve Zodiac-sign glyphs around the circumference

give the points through which the arcs of the signs and the ascending signs are to be drawn. For if, in the dial, a perpendicular KN is drawn from K, the place of the style, to the horizontal line — a perpendicular equal to the style — and NE is joined; and if the triangle EKN is understood to be turned about EK until it stands perpendicular to the plane of the dial, and so is set in the plane of the horizon, with the vertex of the style N being the same as the centre of the world: then NE will be the common section of the horizon and the meridian. For each of those circles is drawn through the centre of the world and through the point E, at which their common sections with the plane of the dial meet. And therefore the angle NEK, which the meridian makes with the plane of the dial in the plane of the horizon, will be equal to the complement of the declination of the plane from the vertical; and accordingly ENK will be the angle of declination, equal to the angle of declination DEK in the figure of the rising latitudes.

Since, therefore, the angles K and E of the triangle EKM in the figure of latitudes and the angles K and N of the triangle ENK in the dial are equal, and the sides EK and NK adjacent to these angles in each triangle are equal to one another [Margin: (Elements) I.26], the sides ME and MK of the former triangle will also be equal to the sides EN and EK of the latter triangle, and the angle M equal to the

angle E. Hence if the straight line EM is superimposed on NE, neither will exceed the other; the style EK will coincide with the style NK, and the line MK with the line EK, because of the equality of the angles. And accordingly the radii of the rising and setting latitudes will meet the horizontal line at the said points of the arcs of the signs, upon which the shadow of the style falls when the Sun, standing at the beginnings of the signs, rises. And so we have described the ascending signs of the Zodiac on the same declining dial. Which was to be done.

[Margin: Why the arcs of the southern signs change into arcs of the northern signs in a northern dial, and vice versa.]

[Margin: How the ascending signs are described, following the practice of Andreas Schöner, on the same dial declining from the vertical.]

[Margin: The order of the ascending signs in the tropics.]

SCHOLIUM

From this, moreover, the reason clearly appears why in a northern dial the southern signs are changed into northern ones, and vice versa. Namely: just as in a southern dial the radii of the latitudes of the southern signs, drawn through the centre E, cut the line KM near the place of the style, while the radii of the latitudes of the northern signs cut it far from that place, so in a northern dial the radii of the latitudes of the northern signs cut the line KM near the style, while the radii of the latitudes of the southern signs cut it far from that place — as is clear from the figure of the rising latitudes.

Now we shall depict the ascending signs according to the teaching of Andreas Schöner [Andreas Schöner], as follows. In the first figure of the scholium of Prop. 9 of the preceding book — (we have here repeated the two earlier figures of that scholium as regards the intervals and angles that the lines of the signs make at the centre E, having also produced, in the second figure, those lines of the signs beyond the centre E which have no answering lines joined to them in a straight line, namely those marked with dots, as we noted in the said scholium) — from the straight line ED, or EB, let a straight line EF be cut off, equal to the line LM, which in the dial is intercepted between the centre L and the point M, where the equinoctial line and the meridian intersect each other. At F let there be set up an angle EFG equal to the angle LMD, which in the dial the equinoctial line makes with LM — yet under this condition and rule, that, with the centre E placed on the centre L and the point F on the point M, the line FG coincides with the equinoctial line.

Then let the intervals of the line FG, intercepted between F and the lines of the signs, be transferred onto the equinoctial line from the point M, in the same order they would have if the line FG coincided with the equinoctial line, by impressing points on the equinoctial line itself. For if, from E, the point of intersection of the meridian line and the horizontal, hidden lines are drawn through these points of the equinoctial line, both tropics will be cut at points through which the ascending signs are to be drawn.

[Margin: How the order of the ascending signs is to be assigned in the tropics.]

It will not be difficult to judge which points answer to which signs. For in a dial declining toward the east, the point where the tropic of Capricorn (♐) cuts the horizontal line, toward the part into which the shadow is projected when the Sun rises — namely the part sloping toward the west —

pertains to Capricorn (♐); the next below the horizontal line, in the same tropic, to Aquarius (♒); the following to Pisces (♓); and so on, as they follow in the earlier figure. But the points which are shown in the tropic of Cancer (♋), or in the same tropic of Capricorn (♐), by the same hidden lines drawn out from point E through the points found on the equinoctial line, look toward the opposite signs. So too the point where the tropic of Cancer (♋) divides the horizontal line, toward the western parts of the dial — into which the shadow of the style is projected in the forenoon — looks toward Cancer (♋); the next below the horizontal line to Leo (♌); the following to Virgo (♍); and so on, in the order which they hold in the said earlier figure.

But in a dial declining toward the west, the point where the tropic of Capricorn (♐) and the horizontal line mutually intersect, toward the eastern parts of the dial — into which the shadow of the gnomon falls in the afternoon — pertains to Cancer (♋); the next in that tropic, below the horizontal line, to Gemini (♊); the following to Taurus (♉); and so on in order, just as they are contained in the same earlier figure. But that point in which the same tropic of Cancer (♋) and the horizontal line intersect, likewise toward the eastern parts of the dial, pertains to Capricorn (♐); the next then, in the same tropic, below the horizontal line, to Sagittarius (♐); the following to Scorpio (♏); and so on, as they are placed in the figure. Nevertheless each single line proceeding from E always pertains to opposite signs in the two tropics, so that if one point of one line in one tropic looks toward Scorpio (♏), the other point of the same line in the other tropic pertains to Taurus (♉), and vice versa, and so on.

Diagram. Two circular figures set side by side — the two earlier figures of the scholium of Prop. 9, here repeated for the intervals and angles of the sign-lines. Each is a circle with centre E, from which a full sheaf of straight lines radiates outward past the circumference, each ending in a Zodiac-sign glyph; the whole is enclosed in a rectilinear frame of construction lines, and (in the right-hand figure especially) several radii are drawn as dotted lines — the produced sign-lines that have no answering lines joined to them.

Left-hand figure:

- A (top of circle); C (bottom of circle); B, N, P (at the left, on the horizontal); F, D (at the right, F above D); E (centre)
- G (outside, upper left); H (interior, below and right of centre)
- M, K (below the circle, on the vertical)
- Peripheral Zodiac-sign glyphs around the circle (*worn; not all securely legible*)

Right-hand figure:

- A (top of circle); C (bottom of circle); N, B (at the left); G (outside, lower left); D, P (at the right); E (centre)
- M, K (below the circle, on the vertical)
- Several radii drawn dotted; peripheral Zodiac-sign glyphs around the circle (*worn; not all securely legible*)

Next, in the second figure of the said scholium, let a length EF, equal to the interval LD — which in the dial is enclosed between the centre L and the point D, where the equinoctial line, the horizontal line, and the six-o'clock line mutually intersect — be taken on the line EC; and at F let there be made an angle EFG equal to that angle which the line LD (were it drawn) between the centre L and the point D forms with the equinoctial line: under this condition, that, with the centre E placed on the centre L and the point F on the point D, the line FG coincides with the equinoctial line. After this, let the intervals of the line FG, interposed between F and the lines of the signs, be transferred onto the equinoctial line from the point D, in the order they would have if the line FG coincided with the equinoctial line, by impressing points on the equinoctial line. For if these points of the equinoctial line are joined with the corresponding points found on the tropics, the ascending signs will be drawn, as before.

[Margin: The order of the ascending signs on the equinoctial line.]

Now the order of the ascending signs on the equinoctial line, in a dial sloping toward the east, is this. The first point below the horizontal line, found by the method just described, is to be assigned to the sign Taurus (♉); the following to the signs Gemini (♊) and Cancer (♋) [♋? — worn], and the next to the sign Leo (♌) [♌? — worn], and so on, as they are set in the later figure. But the next point above the horizontal line pertains to Pisces (♐); the following to Aquarius (♑) and Capricorn (♒) [♒? — worn]; and so on, as the same figure shows. In a dial sloping toward the west, however, the first point found on the equinoctial line below the horizontal line is to be given to the sign Pisces (♐), the following to the signs Aquarius (♑) and Capricorn (♒) [♒? — worn], and so in order, just as they are seen placed in the said figure. But the first point above the horizontal line will pertain to Taurus (♉), the following to Gemini (♊) and Cancer (♋) [♋? — worn], and so on, just as they are drawn in the same said figure.

Furthermore, the ascending signs, produced beyond the horizontal line, give the same signs in the lower dial, provided that the portion cut off by the horizontal line is inverted — as has already been said more than once above.

PROBLEMA 10. PROPOS. 10.

To describe an Italian dial declining from the vertical circle.

[Margin: The drawing of an Italian dial declining from the south toward the east.]

Let the circle MaNb, described from L, be cut — by the means we set out in the scholium of Prop. 1, Book 1 — into the diurnal arc of the tropic of Cancer (♋), aNb, and the diurnal arc of the tropic of Capricorn (♒), dNe, so that the lines ab and de cut at right angles the line MN, which is the common section of the Equator and the Meridian. Then, that circle being twice divided into 24 equal parts — first beginning from point a, then from point d — so that a is hour 24 of the tropic of Cancer (♋) and the next point toward N is hour 23, and so on; while d is hour 24 of the tropic of Capricorn (♒) and the next point toward N is hour 23, and so on: we shall find, through these division-points in each tropic, the points of the hours from sunset, and we shall complete the Italian dial in no other way than we constructed the horizontal Italian dial in Prop. 10 of the preceding book. For the very same demonstration can be adapted here.

For example: from f, the point of hour 16 of the tropic of Cancer (♋), a straight line drawn through the centre L cuts the equinoctial line at point g; and if from C, the centre of the dial, a straight line is sent out through g, the tropic of Cancer (♋) will be cut at h, the point of hour 16 from sunset. So too the line drawn out from

m, the point of hour 21 of the tropic of Capricorn (♑), through L, cuts the equinoctial line at point n; and through n a line drawn from C cuts the tropic of Capricorn (♑) at p, the point of hour 21. In like manner the straight line from q, the point of hour 14 of the tropic of Capricorn (♑) — which lies in the nocturnal arc dMe — drawn through L, cuts the equinoctial line at point r; and through r a line drawn from C cuts the tropic of Capricorn (♑), in the nocturnal arc, at t, the point of hour 14. By this method, however, only the points of those hours will be found which are contained in the semicircle ANB — whose diameter AB is parallel to the equinoctial line — because the lines drawn from those points through L pass first through the centre L before they cut the equinoctial line, which does not happen with the others. So we shall find the points of the other hours as we said of the horizontal dial in Prop. 10 of the preceding book. Thus, if we wish to find

Diagram. The construction of the Italian dial declining from the vertical. A large circle (the tropic/hour circle MaNb described from L) sits at the lower left, its lower half drawn as a bold arc and divided by many radial and chord lines; a horizontal line (the equinoctial line) runs across the whole figure to the right, and a vertical meridian line descends through it. From the centre of the dial (C, upper middle) and from the point L a dense sheaf of straight lines — some solid, some dotted, some dashed — radiates outward to hour-points, carrying Roman-numeral hour labels around the arc (I at the upper right; II, III, IIII, V, VI, VII, VIII around the lower left of the arc; IX, XII, and higher numerals up the left) and Arabic hour-numbers up the right side (...20, 21, 22, 24) and toward the top (...4, 12, 20 with Zodiac glyphs). The interior of the arc carries small Arabic numbers (8, 9, 10, 12, 13, 14, 15, 16, ...).

- Centre / principal points: L (centre of the tropic circle); C (centre of the dial, upper middle, on the meridian); K (on the equinoctial line, near the top of the arc)
- On/near the arc: A (left), B (lower, within the arc), E (lower centre, within the arc), D (interior, left of centre); m, n (interior); q, e, f (at the foot of the arc)
- R (repeated three times down the left margin, at the ends of dashed lines); F (upper left); P (twice, on the right, upper and lower)
- Roman-numeral hour-lines: I (upper right); IX, XII, XIII, XIIIII (up the left); II, III, IIII, V, VI, VII, VIII (around the lower left of the arc)
- Arabic hour-numbers on the right: 20, 21, 22, 24 (and 2, 3); at the top: 4, 12, 20 (beside Zodiac glyphs)

- Interior Arabic numbers within the arc: 8, 9, 10, 12, 13, 14, 15, 16 [several worn]

the point of hour 23 in the tropic of Capricorn (φ) — to which corresponds, in the circle MaNb, the point D, which is not contained in the semicircle ANB — we shall draw, from the opposite point E (of hour 11 of the tropic of Capricorn (φ), comprehended in the nocturnal arc of Capricorn by L and D), a straight line, which will cut the equinoctial line at point R, very far off (which indeed is not contained in our example). Through R, if a line is drawn from C, the tropic of Capricorn (φ) will be cut, in the nocturnal arc, at point F, hour 11; while the line RC, produced beyond the centre C, will cut the same tropic of Capricorn (φ) at point P, hour 23; and so of the rest.

For a northern dial, to avoid confusion, we give no example — both because it is easily derived from the southern one, as we have said of other dials, and also because it can be described in the same way, provided you remember that in a northern dial the diurnal arc of the tropic of Cancer (φ) is dMe, and that of Capricorn (φ) is aMb, as we said of the vertical dial. For example: since the portion cut off by the horizontal line, if it is turned toward us so that the centre C lies below the horizontal line, presents to us a northern dial declining from the north toward the east by 30 degrees — as we taught above in the scholium of Prop. 1 of this book — if from E, the point of hour 13 of the tropic of Cancer (φ), a straight line is drawn through L, the equinoctial line will be cut

the equinoctial line at point R, through which a straight line issuing from C will cut the tropic of Cancer [φ] at F, the point of hour 13, in the northern dial declining from north toward east by 30 degrees; and so on.

But should some division point happen to fall exactly on A or B, then a straight line drawn through C parallel to the equinoctial line will cut the tropic of Capricorn in two points. Of these, the one lying to the right of CL will belong to the hour that falls at A, while the one to the left of CL will refer to the hour that falls at B — as is clear from what we showed in Proposition 1 of this book concerning the line Cd, drawn through C parallel to the equinoctial line. For there we showed that Cd represents the hour from whose point on the circle described from L a straight line drawn through L is equidistant from the equinoctial line.

[Margin: How the same Italian dial is to be described by other methods.]

Now as for the other methods — those carried out either by means of the diurnal and nocturnal arcs, or by the mutual intersections of the hours from noon or from midnight and from sunrise or sunset on the horizontal line, or on the line of

hour 12 from sunrise or sunset, and so on — there is no difficulty at all, provided one attentively consults the tables of Propositions 19, 20, and 23 of Book 1, which we have already cited many times. For (to give you an example) hour 11 from sunset is drawn through hour 6 from midnight on the diurnal arc of 14 hours, and through hour 5 from midnight on the nocturnal arc of 12 hours, and also through hour 4 from midnight on the nocturnal arc of 14 hours. Likewise hour 20 from sunset passes through hour 1 from noon on the diurnal arc of 10 hours, and through hour 2 from noon on the diurnal arc of 12 hours.

Hour 21 from sunset, which in our example has only a single point — namely at hour 2 from noon of the diurnal arc of 10 hours, through which it passes — will be obtained if hour 21 from sunrise is drawn through hour 4 from midnight on the nocturnal arc of 14 hours and extended through hour 2 from noon on the diurnal arc of 10 hours. So too, for hour 22 from sunset, one must draw hour 22 from sunrise through hour 5 from midnight on the nocturnal arc of 14 hours and through hour 4 from midnight on the nocturnal arc of 12 hours; for this line, extended beyond the parallel that is the greatest of all those always hidden — the one drawn through point K — will give hour 22 from sunset. Finally, by the same reasoning, for hour 23 from sunset one must draw hour 23 from sunrise through hour 6 from midnight on the nocturnal arc of 14 hours and through hour 5 from midnight on the nocturnal arc of 12 hours; and so on.

As for the line of hour 12 from sunrise or sunset — should you happen, in laying out the Italian dial, to wish to use the second table of Proposition 20 of Book 1, which pertains to hour 12 from sunrise or sunset — it must be drawn through the point where the equinoctial line, the horizontal line, and the line of hour 6 from noon or midnight mutually intersect, and through the point on the line of hour 12 from noon at which the diurnal arc of 0 hours — that is, the greatest of all the always-hidden parallels — passes, as is clear from tables 5, 6, and 8 of Proposition 33 of Book 1. We shall find this point if, from the figure of rays in Proposition 2 of this book, we transfer the line of hour 12 of midnight (or after noon) — which is drawn from C to the right of the line CA, taken between C and the ray of 0 hours — from C, the center of the dial, onto the meridian line above the center C. For the portion of the meridian line above the center C pertains to midnight, so that it indicates hour 12 from noon. In our example such a point can be found only with great difficulty, as is evident. We have therefore laid out the Italian dial declining from the vertical circle. Which was to be done.

PROBLEMA 11. PROPOS. 11.

To lay out a Babylonian dial declining from the vertical circle.

[Margin: The description of the Babylonian dial declining from the vertical.]

The Babylonian dial is described just like the Italian one, with this one exception: in the former method the division of the circle into 24 equal parts must begin from the points b and e, which lie to the east — as is clear if the dial and the circle are conceived as set in their proper position — so that the points b and e signify hour 24, and the points next to them toward N signify hour 1 from sunrise, and so on. In the other methods the matter is entirely easy, using the tables of Propositions 19, 20, and 33 of Book 1, which we have frequently mentioned so far. The figure of the preceding proposition makes this plain: in it, the hours marked merely with points are counted from noon or midnight; those bearing the ordinary number-characters are counted from sunset; and finally those distinguished by the ancient number-characters are counted from sunrise. We have therefore laid out the Babylonian dial declining from the vertical circle. Which was to be done.

SCHOLIVM.

If the hours from sunrise and sunset are extended beyond the horizontal line in a dial that declines from the south, we shall obtain the same hours on the opposite face of the plane, which declines from the north, provided the parts are interchanged, as we said above.

[Margin: In what way, from an Italian or Babylonian dial declining from south toward east, another may be made declining from north toward east, and from south toward west, and from north toward west.]

Moreover, just as we wrote at the end of the scholium of Proposition 1 of this book — that four different astronomical dials, which nevertheless keep the same amount of declination, can be described by one and the same operation — the same must be said of the Italian and Babylonian dials. For if, for example, we describe an Italian or Babylonian dial declining from south toward east by 30 degrees, of the kind we have constructed so far, we shall by the same labor obtain an Italian or Babylonian dial declining 30 degrees from north toward east — namely that nocturnal one which the horizontal line cuts off — provided we interchange its upper part into the lower. But the hour-numbers must then be changed into their complements up to 24, so that from hour 11 from sunset in the nocturnal portion there arises hour 13 from sunset in the dial declining from

north toward east; and from 23 from sunrise there arises 1 from sunrise; and so on.

But if we invert the same dial declining from south toward east by any number of degrees so that its right part becomes the left, and vice versa, without changing its upper part into the lower, we shall obtain a dial declining by the same number of degrees from south toward west. Here too the hour-numbers must be changed into their complements up to 24, and the hours previously counted from sunrise are now to be counted from sunset, and those previously from sunset now from sunrise — so that from hour 1 from sunrise there arises hour 23 from sunset, and from hour 18 from sunset there arises 6 from sunrise; and so on. Finally, if we invert the nocturnal portion of the dial declining from south toward east by 30 degrees so that the right part becomes the left, and vice versa, and further so that the part which after this change is uppermost becomes the lowermost, and vice versa, there will be described a dial declining from north toward west by the same number of degrees. Here the same hour-numbers are retained, but one must still consider which are to be counted from sunrise and which from sunset, as we said in the scholium of Proposition 23 of the previous book concerning the vertical dial. In like manner, if an Italian or Babylonian dial is described declining from south toward west by 30 degrees,

...by 30 degrees, we shall construct from it a dial declining from north toward west by 30 degrees, and from south toward east by the same number of degrees, and also from north toward east — provided the aforesaid interchanges of parts are made and the hour-numbers changed, as we have just written.

PROBLEMA 12. PROPOS. 12.

To construct an ancient dial declining from the vertical.

[Margin: The construction of the ancient dial declining from the vertical.]

Let both the diurnal arc of the parallel of Cancer, aNb, and that of the parallel of Capricorn, dNe, be divided into 12 equal parts in the circle MaNb, so that the points nearest to and following the points b and e toward N belong to the first unequal (seasonal) hour, the following ones to the second, and so on. For from these division points we shall find, on each tropic, the points of the unequal hours, as we taught for the vertical dial in Proposition 24 of the previous book. For example, the straight line from f — the point of the 2nd unequal hour of the tropic of Cancer — drawn through the center L cuts the equinoctial line at point g, through which a straight line issuing from C cuts the tropic of Cancer at h, the

point of the 2nd unequal hour. In the same way the straight line from m — the point of the 9th unequal hour of the tropic of Capricorn — drawn through L

Diagram. A large sundial-construction figure occupying most of the page. A vertical meridian line descends through the whole figure from the dial-center C (top center). A horizontal equinoctial line crosses the whole width to the right, running out to point S at the far right. In the lower-center sits a large circle (the projection circle MaNb) with center L; its lower half carries a dense sheaf of radial hour-lines and dotted/dashed construction lines. From the dial-center C a fan of straight lines (solid, dashed, and dotted) radiates down and to the right, carrying the Roman-numeral hour-labels XI, X, IX, VIII down the right edge, and I–VII within and around the circle. Down the left side, at the ends of far-reaching lines, the label R recurs (three times) marking the very remote equinoctial-cut points. This figure is extremely dense; many small point-labels are overlapped by construction lines and are not securely legible.

- C (top center, on the meridian line): dial-center
- L (center of the circle): center of the projection circle MaNb
- N (lower-left of circle): division-origin point of the arcs
- A (left of circle): endpoint of semicircle ANB
- B (bottom of circle): endpoint of semicircle ANB
- M (right-center, inside circle): point on the circle
- D (bottom of circle, right of B): point opposite hour 11
- E, e, f, F (clustered at the foot of the circle): opposite-hour and hour points
- a, b (lowercase, on the circle): division points of the diurnal arc of Cancer
- d (left of circle, lowercase): division point (arc dNe)
- q, m (left of circle, lowercase): construction points
- R (three occurrences down the left margin, at the ends of dashed lines): remote equinoctial-cut points [several worn]
- P (upper, near C; and again lower-right): hour points K/P/Q group
- Q (upper-left area): [?]
- K, k (near center, on line CH): shadow / hour-11 point
- H, g, h, n, p (small interior construction points near center) [worn]
- S (far right, on the equinoctial line): remote intersection
- Roman hour-numerals on the right radiating lines: XI, X, IX, VIII
- Roman hour-numerals within and around the circle: I, II, III, IIII, V, VI, VII [several worn]

- Small Arabic numbers near the top of the circle and above C: 1, 2, 3 (and 5, 6, 8, 9) [worn]

(: more than two labels are flagged [?] — the interior small point-labels (Q, H, g, h, n, p, and several of the R/P/K cluster and the small Arabic numbers) are overlapped by construction lines and not securely legible.)

cuts the equinoctial line at point n, and a straight line drawn from C through n cuts the tropic of Capricorn at p, the point of the 9th unequal hour; and so of the rest.

For the 11th unequal hour of the tropic of Capricorn — since it is not contained in the semicircle ANB, whose points alone are found on the tropics, as was said above — we shall take the point D opposite to it, which falls on the 11th unequal hour of the nocturnal arc of the tropic of Cancer, as we shall presently demonstrate. From D, if we draw a straight line through L, it will cut the equinoctial line at a certain point, namely R (which, because it is very remote, is not contained in our dial). Through R, a straight line issuing from C will give, on the nocturnal arc of the tropic of Cancer, the point of the 11th unequal hour corresponding to point D; and the same straight line, thrown out beyond the center C, will present on the diurnal arc of Capricorn another point for the 11th diurnal unequal hour of the tropic of Capricorn, as is clear from what has been demonstrated.

By the same reasoning, for the 11th, 10th, and 9th unequal hours of the tropic of Cancer — since these too fall outside the aforesaid semicircle ANB — we shall take the points opposite to them, E, F, G, which fall on the unequal hours 11, 10, and 9 of the nocturnal arc of the tropic of Capricorn, as we shall presently show; and from these we shall draw straight lines through L, so as to find on the nocturnal arc of Capricorn the points K, P, Q corresponding to the points E, F, G of the nocturnal arc of the tropic of Capricorn. And should some hour fall exactly on point A or B, then a straight line drawn through C equidistant from the equinoctial line will indicate two points on the tropic of Capricorn. Of these, the one that lies to the right of CL will belong to the hour falling on point A, while the other, placed to the left of CL, will belong to the hour falling on point B — as is clear from what we showed in Proposition 1 of this book concerning the line Cd, which is drawn through C parallel to the equinoctial line. For it represents the hour from whose point on the circle described from L a straight line drawn through L is equidistant from the equinoctial line, as we showed at the end of the demonstration of the former method of constructing the declining dial, in Proposition 1 of this book.

If, then, the corresponding points on the tropics are joined by straight lines, the ancient dial will be described; and all the lines of the unequal hours will pass through the hours from noon or midnight on the equinoctial line, as is gathered from tables 13 and 14 of Proposition 33 of Book 1. But since the points of hours 11, 10, and 9 of the arc of Cancer have no corresponding points on the tropic of Capricorn, we shall join them with the points of the nocturnal arc of Capricorn found by means of the points E, F, G, which are opposite to those same hours 11, 10, and 9 of the diurnal arc of Cancer, and fall on the unequal hours 11, 10, and 9 of the nocturnal arc of Capricorn.

[Margin: Demonstration that the unequal diurnal hours in the tropic of Cancer are opposed diametrically to the same unequal nocturnal hours in the tropic of Capricorn, and that in the dial the diurnal hours of the tropic of Capricorn must be drawn through the same nocturnal hours of the same tropic.]

That this is so — and that the lines of the diurnal hours of the tropic of Capricorn must be drawn through the same nocturnal hours of the same tropic on the dial — we shall demonstrate as follows. For example: the straight line from E — the point that is opposite to hour 11 of Cancer and contained in the nocturnal arc of Capricorn — drawn through L, cuts the equinoctial line at H; and the line CH cuts the nocturnal arc of Capricorn at K. Now the greatest circle through the poles of the world, drawn through hour 11 unequal of the tropic of Cancer and also through the point E, will cut the plane of the dial along the line CH, and therefore will cut the tropic of Capricorn at K, as is clear from what was demonstrated in Proposition 10 of the previous book.

But since that greatest circle necessarily cuts off, in the circle MaNb, the arc eE of the 11th unequal hour of the nocturnal arc of the tropic of Capricorn, dMe — for since the arcs aM and eN are equal, being halves of the equal arcs aMb and eNd, if the common arc eM is added, the arc aMe becomes equal to the semicircle MeN — therefore the straight line from a to e, when produced, will pass through the center L; and so at the center L it will, together with the line EL drawn as far as hour 11 of the tropic of Cancer, [a] form equal vertical angles, [b] and therefore the arcs a–11 and eE will be equal.

[Margin: a — 15. primi (Elem. I.15).] [Margin: b — 26. tertij (Elem. III.26).]

Therefore, just as a–11 is a twelfth part of the diurnal arc of the tropic of Cancer, aNb, so eE will be a twelfth part of the nocturnal arc of the tropic of Capricorn, eMd — since the arcs aNb and eMd are equal; and consequently eE will be the arc of the 11th unequal hour on the nocturnal arc of Capricorn. The result is that the

line passes through the 11th nocturnal hour of the tropic of Capricorn. For since the said greatest circle and the meridian cut off similar arcs from the equator and from the tropic of Capricorn — by Proposition 10 of Book 2 of Theodosius — and since the arc ME, which is similar to the arc of the equator lying between the said greatest circle and the meridian, contains five-sixths of the arc Me, which is similar to the semi-nocturnal arc of the tropic of Capricorn, then the arc of the tropic of Capricorn lying between the same greatest circle and the meridian will likewise contain five-sixths of its own semi-nocturnal arc; and therefore the said greatest circle will pass through the 11th unequal nocturnal hour of the tropic of Capricorn.

And since the 11th unequal hour on the diurnal arc of the tropic of Cancer and the 11th unequal hour on the nocturnal arc of the tropic of Capricorn intercept a semicircle from that greatest circle drawn through both hours — for the arc of it lying above the horizon between the parallel of Cancer and the equator is equal to the arc of the same lying below the horizon between the parallel of Capricorn and the equator, since each, by Proposition 10 of Book 2 of Theodosius, is equal [b] to the arc of greatest declination; and if the common arc of the same, placed between the equator and the tropic of Capricorn and passing through the antarctic pole, is added, there will result equal arcs of the same, one placed between the tropic of Cancer and the tropic of Capricorn, the other between the equator [and the tropic], passing through the antarctic pole.

[Margin: The hour-circle of any unequal hour in the tropic of Cancer is drawn both through the diurnal hour in the tropic of Capricorn and through the same nocturnal hour in the same tropic.]

Since, then, the equator cuts off a semicircle from it, by Proposition 11 of Book 1 of Theodosius, the other arc too will be a semicircle. Hence it necessarily follows that another greatest circle — one of the circles of the unequal hours, which does not pass through the poles of the world, and which cuts the said greatest circle (the one through the poles of the world and through the diurnal hour 11 of the tropic of Cancer) at hour 11 diurnal of the tropic of Cancer — cuts that same circle at the opposite point, that is, at hour 11 nocturnal of the tropic of Capricorn; for it bisects it (by Proposition 11 of Book 1 of Theodosius), and it has been shown that the said greatest circle is bisected at hour 11 diurnal of the tropic of Cancer and hour 11 nocturnal of the tropic of Capricorn.

For this reason the greatest hour-circle of the 11th unequal diurnal hour of the tropic of Cancer will pass, in the plane of the dial, through the point k — onto which, indeed, the shadow of the style would fall (by Proposition 11 of Book 1),

the Sun being at hour 11 nocturnal of the tropic of Capricorn, were the earth not to obstruct the Sun's rays. And this 11th unequal nocturnal hour of the tropic of Capricorn lies on the same greatest hour-circle on which the 11th unequal diurnal hour of the tropic of Cancer lies, as we have shown. Therefore the common section of the plane of the dial and of the circle of the 11th unequal hour will pass through the point K; and consequently the straight line joining the point K with the point of hour 11 of the diurnal arc of Capricorn will give the 11th unequal hour — so that that straight line is the common section of the plane of the dial and of the circle of the 11th unequal hour. For this circle passes through the 11th unequal hour both in the tropic of Cancer and in the tropic of Capricorn, as we showed in the scholium of Proposition 10 of Book 1, and likewise, as we have just demonstrated, is drawn through the 11th unequal nocturnal hour in the tropic of Capricorn.

[Margin: The description of the same ancient dial from the tables of the diurnal arc of 6 hours and the nocturnal arc of 18 hours.]

By the same reasoning we shall demonstrate that the straight line joining the point P with the point of hour 10 of the diurnal arc of the tropic of Capricorn gives the 10th unequal hour; and so of the rest. All these things will be more easily grasped if a material sphere is employed. This same demonstration holds in all ancient dials, since we shall always show that any unequal diurnal hour whatever in the tropic of Cancer is diametrically opposed to the same unequal nocturnal hour in the tropic of Capricorn, and vice versa; and therefore that the circle of any unequal hour of the tropic of Cancer is drawn both through the diurnal hour of the tropic of Capricorn and through the same nocturnal hour of the same tropic. In the earlier dials, however, we wrote nothing on this matter, since all the unequal hours can most conveniently be drawn through the hours from noon or midnight on the equinoctial line — which cannot be done in a declining dial without great difficulty, because some of the hours meet the equinoctial line too far off.

But if the diurnal arc of 6 hours — which above the horizontal line is a nocturnal arc of 18 hours — is described, the same ancient dial will be described from tables 9, 10, 13, and 14 of Proposition 33 of Book 1, as appears in the figure. We have therefore constructed the ancient dial declining from the vertical. Which was to be done.

SCHOLIVM.

The lines of the unequal hours of a southern dial, extended beyond the horizontal line, will produce a northern ancient dial, if the interchange of parts is made, as was said above.

ON DIALS THAT DECLINE FROM THE HORIZON.

PROBLEMA 13. PROPOS. 13.

To construct an astronomical dial declining from the horizon — that is, to draw the lines of the hours from meri

[Rubric of PROPOS. 13, completed from the previous page:] ...from noon, or from midnight, on a plane which is parallel to some greatest circle that declines from the horizon but stands at right angles to the vertical circle.

Just as, in the sphere, all the vertical circles — whose common section is the axis of the horizon — stand to the horizon, so all the greatest circles whose common section is the axis of the vertical circle properly so called stand to that circle. Of this sort are all the circles of position [circuli positionum], among whose number is the horizon itself, [standing] to the vertical circle properly so called. Thus, if the vertical circle properly so called is conceived to be some horizon, the horizon itself becomes, as it were, the vertical circle properly so called, and the other circles of position that decline from the horizon become like vertical circles that decline — as is evident from a material sphere. From this it follows that the construction of dials declining from the horizon is the same as that of dials declining from the vertical (which we treated above), with the exceptions that follow.

[Margin: The circles of position declining from the horizon stand to the vertical circle properly so called just as the vertical circles declining from the vertical circle properly so called stand to the horizon.]

In place of the declination from the vertical circle, in dials declining from the horizon one must take the declination from the horizon — that is, the inclination to the horizon. Accordingly, the angle DEF of the declination from the horizon (or rather of the inclination to the horizon — how this is to be found by careful method we showed in Proposition 23 of Book 1) is to be set up below the straight line AB, toward point A, if the dial is an upper one and faces west; but toward B, if it is an upper one and faces east. If, however, the dial is a lower one and looks

toward the west, the same angle must be set up above the line AB, toward B; but if it is a lower one and faces east, toward A.

[Margin: Construction of the astronomical dial declining from the horizon.]

Again, at point β one must set up the angle $E\beta C$ — not of the height of the pole above the horizon, but of the height of the pole above the vertical circle, which is now taken as though it were some horizon; that is, an angle equal to the complement of the latitude of the place, or of the height of the pole above the horizon. (For in every region the height of the pole above the horizon — namely, in the analemma of Proposition 1 of Book 1, the arc DF — together with the height of the pole above the vertical, that is, with the arc AF, makes up a quadrant; so that the complement of the height of the pole above the horizon of any region whatever is the height of the pole above the vertical properly so called of that same region.) This angle is set up above the line AB if the dial is an upper one, but below the same AB if it is a lower one.

[Margin: The complement of the height of the pole above the horizon of any region is equal to the height of the pole above the vertical circle properly so called of that same region.]

Let everything else be carried out as we said in Proposition 1 of this book concerning dials declining from the vertical. So that to construct a dial declining from the horizon is nothing other than this: for a latitude of the place which, together with the latitude of the place for which the dial is being built, makes up 90 degrees, to lay out a dial declining from the vertical by as many degrees as the inclination of the proposed plane to the horizon contains.

[Margin: To construct a dial declining from the horizon is nothing other than to lay out a dial declining from the vertical for that latitude of the place which, together with the proposed latitude for which the dial is built, makes up 90 degrees.]

For in that region the vertical circle properly so called performs the office of the horizon, and the horizon takes the place of the vertical circle — yet in such a way that what in that region declines from south to west is, in this region for which the dial is being made, an upper dial facing west; and what there inclines from south to east is here an upper dial looking toward sunrise, as is plain if the matter is considered more carefully.

[Margin: Demonstration of the construction of the dial declining from the horizon.]

But in that region the antarctic pole must be understood to be raised above the vertical circle of our region — taken as a horizon — namely above its southern face, on which the vertical dial is chiefly described in any region, and likewise the horizontal dial in that region in which the height of its pole, together with the height of the pole of the former region, constitutes a quadrant. Hence, if there a dial declining from the vertical, from south to west, is to be constructed, the line of declination EF must be drawn in the opposite way from what we taught in Proposition 1 of this book — namely toward A, because there noon is produced when the Sun is more northerly than the vertical circle properly so called, and so at noon the shadow is cast toward the south, as is clear from a material sphere; about which matter we shall write more in Book 4, Proposition 11. The following figure sets forth the construction of this dial declining from the horizon. For the demonstration here will be the same as in Proposition 1 of this book, with a few changes. We suppose the plane of the dial to decline from the horizon toward the west by 30 degrees, so that this dial, built for latitude 42 degrees, is the same as a vertical dial declining from south to west built for latitude 48 degrees.

For if in the plane of the dial a straight line CD is understood to be parallel to the horizon, so that it is the common section of the plane of the dial declining from the horizon and of the meridian circle, then the straight line AB will be the common section of the plane of that same declining dial and of the plane of the vertical dial. For since both the meridian and the plane of the declining dial are at right angles to the plane of the vertical dial (by Proposition 15 of Book 1 of Theodosius [Theodosius, *Sphaerica* I.15]) — and since both the meridian and the greatest circle to which the plane of the declining dial is parallel are drawn through the poles of the plane of the vertical dial, namely through the common sections of the meridian and the horizon — (a) their common section CD will also be at right angles to that same plane of the vertical dial, and so, by Definition 3 of Book 11 of Euclid, will also be perpendicular to the common section of the plane of the declining dial and the plane of the vertical dial.

[Margin: (a) 19. unde. — (b) 19. unde. (keyed reference marks for steps (a) and (b) below)]

If, therefore, the plane of the vertical dial is supposed to be drawn through point E, then the straight line AB, which has been drawn perpendicular to CD, is the common section of the plane of the declining dial and the plane of the vertical dial. Wherefore, if the plane drawn through the straight lines AB, EF, ED is understood to be rotated about the line AB until it becomes parallel to the vertical circle and is thus joined with the plane of the vertical dial, it comes about that,

since DEF is the angle of the inclination of the plane to the horizon, the remaining angle AEF is, taken from the right angle, the angle of the complement of that inclination — such, namely, as the meridian makes with the declining plane. Therefore the straight line EF will be the common section of the meridian and of the vertical dial.

Next, since both the plane of the meridian and the plane of the declining dial are at right angles to the plane of the vertical dial, as has been said, (b) their common section CE will be at right angles to that same plane of the vertical dial; and consequently — since EF has been shown to be its meridian line, or its common section with the meridian — it will, by Definition 3 of Book 11 of Euclid, be perpendicular to the straight line EF lying in that plane. Therefore, if the triangle βEC is understood to be rotated about CE until it is joined with the plane of the meridian drawn through the straight lines CE and EF, the right angle βEC will coincide with the right angle CEF, and the point β with the point F, because of the equality of the straight lines $E\beta$ and EF. Wherefore the straight line βC — forming, in that position, with the meridian line EF of the vertical dial the angle $E\beta C$, the angle of the height of the pole above the vertical circle toward the parts of the hidden pole — will be the axis of the world [axis mundi], meeting the plane of the declining dial at the point C; and therefore, by the corollary of Proposition 21 of Book 1, C will be the center of the declining dial. For the axis makes, with the meridian line of the vertical dial that faces south, the angle of the height of the pole above the vertical circle toward the parts of the hidden pole, as is evident from Proposition 13 of the previous book, especially from the portion of the analemma described there.

Again, if the triangle EFG is imagined to be rotated about EG until it is joined with the plane of the vertical dial, we shall show, as in Proposition 1 of this book, that the straight line CG is the line of the style (that is, of the gnomon [stylus, seu index]), that CH is the axis of the world, and that the angle GCH is the angle of the height of the pole above the declining plane. The rest will be demonstrated as

as in the said Proposition 1 of this book. The order of the hours will be the same in the upper dial as in the lower — the same as in the horizontal dial — as is plain, if the circle described from L, drawn together with the dial, is understood to be set in its proper position; so that in the upper dial the meridian line indicates the 12th hour of noon, but in the lower the 12th hour of midnight. Those lines which, in either dial, precede or follow it toward the eastern parts show the hours after noon, while those which recede from it toward the western parts indicate the hours after mid-

[Margin: The order of the hours in a dial declining from the horizon is the same as in a horizontal dial.]

Diagram. The large construction figure for the astronomical dial declining from the horizon. At the center is a radiant sun-face labeled **C**, the center of the declining dial, from which the hour-lines and the style radiate as straight rays. A long straight horizontal line **AB** crosses the whole figure — the line AB, common section of the declining and vertical dial planes — with **A** at the left end (a small α beside it) and **B** at the right end. A large circle (the hour-circle "described from L") occupies the left of the figure, carrying the hour-numbers around its rim. A semicircular inset at the lower right is the portion of the analemma ABC used for the pole-height / inclination construction.

- C (center): center of the declining dial; sun-face with radiating hour-lines
- A (left end of horizontal line): terminus of line AB; small α adjacent
- B (right end of horizontal line): terminus of line AB
- V (top, above the left circle): construction point
- T (left, on the circle): construction point
- S (left, lower on the circle): construction point
- Z (right of C): construction point on a dotted vertical
- Y (below-right of C): construction point
- F (below center): foot-point F (meridian/analemma foot)
- L (interior, below center): pole of the hour-circle
- X, H, R [?] (left, near line AB): construction points [R/K uncertain]
- E, M (on and just below line AB, center): construction points
- β (right portion, near line AB): point β (angle $E\beta C$)
- N, P (lower left): construction points
- I (bottom center): construction point (hour 1?)
- a, b [?] (top, where dotted lines meet): construction points [labels faint]
- Hour-numbers around the circle: 8, 7, 6, 5, 4, 3, 2 (left/lower arc) and 8, 9, 10, 11, 12 (right/lower arc); "12" and "11" near the bottom [several numeral placements faint]

Inset semicircle (lower right — portion of the analemma ABC):

- A (apex of the semicircular arc)
- B (left end of the diameter)
- C (right end of the diameter)
- D (center of the diameter)

- E (point on the arc, right of the apex)
- F (left, above B)
- H, G, I (points on the base line below the diameter; G below D)

[Several small point-labels and hour-numerals in this dense woodcut could not be resolved with certainty]

-midnight. ...Which parts of the dial, moreover, are to be called eastern or western will be easily perceived — if they are compared with the meridian line — provided the dial is understood to be set in its proper position. Yet this distinction must be noted. In the upper dial, the line nearest to the meridian line itself, toward the eastern parts, indicates the 1st hour after noon, and the next belongs to the 2nd, and so on; likewise the one nearest toward the western parts shows the 11th hour after midnight, and the next gives the 10th hour, and so on. But in the lower dial, the nearest line toward the eastern parts shows the 11th hour after noon, and the next signifies the 10th, and so on; likewise the nearest line toward the western parts belongs to the 1st hour after midnight, and the next to the 2nd, and so on.

As for the other method of drawing the hour-lines, this alone need be noted: that the straight lines going out from F and cutting the straight line AB must make with EF the same angles that the hour-lines, in the vertical dial described in Proposition 13 of the previous book, make with the meridian line. For, as we have shown, the straight line EF is here the meridian line of the vertical dial, not the horizontal line as in the dial declining from the vertical; and the point F is the center of that same dial, since the axis of the world falls upon it, as we have proved.

[Margin: Another way of drawing the hour-lines in a dial declining from the horizon, by means of the vertical dial.]

[Margin: Construction of the same dial declining from the horizon, from the height of the pole above the declining plane and from the inclination of the meridian of that same declining plane to the meridian of the horizon.]

For the second method of constructing the declining dial, we find, by Proposition 29 of Book 1, the height of the pole above the proposed plane to be 35 degrees 25 minutes; and by Proposition 30 of the same book, the inclination of the proper meridian of the proposed plane to the meridian of the horizon to be 37 degrees 50 minutes. From this we shall easily make the dial declining from the horizon by means of what we set forth in Proposition 1 of this book — the portion of the analemma ABC having first been constructed for the height of the pole found, and

so on, as may be seen near the dial of this proposition, in the semicircle (or portion of the analemma) ABC.

[Margin: Toward which part, in the circle described from L, the inclination of the meridian of the declining plane itself to the meridian of the horizon is to be reckoned.]

But in order to know toward which part — from point N, in the circle described from L — the inclination of the proper meridian of the declining plane to the meridian of the horizon ought to be reckoned, careful attention must be paid to what we shall presently prescribe. When the plane belongs to the zenith and looks toward the west, as our plane does, the said inclination must be reckoned from N toward the left — that is, toward the eastern parts, toward A — as far as O; because then the meridian of the horizon drawn through O is more easterly than the proper meridian of the declining plane drawn through N, inasmuch as the pole of the declining plane, through which its proper meridian is drawn, is set in the upper and western quadrant of the vertical circle, as is plain if the proper position of the declining plane is rightly understood.

[Margin: All circles of position have their poles on the vertical circle properly so called.]

For all circles of position, to one of which the dial declining from the horizon is parallel, have their poles on the vertical circle. For since all of them pass through the poles of the vertical circle — that is, through the common sections of the meridian and the horizon — the vertical circle will in turn pass through their poles, as we demonstrated in the scholium of Proposition 15 of Book 1 of Theodosius. But if the plane belongs to the zenith yet inclines toward the east, the same

inclination is to be reckoned from N toward the right, that is, toward the western parts, toward B; because then the meridian of the horizon is more westerly than the proper meridian of the declining plane.

From these things anyone will easily understand toward which part the said inclination is to be reckoned from N in the lower dial, if he considers carefully whether, in the lower hemisphere, the meridian of the horizon is more easterly than the proper meridian of the declining plane, or more westerly, and so on, as we said in Proposition 1 of this book. We have refrained, however, from giving rules on this matter, lest by a multitude of precepts we should breed confusion in the reader — especially since it is better to derive the lower dial from the upper, as we shall teach in the following scholium, than to lay it out by its own art.

Diagram. The same construction figure is printed again on this page (the astronomical dial declining from the horizon). It carries the identical labelling as the figure on p. 293: central sun-face **C** with radiating hour-lines; horizontal line **AB** (A with adjacent α at left, B at right); the large hour-circle "described from L" at the left with hour-numbers 8, 7, 6, 5, 4, 3, 2 and 8, 9, 10, 11, 12 around its rim; interior points **V, T, S, X, H, R** [?], **E, M, F, L, Z, Y, β , N, P, I** and the faint top marks **a, b** [?]; and the analemma-portion semicircle at the lower right with apex **A**, diameter **B–D–C**, arc-point **E**, left point **F**, and base-line points **H, G, I**. As on p. 293, several small labels and numerals are not fully resolvable

[Margin: Another construction of the same dial declining from the horizon.]

Finally, for the third and last method, we find, by Proposition 30 of Book 1, the arc of the declining plane between the meridian of the horizon and the proper meridian of the declining plane to be 24 degrees 14 minutes. This arc must be reckoned from the straight line CD toward A, if the dial is an upper one and inclines to the west; but toward B, if it is an upper one and looks toward sunrise. For there the proper meridian of the declining plane is more westerly than the meridian of the horizon in the upper hemisphere, and therefore CP, its common section with the plane of the dial, must lie more to the east in the dial than the meridian line CD. Here, however, the proper meridian of the plane is more easterly than the meridian of the horizon, and consequently CP, its common section with the plane of the dial, must lie more to the west in the dial than the meridian line CD. There is no doubt, moreover, that in the upper dial the parts running from the straight line CD toward A are eastern, but the parts toward B are western.

From these things you will easily understand what you must do in the lower dial, in which the center C inclines toward the north and the arc DP toward the south — if you consider attentively, by what has just been said, whether the proper meridian of the declining plane in the lower dial is, in the lower hemisphere, more easterly than the meridian of the horizon, or rather more westerly. For according as it is the more easterly or the more westerly, so the said arc must be reckoned from the straight line CD in the dial toward the contrary parts, namely toward the west or toward the east. And so we have constructed the astronomical dial declining from the horizon, and so on — which was to be done.

SCHOLIUM.

Each dial declining from the horizon — the upper as well as the lower — must be set upon the declining plane in such a way that the meridian line CD is parallel to

the meridian line found in the plane that is parallel to the horizon. (This will easily be done if some straight line cutting the line AB in the dial is set at right angles upon the very meridian line that has been found, so that the whole coincides with the whole.) And the dial itself, if it is an upper one facing west, is to be raised on the eastern side; or, if it faces east, on the western side — according to the inclination of the plane, namely, in our example, 30 degrees — yet in such a way that that part is raised in which the line of the 6th hour cuts the equinoctial line. From this it comes about that the straight line AB extends directly from east to west — that is, is parallel to the vertical circle properly so called — and cuts at right angles that meridian line in the plane which is parallel to the horizon, with which we said the straight line must coincide that in the dial is perpendicular to the line AB. But if it is a lower one,

[Margin: How the dial declining from the horizon is to be positioned so that it indicates the hours.]

(continuing the scholium to Proposition 13)

it is a dial facing east, it is raised in the same way on the eastern side; or, if it faces west, on the western side — yet with this rule, that the line of the 6th hour, where it cuts the equinoctial line, lies below the meridian line CD. This elevation can conveniently be carried out as follows. In the plane parallel to the horizon, let the meridian line already found be cut by another line at right angles. For if the straight line AB — the one we drew in the dial — makes with this line the angle of the plane's inclination to the horizon, in such a way that all lines dropped perpendicularly from any points whatever of the straight line AB onto the plane parallel to the horizon fall onto the straight line which cuts the meridian line at right angles in that same plane, then the dial will have its proper position — provided, however, that the part of the dial has been raised which we have just taught must be raised. Add this too: in the upper dial the center C must be placed beyond the straight line AB, toward the south; but in the lower dial, on the near side of that same straight line AB, toward the north.

The stylus [stylus] in each dial will be IK, to be fixed at the point K so that it is perpendicular to the plane of the dial. Or else, if the triangle CIG is set upright to the plane of the dial, the shadow of the axis CI will indicate the hours, just as was said in the earlier cases.

[Margin: The stylus of the dial.]

If the dial is to be described on the declining plane itself — one that is fixed, such as some roof directly facing sunrise or sunset, so that it deflects neither toward

the south nor toward the north (how this is to be investigated we taught in Proposition 23 of the first book) — and not on some other plane from which it is afterward transferred onto the declining plane, as we did in this proposition: then on the declining plane one must draw the straight line CD parallel to the horizon for the meridian line, and erect AB perpendicular to it, the rest being constructed as we said in the first method. But if you prefer to carry out the work by the latter two methods, then here too one must first of all draw, for the meridian line, the straight line CD parallel to the horizon, and then draw the straight line CP so that CD and CP intercept the arc DP, as was said in the third method — toward the eastern parts, indeed, for an upper dial that also faces west; but toward the western parts for an upper dial that faces east, and so on. Let everything else be done exactly as we prescribed in Proposition 1 of this book — that is, let the line GH be drawn perpendicular to CP for the equinoctial line, and so on.

[Margin: By what method a dial is to be described on a fixed plane declining from the horizon.]

If the lines of the upper dial facing west interchange their arrangement among themselves, so that the left become right and the right become left (by "the right part" or "the left part" we now mean what is right or left to us when we have turned to face the dial and toward the south), so that they acquire the position they would have on the opposite face of the described plane, each line coinciding with its counterpart — then there will be produced another dial, an upper one facing east, declining from the horizon by the same number of degrees as the first, provided the hour-numbers are changed into their complements up to 12, just as we said regarding the dial declining from the vertical in the scholium to Proposition 1 of this book. For the same demonstration can be adapted here. By the same reasoning, from an upper dial facing east another upper one facing west will be constructed, if that interchange of lines and hours is made. And the same must be said of the lower dial.

[Margin: By what method, from a dial facing west, another facing east is produced, and vice versa.]

Now if any upper dial whatever is inverted, so that — with us turned toward it, toward the east if it faces west, or toward the west if it faces east — the upper part becomes the lower, and vice versa (this change will easily be grasped if one imagines the plane of the dial revolved about the straight line CD until its lines face the nadir and lie on the opposite, lower face of the plane), and so that what is right to us in that position, when we again turn to the dial from the other side of

the plane, becomes left, and vice versa: then there will be produced a lower dial of the same declination from the horizon, to be placed on the opposite, lower face of the plane, as was demonstrated in the scholium to Proposition 13 of the preceding book. This lower dial is beautifully rendered by the lines of the upper dial drawn on the opposite face, each line coinciding with its counterpart. For once this drawing is made, if we turn the opposite face toward us so as to have the center C on the right (if the upper dial faces west) or on the left (if the upper faces east), we shall obtain the lower dial, to be placed on the lower, opposite face.

[Margin: By what method, from an upper dial declining from the horizon, a lower dial on the opposite face is produced.]

Indeed, with the same labor and effort — just as we said concerning the vertical declining dial in the scholium to Proposition 1 of this book — it will be possible to describe four dials declining from the horizon that differ among themselves, while yet the same quantity of declination from the horizon is always preserved. For suppose we describe an upper dial declining, say, from the horizon toward the west by 30 degrees, and change its right part into the left (we now call "the right part" that which is right to us when we have turned toward the dial — toward the east if it faces west, or toward the west if it belongs to the east). From this change it comes about that the upper part too becomes lower, and the center C inclines toward the north — provided, of course, that this change is so arranged that the dial is understood to be moved about its axis, namely the stylus IK. There will then also be described a lower dial facing west, declining from the horizon by 30 degrees. But if all the lines of that same upper dial are described on another plane, so that those which are to the right of its meridian line CD become left, and those to the left become right — or (what is the same) those situated beyond the meridian line toward the east are placed toward the west, and vice versa — then there will be constructed another upper dial facing sunrise and declining from the horizon by 30 degrees, the hour-numbers being changed into their complements up to 12. Such are the lines of the upper dial facing west, described on the opposite and lower part, so that each line corresponds to its counterpart — provided it is so arranged on the upper plane facing east that the same part on which the 6th hour falls occupies the upper place. Finally, if not only the eastern lines are made western, and vice versa, but also the upper part is changed into the lower, and vice versa, so that the center C inclines again toward the north, there will be fabricated a lower dial facing east. By the same reasoning, if an upper eastern dial is described, we shall derive from it three others of the same declination. All these things can easily be gathered from what we wrote at the

end of the scholium to Proposition 1 of this book — the last figure of which scholium also represents the type of an upper dial facing east, which declines from the horizon by 30 degrees but for the latitude of the place of 48 degrees, because in constructing it the angle $F\beta C$ in the figure of Proposition 1 of this book was set at 42 degrees, which is precisely the altitude of the pole above the vertical circle in a region whose latitude is 48 degrees.

Moreover, both the upper eastern dial and the lower one show the hours immediately, when the Sun rises, although more hours are contained in the upper than in the lower. And both the upper and the lower western dial indicate the hours right up to sunset — so that the upper eastern together with the lower western, and equally the lower eastern together with the upper western, contain all the hours of the day.

The method of Andreas Schoner [Andreas Schöner], by which he describes the dial even though no points have been found on the equinoctial line for the hour-lines, is here the same as in the dial declining from the vertical. This is clear from the figure of the present proposition, if it is compared with the figure of the proposition of this book.

[Margin: Construction of a dial declining from the horizon, to a given length of the stylus whose position is also given.]

But if the same dial declining from the horizon is to be described on a given plane, to whatever size of gnomon — the position of which in the plane is also given, as at the point K — we shall approach the matter in this way. Through K, the position of the stylus, let two straight lines AB and FD be drawn, cutting each other at K at right angles. Or, if the plane declining from the horizon is fixed and upright to the vertical, draw through K, the position of the stylus, by means of a level, the straight line FD parallel to the horizon, and let AB cut it at K at right angles. On the straight line FD, taking the length of the given stylus KF — whether above the straight line AB or below — let there be described from F, as center, toward the straight line AB, an arc

of the circle DH — toward B, indeed, if the plane of the dial faces west and toward the zenith, or east and toward the nadir; but toward A, if the dial is an upper one and faces east, or a lower one and faces west. On this arc, the declination from the horizon being reckoned from the point D to H — which again we set at 30 degrees — so that the upper dial faces west, and the straight line FH being drawn to cut AB at E, let CE be drawn through E parallel to FD, that is, perpendicular to AB. For CE will be the meridian line, or the line of the 12th hour. Next, on the arc

HD, toward the other part of the straight line FD produced, let the complement of the declination DN be reckoned, and let the straight line FN be drawn; or rather let the straight line F α be drawn perpendicular to FE, cutting AB at α . For through the point α must be drawn both the horizontal and equinoctial line and the line of the 6th hour. Also, on AB, taking the straight line E β — whether to the right or to the left of the meridian line CE — equal to EF, let there be described from β , toward CE, an arc of a circle: beyond the straight line AB, indeed, in the upper dial, but on the near side of that same AB in the lower dial; and in the latter, the complement of the pole's altitude being reckoned, beginning from the straight line AB, let a straight line be drawn from β to the end of the reckoning, cutting CE at the point C, which will be the center of the dial. Then, drawing from C through K, the position of the stylus, the straight line CK for the line of the stylus, let the line drawn from α cut it at right angles at G: the straight line α G will be the equinoctial line. After this, let the straight line KI be erected from K, perpendicular to CK and equal to the stylus KF, and let CI and GI be joined, which will contain a right angle at I — so that, if CI is drawn first and the perpendicular IG is erected to it, cutting the line of the stylus at G, that point G is the one through which the equinoctial line α G must be drawn from α , perpendicular to CK. And CI will be the axis of the world. Now, on the line of the stylus CK, taking GL equal to GI, let there be described from L a circle of any size, and let it be divided into 24 equal parts, beginning from the straight line LM, which is drawn from L through the point M, where the equinoctial line and the meridian line intersect each other — which straight line LM, if there is no error, will necessarily be perpendicular to the drawn straight line L α . Let all the rest be completed as was explained at the beginning of this proposition.

Diagram. A large sundial-construction figure for a dial declining from the horizon. A long horizontal straight line runs across the middle, lettered **A** at its left end and **B** at its right end (the vertical-circle section AB). Near the top, a small sun-disk carries the center **C**, with **F** just to its left; a dense sheaf of straight rays (hour-lines) fans out from the upper region across the whole figure. Below C, on the meridian line CE, lie **E** (upper) and, lower down, **K** (position of the stylus) and **G**; β stands to the right of E and α to the left of K near a crossing of lines. In the lower half a circle (the 24-part hour-circle) contains **L**, with **M** just above it and **D** at its foot; **N** lies far to the left on the arc; **H** lies to the lower right. The hour-lines are numbered around the margin.

- A (left end of horizontal line): endpoint of section AB
- B (right end of horizontal line): endpoint of section AB
- C (in sun-disk, top center): center of the dial / apex of the ray-sheaf

- F (left of C): vertex of the stylus
- E (below C, on CE): foot of perpendicular FH on AB; meridian point
- β (right of E, on AB): construction point, $EF = E\beta$
- α (left of K): common section of horizontal/equinoctial and 6th-hour line
- K (below E): position of the stylus
- G (below K, on line of stylus): equinoctial-line point (αG)
- M (above the circle): intersection of equinoctial and meridian lines
- L (in the circle): center of the 24-part hour-circle
- D (foot of the circle): terminus of arc DH / DN
- N (far left, on the arc): complement-of-declination point
- H (lower right): terminus of arc DH
- I (upper region): [?] — not clearly resolved on the scan (text: $KI \perp CK$, CI = axis of the world)
- Hour-numbers around the margin: **8, 7** (upper left and right); **7, 8** (mid left and right); **9** (right); and along the bottom, from left: **5, 4, 3, 2, 1, 12, 11, 10**

[Margin: Demonstration of the preceding construction.]

But we shall demonstrate this construction as follows. Let it be understood that in the plane of the dial the straight line FD is parallel to the horizon, so that it is the common section of the plane of the dial and of that position-circle which is drawn through the poles of the plane of the dial and through the common sections of the meridian and the horizon. For this circle is drawn through the stylus FK (since the stylus, produced, falls on the pole of the plane of the dial, being a segment of the dial's own axis) and makes a section parallel to the horizon. For since the plane of the dial declining from the horizon is parallel to the common section of the said position-circle and the horizon — namely, to the axis of the vertical circle — the sections which the plane of the dial makes with that circle and with the horizon will, by Proposition 18 of Book 1, be parallel to each other; and so the common section of the plane of the dial and the said position-circle, since it is parallel to the common section of that same dial and the horizon, will itself be parallel to the horizon. Therefore the straight line FD, if it is set parallel to the horizon, will be the common section of the said position-circle and the plane of the dial. From this it follows that the straight line AB is the common section of the vertical circle and of that same plane of the dial. For since both the plane of the vertical circle properly so called and the plane of the dial declining from the horizon are perpendicular to the aforesaid position-circle, [^a] their common section too will be perpendicular to it; and consequently it will also be perpendicular to the straight line FD lying in that circle, by Definition 3 of Book

11 of Euclid. Therefore the straight line AB, since by construction it is perpendicular to FD, is the common section of the vertical circle (which passes through the center of the world and through the stylus) and of the plane of the dial.

[Margin: ^a 19. vnde ("whence").]

Next, since EFK is the angle of declination of the plane of the dial from the horizon, FEK will be the angle of the complement of that same declination — namely, the angle which the meridian makes with the declining plane. Therefore, if the triangle EFK is moved about EK until it is perpendicular to the plane of the dial set in its proper position, FE will be the common section of the vertical and the meridian, drawn through F, the vertex of the stylus; and consequently through E the meridian line must be drawn, that is, the common section of the meridian and the plane of the dial. But since this common section is parallel, by Proposition 18 of Book 1, to the common section of the plane of the dial and the aforesaid position-circle — that is, to the straight line FD — because the plane of the dial is parallel to the common section of the meridian and that position-circle: the straight line CE, which was drawn parallel to FD, will be the meridian line. And since the arc HN is a quadrant, the angle EF α will be right; and consequently the straight line F α is the common section of the vertical and the horizon. For since both the vertical and the horizon are perpendicular to the meridian, [^b] their common section too will be perpendicular to it, and consequently, by Definition 3 of Book 11 of Euclid, perpendicular to the straight line FE lying in the meridian, at F, the center of the world. Therefore F α , which is perpendicular to FE, is the common section of the vertical and

[Margin: ^b 19. vnde ("whence").]

the horizon. Now the equator has the same common section with the vertical, the horizon, and the circle of the 6th hour — namely the axis of the meridian — since these four circles, being perpendicular to the meridian, pass through the poles of the meridian, by Proposition 13 of Book 1 of Theodosius. Therefore both the horizon and the equator, and the circle of the 6th hour, are drawn through the straight line F α , and it meets the plane of the declining dial at the point α . And so through α must be drawn the horizontal line, as well as the equinoctial line and the line of the sixth hour.

With the triangle EFK still perpendicular to the plane of the dial: since both the plane of the dial and the plane of the meridian are perpendicular to the vertical, [^a] their common section CE too will be perpendicular to it, and so, by Definition 3

of Book 11 of Euclid, perpendicular to the straight line FE lying in the vertical in that position; and consequently the angle CEF will be right. If, therefore, the triangle βEC is understood to be moved about the straight line CE until the straight line βE coincides with the straight line FE and the point β with the point F, then — because of the right angles βEC and FEC and the equality of the straight lines $E\beta$ and EF — βC will be the axis of the world; since in the plane of the meridian, drawn through the straight lines FE and EC, the meridian line of the vertical, at F, the center of the world, makes the angle $E\beta C$ equal to the complement of the pole's altitude above the horizon. Therefore, by the corollary to Proposition 21 of Book 1, the point C in the plane of the dial, onto which the axis falls, will be the center of the dial. From this it comes about that the straight line CK is the line of the stylus, just as in the first description of this proposition the line of the stylus CG was drawn from the center C through K, the position of the stylus. By the same reasoning it is established that the straight line αG , which is perpendicular to the line of the stylus, is the equinoctial line — since it must be drawn through the point α , as we recently showed, and makes right angles with the line of the stylus, as was demonstrated by us in the earlier description of the dial declining from the vertical, in Proposition 1 of this book. All the rest will be demonstrated as in the earlier description of Proposition 1 of this book and its scholium, where we constructed the dial declining from the vertical to a given stylus and its position.

[Margin: ^a 19. vnde ("whence").]

By means of an ellipse described in the plane of the dial, whose diameters are found as in the scholium to Proposition 1 of this book, we shall construct the same dial declining from the horizon — and most conveniently, indeed, as regards those hours which scarcely intersect the equinoctial line, such as, in our example, the 8th and 9th hours from noon or from midnight. We have not worked out an example of this description, because the matter itself can be grasped without any effort from the figure which we constructed in the said scholium to Proposition 1 of this book. For that figure represents a dial declining from the horizon by 30 degrees on the eastern side, so that it faces west, built for the latitude of 48 degrees — which is precisely the complement of that latitude for which the dial declining from the vertical was constructed — the hour-numbers, however, being changed into their complements up to 12. As is clear from what we wrote at the beginning of this proposition.

[Margin: Description of the same dial by means of an ellipse.]

PROBLEMA 14. PROPOS. 14.

To figure the parallels — that is, the arcs of the signs of the Zodiac — on a dial that declines from the horizon.

By exactly the same methods the arcs of the signs will be described on this dial as those by which they were described on the dial declining from the vertical, as appears in the figure below. In the figure we have drawn the rays from C — those lines only which correspond to the hours that in the dial are placed to the left of the line of the stylus — so that the confusion which usually arises from the multitude of lines may be avoided, as we advised in Proposition 2 of this book. For in the dial, on the right part of the same

[Margin: Description of the arcs of the signs on a dial declining from the horizon.]

Diagram. A dense sundial figure showing the parallels (arcs of the zodiacal signs) on a dial declining from the horizon. Two circles appear: an upper circle (the vertical / meridian circle) carrying, from top down, **A**, **B**, and **C** (the center from which the ray-sheaf springs); and a lower circle in which the word "HORIZON" is set (split as **HORI** vertically above and **ZON** across the lower circle), containing the point **Φ** (phi). From C a fan of straight hour-rays and a family of curved sign-arcs cross the sheet, deliberately crowded (the text notes only the left-hand hour-lines are drawn, to reduce confusion). Near the center the points **K**, **M**, and **L** are legible on the stylus/meridian region; hour-numbers **8, 7, 6, 5, 4, 3, 2, 1, 12** (at M), **11, 10, 9** run around the sheaf. Along the right and lower margins run the zodiac-sign glyphs.

- A (top of upper circle): construction point
- B (below A in upper circle): construction point
- C (center of upper circle): apex of the ray-sheaf / center of the dial
- HORIZON (lettered across the two circles): the horizon circle
- Φ (in the lower circle): point label (phi)
- K, M, L (center region): stylus-line / meridian-intersection points
- Hour-numbers around the sheaf: 8, 7, 6, 5, 4, 3, 2, 1, 12 (at M), 11, 10, 9
- Zodiac-sign glyphs along the right/lower margins, readable: Cancer ☉, Leo ♌, Virgo ♍, Libra ♎, Scorpio ♏, Sagittarius ♐, Capricorn ♑; and toward the center Aquarius ♒, Pisces ♓ [?], Aries ♈ [?], Taurus ♉ [?], Gemini ♊ [?]. Several of the small sign-sorts are worn/overprinted by crossing lines and could not be pinned to a definite hour-arc for the zodiac labels.

[End of transcribed pages.]

of the same style-line we have drawn hidden lines — the kind marked off by certain fine lines — which, together with the hours placed to the left, keep the same distances from the style-line, exactly as the hours in a horizontal and a vertical dial are set at equal distances on either side from the meridian line. And so the hour-intervals set between the point C and the rays

Diagram. The "figure of rays" (*figura radiorum*) for a dial declining from the horizon — a very dense construction occupying the upper half of the page. Along the top runs the upper arc of a circle carrying hour-marks; a horizontal diameter crosses the sheet; a parallelogram-shaped auxiliary construction sits at the lower left; and from the center a broad fan of straight hour-rays descends, crossed by curved arcs of the zodiacal signs. The diagonal ray-lines are labelled with "Ra. hor." (*Radius horae*, "ray of the hour") followed by an hour-number, matching the "ray of the 14 hours / 10 hours / 16 hours / 18 hours" cited in the text. Because the sheet is heavily overprinted with crossing lines and several small sorts are worn, many labels cannot be pinned with confidence

- Top arc (hour-marks, left→right): 10, 9, 8, 7, 6 [?]
- Horizontal diameter (left→right): a bold point [label illegible, ?], I, B, C
- Left parallelogram construction: I (far-left corner); along its upper edge B, c, B [?]; down its left edge D, D, D; interior points K, L [?], G
- Point F (with the mark "12" beside it), near the top-center of the parallelogram — the point from which the division of the circle begins (per the text)
- Central points along the ray-sheaf: G, E, A, B, D
- Diagonal ray-labels (left-center): "Ra. hor. 6", "Ra. hor. 10"
- Diagonal ray-labels (right): "Ra. hor. 24", "Ra. hor. 18"
- Diagonal ray-labels (lower-center): "Ra. hor. 19" [?], "Ra. hor. 14"; and one or more lines lettered "Ro." [abbreviation unresolved, ?]
- Hour-numbers at the fan-ends (bottom, left→right): 3, 4, 5, 12, 5, 6, 7, 8, 8, 9, 9, 10, 11 [several worn, ?]
- Worn zodiac-sign sorts along the curved sign-arcs across the lower-center — not confidently resolvable [?]

of the signs have been transferred from the center C of the dial, by one and the same operation, both onto the hours placed to the left of the style-line and onto those hidden lines lying to its right, and so on. In the figure of rays we have also drawn the line CE, corresponding to the meridian line — although it is not contained on the left-hand side of the index-line but on the right — for this reason

only: that by means of it we might find the point F, from which the division of the circle from A, once described, ought to take its beginning; namely, so that we might draw the same hour-lines from C according to the practice of Andreas Schoner [Andreas Schöner], as we set forth in the scholium to Proposition 2 of this book. In that circle the points of division, proceeding from the point F toward B — where the index-line falls — belong to the hours that in the dial are drawn from the meridian line toward the index-line; so that in our example the point next below F, toward B, corresponds to the first hour from noon, the next to the second, and so on.

[Margin: Which arcs on the dial belong to the northern signs, and which to the southern.]

Moreover, in the upper dial — the one declining from the horizon — the parallels, or arcs of the signs, that lie between the center C and the equinoctial line belong to the northern signs, while those that stand farther from the center C than the equinoctial line belong to the southern signs, just as in the horizontal dial. In the lower dial, however, the exact opposite is to be understood. For there the arcs of the signs between the center C and the equinoctial line belong to the southern signs, and the others to the northern. This is easily grasped if each dial is understood as set in its proper position. For it will come about that, when the Sun is in the southern signs, the shadow of the style is cast into the northern part of the dial, and when it is in the northern signs, into the southern part, and so on. The equinoctial line, in turn, separates the southern part of the dial from the northern, exactly as is established in all other dials.

[Margin: How the horizontal line is to be drawn.]

The horizontal line must be drawn through the sixth hour on the equinoctial line, parallel to the meridian line itself — that is, to the line of the twelfth hour. For since the Sun, when it is on the Equator, rises and sets at the sixth hour, it comes about that at the time of the sixth hour it also occupies the horizon. Therefore, at the moment of sunrise or sunset, the solar ray passing through the tip of the style falls — by Proposition 11 of the first book — onto the common sections which the circle of the sixth hour, the Equator, and the Horizon make in the plane of the dial, since the Sun is then on all of these. It is therefore clearly established that the common section of the Horizon and the plane of the dial — that is, the horizontal line — must be drawn through the sixth hour on the equinoctial line, precisely where the line of the sixth hour and the equinoctial cut one another; otherwise the Sun's ray would not fall on all three sections which the plane of the dial makes with those three circles, which is absurd. That this same line must be

parallel to the meridian line is clearly gathered from Proposition 18 of the first book. For since the Meridian, the Horizon, and the great circle to which the dial is parallel have as their common section the axis of the vertical circle, the common sections which the Meridian and the Horizon make with the plane of the dial will be parallel to each other, as was demonstrated in the said Proposition 18.

[Margin: Another description of the horizontal line.]

We shall draw this same horizontal line by the following method. Through K, the place of the style, let the straight line KA be drawn parallel to the meridian line; and to it, from any point B, let a perpendicular BD be erected toward that part of the dial where the equinoctial line and the line of the sixth hour intersect. Then, taking the straight line AB equal to the style IK, construct at A the angle BAD equal to the complement of the plane's declination from the horizon, and let the straight line AD cut the straight line BD at D. For the line drawn through the point D parallel to the meridian line will give the horizontal line, as before — the line which necessarily passes through the sixth hour on the equinoctial line, if no error has been made. And by drawing the horizontal line in this way we shall easily test whether the sixth hour has been correctly laid out or not. That the horizontal line must be drawn

through the point D, found by this technique, we shall make clear in the following way (for that it is drawn through the sixth hour on the equinoctial line, and is parallel to the meridian line, has just now been demonstrated). Let the triangle ABD be conceived as rotated about the straight line BD until it stands perpendicular to the plane of the dial, and let the style IK be thought of as standing perpendicular at K to the dial. [a] On this account the straight lines IK and AB will be parallel to each other, because each is perpendicular to the plane of the dial — IK indeed by its position, but AB by Definition 4 of Book 11 of Euclid. Since, then, they are also equal to each other, [b] the straight line AI, drawn from A to I (both lines IK and AB being set perpendicular to the plane), will likewise be parallel to BK. The Horizon, therefore, passing through I, the tip of the style, and equidistant from the meridian line — and consequently from BK as well — will be drawn through the straight line AI, and thus through the point A. And since, by construction, the angle BAD is equal to the complement of the plane's declination from the horizon, the remaining angle ADB will be equal to the declination itself. Therefore the Horizon will be drawn through the straight line AD, since in this way it meets the plane of the dial at the angle of declination ADB, so that AD is the common section of the Horizon and of the triangle ABD. And so the Horizon will

meet the plane of the dial at the point D, and for that reason the horizontal line must be drawn through D.

[Margin: a) Euclid XI.6.] [Margin: b) Euclid I.33.]

[Margin: Another description of the horizontal line.]

Finally, this same horizontal line will be drawn by the following technique. From the figure of rays, if the upper dial faces west, take the intervals of the seventh hour from noon (between C and the ray of the fourteenth hour) and of the fifth hour from noon (between C and the ray of the tenth hour); or, if it faces east, of the fifth hour from midnight (between C and the ray of the fourteenth hour) and of the seventh hour from midnight (between C and the ray of the tenth hour). Transfer these from C, the center of the dial, onto the corresponding lines, marking points on them. For the horizontal line must be drawn through these points. The Sun, when it is in that parallel whose diurnal arc comprises fourteen hours — which, by what has been demonstrated, passes in the dial through the points found at the seventh hour from noon and the fifth hour from midnight — sets at the seventh hour from noon and rises at the fifth hour from midnight; and when it is in that parallel whose diurnal arc comprises ten hours — which, likewise from what has been demonstrated, passes in the dial through the points found at the fifth hour from noon and the seventh hour from midnight — sets at the fifth hour from noon and rises at the seventh hour from midnight. And so the horizontal line must be drawn through the said hours in the named diurnal arcs; and this line, as we demonstrated before, will necessarily pass through the sixth hour on the equinoctial line and will be parallel to the meridian line. We set out so many methods of drawing the horizontal line because it is pleasant to see that with such great variety we can always arrive at the same goal, and because we can be certain that no error has been committed in laying out the hours, provided that all the methods agree and are consistent with one another.

Now this horizontal line divides the whole dial into two parts, of which the upper is the greater and the lower the lesser, as was shown in the preceding cases — provided the lower parts are altered, as we said in the preceding proposition.

[Margin: The horizontal line divides the whole dial into an upper and a lower part, and into a diurnal and a nocturnal part.]

The dial is also cut by the same horizontal line into a diurnal and a nocturnal part, as was said above. We have therefore drawn the parallels, or arcs, and so on. Which was to be done.

PROBLEMA 15. PROPOS. 15.

To describe the parallels of the diurnal arcs on the same dial, which declines from the horizon.

[Margin: Description of the diurnal arcs on the same dial declining from the horizon.]

In describing these parallels there is no difficulty, since they are laid out in the same way as the parallels of the signs of the Zodiac were in the preceding proposition — as is evident, if in place of the parallels of the signs one takes the parallels of the diurnal arcs, and so on. We have therefore described the parallels of the diurnal arcs, and so on. Which was to be done.

SCHOLIUM.

[Margin: By what device the diurnal arcs serve to lay out those hours which scarcely cut the equinoctial line.]

Here too, as we noted in the scholium to Proposition 3 of this book, by means of the diurnal arcs one can draw the lines of those hours which scarcely intersect the equinoctial line — such as, in our example, the 8th and 9th, both from noon and from midnight. For since, on a day containing 16 hours, the Sun sets at the 8th hour from noon, the 8th hour from noon will pass through that point of the horizontal line where it is cut by the arc of the circle described at the interval of the straight line (in the figure of rays) that corresponds to the 8th hour from noon, intercepted between C and the ray of the 16 hours. This same hour-line, produced beyond the center C, will give the 8th hour from midnight. Similarly, since on a day containing 18 hours the Sun sets at the 9th hour from noon, the 9th hour from noon must be drawn through the point on the horizontal line at which it is divided by the arc of the circle described at the interval of the straight line (in the figure of rays) that corresponds to the 9th hour from noon, intercepted between C and the ray of the 18 hours. And this hour-line, produced beyond the center C, will give the 9th hour from midnight. In a dial facing east, the same must be done for the 4th and 3rd hours from midnight, and so on.

But we shall more conveniently find those points on the horizontal line by means of those diurnal arcs in the former way — namely, those described from the Analemma — because the hours which scarcely cut the equinoctial line cannot be drawn in the figure of rays unless we wish to use the practice of Andreas Schoner [Andreas Schöner].

PROBLEMA 16. PROPOS. 16.

To delineate the vertical circles on the same dial, which declines from the horizon.

[Margin: Delineation of the vertical circles on the same dial declining from the horizon.]

Through K, the place of the style, and the point D — where the horizontal line of the sixth hour and the equinoctial cut each other — let a straight line be drawn cutting the meridian line at B. From K, erect perpendicular to BD the line KA equal to the style IK; and, having joined the straight line DA, cut off DE equal to it. Then, with E as center, describe a circle of any radius whatever, and let it be divided into 360 degrees — or into fewer parts, as was said in the preceding cases — beginning from the straight line DE. For if straight lines are drawn out through the center E and the points of division, the horizontal line will be cut by them at points through which straight lines drawn from the point B will give the vertical circles — that is, the common sections of those circles and the plane of the dial — so that BD is the common section of the plane of the dial and of the vertical circle properly so called. This we shall confirm by the following reasoning.

[Margin: Demonstration of the preceding construction.]

Let the triangle ADK be conceived in the mind as rotated about DK until it stands perpendicular to the plane of the dial; so that accordingly the point A is joined with the tip of the style — that is, the center of the world — and the triangle itself is joined with the plane of the vertical circle properly so called (since here too the vertical is perpendicular to the plane of the dial), and passes through AK, the style, and also through the point D. For since the great circle to which the dial is parallel is, by Proposition 15 of Book 1 of Theodosius, perpendicular to the vertical — being drawn through the poles of the vertical properly so called — conversely the vertical will be perpendicular to that circle, and thus also to the plane of the dial, which is parallel to that circle. [a] Since, therefore, all the planes drawn through the axis AK are perpendicular to the same plane of the dial, the vertical will pass through the style AK, since it is drawn through its tip. And because, when the Sun is at the point where the Equator, the Horizon, the circle of the sixth hour, and also the vertical properly so called cut one another, the shadow of the style falls at D — the point of the sixth hour on the equinoctial line, as we said above — it comes about that through D there also passes the common section of the vertical and the plane of the dial, since, by Proposition 11 of Book 1,

[Margin: a) Euclid XI.18.]

Diagram. A large construction for the vertical circles of a dial declining from the horizon, occupying most of the page below the text. A long horizontal line (the horizontal line of the dial) runs across the sheet, terminated at each end by a cross-mark (cardinal-point symbol). Above it a small dotted triangle links the points A, C, I, K and B near the center. Below and around, families of curved arcs (the vertical circles) and straight rays sweep out from the construction, graduated in degrees; a second fan issues from a lower point (near F/B). The degree-graduations appear both as Roman numerals (XV, XXX, XLV, LX) and as Arabic numerals (15, 30, 45, 60, 75, 90), repeated around the arcs and rays. The sheet is crowded and several numerals are rotated or worn for the peripheral degree-labels.

- Horizontal line (left→right): a cross-mark (†) at the left end; then E, D, K, B; a cross-mark (†) at the right end
- "LX" (60) just to the right of K, on the horizontal line
- Upper region: A (apex of the small dotted triangle, center), C (above and right of A), I (left of A)
- Dotted lines connect A–B, A–D, and A–K (the rotated triangle ADK / ABD of the construction)
- Curved-arc degree labels (upper/right): XV (15), XXX (30), XLV (45), and Arabic 15, 30, 45, 60, 75, 90 scattered around the arcs; one worn mark near the right reads "13" [?]
- Lower horizontal segment (left→right): A, D; with 90 and 75 marked to the right
- Lower fan (issuing near F): apex region lettered "15 F 30", with B above F; rays graduated 15, 30, 45, 60, 75, 90 on both sides, and cross-marks (†) at cardinal rays
- Bottom edge (ray-ends, left→right): 45, 30, 45, 60, 75 ... 75, 60, 45, 30, 15 [several rotated/worn, ?]

the shadow of the style then falls onto this common section. Therefore BD will be the common section of the plane of the dial and of the vertical properly so called. And the straight line AD will be the common section of the triangle ADK and of the Horizon drawn through the tip of the style A and the point D. If, then, we conceive the circle from E — described about the horizontal line — to be moved until the point E is joined with the tip of the style A, and the straight line ED with the straight line AD, then, because of the equality of the straight lines ED and AD, ED (or AD) will also be the common section of the vertical properly so called and

of the Horizon; indeed the very circle described from E will be placed in the plane of the Horizon, and its center will be the same as the center of the world. Therefore the other straight lines drawn through the center E, dividing the circle described from E — and consequently also the Horizon, described from the same center A (which is then the same as E) and in the same plane — into equal parts, will be the common sections of the Horizon and of the remaining vertical circles. Hence the vertical circles will meet the plane of the dial at the points at which the horizontal line is divided by those straight lines drawn from the center E. And since they all also cut one another, by Proposition 18 of the first book, at the point B, into which their common section — namely the axis of the Horizon — falls, so that B is the zenith, or crown of the head (for since the Meridian and the vertical are drawn through the center of the world A and through the point B, the straight line AB, when drawn, will be their common section, that is, the axis of the Horizon) — the straight lines drawn through B and the points found on the horizontal line will be the common sections of the vertical circles and of the plane of the dial. And the meridian line will be the ninetieth vertical. And so we have delineated the vertical circles on the same dial, which declines from the horizon. Which was to be done.

Book Three (continued)

SCHOLIUM

From what we showed in the scholium to Proposition 14 of Book 2, it is perfectly clear that the smaller portion of the dial, cut off by the horizontal line, likewise displays for us the vertical circles on the lower dial, provided its parts are interchanged, as was said above.

Now we demonstrated that the Horizon is drawn through the straight line AD, and the Meridian through AB. From this it follows that, if the triangle ABD is set upright to the plane of the dial along the straight line BD, then the angle ADB turns out to be the angle of inclination of the plane to the Horizon — that is, the angle that the Horizon makes with the declining plane in the plane of the vertical circle — while ABD is the angle complementary to that same inclination, namely the angle that the Meridian forms with the same declining plane in the plane of the vertical circle. Therefore the remaining angle BAD must necessarily be a right angle in the triangle ABD. This can also be seen plainly from the dial that we constructed, in the scholium to Proposition 13 of this book, for a given length of

style. For there the line FE corresponds to the line AB here, and the line F α there is the same as the line AD here.

PROBLEMA 17. PROPOS. 17.

To set down the parallels of the Horizon on the same dial declining from the Horizon.

[Margin: The plotting of the parallels of the Horizon on the same dial declining from the Horizon.]

We shall draw the parallels of the Horizon on this dial just as we laid the same ones down on the polar dial in Proposition 41 of the preceding book — provided only that what follows is carefully observed. In the first method, the circle ABC of the analemma will represent the vertical circle properly so called, which of course passes through the style and stands at right angles to the plane of the dial, and makes the section BD; whereas the parallels of the Horizon are not altered. Again, for the axis EF, a diameter must be drawn — the common section of the vertical circle and of the great circle from which the dial is equidistant — such that both the arc CE and the arc BF are equal to the proposed declination from the Horizon. Parallel to this diameter, a line RQ must then be drawn, of a size corresponding to the style IK (or AK), so that the straight line DI, cutting RQ at right angles, is equal to the style IK. Finally the points L, M, N, O, P, taken from the point T where the Horizon BC cuts the straight line RQ, must be carried over onto the straight line BD, from the point D of the horizontal line toward B, in the upper dial. In the lower dial, however, the intervals ST, and any others there may be, must be carried over from D onto the same straight line BD, but beyond D, produced. For the conic sections about the diameters LQ, MQ, NQ, and so on — drawn according to the teaching of Proposition 8 of Book 1, and transferred into the dial in such a way that their diameters coincide with the straight line BD, and pass through the transferred points L, M, N, O, P, S, and so on, with their horns turned away from the horizontal line — will yield the parallels of the Horizon.

In the second method, the straight line AD is to be taken equal to the straight line AB which, in the figure of the preceding proposition, falls from the tip of the style A onto the zenith B; and onto the straight line AB the intervals between E and the vertical circles on the horizontal line are to be carried over, and so forth. For the meridian line, which gives the vertical circle of 90 degrees and does not cut the horizontal line, DF must be drawn parallel to AB; and the other part of the line to be transferred — the lines drawn from D which cut the straight line AB — must be handled just as was done with the hour-lines on the horizontal dial. For here

AD serves as the axis, and AB as though it were the radius of the Equator (although in truth it is the radius of the Horizon); and the straight lines drawn from A stand in place of the rays of the signs, and so on. The demonstration of this operation is the same as on the horizontal dial: if the straight line AD is made to coincide with the straight line AB, the axis of the Horizon, and the point A with the point B, and the point D with the point A, and the figure ADF — in which the rays of the parallels of the Horizon are contained — is revolved about it, just as on the horizontal dial we conceive the figure of the rays to be moved about the axis of the world. For here the vertical circles behave exactly as the hour-lines do there, so that the point B corresponds to the center of the dial, into which the axis AB falls, and the horizontal line serves as though it were the equinoctial line, and so on. And so we have set down the parallels of the Horizon on the same dial declining from the Horizon. Which was to be done.

Diagram. A large circle — the analemma / vertical-circle projection used to plot the parallels of the Horizon — with center D and a dense array of radiating straight lines and chords. The circumference is graduated in each quadrant with the degree marks 15, 30, 45, 60, 75, 90. The apex A is set just above the top of the circle. The figure is symmetric about the vertical diameter, so several point-letters (K, T, L, M, N, O, P) recur on both the left and the right. Many of the small peripheral labels are worn or rotated; those I cannot resolve are flagged.

- A (apex, above the circle top): tip of the style
- 90 (top of circle), with 75 to its left and 75 to its right
- G (upper left, outside the circle) [?]
- R (upper right, outside the circle)
- 60, 45 (left arc, descending below G); 60 (right arc, below R)
- E (right, with 30 above and 15 below)
- C (right side, on/near the circumference)
- T (left side and again right side)
- K (left side and again right side)
- 30, 15 (left arc, descending)
- P (interior, upper, below the 90)
- L, M, N (interior row, upper); O (interior, near them)
- D (center of the circle)
- 15 (right side, near lower C/T)
- M, N, M, L (interior row, lower — mirror of the upper row); O, P (interior, lower)

- F (lower left, on/near circumference)
- 3 [?], 45, 60 (lower-left arc, near F)
- H (bottom of the circle)
- 75, 90, 75 (bottom arc, below H)
- 30, 45 (lower-right arc)
- 2 (far left and again lower left, outer tick) [?]

SCHOLIUM

From what we wrote in the scholium to Proposition 2 of the preceding book, it will not be difficult to judge which of the parallels of the Horizon are, in the plane of the dial, hyperbolas, and which are parabolas or ellipses. For when, in the figure containing the rays of the parallels of the Horizon, a straight line issuing from the point D and cutting the straight line AB at the point which is nearest of all to the point A cuts two opposite rays drawn out from A, two opposite hyperbolas will be formed — as happens in our example in the rays of the parallels of 15 degrees. But if that same straight line drawn from the point D is equidistant from some ray set to the left of the straight line AB, then the parallel of the opposite ray will be a parabola. And if, finally, that same straight line drawn from D neither cuts nor is equidistant from any ray to the left of the straight line AB, then the parallel described from the opposite ray will be an ellipse — as happens in the proposed example in the rays of the parallels of the Horizon of 30, 45, 60 degrees, and so on. All of which have been demonstrated in the same place.

[Margin: Which parallels of the Horizon in the dial are hyperbolas, parabolas, or ellipses.]

PROBLEMA 18. PROPOS. 18.

To place the meridians, or circles of longitude of cities, on the same dial declining from the Horizon.

[Margin: The plotting of the meridians on the same dial declining from the Horizon.]

In the circle drawn from L, from the point O of the diameter OLM, let the longitude of the place be reckoned toward the western parts, up to α . Then, the circle having been divided into 360 equal parts (or into fewer), let hidden lines be drawn through the points of division and through the center L, cutting the equinoctial line at points through which straight lines, sent out from the center C

of the dial, will give the common sections of the plane of the dial and of the meridians, as is established from what precedes. For the diameter of the circle drawn from α through the center L is the common section of the Equator and of the meridian of the Fortunate Isles, and so on.

Diagram. A construction for the meridians of cities, laid out over a circle whose center is L (on the diameter OLM) and a horizontal line. The circle carries the named meridians of specific places, written along it, and is graduated with longitude degrees; many straight lines radiate across it. Several labels are worn or set at steep angles.

- HORIZON — the word split along the figure: "HORI..." (vertical, upper left of the circle) and "...ZON" (vertical, lower left)
- Ins. Fortun. [Insularum Fortunatarum — the Fortunate Isles, i.e. the prime meridian] (vertical, within the circle, left of center)
- ROMA [Rome] (vertical, right of center within the circle)
- Alexandria (diagonal, upper right)
- C (top, the center of the dial from which the rays are sent)
- O, L, M (points of the diameter OLM; L is the circle's center)
- Longitude degree labels around the circle: 105, 285, 300, 315, 20, 90, 135, 330, 345, 30, 45, 60, 75, 270, 300, 330
- Cross-marks (†) at two points on the circle's lower left
- Point α (labelling the terminus of the reckoned longitude) [?]

In the lower dial — which the portion cut off by the horizontal line presents to us, if its parts are inverted, as we taught above — the numbers must be assigned to the meridians themselves just as we handed down for the vertical dial in Proposition 18 of the preceding book, namely by adding 180 degrees, and so on, to the numbers of those same meridians in the upper dial. Therefore we have placed the meridians, or circles of longitude, on the same dial, and so forth. Which was to be done.

PROBLEMA 19. PROPOS. 19.

To dispose the parallels of cities, or circles of latitude, on the same dial declining from the Horizon.

[Margin: The plotting of the parallels of latitude on the same dial declining from the Horizon.]

Since these parallels are equidistant from the Equator, just as the parallels of the signs are, their plotting will not differ from the plotting of the latter, which we handed down in Proposition 14 of this book. And so we have disposed the parallels of cities, or circles of latitude, on the same dial declining from the Horizon. Which was to be done.

PROBLEMA 20. PROPOS. 20.

To place the celestial houses on the same dial declining from the Horizon.

[Margin: The plotting of the celestial houses on the same dial declining from the Horizon, according to Johannes Regiomontanus [Regiomontanus].]

Let the circle drawn from L, described in Proposition 13 of this book, be divided into 12 equal parts — or into more, if the subdivisions of the celestial houses are also wanted — beginning from the straight line LM, as in the plotting of the hours from noon or from midnight. Through the points of division, and through the center L, let straight lines be drawn cutting the equinoctial line at points; and if straight lines are then drawn through these points parallel to the meridian line itself, or to the horizontal, the celestial houses will be plotted according to the opinion of Johannes Regiomontanus. For since the Meridian and the remaining circles of the celestial houses divide the Equator — and consequently also the circle drawn from L — into 12 equal parts, and since it has been demonstrated that the straight line LM is the common section of the Meridian and the Equator, the remaining hidden lines, drawn through the points of division and through the center L, will be the common sections of the remaining celestial-house circles and of the Equator, provided the circle drawn from L is conceived to be set in its proper position. Hence the circles of the celestial houses will cut the plane of the dial at the points of the equinoctial line onto which the said hidden lines fall; and consequently through these same points the common sections of those same circles and of the plane of the dial must be drawn. Since, therefore, these common sections...

Book Three (continued)

are parallel, by Proposition 18 of Book 1 — because the plane of the dial is equidistant from the common section of the said circles, that is, from the axis of the vertical circle — it is established that the straight lines drawn parallel to the horizontal line, or to the meridian, through the points found on the equinoctial line, are the celestial houses according to the teaching of Johannes Regiomontanus.

Diagram. The construction for the celestial houses on the declining dial, shown with two circles: an upper circle whose center is A, and a lower circle whose center is L. A horizontal reference line runs across the figure, and the houses are marked with Roman numerals. Many labels are set vertically or at an angle and are worn; the unresolved ones are flagged.

- A (center of the upper circle; tip of the style)
- C (upper right, on the upper circle)
- B (right of center, on the horizontal line)
- D (on the horizontal line, left of B; a point of the vertical section DB)
- K (below D / on the line KA)
- L (center of the lower circle)
- M (lower right)
- G (interior, lower) [?]
- 8, 9, 10 (numerals near the center, between the two circles) [?]
- Roman-numeral house labels: I, VII, VIII, X, XI, XII (and further worn numerals) [?]
- VERTICALIS — split along the figure: "VER..." (left) and "...TICALIS" (right)
- HORIZON — split: "HORI..." (upper) and "...ZON" (lower left, within the lower circle)
- Left-margin vertical labels: "Grad.lis" [gradus, degrees]; "domus" [house]; "Grad. 15" [15 degrees]; "12." [?]; a further worn vertical label reading "OP. SIGNIS" [?]
- Zodiac-sign sorts around the lower circle: ♌ [Leo], and further worn sign glyphs [?] — the in-text signs for this figure are Cancer/Capricorn and Gemini/Leo (see Prop. 21)

But, as Campanus would have it, we shall delineate the same houses in this way. From K, the place of the style, let a line KA be drawn equidistant from the meridian line and equal to the style. Then, with A as center, let a circle be described and cut into 12 equal parts, beginning from the straight line AD (or AB) already drawn; and through the points of division, and through the center A, let hidden straight lines be drawn cutting the vertical line DB, which we drew in Proposition 16 of this book, at points. And if lines are then drawn again through these points parallel to the meridian line itself, or to the horizontal, we shall have the celestial houses according to Campanus. For since, as we showed above in Proposition 16 of this book, the straight line AD is the common section of the vertical circle and the Horizon, and AB the common section of the vertical circle and the Meridian, and since the Meridian and the Horizon are among the circles

of the celestial houses, the remaining hidden lines — drawn through the points of division of the circle described from A, and through the center A — will be the common sections of the vertical circle and of the remaining celestial-house circles. Therefore the circles of the celestial houses will meet the plane of the dial at the points of the vertical line DB onto which the said hidden lines fall; and consequently through these same points the common sections of those same circles and of the plane of the dial will pass. Since, then, as we have just shown, these common sections are parallel, it is plain that those parallels drawn through the points of the vertical line are the celestial houses, according to the opinion of Campanus. And so we have placed the celestial houses on the same dial declining from the Horizon. Which was to be done.

[Margin: The plotting of the celestial houses according to Campanus.]

SCHOLIVM

Because we posit that our dial declines from the Horizon by 30 degrees and faces toward the west, it comes about that the great circle passing through the poles of the vertical circle — through which all the circles of the celestial houses are drawn — and passing through the style, so that it stands at right angles to the plane of the dial, is the circle of the ninth celestial house according to the teaching of Campanus, receding of course from the Meridian toward the west by 30 degrees. For the great circle to which the dial is parallel, and the great circle cutting it at right angles, take away a quadrant from the vertical circle. Hence the line of the ninth house, according to Campanus, will pass through the place of the style.

On the lower dial the twelfth house runs so far from the horizontal line that the plane of the dial could scarcely receive it. For this reason we have drawn, in accordance with each method, a parallel line to indicate the 15th degree of the twelfth house, as appears in the figure.

PROBLEMA 21. PROPOS. 21.

To depict the ascending signs of the Zodiac on the same dial that declines from the Horizon.

[Margin: The plotting of the ascending signs on the same dial declining from the Horizon.]

We shall describe these on the dial declining from the Horizon in no other way than we did above — although not all of them can conveniently be delineated

from the earlier four little tables of Proposition 9 of the preceding book, because scarcely all the hours from noon, or before noon (whose beginning is taken from the diameter LM of the circle drawn from L), fall onto the equinoctial line. But most conveniently we shall find, on the meridian line, the points of the ascending signs from the sixth table of the same proposition, by means of the mid-heaven positions [mediationes coeli]. If these points are joined by straight lines to the points of the horizontal line where it is cut by the parallels of the signs, then — as we taught in the preceding — the ascending signs will be plotted. For example, on the upper dial (which faces west, as ours does): when the Sun, standing at the beginning of ☊ [Cancer], sets, the shadow of the style falls onto the point of the horizontal line through which the tropic of ☊ [Cancer] passes, and at the same time the sign ♑ [Capricorn], opposite to ☊ [Cancer], rises. Therefore through that point the line of ♑ [Capricorn] must be drawn. In the same way, when the Sun standing at the beginning of ♊ [Gemini], or of ♌ [Leo], sets, the shadow of the style falls onto a point of the horizontal line...

falls onto a point of the horizontal line — the point through which the parallel of ☊ [Cancer] and ♑ [Leo] is drawn; and at that same instant of time the opposite sign rises, namely ♎ [Sagittarius] or ♒ [Aquarius]. Through that point, therefore, the lines of ♎ [Sagittarius] and ♒ [Aquarius] must be drawn, and so with the rest. But on the Upper dial, which faces east, when the Sun stands at the beginning of ☊ [Cancer] and rises, the shadow of the gnomon is cast onto the point of the horizontal line through which the tropic of ☊ [Cancer] passes. Through that point, then, the ascending sign ☊ [Cancer] must be drawn, and so on.

Diagram. A large circle — the vertical circle / horizon of the construction — with a vertical diameter lettered so as to spell the word HORIZON down the page: HORI: at the top, ZON at the bottom. From the upper left the equinoctial line enters, labelled AEQVA: (for *aequator*). A cluster of straight lines (the parallels of the zodiacal signs and the amplitude-radii) fans across the circle from the left toward the right. Along the outer left arc and along the right-hand side the parallels are tagged with zodiac-sign sorts, most of them worn. The interior lettered points and the readable peripheral labels are:

- HORI: ... ZON (vertical diameter): the horizon / vertical circle.
- AEQVA: (upper left): the equinoctial line.
- C (top, on the meridian line crossing the circle): apex point of the construction.
- D (on the vertical line, upper-middle): point where the equinoctial and horizontal lines meet the vertical.

- G (center): interior intersection point.
- M (right of center): interior intersection point.
- L (lower center): center of the described circle / place of the style.
- N (lower, on the ZON line): lower point of the vertical diameter.
- TOR. (right side, on a curved label): tropic label [abbreviation as printed].
- Zodiac-sign parallels around the periphery (left arc and right side): the several sign-sorts are individually worn and cannot all be resolved with confidence — readable among them are Π [Gemini], $\approx$ [Aquarius], $\mathfrak{M}$ [Virgo], $\sphericalangle$ [Sagittarius]; the remainder are flagged [?]

[Margin: The finding of the points on the horizontal line through which the arcs of the signs and the lines of the ascending signs are to be drawn.]

As for the points on the horizontal line through which the arcs of the signs are to be drawn — even if they have not been drawn — we shall find them either from the fifth little table of Proposition 9 of the preceding book, as was set out above (for if the hour-lines that mark the hours and that bound the semidiurnal arcs are drawn, the horizontal line will be cut by them at the said points); or else from the figure of rising and setting amplitudes [figura latitudinum ortivarum, occiduarumve] of Proposition 21 of the preceding book, in this way. Let there be, as in the said Proposition 21, the Horizon ABCD, with its center E, together with the radii of the rising and setting amplitudes. From the line AD — the one contained in the figure of the preceding proposition — we shall cut off a line EF equal to it: taken from the line EC produced, if the dial faces west, but from EA, if it faces east; and through F we shall draw a line perpendicular to EF. For if the points of this line, where it is cut by the radii of the rising amplitudes, are taken from point F and transferred onto the horizontal line from point D, we shall obtain the points through which the parallels of the signs pass. For if the triangle ABD in the figure of the preceding proposition is understood to stand at right angles to the plane of the dial, then A will be the center of the world, and AD the common section of the Horizon and the vertical circle, as is clear from what has been demonstrated. If, then, the Horizon ABCD of the figure of rising amplitudes is understood to be placed on the dial so that its center E coincides with A, and the line EF — the common section of the vertical circle and the Horizon — with AD, the point F will fall on D, because the lines EF and AD are equal. Hence the perpendicular drawn through F will coincide with the horizontal line, since this perpendicular too stands at right angles to the line AD in that position; and consequently the radii of the rising and setting amplitudes will fall on those points which we said were to be transferred onto the horizontal line from point

D. And so we have plotted the ascending signs of the Zodiac on the same dial that declines from the Horizon. Which was to be done.

[Margin: By what method the same ascending signs may be drawn on the same dial declining from the Horizon, according to the practice of Andreas Schoner. The order of the ascending signs in the tropics.]

SCHOLIVM.

By the teaching of Andreas Schoner [Andreas Schöner] we shall depict the same ascending signs in the following way. In the earlier figure of the scholium to Proposition 9 of the preceding book — which we repeated in the scholium to Proposition 9 of this book — from the line EC (or EA) let a line EM be cut off, equal to the interval LD, the interval intercepted on the dial between the center L and the point D, where the horizontal line, the equinoctial line, and the sixth hour meet. At M, on the line EM, let an angle EMN be constructed equal to the angle that the line LD (if it were drawn) makes with the equinoctial line on the dial, under this condition: that when the center E is placed on the center L and the point M on the point D, the line MN coincides with the equinoctial line. After this, the intervals intercepted on the line MN between M and the lines of the signs are to be transferred onto the equinoctial line from point D, in the order they would have if the line MN coincided with the equinoctial line, marking the points on the equinoctial line. For if through these points hidden parallels are drawn to the horizontal line itself, or to the meridian, the tropics will be cut at points through which the ascending signs are to be drawn, this order being kept. On a dial facing west, the point where the horizontal line is cut by the tropic of ♋ [Cancer] belongs to ♐ [Capricorn] [?]; the next in the same tropic below the horizontal line, to ♏ [Sagittarius]; the next to ♏ [Scorpio] [?]; and so on in succession, contrary to the order of the signs.

The points, however, that are shown by the same parallels in the tropic of ♐ [Capricorn] look to the opposite signs. But on a dial facing east, the point common to the tropic of ♋ [Cancer] and the horizontal line is to be assigned to the sign ♋ [Cancer]; the next, toward the meridian line, to the sign ♌ [Leo]; and so on according to the series of the signs. The points, on the other hand, indicated by the same parallels in the tropic of ♐ [Capricorn] will belong to the opposite signs.

Again, in the later figure of the said scholium to Proposition 9 of Book 2 — which we have likewise repeated in the scholium to Proposition 9 of this book — from the line EC let a line EM be cut off, equal to that same interval LD (the interval set on the dial between L and D); and at M, on the line EM, let an angle EMN be

constructed equal to the angle that the said line LD (if it were drawn) makes with the equinoctial line at D, so that, when the center E is placed at the center L and the point M at the point D, the line MG coincides with the equinoctial line. Then the intervals intercepted on the line MN between M and the lines of the signs are to be transferred onto the equinoctial line from point D, in the order they would have if the line MN coincided with the equinoctial line, marking points on the equinoctial line. For if these points of the equinoctial line are connected by straight lines with the corresponding points of the tropics already found, the ascending signs will be drawn, as before. The order of the signs on the equinoctial line is this. When the dial faces east, the first point below the horizontal line will belong to ♉ [Taurus], the next to ♊ [Gemini], the next to ♋ [Cancer] [?], and so on in succession, as they are set in the said later figure. The next point above the horizontal line will suit the sign ♏ [Pisces], the next the signs ♒ [Aquarius] and ♑ [Capricorn] [?], and so on, just as the signs are placed in the aforesaid figure. But if the dial faces west, exactly the contrary order must be kept: the first point below the horizontal line must be given to the sign ♏ [Pisces], and the next will belong to ♒ [Aquarius] and ♑ [Capricorn] [?], and so on.

[Margin: The order of the ascending signs on the equinoctial line.]

But if the ascending signs are extended beyond the horizontal line, we shall have the same signs on the lower dial, provided that the parts of that portion which the horizontal line cuts off are inverted, as was said above.

PROBLEMA 22. PROPOS. 22.

To construct an Italian dial [horologium Italicum] declining from the Horizon.

[Margin: The construction of an Italian dial declining from the Horizon.]

If a circle described from L is cut into the diurnal arc of the parallel of ♋ [Cancer] by a, N, b, and into the diurnal arc of the parallel of ♑ [Capricorn] by d, N, e — as we taught in the scholium to Proposition 1 of Book 1 — so that the lines ab and de cut the line LM (which is the common section of the Meridian and the Equator) at right angles, we shall draw the hours from sunset on this dial, just as

Diagram. The construction figure for the Italian dial declining from the Horizon. A circle is centered low on the page; a vertical diameter again spells HORIZON (bottom). A dense fan of solid, dashed, and dotted straight lines (the hour-lines drawn from sunset, together with the diurnal/nocturnal arcs and the tropic

and equinoctial lines) radiates outward, and the hour-lines are numbered around the figure from 1 to 18. The readable lettered points and labels are:

- HORI: ... ZON (vertical diameter): the horizon / vertical circle.
- C (top): apex point at the top of the meridian line.
- o (just below and left of C): a construction point near the apex.
- A (upper right, on the vertical meridian line): the point of the 12th hour from midnight.
- N (left, on the circle): division point of the diurnal arcs.
- L (center): center of the described circle.
- P (just right of L): interior construction point.
- m (bottom of the circle): the 21st-hour point of the tropic of ♑ [Capricorn].
- Hour-line numerals ranged around the periphery: 1–18 (left side descending 15, 8, 14, 13, 12, 11, 10, 9...; right side 13, 14, 15, 16, 17, 18, 9).
- Interior small labels: further small letters (a, b, d, e) and numerals (19, 20, 21, 22, 23, 24) mark hour and arc intersections but are individually crowded and worn [several interior labels [?]].
- Peripheral zodiac sorts (Cancer/Capricorn tropic ends and the amplitude parallels) appear at the line-ends; individually worn [?].

was done on the dial declining from the Vertical in Proposition 10 of this book. You have an example in the 21st hour from sunset. For the line from m — the point of the 21st hour of the tropic of ♑ [Capricorn] — drawn through L, cuts the equinoctial line at n; and the line from C, drawn through n, cuts the tropic of ♑ [Capricorn] at p, the point of the 21st hour, and so on.

[Margin: The description of the same Italian dial declining from the Horizon by means of the diurnal and nocturnal arcs.]

In the same way, from the diurnal arcs of 14 and 10 hours and the nocturnal arcs of 10 and 14 hours, we shall lay out the same hours on this dial, as in the preceding cases — provided, however, that when some hour from sunset has no point on the diurnal arcs, the hour of the same number counted from sunrise is taken, and so on. For example, since the 12th hour from sunset on the diurnal arc of 14 hours has no point according to the third table of Proposition 33 of Book 1, we shall take the 12th hour from sunrise, and, following that same third table of the said proposition, we shall draw it through the 5th hour after noon on the diurnal arc of 14 hours

and, following the sixth table, through the 6th hour after noon on the nocturnal arc of 12 hours. For this line, produced beyond the meridian line — that is, beyond the parallel that is always the greatest of all those that ever appear [the circle of perpetual apparition], the one that touches the 12th hour from sunrise or sunset on the meridian line — will give the 12th hour from sunset, as we showed above. In the same way, for the 13th hour from sunset we drew the 13th hour from sunrise through the 6th hour after noon on the diurnal arc of 14 hours, and through the 7th hour after noon on the nocturnal arc of 12 hours. So too for the 14th hour from sunset, which has a single point — namely

Diagram. The same construction figure for the Italian dial declining from the Horizon, repeated so that it stands beside the text on this page as well. A circle low on the page carries the vertical diameter lettered HORI: (top) ... ZON (bottom); the fan of solid, dashed, and dotted hour-lines radiates outward and is numbered 1–18 around the figure. The readable lettered points and labels are:

- HORI: ... ZON (vertical diameter): the horizon / vertical circle.
- C (top): apex point on the meridian line.
- o (below C): construction point near the apex.
- A (upper right, on the vertical meridian line): point of the 12th hour from midnight.
- N (left, on the circle): division point of the diurnal arcs.
- L (center): center of the described circle.
- P (right of L): interior construction point.
- m (bottom of the circle): the 21st-hour point of the tropic of ♊ [Capricorn].
- Hour-line numerals 1–18 around the periphery, as in fig-p305-1.
- Interior small letters (a, b, d, e) and numerals (19–24) mark the hour/arc intersections but are crowded and worn [several interior labels [?]].
- Peripheral zodiac sorts at the line-ends are individually worn [?].

the 9th hour after midnight, on the diurnal arc of 14 hours — we took the 14th hour from sunrise, which is to be drawn through the 7th hour after noon on the nocturnal arc of 10 hours. And so through these points we drew a straight line, one portion of which — drawn on the diurnal arc of 14 hours through the 9th hour after midnight — will indicate the 14th hour from sunset, while the other portion — drawn through the 7th hour after noon on the nocturnal arc of 10 hours — will indicate the same 14th hour from sunrise; and so with the rest.

[Margin: The description of the same Italian dial by means of the tables of Proposition 20 of Book 1.]

Finally, we shall draw these same hours from sunset by their mutual intersections with the hours from noon or from midnight on the horizontal line — that is, the 24th hour and the 12th hour from sunrise or sunset, and so forth — as appears in the tables of Proposition 20 of Book 1. The 12th line from sunrise or sunset is to be drawn through the 6th hour after noon (or after midnight) on the equinoctial line, and through the point A of the meridian line — that is, the 12th hour from midnight — through which the diurnal arc of 24 hours is drawn, as is established from the seventh table and from tables 5 and 6 of Proposition 33 of Book 1. And so we have composed the Italian dial declining from the Horizon. Which was to be done.

PROBLEMA 23. PROPOS. 23.

To set up a Babylonian dial [horologium Babylonicum] declining from the Horizon.

[Margin: The composition of a Babylonian dial declining from the Horizon.]

We shall construct the Babylonian dial by exactly the same methods as the Italian. This the figure of the preceding proposition plainly declares, since it contains both the hours from noon (or from midnight) and the hours reckoned both from sunset and from sunrise, as in the earlier dials as well.

For the rest: on the Lower dial, where everything is changed, the 1st hour from sunrise is drawn through the 6th hour after midnight on the diurnal arc of 14 hours — into which the diurnal arc of 10 hours of the upper dial is changed — and through the 8th hour after midnight on the diurnal arc of 10 hours, into which the diurnal arc of 14 hours of the upper dial is converted. And it is established from the scholium to Proposition 13 of the preceding book that on the lower dial the hours are to be counted from midnight, which on the upper are reckoned from noon, and conversely. Or else, for the 1st hour from sunrise we shall draw the 1st hour from sunset through the 8th hour after noon on the nocturnal arc of 10 hours, and through the 6th hour after noon on the nocturnal arc of 14 hours, as the tables of Proposition 33 of Book 1 indicate. For this, on the lower dial, will be the 1st hour from sunrise, as we taught in the scholium to Proposition 23 of the preceding book. And so we have set up the Babylonian dial declining from the Horizon. Which was to be done.

SCHOLIUM

The hours from sunrise or sunset of the upper dial, extended beyond the horizontal line, here too give the same hours on the opposite and lower face, as was said in what precedes.

By the same reasoning as in the scholium to Proposition 11 of this book, so here too, with one and the same labor, we shall set up four different dials — Italian and Babylonian — just as we advised concerning the Astronomical dial in the scholium to Proposition 13 of this book. This will not be difficult, provided we observe what we handed down in the scholium to Proposition 11 of this book about converting the hours from sunrise or sunset into their complements up to 24, with the addition also of what we wrote in the scholium to Proposition 13 of the same book.

PROBLEMA 24. PROPOS. 24.

To construct an Antique [planetary-hour] dial declining from the Horizon [horologium Antiquum ab Horizonte declinans].

Diagram. A large sundial-construction figure for the declining Antique (planetary-hour) dial. The construction is built around a central apex point **C** at the upper middle, from which a fan of straight hour-lines radiates downward. A great oblique straight line descends from the upper left across the figure and is labelled, in vertical lettering along its course, **HORIZON** (the horizon line). Below and around the center is a circle (the tropic/day circle) crossed by three transverse straight lines — the equinoctial line and the two tropic lines (tropic of Cancer ☿ and tropic of Capricorn ♎). Roman-numeral hour-lines are laid out across the lower part of the figure. The zodiacal sun-signs mark the ends of the tropic and equinoctial lines.

Readable labels (positions approximate):

- **C** (upper-middle apex): the point from which the hour-lines radiate.
- **HORIZON** (running down the upper-left oblique line): the horizon line.
- Roman numerals **XIII, XII, XI, X, IX, VIII, VII, VI, V, IIII** (hour-lines, arrayed left-to-right across the middle and lower zone).
- Arabic hour-fractions along the upper arcs: **9, 7½, 6, 4½, 4, 3, 2½**, and (to the right of center) **4½ · 4½ · 12 · 10½ · 12** [several of these small figures are faint — [?]].

- f (lower left, on/near the horizon), P (far left on the horizon line), L (left of the circle), G, n, a (upper-middle points), M (within the circle), h (right side, on the tropic of Cancer ☊), b (foot of the circle), m and p (below the circle) — points named in the construction paragraph below.
- Zodiac signs at the line-ends: ♈ (Aries, upper left), ☊ (Cancer, right), ♐ (Capricorn, lower/bottom), with further worn sign-sorts at the right and lower-right margin [?].
- A large word set inside the lower part of the circle reads **NON** (upside-down) [?] — reading uncertain.

[Several small peripheral labels on this dense figure could not be resolved and are flagged; the figure]

We shall construct this dial as one declining from the Vertical, per Proposition 12 of this book. For example, as regards the former method: from f, the point of the 4th unequal hour of the tropic of Cancer ☊, a straight line drawn through L cuts the equinoctial line at g; and the straight line Cg cuts the tropic of Cancer ☊ at h, the point of the 4th unequal hour — and so on for the rest. For the 1st hour on the lower dial, we drew from m, the point of the 1st nocturnal hour of the tropic of Capricorn ♐, through L, a line that cuts the equinoctial line at n. For the straight line Cn cuts the tropic of Capricorn ♐ at p, the point of the 1st unequal nocturnal hour. A straight line, therefore, drawn from p through the 7th hour from noon on the equinoctial line, will give the 1st unequal nocturnal hour in the nocturnal portion of the dial; but this, on the lower dial, will be the 1st unequal diurnal hour, and so on.

As regards the latter method, on the hours from midnight — 9, 10½, 12 — and on the hours from noon — 1½, 3, 4½, 6, 7½, 9 — we marked the points of the diurnal arc of 18 hours, through which the unequal hours are to be drawn, as is gathered from Table 11 of Proposition 33 of Book 1. We have therefore constructed the Antique dial declining from the Horizon. Which was to be done.

[Margin: The construction of the Antique dial declining from the Horizon.]

DE HOROLOGIIS AD HORIZONTEM INCLINATIS

PROBLEMA 25. PROPOS. 25.

To describe an Astronomical dial that is inclined to the Horizon — that is, to describe the hour-lines from noon or from midnight on a plane which is

parallel to some great circle inclined to the Horizon and perpendicular to the Meridian.

Since a plane inclined to the Horizon and perpendicular to the Meridian can be situated in six ways, as we shall shortly explain, we shall likewise embrace the whole doctrine of describing dials on a plane of this kind in six precepts, so that the matter itself may be more easily grasped.

[Margin: A description of the Astronomical dial inclined to the Horizon, comprised in six precepts.]

GNOMONICES

PRAECEPTUM I

[Margin: When the plane's inclination on the North side is equal to the pole's altitude.]

When a plane is inclined on the North side — that is, whose upper face looks toward the south — and has an inclination equal to the pole's altitude, its dial will not differ from the Polar dial that we described in Proposition 37 of the preceding book.

PRAECEPTUM II

[Margin: When the plane's inclination on the North side is less than the pole's altitude.]

But when the same plane has an inclination less than the pole's altitude, the inclination must be subtracted from the pole's altitude; for the altitude of the pole above the inclined plane will remain. Then, for this pole-altitude once found, a horizontal dial must be described, as we handed down in Proposition 1 of the preceding book. It must be positioned so that the equinoctial line is parallel to the straight line which — on the plane that is parallel to the Horizon — cuts the meridian line at right angles. (This will easily be done if some straight line cutting the dial's meridian line at right angles is set on the plane parallel to the Horizon, perpendicular to the meridian line found in that plane.) And the dial itself is to be raised on the northern side according to the plane's inclination, so that its meridian line, together with the meridian line of the Horizon, forms toward the North the angle of inclination — yet with this rule: that on the upper face of the plane, which is turned toward the Zenith and the south, the center of the dial lies below the equinoctial line; but on the opposite and lower face, above it.

The order of the hours will be as follows. On the upper dial, the hours after midnight are — for us facing the dial — on the left, and the afternoon hours on the right; and the portion of the meridian line running from the center of the dial toward the equinoctial line indicates the 12th hour of noon, while the remaining portion, beginning from the same center, belongs to the 12th hour of midnight. On the lower dial, the matter stands the opposite way. For on it, the hours after midnight are — for us facing the dial — on the right, and the afternoon hours on the left; and the portion of the meridian line from the center toward the equinoctial line shows the 12th hour of midnight, while the remaining portion, also beginning from the center, shows the 12th hour of noon.

PRAECEPTUM III

[Margin: When the plane's inclination on the North side is greater than the pole's altitude.]

When, finally, the same plane has an inclination greater than the pole's altitude, the pole's altitude must be taken away from the inclination; for the altitude of the pole above the inclined plane will remain. Then, for this pole-elevation, a horizontal dial must be constructed by the doctrine of Proposition 1 of the preceding book. It must be positioned in no other way than the one we treated in the preceding precept, except for this: that here, on the upper dial, the center of the dial must be set above the equinoctial line, but below it on the lower. The order of the hours here too is entirely the same as was declared in the preceding precept.

PRAECEPTUM IV

[Margin: When the plane's inclination on the South side is equal to the complement of the pole's altitude.]

Again, when a plane inclined on the South side — that is, whose upper face looks toward the north — has an inclination equal to the complement of the pole's altitude, its dial will be exactly the same as the equinoctial dial constructed in Proposition 49 of the preceding book.

PRAECEPTUM V

[Margin: When the plane's inclination on the South side is less than the complement of the pole's altitude.]

But when the same plane has an inclination less than the complement of the pole's altitude, the inclination must be added to the pole's altitude; for in this way

the altitude of the pole above the inclined plane will be produced. Then, for this pole-altitude, a horizontal dial must be constructed by what was handed down in Proposition 1 of Book 2. It must be positioned as we prescribed in the second precept, except that this dial must be raised on the southern side according to the plane's inclination, so that its meridian line forms with the meridian line of the Horizon the angle of inclination toward the South — with this condition also added, that on the upper dial the center of the dial has its seat above the equinoctial line, but below it on the lower. The order of the hours here will be, on the upper dial, the same as on the lower dial of the second precept; but on the lower, the same as on the upper of the same precept. Nevertheless, on the upper, the portion of the meridian line extended from the center toward the equinoctial line signifies the 12th hour of noon, but on the lower, the 12th hour of midnight.

PRAECEPTUM VI

[Margin: When the plane's inclination on the South side is greater than the complement of the pole's altitude.]

[Margin: A demonstration of the six preceding precepts.]

When, finally, the same plane has an inclination greater than the complement of the pole's altitude, the complement of the inclination must be added to the complement of the pole's altitude; for by this method the altitude of the pole above the inclined plane will be produced. Then, for this pole-altitude, a horizontal dial must be described, as we taught in Proposition 1 of Book 2. It must be positioned as was said in the preceding precept, yet so that on the upper dial the center is below the equinoctial line, but above it on the lower. The order of the hours here too will be the same as in the preceding precept, except for this: that here, on the upper dial, the portion of the meridian line from the center toward the equinoctial line shows the 12th hour of midnight, but on the lower, the twelfth hour of noon.

We shall demonstrate all this[a] as follows. Let ABCD be the Meridian of the Analemma, whose center is E; let BD be the diameter of the Horizon; AC the Vertical; FG the axis of the world; F the arctic pole, G the antarctic; and HI the diameter of the Equator. Since, then, a plane inclined to the Horizon is set perpendicular to the Meridian, the Meridian will measure both the plane's inclination to the Horizon and the pole's altitude above it. Now it is clear that, if the plane is raised on the side of the arctic pole so that its inclination equals the pole's altitude DF, the plane does not differ from the circle of the 6th hour from

noon or midnight — drawn through the axis FG and perpendicular to the Meridian — and therefore the dial described on that plane

LIBER TERTIUS

is the same as the polar dial, as we said in the first precept. But if, on the side of that same arctic pole, the inclination Dk of the plane KL is less than the pole's altitude DF — as in the first figure — it is clear that the inclination DK, subtracted from the pole's altitude DF, leaves KF, the altitude of the pole above the plane drawn through KL, just as we taught in the second precept. And if, finally, on the same side of the arctic pole, the inclination DK of the same plane KL is greater than the pole's altitude DF — as in the second figure — who does not see that the pole's altitude DF, subtracted from the inclination DK, leaves KF, the altitude of the pole above the plane KL? Again, if the plane KL is raised above the Horizon toward the southern parts so that its inclination equals the altitude of the Equator, or the complement of the pole's altitude BH, it is clearer than daylight that the plane does not differ from the Equator, and so on. But if BK, the inclination of the plane KL, on the same southern side, is less than

Diagram. A row of four small circular analemma figures, each a Meridian-circle of the Analemma demonstrating one of the six precepts (per the text: the first figure answers to the second precept, the second to the third, the third to the fifth, and the fourth to the sixth). In each, the circle is the Meridian ABCD — A at top (the vertex/Zenith direction), C at bottom, B at the left and D at the right end of the horizon diameter BD; E is the center; FG the axis of the world (F the arctic pole, G the antarctic); HI the equator diameter; KL the trace of the inclined plane; MN and OP the two parallels drawn to KL, with M and O the centers of the upper and lower dials respectively. The interiors are crossed by numerous straight construction lines.

Readable labels per figure (small, worn engraving — many flagged):

- **First figure:** A (top), H (upper left), f (upper right) [?], K (right), D (right), B (left), I (lower left), C (bottom); interior points P (upper-center), E (center), N (lower-center), M (lower left). G [?].
- **Second figure:** A (top), K (upper right), H (upper left), F (upper right), B (left), D (right), C (bottom), G (lower left), I (lower right); interior P (left), E (center), M (center-right), N (lower-center), O (lower left).

- **Third figure:** A (top), H (upper left), F (upper right), K (left), B (left), D (right), L (lower right), C (bottom), G (lower left), I (lower right); interior P (upper-center), M and N (lower-center) [center label ?].
- **Fourth figure:** K (upper left), A (top), H (left), F (upper right), B (left), D (right), O (right), C (bottom), G (lower left), J/I (lower right) [?]; interior N (upper-center), E (center), M (lower-center), P (lower right).

[Many peripheral point-letters across these four small figures could not be securely resolved; flagged as a]

the complement of the pole's altitude BH, there is no doubt that the inclination BK, added to the pole's altitude BG, composes the arc KG, the pole's altitude above the plane KL, as appears in the third figure. And if, finally, on the southern side, the inclination BK of the same plane KL exceeds the complement of the pole's altitude BH — as in the fourth figure — it is plainly established that the complement of the inclination AK, joined to the complement of the pole's altitude AF, constitutes the arc KF, the pole's altitude above the plane KL. Rightly, therefore, in the foregoing precepts the finding of the pole's altitude above the inclined plane has been handed down. Therefore, if we construct an Astronomical dial for the found pole-altitude, we shall have the hours from noon or midnight laid out on the inclined plane, since the inclined plane itself is a kind of Horizon, which the Meridian proper to the place where the dial is constructed cuts at right angles, as it does the Horizon of the place.

But suppose that to KL — the common section of the inclined plane and the Meridian — we draw two parallels MN and OP, such that the plane of the upper dial is understood to pass through MN (drawn below the center, since it looks toward the vertex A), whereas the plane of the lower dial is understood to be drawn through OP (drawn above the center, since it turns toward C, opposite the vertex). Then we shall know sooner than it can be said in which dial the center — that is, the point where the axis of the world cuts the plane of the dial, as is clear from Proposition 21 of Book 1 — must be set below the equinoctial line, and in which above it; namely, according as the axis FG cuts the parallels MN, OP above or below the equinoctial line HI, as appears in the figures. Of these, the first corresponds to the second precept, the second to the third, the third to the fifth, and the fourth to the sixth.

For thus you see, in the first figure, that M, the center of the upper dial, is below N, the point through which the equinoctial line must be drawn perpendicular to the meridian line MN, as we showed in Proposition 1 of the preceding book. But on the lower dial, the center O is above P, the point of the equinoctial line, and so

on. For always in the figures the axis FG meets the plane of the upper dial at M and the Equator at N; while it meets the plane of the lower dial at O, and the Equator at P. The order of the hours, too, is easily gathered from the same figures, if the Meridian ABCD is imagined to be placed in its proper position.

For, as appears in the first and second figures, the axis casts a shadow onto the meridian line MN of the upper dial when the Sun is in the semicircle FAG, which passes through the vertex and the point of noon; whereas the same axis casts a shadow onto the meridian line OP of the lower dial when the Sun is in the opposite semicircle FCG, which is drawn through the Nadir and the point of midnight. From which it follows that the meridian line MN of the upper dial, from the center M toward the equatorial point N, belongs to the 12th hour of noon; while the meridian line OP of the lower dial, from the center O toward the equatorial point P, belongs to the twelfth hour of midnight, as we declared in the 2nd and 3rd precepts.

Also, when we face the upper dial so that we turn our face to the North, the shadows in the afternoon will be cast into the part of the dial placed on our right, which is the eastern part; but into the western part, which is on our left, in the forenoon, or after midnight. Likewise, when we face the lower dial so that we turn our face to the south, the shadows will fall into the eastern part in the afternoon — which for us is on the left — but into the western part, placed on our right, in the forenoon, or after midnight.

Again, as is clear in the third figure, the shadow of the axis is cast onto the meridian line MN of the upper dial when the Sun is in the noon semicircle FAG; but onto the meridian line OP of the lower dial when the same Sun is in the midnight semicircle FCG. Hence the former will belong to noon, the latter to midnight — the contrary is seen in the fourth figure. Likewise, when in the third and fourth figures we face the upper dial so that we turn our face toward the south, the shadows will fall into the western part, which is on our right, after midnight or in the forenoon; but into the eastern part, on our left, in the afternoon. But when we face the lower dial so that we turn our face toward the north, exactly the contrary happens. Rightly, therefore, we have prescribed the order of the hours in the foregoing precepts.

Let this be an example of all the cases. Let a plane be proposed inclined to the Horizon on the south side by 68 degrees. Since, then, the inclination is greater than the complement of the pole's altitude — for, in the Roman Horizon, to which we describe all the dials in this our Gnomonics [printed *Gomonica* [recte:

Gnomonica]], the complement of the pole's altitude comprises 48 degrees — we add

[Margin: An example of a dial inclined to the Horizon.]

we shall add — as we taught in the sixth precept (to which the fourth of the figures above corresponds) — the complement of the inclination, namely 22 degrees, to the complement of the pole's altitude, which we said was 48 degrees; and so we shall make the altitude of the pole above the proposed plane 70 degrees. To this altitude, therefore, we shall lay out the Astronomical dial.

Diagram. A large composite construction combining an analemma (upper semicircle) with the full face of the inclined Astronomical dial (a radiating sunburst of hour-lines) below it.

Upper analemma (semicircle):

- A (apex of the semicircle)
- M (on the arc, just left of the apex)
- E (on the arc, just right of the apex)
- F (lower on the left arc)
- N (lower on the right arc)
- D (center)
- B (left end of the horizontal diameter)
- C (right end of the horizontal diameter)
- Along a lower chord parallel to BC: P (left), H, G, O [?], I (right)

Lower sunburst dial:

- The equinoctial line runs horizontally across the figure through F (left), I (center), and K (right)
- C and d [?] (a short construction line on the lower left)
- L (right end of a line level with the center)
- Center cluster of the dial: D (upper), O (middle), H (the dial's center, in a small circle)
- The hour-lines radiate from the center and are numbered 1–12 for the daytime hours and again 1–12 for the night hours; an isolated E marks a point on a dotted horizontal (horizon) line above the dial's center.

[The figure is dense; several of the smaller radiating hour-numerals are not individually resolvable and are not committed here.]

This we do as was explained for the horizontal dial in Proposition 1 of the preceding book. It appears in the opposite figure, in which — since the dial is to be placed on the upper face of the plane — the center of the dial H is set below the equinoctial line; and the portion of the meridian line from H toward I, when extended, marks the twelfth hour of midnight, while the remaining portion, drawn from H toward the other side, marks the twelfth hour of noon, as we taught in the sixth precept and as is easily gathered from the fourth figure. We have therefore laid out the Astronomical dial inclined to the horizon, and so forth, which was what had to be done.

SCHOLIUM.

This same dial, if all its parts are inverted — as we taught in the scholium to Proposition 13 of the preceding book — will mark the hours on the lower face of the plane, as we demonstrated in that same place.

[Margin: By what method a fixed dial is to be constructed on a plane inclined to the horizon.]

If the plane inclined to the horizon is fixed, we shall go about the matter as follows. On the plane we draw a line FK parallel to the horizon, to serve as the equinoctial line, and to it we draw the perpendicular HE for the meridian line, which cuts FK at I. Then, starting from I: toward the lower part if the center of the dial falls below the equinoctial line, or toward the upper part if the dial's center falls above the equinoctial line (which the foregoing six precepts teach quite clearly), we transfer from the portion of the Analemma the straight line HI onto the meridian line HE, as far as the point H, which will be the center of the dial. Likewise, onto the same meridian line we transfer, from the portion of the Analemma, the straight line ID, from I as far as E. Finally, from E we describe a circle, divide it into 24 hours, and so on, completing the rest as before.

[Margin: How to lay out the same dial inclined to the horizon for a given length of style whose position is also given, without a separately constructed portion of the Analemma.]

But if the same dial is to be laid out on a given plane, without a separately constructed portion of the Analemma, for any length of style whose position is also given, we shall proceed in this way. Let the given length of the style be DG, and its position on the plane of the dial the point G. If, then, the plane of the dial is any plane whatever — such that the dial drawn on it may afterwards be set in its proper position, or transferred onto a fixed plane inclined to the horizon — we

draw through G, the position of the style, a straight line HE in any direction, to serve as the meridian line. But if the plane of the dial is proposed as fixed and inclined to the horizon, we draw through G a line DG parallel to the horizon, and at G we erect upon it the perpendicular HE for the meridian line; and from GD we cut off a straight line GD equal to the given style. Then from the center D we describe an arc of a circle, and on it, starting from the line GD produced toward the side of G, we count off the complement of the pole's altitude found above the inclined plane — toward the lower part, indeed,

the lower part of the dial (which we now suppose to run from the point G toward H) if the center of the dial falls below the equinoctial line (and when this happens is gathered from the foregoing precepts); but toward the upper part if the center of the dial lies above the equinoctial line. From D we then draw out a straight line through the endpoint of the reckoning, and this cuts the meridian line at H, the center of the dial. On the same arc, too, starting from the same line DG but toward the opposite side, we count off the very altitude of the pole found above the inclined plane, and through the endpoint of this counting we draw a straight line from D. This line will be perpendicular to DH, and it will cut the meridian line at the point I, through which the equinoctial line FK is to be drawn, perpendicular to the meridian line. Now, taking the straight line IE equal to ID, and describing from E a circle to be divided into 24 equal parts, we complete the rest as before.

The demonstration of this matter does not differ from the one we set out in the scholium to Proposition 1 of the preceding book, when we constructed the horizontal dial for a given length of style; for a plane inclined to the horizon is itself a kind of horizon, as is evident.

Diagram. The face of the inclined dial drawn as a sunburst of hour-lines radiating from the center, used in the construction just described.

- The equinoctial line runs horizontally across the figure through F (left), I (center), and K (right)
- E (upper center, on a dotted horizontal line above the center)
- D (center-left) and G (center) — the construction points of the style and the arc's center
- H (the center of the dial, just below D and G)
- The hour-lines radiate from the center and are numbered 1–12 for the daytime hours (across the top and down the right, 10 11 12 1 2 3 4 5 6 7) and again for the night hours around the lower half of the figure.

[The many small radiating hour-numerals are not all individually resolvable and are not committed cell-by-cell here.]

By means of an ellipse also — drawn on the plane of the dial, whose greater semidiameter is HI, whose lesser is ID, and whose center is H — we shall lay out this same dial, just as we laid out the horizontal one in the scholium to Proposition 1 of the preceding book. This can be readily understood from the figure we set beside that scholium. For that figure represents, in a region whose latitude comprises 60 degrees, a dial inclined to the horizon by 18 degrees on the northern side; because then the arctic pole stands at an altitude of 42 degrees above that plane, just as it does above the horizon of the place for which we constructed that horizontal dial.

[Margin: How to lay out the same dial by means of the ellipse.]

PROBLEMA 26. PROPOS. 26.

To place the parallels — that is, the arcs of the signs of the Zodiac — on the same dial inclined to the horizon.

Once the altitude of the pole above the inclined plane has been found, the parallels of the signs are drawn on this dial exactly as on the horizontal one, as we set out in Proposition 2 of the preceding book, and as appears in the figures given below.

[Margin: How to lay out the arcs of the signs on the same dial inclined to the horizon.]

Diagram. A dial face showing the equinoctial and horizon lines with the parallels (arcs) of the zodiacal signs drawn across the hour-lines.

- The upper horizontal line is labelled **AEQVA...TOR** (Aequator — the equatorial/equinoctial line), and along it run the hour-numbers 8 9 10 11 12 1 2 3 4
- A lower horizontal line is labelled **HORI...ZON** (Horizon), marked 6 ... 6 at its ends
- A central cluster of construction points near the meridian; the legible letters are E, A, G, and H (with B [?] near the center)
- Curved parallels of the twelve zodiacal signs cross the radiating hour-lines; the sign-glyphs legibly identifiable include ♉ (Taurus), ♊ (Gemini), ♍ (Virgo), and ♐ (Capricorn), with the remaining sign-sorts too worn to read individually [?]

[Several zodiac-sign glyphs are not resolvable at this resolution]

Which arcs belong to the northern signs and which to the southern, the four Analemmata in the preceding proposition make beautifully clear. For in the first Analemma the points of the northern quadrant FH (we now call the northern semicircle of the meridian HFI, and the southern one HGI) cast their shadow at noon, through the center E, onto the portion of the meridian line MN of the upper dial that lies between the center and the equinoctial line; while the points of the southern quadrant GI cast their shadow through the center E onto the portion of the meridian line

OP that lies between the center and the equinoctial line of the lower dial. It thus comes about that, in the upper dial elevated on the northern side — whose inclination is less than the pole's altitude, as appears in the first Analemma — the arcs of the northern signs are contained between the center of the dial and the equinoctial line, while the arcs of the southern signs lie beyond the equinoctial line. In the lower dial, the contrary holds.

Again, since in the second Analemma the points of the northern quadrant FH cast their shadow through the center E onto the portion of the meridian line

Diagram. A second dial face with the equinoctial and horizon lines and the parallels of the zodiacal signs, corresponding to a different one of the four cases.

- The upper horizontal line is labelled **AEQVA...TOR** (Aequator), with hour-numbers 8 9 10 11 12 1 2 3 4 along it
- A lower horizontal line is labelled **HORI...ZON** (Horizon), marked 6 ... 6 at its ends
- Down the vertical meridian, from top to bottom, the legible construction points are E, B, A, G, and H
- The parallels of the twelve zodiacal signs curve across the hour-lines; legibly identifiable glyphs include ♉ (Taurus), ♊ (Gemini), ♍ (Virgo), and ♓ (Pisces), the remaining sign-sorts being too worn to read individually [?]

[Several zodiac-sign glyphs are not resolvable at this resolution]

MN of the upper dial, beyond the equinoctial line, MN being produced through N; while the points of the southern quadrant GI cast their shadow through the center E onto the portion of the meridian line OP of the lower dial, beyond the equinoctial line, OP being produced through P. It thus happens that, in the upper dial elevated on the northern side — whose inclination is greater than the pole's altitude, as is seen in the second Analemma — the arcs of the northern signs fall

beyond the equinoctial line, and those of the southern signs between the center and the same equinoctial line. In the lower dial, the matter stands the contrary way.

Moreover, since in the third Analemma the points of the northern quadrant FH cast their shadow onto the portion of the meridian line MN of the upper dial that lies between the center and the equinoctial line, while the points of the southern quadrant GI cast their shadow onto the portion of the meridian line OP that lies between the center and the equinoctial line of the lower dial, it happens that, in the upper dial elevated on the southern side — whose inclination is less than the complement of the pole's altitude, as in the third Analemma — the arcs of the northern signs lie between the center and the equinoctial line, and those of the southern signs beyond the equinoctial line. In the lower dial, the contrary.

Finally, since in the fourth Analemma the points of the northern quadrant FI cast their shadow onto the portion of the meridian line MN of the upper dial that lies between the center and the equinoctial line, while the points of the southern quadrant GH cast their shadow onto the portion of the meridian line OP of the lower dial that lies between the center and the equinoctial line, it comes about that, in the upper dial elevated on the southern side — whose inclination exceeds the complement of the pole's altitude, as appears in the fourth Analemma, and which is just the kind of dial proposed to us — the arcs of the northern signs are comprehended between the center and the equinoctial line, and those of the southern signs beyond the same equinoctial line. In the lower dial, the contrary.

All of this is evident, if the said Analemmata are attentively considered. And the fact that certain points of the northern semicircle HFI, in each of the two later Analemmata, cast their shadow beyond the center M as well, is proof that the arcs of the signs are in that case ellipses — so that each of them cuts the meridian line in two places, one of which necessarily lies between the center M and the equinoctial line. Hence it is always true that the arcs contained between the center and the equinoctial line of the upper dial, in the two later Analemmata, belong to the northern signs, although some poin-

Diagram. An analemma / shadow-projection construction in the lower-left corner, showing the gnomon's shadows projected from the center onto the meridian line, with the circle (ellipse) of the sign-arcs.

- H, D, A along the horizontal line at the top (D is the center)
- G (apex/vertex just below D, where the projection lines converge)
- I (on the meridian, below the apex)

- P (left) and B (right) — points where an inner arc crosses
- V (left of center) and Φ [?] (right of center) on a horizontal diameter
- A large circle enclosing the lower portion
- Two rows of hour-numbers run along the base (day-hours and night-hours, 1–12); the individual digits are too small and worn to commit cell-by-cell here [?]

the northern-quadrant points FI, in the third Analemma, and the northern-quadrant points FH, in the fourth, cast their shadow beyond the center M onto the meridian line.

In our example the arc of Cancer [♋] in the upper dial and the arc of Capricorn [♐] in the lower, as well as the arcs of Gemini [♊] and Leo [♌] in the upper and the arcs of Sagittarius [♐] and Aquarius [♒] in the lower, form an ellipse, as is gathered from the corollary of Proposition 7 of the first book — because the declination of these signs exceeds the complement of the pole's altitude above the proposed plane. The latter arc, however, is very nearly a parabola, since the declination of those signs is almost equal to the complement of the pole's altitude above the inclined plane: the difference amounts to only 12 minutes, as is evident. By contrast, the arcs of Taurus [♉] and Virgo [♍] in the upper dial, and the arcs of Scorpio [♏] and Pisces [♓] in the lower, form a hyperbola, as we set out in the corollary of Proposition 6 of the same first book — because the declination of these signs is less than the complement of the pole's altitude above the proposed inclined plane. The same can also readily be concluded from what we wrote in the scholium to Proposition 2 of the preceding book.

[Margin: The horizontal line, and the method by which it is drawn.] The horizontal line is drawn as follows. Through G, the place of the style, draw GA perpendicular to the meridian line, and from it cut off GA equal to the length of the style. Then at A construct the angle GAB equal to the complement of the plane's inclination to the horizon — turned upward in the upper dial, but downward in the lower. (This is easily done if, from A, an arc of a circle is described toward the meridian line, on which the complement of the inclination is measured off from the straight line AG, and so forth.) Let the straight line AB cut the meridian line at B. I say that the line drawn through B parallel to the equinoctial line — that is, perpendicular to the meridian line — is the horizontal line, namely the common section of the horizon and the plane of the dial. For if the triangle ABG is turned about BG until it stands at right angles to the plane of the dial, and so lies in the plane of the meridian, and the style's vertex A is joined to the center of the world: then, since the angle GAB is equal to the complement

of the inclination, ABG will be the angle of inclination. Accordingly, since the horizon passes through A, the style's vertex, the straight line AB will be the common section of the horizon and the meridian, making in the plane of the meridian, with the meridian line of the dial, the angle of inclination, as the matter requires. Therefore, since the horizon meets the plane of the dial at B, the horizontal line must be drawn through the point B; and this line is necessarily parallel to the equinoctial line, by Proposition 18 of the first book, since the equator, the horizon, and the great circle to which the dial lies parallel all have one and the same common section, and so forth.

[Margin: Another way of drawing the horizontal line.] We shall find the same point B by this method. From the figure of the rays we take the portion of the 12-o'clock line pertaining to midnight, lying between H and the diurnal ray of the 24 hours — which in our example is the straight line HI. This we transfer from H, the center of the dial, onto the portion of the meridian line that marks the 12th hour of midnight (or, what is the same, from noon), carrying it as far as B. For through the point B the horizontal line, that is, the line of the 24th hour from sunrise or sunset, must be drawn as the diurnal arc of 24 hours, as is established from Table 7 of Proposition 33 of the first book.

This horizontal line divides the whole dial in two, upper and lower, and likewise day and night, as we said of the vertical dial and the others. We have therefore placed the parallels — that is, the arcs of the signs of the Zodiac — in the dial inclined to the horizon. Which was to be done.

PROBLEMA 27. PROPOS. 27.

To place the parallels of the diurnal arcs in the same dial inclined to the horizon.

[Margin: The drawing of the diurnal arcs in a dial inclined to the horizon.] If, in place of the parallels described through the signs of the Zodiac, the parallels of the diurnal arcs are taken, the diurnal arcs will be traced out just like the arcs of the signs, as was done in the preceding cases. And so we have placed the parallels of the diurnal arcs in the same dial inclined to the horizon. Which was to be done.

PROBLEMA 28. PROPOS. 28.

To delineate the vertical circles in the same dial inclined to the horizon.

[Margin: The drawing of the vertical circles in the same dial inclined to the horizon.]

Diagram. A vertical-circles construction for the inclined dial. A semicircular fan of straight rays radiating from the central region downward, crossed by three horizontal lines labelled (left-to-right, the label split across the figure) AEQVA...TOR (the equator), HORI...ZON (the horizon), and VERTI...CALIS (the vertical). The rays are graduated in azimuth/altitude. This same figure is repeated at the top of the facing page (p. 302).

- AEQVA — TOR (upper horizontal line): the equator
- HORI — ZON (middle horizontal line): the horizon
- VERTI — CALIS (lower horizontal line): the vertical
- Central points (clustered, small type): A, B, G, H near the center; C on the vertical axis below; D at the top of the inner divided circle
- Inner-arc degree divisions about the center D: 30, 45, 60, 75 ... 75, 60, 45, 30 [several worn — ?]
- Peripheral graduation numerals along the rays: XX and XXX (upper); XV, XXX, XLV, LX (lower left and lower right, symmetrically)
- Zodiac-sign glyphs at the lower ray-ends: Capricorn [♐] on each side [worn — ?]

Draw GA from G, the place of the style, perpendicular to the meridian line and equal to the style; and at A, upon GA, construct the angle GAC equal to the inclination of the plane — downward in the upper dial, but upward in the lower

— that is, in the lower dial toward the part opposite to that in which, in Proposition 26 of this book, the straight line AB was drawn to find the point B for drawing the horizontal line. Let the straight line AC cut the meridian line at C. Then, having drawn the straight line AB, cut off BD equal to it along the meridian line, upward or downward. With D as center, describe a circle and divide it into 360 parts, or fewer; and through the center D and the points of division send out straight lines cutting the horizontal line at points. If straight lines are then drawn from C through these points, the vertical circles will be described — that is, the common sections of those circles and the plane of the dial, whose origin is fixed on the vertical line, which is drawn through the found point C parallel to the equinoctial line. All of which we shall demonstrate as follows.

Diagram. The same vertical-circles construction as on the facing page (fig-p301-1), repeated at the top of p. 302. A semicircular fan of straight rays crossed by the three horizontal lines AEQVA...TOR, HORI...ZON, VERTI...CALIS, with the graduation numerals and central point-cluster as before.

- AEQVA — TOR: the equator line
- HORI — ZON: the horizon line
- VERTI — CALIS: the vertical line
- Central points: A, B, G, H near center; C on the vertical axis below; D at the top of the inner divided circle
- Inner-arc degree divisions about D: 30, 45, 60, 75 ... 75, 60, 45, 30 [several worn — ?]
- Peripheral graduation numerals: XX, XXX (upper); XV, XXX, XLV, LX (lower left and right)
- Zodiac-sign glyphs at the lower ray-ends: Capricorn [

[Margin: Demonstration of the drawing of the vertical circles. — (a) whence, from Proposition 19.] Let the triangle ABC be conceived at right angles to the plane of the dial, so that it lies in the plane of the meridian, and let the style's vertex A be the same as the center of the world. And since, as we demonstrated in Proposition 26 of this book, the straight line AB is the common section of the horizon and the meridian, and the angle BAC is a right angle — being composed of the angle of inclination GAC and the angle of the complement of the inclination GAB — the straight line AC will be the common section of the vertical (properly so called) and the meridian, so that C is the vertical point, upon which of course the axis of the horizon falls. For since both the meridian and the vertical are perpendicular to the horizon, [a] their common section (namely the axis of the horizon) will be perpendicular to that same horizon; and thus, by Definition 3 of Book 11 of Euclid, perpendicular, at the center of the world A, to the straight line AB lying in the horizon. The straight line AC, then, standing perpendicular to AB in the plane of the meridian, is the common section of the meridian and the vertical properly so called, and hence of all the verticals as well. This can also be made manifest from the fact that the angle ACG is equal to the complement of the inclination — the very angle that the inclined plane makes with the vertical. Now if the circle described from D is imagined to be moved about the horizontal line until its center D is joined to the center of the world A, and the straight line BD to the straight line BA, then, because the straight lines BD and BA are equal, the said circle will lie in the plane of the horizon, described about its center. Therefore, since the vertical circles cut the horizon — and so also cut the circle described from D concentric with it — into equal parts, beginning from the vertical or the meridian (which is itself one of the vertical circles), the lines drawn through D and through the points of division will be the common sections of the vertical circles and the horizon. Hence the vertical circles will meet the plane of the dial

at the points of the horizontal line onto which the said lines fall; and accordingly, through those points the common sections of the vertical circles and the plane of the dial must be drawn. Since, then, all these same sections also meet at the point C — by Proposition 18 of the first book, the point upon which the axis of the horizon, or their common section, falls — the lines drawn through C and through the points found on the horizontal line will be the common sections of the vertical circles and the plane of the dial. Moreover, the common section of the vertical (properly so called) and the plane of the dial, drawn through C, is parallel — by the same Proposition 18 of the first book — to the equinoctial line, and also to the horizontal line; because the equator, the horizon, the vertical properly so called, and the great circle to which the dial lies parallel all have one and the same common section. Therefore we have delineated the vertical circles in the same dial inclined to the horizon. Which was to be done.

PROBLEMA 29. PROPOS. 29.

To depict the parallels of the horizon in the same dial inclined to the horizon.

In this dial we shall describe the parallels of the horizon just as in the polar dial of Proposition 41 of the preceding book, with a few changes. For in place of the axis EF (so far as the former method is concerned), we must draw EF, the common section of the meridian and the inclined plane, in such a way that the arc CE measures the inclination of the plane above the horizon; and parallel to this common section EF we must draw QR, as there, for the given magnitude of the style. Then the points K, L, M, N, O, taken from the point T where the horizon BC cuts the straight line QR, must be transferred onto the meridian line of the dial from B, the point of the horizon, toward the vertical point C, in the upper dial; but in the lower dial the intervals TS, and others, if there be any, must be transferred from B onto the other part of the meridian line, and so forth. The demonstration is entirely the same as in Proposition 41 of the preceding book, provided the meridian ABC of the Analemma is understood to be set in its proper position, so that the point C looks toward the north if the plane is elevated on the northern side, but toward the south if it is raised on the southern side, as in our example, and so forth.

As regards the latter method: AD must be taken equal to the axis of the horizon AC in the figure of the preceding proposition — that is, to the straight line which falls from A, the style's vertex, to C, the Zenith; and onto the straight line AB must be transferred all the intervals between D and the vertical lines on the horizontal line.

Diagram. A full circle densely crossed by chords and diameters (the Analemma-type construction for the horizon-parallels), placed at the upper right of the page. The circumference is graduated in degrees by quadrant (...15, 30, 45, 60, 75...), and a cluster of small point-letters lies about the center.

- Top of circle: A, R, and E (E just inside the rim); a second R at the upper right rim
- Center: D
- Left rim (top to bottom): 75, 60, 45, 30, 15, then G and B, then 15, 30 lower
- Right rim (top to bottom): 45, 30, 15, then C, 15, H, 30, 45
- Bottom rim: 60, 75, then Q, F, and a second Q; 30
- Near-center small letters: N, O (upper), S, T (mid), M (lower) [several worn — ?]

[Note: this dense figure carries many worn peripheral numerals and central letters; more than two labels are uncertain]

The rest is to be completed as was stated in Proposition 41 of the preceding book. For the same demonstration can be adapted here. And so we have depicted the parallels of the horizon in the same dial inclined to the horizon. Which was to be done.

Diagram. A fan-shaped dial (the finished horizon-parallels dial) below the circular figure. Along the top runs a horizontal line carrying the points A, D, C; from the central region straight rays fan downward, and a dashed semicircular arc spans the middle. The margins are graduated 90, 75, 60, 45, 30, 15.

- Top horizontal line (left to right): A, D, C
- E: just below A on the axis; B: on the vertical axis below the center
- Left-margin numerals (top to bottom): 90, 75, 60, then 90, 75, 60, 45, 4.5 [45 — ?], 30
- Right-margin numerals (top to bottom): 90, 75, 60, 45, 30, and 60 lower
- Foot numerals (left to right): 30, 15, [axis], 15, 30, 45, 15 [rightmost — ?]
- Two small cross/dagger hour-markers (†) at the foot of the vertical axis

—as was stated in the preceding book. For the same demonstration can be adapted here. And so we have depicted the parallels of the horizon in the same dial inclined to the horizon. Which was to be done.

PROBLEMA 30. PROPOS. 30.

To arrange the meridians, that is, the longitude-circles of cities, in the same dial inclined to the horizon.

[Margin: The drawing of the meridians in the same dial inclined to the horizon.] Here we shall describe the meridians in no other way than in the preceding dials: namely, in the circle described from E in Proposition 25 of this book, the longitude of the place is counted, from the common section of the meridian and the equator EI, toward the western parts, up to the point O — beginning from the point of that section which looks toward noon, which in our example is the point M in the upper dial (as is evident if the said circle is conceived to be set in its proper position). For the hidden straight line drawn through the center E, from the point N which is opposite to the point O of the Fortunate Isles, will give on the equinoctial line the meridian of 180 degrees — namely the semicircle opposite to the semicircle drawn through the Fortunate Isles; but this meridian, produced beyond H, the center of the dial, will give the opposite semicircle, which of course passes through the Fortunate Isles, according to what we wrote in the scholium to Proposition 1 of the preceding book. The rest is clear from the figure. There too you see that in the lower dial numbers are set against the meridians, which arise by adding 180 degrees to the numbers of the meridians of the upper dial, and so forth, as we explained in Proposition 18 of the preceding book. We have therefore arranged the meridians, that is, the longitude-circles, and so forth. Which was to be done.

THE FIGURE FOLLOWS.

Diagram. The figure promised at the close of Proposition 30 ("THE FIGURE FOLLOWS") — the dial of the meridians (longitude-circles of cities) drawn in the dial inclined to the horizon. It has two parts sharing one vertical axis. Above is the equatorial dial: a large circle with center **E**, crossed horizontally by the equator line (labelled **Æquator**), from whose region straight meridian-rays fan outward, each carrying a longitude value in degrees (many printed mirror-reversed along their rays). Below the horizon line (labelled **Horizon**) is a lower fan-shaped dial whose radial meridians carry the opposite (+180°) longitudes. The prime meridian of the Fortunate Isles (**Insulæ Fortunatæ**) is marked with a cross ☩, appearing once at the upper right and once at the lower left.

- Vertical axis, top to bottom: **N** (top of the upper circle) — **E** (center of the upper circle) — **I** (on the equator line) — **O** (small, just right of I) — **M** (below I) — **B** (center of the horizon line) — **G, H** (just below the horizon)

- Horizontal lines: **Æquator** (through E and I); **Horizon** (through B)
- Slanted labels: **Insula Fortunatæ** (upper right, with ☐) and **Insula Fortunatæ** (lower left, with ☐)
- Upper-dial meridian degree-labels (as read; several worn): top rays 60, 45, 30, 15; left side 75, 150, 90, 105; equator ends 105 [?] (left) and 105 [?] (right, printed "for"); right side 15, 345, 330
- Horizon-line ends: 120 (left, printed "021") and 315 (right, printed "SIE")
- Lower-dial meridian degree-labels — left rays (top to bottom): 285, 300, 315, 330, 345; right rays (top to bottom): 135, 120, 105, 90, 75

[This construction dial carries more than two worn/uncertain labels]

PROBLEMA 31. PROPOS. 31.

To lay out the parallels of cities, or the circles of latitude, in the same dial inclined to the horizon.

[Margin: The drawing of the circles of latitude in the same dial inclined to the horizon.]

Since the parallels drawn through the zeniths of places are equidistant from the equator — exactly as the parallels of the [zodiac] signs are — it is plainly established that their construction is the same as that of the latter, as we noted in the preceding propositions. We have therefore laid out the parallels of cities, or the circles of latitude, and so on. Which was to be done.

PROBLEMA 32. PROPOS. 32.

To construct the celestial houses in the same dial inclined to the horizon.

[Margin: The drawing of the celestial houses according to Johann Regiomontanus [Regiomontanus] in the same dial inclined to the horizon.]

Let the circle drawn from E — the one by whose aid we constructed the astronomical dial in Proposition 25 of this book — be divided into 12 equal parts, beginning from the meridian line. For the straight lines emitted from the center E through the points of division will mark points on the equinoctial line; and if from these, through the point B where the meridian line and the horizontal line intersect one another, straight lines are drawn, we shall obtain the common sections of the plane of the dial and of the great circles drawn through the beginnings of the houses — following the view of Johann Regiomontanus, who draws such circles through the divisions of the equator. For if the circle drawn

from E is understood to be set in the plane of the equator, so that its center E does not differ from the center of the world, and EI is the common section of the equator and the meridian, then the straight lines emitted from E through the division-points of that same circle will be the common sections of the equator and of the circles of the celestial houses, according to Johann Regiomontanus — since indeed they divide the equator, and hence also that circle concentric with it, into 12 equal parts. The circles of the celestial houses therefore meet the plane of the dial in the points of the equi-

LIBER TERTIVS.

noctial line onto which those straight lines drawn from E fall; and so the lines of the celestial houses must be drawn through those points — namely, the common sections of the plane of the dial and of the circles of the celestial houses. Since, then, these same sections all pass — by Proposition 18 of the first book — through the point B onto which the vertical axis AB falls (the point where all the circles of the celestial houses cut one another), it is clear that the straight lines drawn from B through the points found on the equinoctial line are the lines of the celestial houses.

[Margin: The drawing of the celestial houses according to Campanus [Campanus of Novara] in the same dial inclined to the horizon.]

The celestial houses, however, as they are understood by Campanus, we shall construct as follows. From the position of the style G, draw GA perpendicular to the meridian line, equal to the gnomon; and at A, upon AG, let the angle of inclination GAC be set up, so that — by what we demonstrated in Proposition 28 of this book — AC is the axis of the horizon and C the ver-

Diagram. The dial of the celestial houses (Problema 32), drawn in the dial inclined to the horizon. It has an upper circle with center **E** (the equatorial construction) and a lower circle with center **D** (the vertical construction), sharing one vertical axis. The equator line is labelled **Æquator** (left **AEQVA-**, right **-TOR**); the horizon line **Horizon** (left **HORI-**, right **-ZON**); the vertical line **Verticalis** (**VERTI- -CALIS**). Two families of house-lines radiate outward: the full lines (Regiomontanus) and the fine dashed lines (Campanus, "marked off by those fine lines"). The houses are numbered around the rim in Roman numerals, with a second set of Arabic numerals; a cross ☒ marks the top (near "10") and the foot (near "10") of the axis.

- Vertical axis, top to bottom: $\square$ / 10 (top) — E (center of upper circle) — I (on the equator) — B (center of the horizon) — A, Q, H (small, clustered just below B) — C (on the vertical line) — D (center of lower circle) — 10 / $\square$ (foot)
- Upper region rim labels (as read, worn): left II, IX, XII [?], XII; right 6, XI, 8, III
- Horizon-line ends: VII / I (left), IIII [?] / I (right)
- Lower region rim labels (as read, worn): left VIII, 8, IX, 9; right XII, XI, II; foot 10
- Small paired numerals near D: 10 / 10 (left and right of the lower circle) [?]

[This house-dial carries more than two worn/uncertain rim labels]

tical point. And the straight line drawn through C perpendicular to the meridian line is the common section of the plane of the dial and of the vertical [circle]. Then, taking the straight line CD equal to CA itself, let a circle be described from D; and this being divided into 12 equal parts, beginning from the meridian line, let straight lines be drawn from D through the division-points, cutting the vertical line in points which, joined with the point B as before, will give the lines of the celestial houses as Campanus takes them — of which sort are the lines distinguished by those fine lines in our example. For if the triangle GAC is understood to stand erect [at right angles] to the plane of the dial, and the circle described from D is understood to be moved about the vertical line until its center D is joined with A, the center of the world, then — because of the equality of the straight lines CA and CD — the circle described from D will, in the plane of the vertical circle, have the same center as that circle itself. Therefore the straight lines emitted from D through the division-points will be the common sections of the vertical [circle] and of the circles of the celestial houses; and hence the plane of the dial will be cut by the circles of the celestial houses in those points of the vertical line onto which the said straight lines fall, and so on. And so we have constructed the celestial houses in the same dial inclined to the horizon. Which was to be done.

PROBLEMA 33. PROPOS. 33.

To mark out the ascending signs of the Zodiac in the same dial inclined to the horizon.

We shall mark out the ascending signs of the Zodiac by exactly the same methods we used in the preceding propositions, as

GNOMONICES

[Margin: The drawing of the ascending signs in the same dial inclined to the horizon.]

appears in the figure below. For example, suppose that in the upper dial the ascending sign Taurus (♉) is to be drawn. I see, in the 1st table of Proposition 9 of the preceding book, that — with the Sun at the beginning of Aries (♈) — it rises at 4 hours 51 minutes before noon. But because such an hour does not cut the equinoctial line, I look for the same sign in the 2nd table, and I find that — with the Sun at the beginning of Libra (♎) — it rises at 7 hours 8 minutes after noon, which hour does indeed cut the equinoctial line. Through this hour, therefore, I find a point on the equinoctial line through which [the sign] is to be drawn.

Diagram. The dial of the ascending signs (Problema 33), drawn in the dial inclined to the horizon. A circle with center **E** sits above; the equator line runs across it, labelled **Æquator** (left end at point **F**, right end at point **K**, with **AEQVA-TOR** on the line); the horizon line **Horizon (HORI- -ZON)** runs below; a further line labelled **Linea** crosses the lower-left. The vertical axis descends through **I** (below **E**) and **B** to **H**. Many straight sign-rays radiate outward, each terminating in a zodiac glyph (the ascending sign it represents); the glyphs are badly worn and mostly illegible at this resolution.

- Vertical axis, top to bottom: **E** (center of circle) — **I** — **B** — **H**
- Equator line: point **F** (left end) — **AEQVA- -TOR** — point **K** (right end)
- Horizon line: **HORI- -ZON**
- Lower-left line: **Linea**
- Ray-end zodiac glyphs: worn throughout; individual signs not securely legible — read only in part [?]

[The zodiac ray-labels are worn and more than two are illegible]

is the sign Taurus (♉) ascending. Next, from the 3rd table, with the Sun at the beginning of Cancer (♋), I find that the same sign Taurus rises at 10 hours 50 minutes before noon — that is, at 1 hour 10 minutes after midnight — and so through this hour I strike a point on the arc of Cancer, through which the same sign is to be drawn. A straight line, therefore, connecting this point with the former one found on the equinoctial line will give the ascending sign Taurus; and so with the rest. By the same tables the same ascending signs will most conveniently be delineated in the lower dial, in which the arc of Cancer is changed into the arc of Capricorn (♐). Thus the same sign Taurus in the lower

dial will have to be drawn on the equinoctial line at 4 hours 51 minutes before noon — as is gathered from the 1st table — and in the tropic of Capricorn at 1 hour 10 minutes after noon, as the fourth table has it, and so forth.

[Margin: The finding of the points on the horizontal line, through which the arcs of the signs are to be drawn.]

The points on the horizontal line through which the arcs of the signs pass, and likewise the lines of the ascending signs, we shall find — as was said above — as follows. In the figure of the rays of the rising amplitudes [radiorum latitudinum ortiuarum] of Proposition 9 of this book: from the straight line EB (if the dial faces north) or from ED (if it faces south), let there be cut off the straight line EL equal to the straight line AB — the line by which, in the figure of Proposition 26 of this book, we found the point B through which the horizontal line is drawn. Through L let a perpendicular to the straight line BD be raised on both sides; this will cut the rays of the rising and setting amplitudes in points which — taken with the compass from L, and transferred onto the horizontal line from the point B — will give the points through which the parallels of the signs must pass. For since, if the triangle ABG in the figure of Proposition 26 of this book is understood to stand erect [at right angles] to the plane of the dial, the straight line AB is the common section of the horizon and the meridian, it comes about that — if the horizon ABCD in the figure of Proposition 9 of this book, in which the rays of the rising amplitudes are contained, is understood to be set in the dial so that its center E coincides with A, the center of the world, and the straight line EL with the straight line AB — the point L falls on the point B, because of the equality of the straight lines EL and AB; and hence also the perpendicular drawn through L coincides with the horizontal line, and so on. The same points can also be found on the horizontal line from Table 5 of Proposition 9 of Book 2, as was likewise done above.

[Margin: In what manner the lines of Aries and Libra are to be drawn.]

Since, however — the Sun being at the beginning of Cancer, whose arc in our example is an Ellipse, as we showed above — the sign Aries rises when the beginning of Cancer stands on the meridian circle below the horizon, that is, at the 12th hour of midnight, the line of Aries must be drawn through that point of the meridian line above the horizontal line through which the arc of Cancer passes: for this point belongs to midnight. Again, since — the Sun being at the beginning of Cancer — the sign Libra rises when the beginning of Cancer is set at noon [on the meridian], the line of Libra must be drawn through another point of

the meridian line below the horizontal line, through which the arc of Cancer passes, since this point belongs to noon, as we said above.

Book Three (Liber Tertius)

(This page opens by completing a word broken across the page-turn — the catchword "mus." of the previous page — and continues the conclusion of Problema 33.)

Both lines — that of Aries [♈] and that of Libra [♎] — run parallel to the horizontal line, or to the equinoctial line, by Proposition 18 of Book One. The reason is that in that case the horizon, the equator, the ecliptic, and the great circle to which the plane of the dial [horologij planum] is parallel all share one and the same common section — namely the axis of the meridian circle — since all those circles stand at right angles to the meridian, as is clear from a material sphere, or certainly can be readily gathered from the *Elements of Spherics* of Theodosius [Elementis sphæricis Theod., Theodosius]. In the worked example, however, the Libra line [♎] has not been drawn, because the ellipse of Cancer [ellipsis ♋] cuts the meridian line below the horizontal line at a point too far removed. We have therefore laid out the ascending signs of the zodiac on this same dial inclined to the horizon. Which was to be done.

SCHOLIUM.

[Margin: The description of the same ascending signs, from the practice of Andreas Schöner (Andreæ Schoneri).]

We shall depict the ascending signs after the method of Andreas Schöner [Andream Schonerum], as follows. In his first figure, from the diameter BD cut off the straight line EP, equal to the straight line EI — the portion of the dial lying between the center E and the equinoctial line (which in our example is exactly equal to the semidiameter EB) — and through P, at right angles to BD, raise a perpendicular on both sides. This perpendicular will cut the lines of the signs at points which, taken with the compass from P and transferred onto the equinoctial line of the dial from I, will give points from which — through B, the point where the meridian line and the horizontal line meet — hidden lines drawn out will cut the tropic of Cancer [♋], or indeed both tropics when both are drawn on the dial, at the points through which the ascending signs are to be traced. Their order you will readily understand from Tables 3 and 4 of Proposition 9 of Book Two. For since, for example, through the point of the meridian line above

the horizontal line there is drawn in our example the sign Aries [♈], and since, when the Sun is at the tropic of Cancer [♋], the sign Taurus [♉] rises after midnight — that is, before noon, as Table 3 shows — it is clear that the first point in the fore-meridian part of the dial, that is, the western part, immediately after that Aries point, belongs to the sign Taurus [♉], and the next to the sign Gemini [♊], and so on.

Again, in the later figure, from the diameter BD cut off the straight line EP equal to the straight line EI, as before (which is again equal to the semidiameter ED), and through P, at right angles to BD, raise a perpendicular. This will cut the lines of the signs at points which, taken with the compass from the point P and transferred onto the equinoctial line from I, will give the points through which the ascending signs are to be traced. Their order we shall readily gather from Tables 1 and 2 of Proposition 9 of Book Two. For since, for example, when the Sun is at the beginning of Aries [♈] the sign Taurus [♉] rises at 4 hours 51 minutes before noon — which in our dial does not cut the equinoctial line — we shall turn to Table 2, in which we shall find that, the Sun being at the beginning of Libra [♎], the sign Taurus [♉] rises at 7 hours 8 minutes after noon, and the sign Gemini [♊] at 8 hours 34 minutes after noon. I conclude that the sign Taurus [♉] must be drawn in the eastern, or afternoon, part of the dial, through a point on the equinoctial line more remote than that of the sign Gemini [♊], and so on.

The same order can also be easily gathered from the said later figure. For once the point through which the sign Taurus [♉] is to be drawn is known — the one that is always more remote than all the rest — the other signs will then follow, just as they are contained in that figure. Thus, since the sign Taurus [♉] must be drawn through the most remote point of the equinoctial line in the afternoon part of the dial, the signs Gemini [♊] and Cancer [♋][?] must be drawn through the next point, and through the following point the sign [?] [the trailing sign-glyph is not clearly resolvable on the scan], and so on.

PROBLEMA 34. PROPOS. 34.

To construct an Italian dial inclined to the horizon.

[Margin: The construction of an Italian dial inclined to the horizon.]

Let the circle described from E be divided, as we taught in the scholium to Proposition 1 of Book One, into the diurnal arc of the tropic of Cancer [♋], aNb, and the nocturnal arc, aMb. Then let the same circle, beginning from the point b, the western point, be cut into 24 equal parts, and let the rest be done as in the

preceding, and the Italian dial will have been laid out. For example, let the line of the 9th hour from sunset [horæ 9.ab occasu] be drawn. From F, the point of the 9th hour, a straight line drawn through the center E cuts the equinoctial line at the point L; and the straight line drawn from L to H, the center of the dial, and extended, cuts the tropic of Cancer [☿] at M, the point of the 9th hour from sunset. And since, as is established from Table 6 of Proposition 33 of Book One, the 9th hour from sunset also passes through the 3rd hour from midnight in the nocturnal arc of 12 hours — which in our dial is represented by the equinoctial line, since the whole of it lies above the horizontal line, or is at any rate drawn through the 3rd hour from noon or from midnight on the equinoctial line simply, whether it refers to a diurnal or a nocturnal arc, as is established from the table of Proposition 19 of Book One — the straight line from M, drawn through the 3rd hour from noon or from midnight on the equinoctial line (which in the worked example is the 3rd hour from midnight in the nocturnal arc of 12 hours), will give the 9th hour from sunset.

But if we wish to draw the line of the 21st hour from sunset [horæ 21.ab occasu], since the straight line from K, the point of the 21st hour from sunset, does not pass through the center E before it passes through the equinoctial line, we shall take the opposite point F — which is always a whole semicircle, that is, 12 hours, distant from it — so that F is the point of the 9th hour from sunset (this is obtained if to 21 we add 12, and from the sum, since it exceeds 24, we subtract 24). From F we shall draw through E and K a straight line that cuts the equinoctial line at L. For the straight line LH will cut the tropic of Cancer [☿] at M, the point of the 9th hour from sunset, as was just said; and produced beyond the center H, it will cut the same tropic at O, the point of the 21st hour from sunset, as we demonstrated in Proposition 10 of the preceding book. Since, then, the 21st hour is also drawn — as is found in the table of Proposition 19 of Book One — through the 3rd hour from noon or from midnight on the equinoctial line, the straight line through O will mark that point, and drawn through the 3rd hour from noon or from midnight on the equinoctial line it will give the 21st hour from sunset. In the same way, a straight line drawn from P, the point of the 1st hour from sunset, through the center E, and through R, the point of the 13th hour from sunset, cuts the equinoctial line at A; and the straight line AH cuts the tropic of Cancer [☿] at B, the point of the 1st hour from sunset, and produced, it cuts the same tropic at C, the point of the 13th hour from sunset, and so on.

[Margin: The description of the same Italian dial by means of the diurnal and nocturnal arcs.]

In the other cases there is no difficulty. For the hours from sunset will be most conveniently laid out by means of the diurnal arc of 14 hours alone in the upper dial — which in the nocturnal portion is the nocturnal arc of 10 hours — according to the tables of Proposition 33 of Book One. But since for the individual hours from sunset we have only single points in the diurnal arc of 14 hours, we shall take, for the same number of hours from sunrise, other points, whether in the same diurnal arc of 14 hours or in the nocturnal arc of 10 hours, as the tables of Proposition 33 of Book One indicate. Thus the 23rd hour from sunset passes through the 6th hour from noon in the diurnal arc of 14 hours, while the 23rd hour from sunrise passes through the 4th hour from midnight in the nocturnal arc of 10 hours. If, then, these two points are joined by a straight line, we shall have in the upper dial the 23rd hour from sunset in the diurnal arc, and the 23rd hour from sunrise in the nocturnal arc, as is clear from what has been demonstrated. For this line touches the greatest of the parallels that are always visible. Hence one part of it will indicate the hour from sunset,

and the other the hour from sunrise. By this same reasoning, for the 20th hour from sunset we have drawn the 20th hour from sunrise through the 12th hour from midnight in the nocturnal arc of 10 hours, and through the 2nd hour from midnight in the nocturnal arc of 12 hours. For this line, produced, likewise gives the 20th hour from sunset, and so on. Because of the narrowness of the space, however, the whole ellipse of Cancer [♋] has not been drawn — the ellipse that the following hours from sunset, 14, 15, 16, 17, 18, 19, and the corresponding hours from sunrise (which we shall treat in the following proposition), 5, 6, 7, 8, 9, 10, would have to cut.

Diagram. A large sundial-construction figure for the Italian dial inclined to the horizon (Problema 34), which also serves the Babylonian dial of Problema 35. At the upper center is a circle (the divided hour-circle described from E) with its center E, containing an inset analemma-like construction of dotted and dashed lines. From a common focus low on the figure, a dense sheaf of hour-lines radiates outward across the whole page; the hour-lines are labeled at their outer ends with Roman numerals I–XII (down both sides) and with Arabic numerals 1–24, and the sign-lines at the top carry zodiac-sign glyphs. A horizontal line spanning the figure is lettered **HORI**(left)...**ZON**(right) [= HORIZON, the horizontal line], and a vertical meridian line runs down through the lower center.

Labeled points that can be resolved on the scan (positions approximate):

- E: center of the upper circle.
- T: on the circle, upper left.

- P: on the circle, upper right.
- a: small label, upper left of the circle (western division point).
- b: small label, upper right of the circle (eastern division point).
- F: left of the circle, below T.
- K: right of center, below E.
- S: below K.
- A: on the horizontal (horizon) line, left of center.
- B: near the center, on/just below the horizontal line.
- X: near the center, right of B.
- G: below center.
- M: right of center, on the tropic.
- L: right end of the horizontal line.
- H: below center (center of the dial).
- D: below H, on the meridian line.
- O: below the horizontal line, left of center.
- C: lower right.
- Y: lower left.

Additional interior points named in the text of Problemata 34–35 (R, V, I, N) are present in the construction but are not individually resolvable against the surrounding line-sheaf on this scan. Because more than two peripheral labels (the radiating hour-numbers and zodiac glyphs, plus R/V/I/N) cannot be transcribed cell-by-cell without guessing, this figure is a for full label recovery.

We shall also aptly lay out the same hours from Table 7 of Proposition 33 of Book One, provided we first draw the diurnal arc of 24 hours, which will touch the lines of the 24th and 12th hours, and so on.

[Margin: How the line of the 12th hour from sunrise or sunset is to be drawn.]

But if someone should prefer to lay out the dial by the mutual intersections of the hours reckoned from noon or midnight with those reckoned from sunrise or sunset — the intersections contained in the tables of Propositions 19 and 20 of Book One — then the line of the 12th hour from sunrise or sunset must be drawn in this way. In the portion of the analemma of Proposition 25 of this book, from the pole E let the altitude of the pole above the horizon of the region for which the dial is being laid out be measured off on both sides, as far as M and N, and let the straight line M, N be drawn. This will be the common section of the meridian and of the greatest of the parallels always visible, if the pole E is the northern

one; or of the greatest of those always hidden, if E is the southern pole. Then, from the points M, N, drawing the straight lines MD, ND through the center D, one of them will be the common section of the meridian and the horizon, and the other the common section of the meridian and the circle of the 12th hour from sunrise or sunset — since the horizon and that circle touch that greatest parallel at the points M, N of the meridian circle. Which of the two is the common section of the horizon and which of the circle of the 12th hour and the meridian, and whether E is the arctic or the antarctic pole raised above the plane of the dial, the four analemmas described in Proposition 25 of this book will plainly teach. For one must consider whether the southern semidiameter of the horizon, BE, or the northern one, DE, drawn out through the center, meets the plane MN of the upper dial; and in which part — whether, that is, between the center M and the equator-point N, or beyond the center M, or beyond the point N. For in the first analemma the southern semidiameter of the horizon, BE, produced beyond the center E, meets the plane MN of the dial beyond N, the equator-point. In the second, the same semidiameter meets the same plane between the center of the dial M and N, the equator-point. In the third, the northern semidiameter of the horizon, DE, extended beyond the center E, cuts the plane MN of the dial beyond M, the center of the dial. In the fourth, finally, the same northern semidiameter cuts the same plane between M, the center of the dial, and N, the equator-point. From these it will not be difficult to recognize which line in the said portion of the analemma is the common section of the meridian and the horizon, and hence which is the common section of the circle of the 12th hour from sunrise or sunset; and whether the pole E raised above the plane of the dial is the arctic or the antarctic pole. For in our example, since the inclined plane is raised above the horizon on the southern side, and has an inclination greater than the complement of the altitude of the pole, it will correspond to the fourth analemma of Proposition 25 of this book. Therefore the northern semidiameter of the horizon will cut the plane of the upper dial between the center of the dial and the equinoctial line; and so the straight line MD, in the said portion of the analemma of the same Proposition 25, cutting the straight line drawn through G between H, the center of the dial, and the point I through which the equinoctial line is drawn, will be the common section of the meridian and the horizon; while the other line, ND, will accordingly be the

common section of the meridian and the circle of the 12th hour from sunrise or sunset; and E will be the northern pole, raised above the plane of the dial along the straight line HI — inasmuch as the axis FG, extended from the arctic pole F through the center E, falls in the fourth analemma at M, the center of the dial.

[Margin: Whether the arctic or the antarctic pole is raised above the plane of the proposed dial. The description of another horizontal line.]

By the same reasoning, in the first and third analemma the arctic pole will be raised above the plane of the upper dial, but in the second the antarctic pole — because in those the axis extended from the arctic pole through the center falls at the center of the dial, whereas in this last it falls there from the antarctic pole. The opposite pole, however, will always be raised above the plane of the lower dial, as is clear from the same analemmas. And so, if in our proposed example we transfer the straight line HO, from the portion of the analemma of Proposition 24 of this book, onto the meridian line of the dial from H, the center of the dial, toward the equinoctial line, we shall find the point B through which the horizontal line is drawn perpendicular to the meridian line. But if instead we transfer the straight line HP from H to the other side, we shall arrive at the point D through which the line of the 12th hour from sunrise or sunset must be drawn — a line which, by Proposition 18 of Book One, will necessarily be equidistant from the equinoctial line, or from the horizontal line, or indeed from the line of the 6th hour from noon or midnight, since the great circles of these lines, and likewise the great circle to which the dial is parallel, have one and the same common section. Therefore the straight line drawn through D, parallel to the equinoctial line, will give the 12th hour from sunrise or sunset. We have thus constructed the Italian dial inclined to the horizon. Which was to be done.

PROBLEMA 35. PROPOS. 35.

To make a Babylonian dial inclined to the horizon.

[Margin: The construction of a Babylonian dial inclined to the horizon.]

We shall lay out the Babylonian dial by exactly the same method as we described the Italian one; but in the earlier procedure the division of the circle described from E must be begun from the point a, the eastern point. You have an example in the preceding figure, in which the hours from sunrise are marked with the ancient numeral characters. There you see that, for the 11th hour from sunrise, there is drawn in the circle whose center is E — from T, the point opposite the 11th hour (namely, from the 23rd hour from sunrise), through the center E and through the point S of the 11th hour from sunrise — a straight line that cuts the equinoctial line at V. For the straight line drawn from V through H, the center of the dial, will cut the tropic of Cancer [☿] at the point X, the 23rd hour from sunrise (which is contained in the nocturnal portion of the dial, just as the point T is contained in the nocturnal arc of the tropic of Cancer [☿]); and produced

beyond the center H, it will cut the same tropic of Cancer [♋] at Y, the point of the 11th hour from sunrise, and so on. And so we have completed the Babylonian dial inclined to the horizon. Which was to be done.

SCHOLIUM.

[Margin: How the lower dial, Italian and Babylonian, arises from the upper.]

The hours from sunrise and sunset of the upper dial, produced beyond the horizontal line, give the same hours in the lower dial — the order being preserved, however, that we prescribed for the vertical dial in the scholium to Proposition 22 of the preceding book. That is, those hours which in the nocturnal portion of the dial are numbered from sunrise, such as 23, 22, 21, and so on, are to be reckoned in the lower dial from sunset; while those numbered from sunset, such as 1, 2, 3, 4, and so on, are to be numbered from sunrise.

PROBLEMA 36. PROPOS. 36.

To compose an Antique dial inclined to the horizon.

Diagram. A large sundial-construction figure for the Antique (unequal-hour) dial inclined to the horizon (Problema 36). At the upper center is a circle with its center E, containing a dotted/dashed inscribed construction (an inset analemma with chord-lines). A sheaf of hour-lines radiates outward from a focus low in the figure, their outer ends labeled with Roman numerals (I–XII and the extended forms IIII, VIIA, VIIIA, etc.) down both sides. A near-horizontal set of parallel lines crosses the middle, and lower down a horizontal line lettered **HORI**(left)... **ZON**(right) [= HORIZON]. Below the horizon line is a small dotted semicircle carrying the unequal (planetary) hours, numbered 1–12 (with a "4½" half-hour graduation visible); zodiac-sign glyphs appear at lower left and lower right.

Labeled points that can be resolved on the scan (positions approximate):

- M: top of the circle.
- E: center of the circle.
- A: on the circle, upper left.
- I: inside the circle, near the top (on the vertical).
- G, C, b: cluster at the upper right of the circle.
- D: left, on the near-horizontal parallel line.
- N: center, on that line.
- L: right, on that line.

- B: center, at the small unequal-hour semicircle below the horizon line.
- H: center, just below B.
- G: center-bottom (a second G, at the base of the semicircle).
- M: center-bottom (a second M, at the base of the semicircle).
- F: lower right.

Because the two central letters recur (an upper M/G on the circle and a lower M/G at the hour-semicircle), and because the radiating Roman/Arabic hour-numbers and the unequal-hour semicircle graduations cannot all be transcribed cell-by-cell without guessing, this figure is a for full label recovery.

The figure itself makes clear that the Antique dial inclined to the horizon is described no differently from the way the foregoing ones were constructed. For, by way of example, at the point A of the 3rd unequal hour [horæ 3.inæqualis], in the circle described from E, we took the point

[Margin: The construction of an Antique dial inclined to the horizon.]

the point opposite to C, and drew the straight line CEA, which cuts the equinoctial line at D. Through D the straight line drawn through H, the center of the dial, and extended, cuts the tropic of Cancer [♋] in the nocturnal arc at a certain point — the one that corresponds to the point C of the said circle in the nocturnal arc; but beyond H it cuts the same tropic in the diurnal arc at F, the point of the 3rd unequal hour [horæ 3. inæqualis], and so on. Yet the same dial will be laid out most conveniently with the help of the nocturnal arc of the tropic of Cancer [♋] alone, as in our example. For in this way you see that the straight line drawn from I — the point of the eleventh hour in the nocturnal arc of the tropic of Cancer [♋] — through E cuts the equinoctial line at L; while the straight line LH cuts the nocturnal arc of Cancer [♋] at M, the point of the 11th nocturnal hour.

Diagram. The large construction figure for the Antique (unequal-hour) dial inclined to the horizon (Problema 36, whose text concludes on this page). At the upper center is a circle with center **E** and top point **M**, containing an inset construction of dashed/dotted chord-lines. A sheaf of hour-lines radiates from a focus low in the figure, their outer ends labeled with Roman-numeral hours (I–XII, some in the extended forms with a superscript Λ). A pair of near-horizontal parallel lines crosses the middle of the figure; below them runs the horizon line lettered **HORI**(left)...**ZON**(right) [= HORIZON]. Below the horizon line is a small dotted semicircle carrying the unequal (planetary) hours graduated 1–12 (with half-hour marks such as "4½" and "7½" visible), flanked at lower left and lower right by zodiac-sign sorts.

Labels that can be resolved on the scan (positions approximate):

- M: top of the circle.
- E: center of the circle.
- I: inside the circle, just below M on the vertical.
- A: on the circle, upper left.
- a: on the circle, left (below A).
- C: on the circle, upper right.
- b: on the circle, right (just below C).
- D: left end of the upper of the two parallel cross-lines.
- N: center of that cross-line (below E).
- K: on that line, right of center (near L).
- L: right end of that cross-line.
- HORI...ZON: the horizon line (split label).
- B, G, H: cluster at the top/center of the unequal-hour semicircle below the horizon.
- F: on the right, between the horizon line and the semicircle.
- The radiating outer ends carry the hour numerals; on the left side (top→bottom) IIII, III, XII, XI, X, IX, VIII; on the right side (top→bottom) IIIA, XI, X, IX, I, II, III, IIII; and along the bottom (dashed) VII, VI, V, IIII. Several of these numerals and the semicircle graduations sit at the resolution floor.

Because the radiating hour-numerals and the unequal-hour semicircle graduations cannot all be transcribed position-by-position without guessing (more than two labels uncertain), this figure is a for full label recovery.

If, then, from M we draw a straight line through the fifth hour from midnight in the nocturnal arc of 12 hours — that is, on the equinoctial line, as is established from table 14 of proposition 33 of the first book — we shall obtain the 11th unequal nocturnal hour; and this, produced beyond the horizontal line, will also give the 11th diurnal hour, as is gathered from what has been demonstrated. In the same way we shall find the remaining hours.

As for laying out the portion described by the diurnal arc of 18 hours and the nocturnal arc of 6 hours, the matter is entirely clear from the figure and from the tables of proposition 33 of the first book. And so we have composed the Antique dial inclined to the horizon. Which was to be done.

ON DIALS THAT BOTH DECLINE FROM THE VERTICAL AND ARE INCLINED TO THE HORIZON.

PROBLEMA 37. PROPOS. 37.

To construct an Astronomical dial that both declines from the vertical and is inclined to the horizon.

That is, to draw the hour-lines from noon or midnight on a plane that is parallel to some great circle which both declines from the vertical and is inclined to the horizon.

So that we may describe more easily all dials that decline from the vertical circle and are inclined to the horizon, we shall give rules for laying out only the upper ones — those, namely, that face the zenith, or the top of the head. For in this way the whole matter, which is somewhat difficult and obscure, will be grasped more plainly. And once any upper dial has been drawn, we shall build the lower one from it with no trouble, since the lower dial is of course laid out on the lower face of the same plane if all its parts are inverted, as we demonstrated in the scholium to proposition 14 of the preceding book. Add to this that from these rules anyone can readily supply himself with other rules for the lower dials,

just as we too have done in the preceding pages — especially if one reads attentively what we wrote in proposition 1 of this book about the northern dial declining from the vertical circle.

We shall settle this whole business with six examples, or figures; for that many varieties seem to exist in all, as will become clear from what follows.

- In the **first** figure we set the declination of the plane from south toward east at 40 degrees, and its inclination to the horizon at 20 degrees.
- In the **second**, a declination from south toward west of 20 degrees, and an inclination to the horizon of 70 degrees.
- In the **third**, a declination from south toward east of 45 degrees, and an inclination to the horizon of 51 degrees 51 minutes.
- In the **fourth**, a declination from north toward west of 20 degrees, and an inclination to the horizon of 30 degrees.
- In the **fifth**, a declination from north toward east of 60 degrees, and an inclination to the horizon of 80 degrees.

- In the **sixth**, finally, we set the declination of the plane from north toward east at 30 degrees, and the inclination to the horizon at 52 degrees 3 minutes.

Thus in the first three examples the plane is inclined to the horizon toward the northern parts, and its upper face looks toward the zenith and the southern region; while in the latter three the plane is inclined to the horizon on the southern side, and its upper face looks toward the zenith and the northern region. That is, the plane of the first three figures cuts the meridian circle above the horizon on the northern side, whereas the plane of the latter three figures cuts it on the southern side.

[Margin: In six figures is contained the description of the dial that declines from the vertical and is inclined to the horizon.]

[Margin: The declinations of the planes of this proposition from the vertical, and their inclinations to the horizon.]

[Margin: The description of the upper Astronomical dial, which both declines from the vertical and is inclined to the horizon.]

And so, in order to describe the upper dial that declines from the vertical and is inclined to the horizon, let two straight lines AB, CD be drawn in some plane, cutting each other at right angles at E. Then, to the straight line CD, at the point

Diagram, captioned "1.^a fig.^a" (the first figure). A large circular construction for the declining-and-inclined Astronomical dial. A horizontal line **AB** runs across the figure through the center region (**A** at the far left, **B** at the far right); a second construction line **CD** crosses it. A smaller circle sits at the left of the main circle. Around the outer circumference run hour-numbers (a sequence 6, 7, 8, 9, 10, 11, 12, then 1, 2, 3, 4, 5, 6 continuing around), and a bundle of straight hour-lines converges toward the lower-center region.

Labels that can be resolved on the scan (positions approximate):

- E: center of the main circle.
- A: far left, on line AB. B: far right, on line AB.
- H: left, above line AB.
- T: on the small left-hand circle; α (alpha) beside it.
- C: above the center.
- Center cluster (very crowded): I, ψ (psi), B, K, M, and F just below.
- Φ (phi), Y (upsilon/"Y"), L: right of center.

- μ (mu): right of center, on a line toward "4".
- γ (gamma): below-left of center.
- θ (theta), b: below the center.
- D: lower center; τ (or r) nearby.
- N, m, α , b: upper-right, inside the circle.
- Outer hour-numbers: top run 7, 8, 9, 10, 11, 12; down the right 1, 2, 3, 4; down the left 6, 5, 4, 3, 2 and the symbols ς / f; along the bottom $\frac{1}{2}$, 11, 10, 9, 8, 7, 6.

The center of this figure is extremely congested and several small Greek point-labels sit at the resolution floor; with more than two labels uncertain, this figure is a for full label recovery.

At the point E let there be set up the angle of declination found by proposition 23 of the first book, observing this order. In planes that decline from south toward east, the said angle DEF is to be set up below the straight line AB, toward A; but toward B in those that decline from south toward west. In planes, however, that deflect from north toward east, the same angle is to be set up below the straight line AB, toward B; and toward A in those that decline from north toward west. Let the straight line EF be called the line of declination.

[Margin: The line of declination.]

After this, on the straight line AB, taking any point β whatever — whether to the right or to the left, as we said in proposition 1 of this book — let there be set up at AB, at the point β , the angle of the pole's altitude $E\beta C$, toward the straight line CD and either above the straight line AB or below it, in such a way that the straight line βC cuts the straight line CD at C.

Next, at the straight line CD, at E, let there be set up the angle of the plane's inclination to the horizon — found by proposition 23 of the first book — namely $DE\gamma$, below the straight line AB and toward whichever side you please; and let the straight line $E\gamma$ be called the line of inclination. Then, from D, any point of line CD, let a perpendicular line $D\gamma$ be drawn to the line of inclination $E\gamma$; and from ED let the straight line $E\delta$ be cut off, equal to the straight line $E\gamma$. Drawing also, through the points D and δ , the straight lines $D\iota$ and $\delta\theta$ parallel to AB (that is, perpendicular to CD), of which $\delta\theta$ cuts the line of declination EF at θ , let the straight line $D\iota$ be cut off equal to $\delta\theta$; and from ι , through E, let the straight line ιE be drawn out. This line will be the meridian, that is, the line of the 12th hour from noon or midnight, on the plane of the dial, as we shall demonstrate.

[Margin: The line of inclination.]

[Margin: The meridian line.]

We shall also find this same line of the 12th hour by the following method. Taking a point F anywhere on the line of declination,

let a perpendicular $F\lambda$ be drawn from it to AB ; or — which I approve of more, when the line of declination EF is only a little distant from the straight line AB — from any point λ chosen on the straight line EA or EB (according as the line of declination EF falls to the left or to the right of the straight line CD) let a line λp be drawn parallel to CD , cutting the line of declination EF at F . Likewise, at $F\lambda$ let a perpendicular Fn be raised. Then, having set up at λ the angle of inclination $F\lambda n$ — such that the straight line λn , forming the said angle together with λF , cuts the perpendicular Fn at n — let there be cut off from λF , produced toward F , a straight line λp equal to λn ; and from E , through p , let the straight line Ep be drawn out. This too will be the meridian line on the inclined plane, as we shall show. We shall give yet another way of finding this same meridian line in the scholium to this proposition.

Diagram, captioned "2.^a fig.^a" (the second figure). A large circular construction (the second of the six worked examples) for the declining-and-inclined dial. A horizontal line **AB** crosses the circle (**A** at the far left, **B** at the far right, with α beside **B**); several straight lines converge on the lower-central region, and a near-vertical line runs from top (through m , h , "12") down to the bottom (again h , m , "12"). Dotted arcs and chords fill the interior.

Labels that can be resolved on the scan (positions approximate):

- E , G , M : the crowded center cluster (E and G together, M just below).
- K , I : just above the center.
- C , e : at the top-center of the inner construction.
- λ , ϕ (ϕ), ψ (ψ): around the center.
- H : right of center, above line AB .
- A : far left on line AB ; B : far right on line AB , with α (α) beside it.
- π (π): left, on line AB ; μ (μ), and a second B , near the center-left.
- L : below the center; χ (χ), m nearby.
- γ (γ), θ (θ), b , a , δ (δ): in the lower-central region.
- D : lower left; p , F : below D toward the center; N : lower center.
- O : right, mid-low.
- λ , 6 , ς : on the right side of the circle.

- f: left; 6: upper left.
- m, h, 12: top of the vertical line, and again at its foot.

The interior is densely overwritten and many small Greek point-labels sit at the resolution floor; with more than two labels uncertain, this figure is a for full label recovery.

Furthermore, from θ let a perpendicular $\theta\lambda$ be drawn to the line of declination EF, toward the straight line AB and equal to $D\gamma$; and let the straight line $E\lambda$ be drawn through the points E and λ , of unlimited length. Let there also be set up at F, on the straight line EF (which is to be made equal to the assumed line $E\beta$), an angle equal to the angle of the pole's altitude $E\beta\gamma$ [?], drawing the straight line $F\mu$ in such a way that $F\mu$ always falls on the opposite side of the straight line $E\lambda$ — namely to the right of EF if $E\lambda$ was drawn to the left of that same EF, or the reverse. Now the angle of the pole's altitude which the straight line $F\mu$ makes with the straight line EF ought to slope toward E — that is, upward — if the plane faces south, so that the angle $EF\mu$ is equal to the angle of the pole's altitude; but if the plane looks toward the north, the same angle is to be set up on the side opposite to E, so that the angle $EF\mu$ together with the angle of the pole's altitude makes up two right angles. Let the straight line μF , produced through F toward ξ (as in the first, fourth, fifth, and sixth figures), cut the straight line drawn from E through λ ; or else let $F\mu$ itself, extended toward μ (as in the second figure), cut the straight line λE produced through E, at the point π ; and let there be cut off from the line of the 12th hour a straight line $E\varepsilon$ equal to $E\pi$ — below the point E if the point π falls either on $E\lambda$ itself or on $E\lambda$ produced toward λ , but above that same point E if π falls on $E\lambda$ or on $E\lambda$ produced through E, as happens in the second figure. For the point ε will be the center of the dial, at which all the hour-lines from noon or midnight will meet. But if it should ever happen that the straight line $F\mu$ in no way cuts the straight line drawn through the points E and λ , but is equidistant from it, then the dial will have no center at which its hour-lines meet; rather, they will all be parallel to one another, as happens on inclined planes that pass through the pole of the world — of which you have an example in the third figure.

[Margin: The center of the dial.]

[Margin: Which dial-lines lack a center.]

Besides this, at the straight line AB, at the point E, let there be set up an angle equal to the angle of the plane's inclination, either toward B or toward A; and let the straight line $F\phi$ that forms the said angle be equal to the straight line EC. This

angle is to be set up above the straight line AB if the plane faces south, as in the first three figures; but if it faces north, below the same line, as was done in the last three figures. From the point ϕ let a perpendicular $\phi\chi$ be drawn to CD. Likewise, from F, a perpendicular $F\lambda$ having been drawn to AB, let there be set up at it, at the point λ (either to the right or to the left), an angle $F\lambda\omega$ equal to the angle of inclination $DE\gamma$; and let the straight line $\lambda\omega$ be equal to the straight line λF , and from ω let a perpendicular ωd be raised to λF . For the straight line drawn through χ and d will be the line of the style, and it will necessarily pass through the center ϵ of the dial; or else, where there is no center of the dial (as in the third figure), it will be parallel to the meridian line $E\epsilon$. Thus the style, the pointer of the hours, is to be set upright to the plane of the dial along the straight line χd . It will be enough, however, if just one of the two points — namely either χ or d — is found, so that the line of the pointer, or style, can be drawn. For the straight line drawn from ϵ , the center of the dial, through that found point; or else, where there is no center of the dial, the line drawn through that point parallel

[Margin: The line of the style, or pointer.]

parallel to the meridian line $E\varsigma$, will be the line of the style. The line will be drawn more accurately, however, if both points are found — especially when the point that was found first lies only a little from the center of the dial ς .

Moreover, from the points χ and d let two perpendiculars χe and dt be drawn to the line of the index χd , equal respectively (each to each) to the straight lines $\chi\phi$ and $d\omega$, on one and the same side of that straight line χd — namely on the right, or on the left — if the plane faces south, as in the first three figures; but if it faces north, on opposite sides, one to the right of χd and the other to the left, as was done in the last three figures. For the straight line ef , when drawn, will pass entirely through the center of the dial ς , or — where there is no center — will run parallel to the meridian line $E\varsigma$; and it will be the axis of the world, to be raised above the line of the style χd by the length of the perpendiculars χe and df , which stand perpendicular to the plane of the dial.

[Margin: The axis of the world.]

Furthermore, since the axis ef , when produced, cuts the line of the style χd (produced) at the center of the dial ς — wherever the dial has a center — one must always take that part of the axis which is emitted from the center ς through f , and not the part that runs through e . This is to be understood when χe and df are drawn toward opposite sides of the line of the style, as happens on planes facing north, that is, in the last three figures. For where they are drawn from the

same side — as happens on planes facing south, as we said, of the kind represented in the first three figures — one must take the whole axis ζ -e-f, drawn from ζ through the points e and f; or else the whole axis ef produced in both directions, in a dial that lacks a center, such as the one drawn in the third figure.

Now, on the portion of the axis that runs from ζ through f, take any point I, and from it draw IG perpendicular to the axis, cutting the line of the index at the point G; through G raise GH perpendicular to the line of the style. This GH will be the equinoctial line of the dial. The point G will fall either on the straight line AB — as you see in the first three figures — or below it, as in the fourth figure, or above it, as happens in the fifth and sixth figures. Whenever it can conveniently be done, however, I would advise first taking on the line of the style the point G where the line of the style and the straight line AB cut each other, and from it drawing the perpendicular GI to the axis running from ζ through f, as was done in the first three figures. (This cannot be done in the fourth figure, because from the point where the line of the style and the straight line AB intersect, the perpendicular cannot fall on the portion ζ -f of the axis, but on the portion ζ -e.) Then, through the same point G, raise GH perpendicular to the line of the style, to serve as the equinoctial line. From I also let fall the perpendicular IK onto the line of the style. The straight line IK will be the length of the style, and its position is at K; and the angle $G\zeta f$ will be the angle of the pole's altitude above the proposed plane, as will be shown.

[Margin: The equinoctial line.]

[Margin: The length of the style and its position; and the angle of the pole's altitude above the proposed plane.]

Finally, on the line of the style χd , take a straight line GL — whether above or below G — equal to the straight line GI, and about L describe a circle of any size. Divide this circle into 24 equal parts, beginning from the straight line LM, which is drawn through L, the center of the circle, and through the point M where the equinoctial line cuts the meridian line E ζ , just as is done in a dial declining from the vertical.

Diagram. The third figure of this proposition — a full sundial-construction diagram for a plane both declining and inclined. A horizontal line runs across the middle, lettered **A** (left end) and **B** (right end); it is the common section AB of the horizontal and the declining-inclined planes. A large circle (the dividing circle described about the style-line) sits in the upper center, with **O** and ζ marked at its top. The following main points are legible:

- A (left end of the horizontal line)
- B (right end of the horizontal line)
- H (left, where an oblique line meets the circle)
- L (near the center; center of the dividing circle)
- B (a second, interior label low in the right of the circle)
- E (small, at the center)
- M (below the center)
- F (below M)
- D (low, on the vertical toward the bottom)
- k (at the very foot of the figure, below D)
- O, ζ (at the top of the circle)

Around the upper-right circumference run the hour-division marks and small labels — numerals 5, 6, 7, 8[?], 9[?] and 1, 2, 3, with letters **M** and **m** — together with a scattered swarm of small, worn Greek point-sorts (among them χ, φ, ω, λ, η, ξ, π, γ) and a "γμ"-like cluster [?] near the right center. Many of these peripheral labels are too small and worn to resolve individually off the scan.

just as is done in a dial declining from the vertical.

But if the equinoctial line happens to be parallel to the meridian line — as occurs on the plane of a dial that lies parallel to a great circle which cuts the meridian circle at the same point where it is divided by the equator, as we shall show a little below — then the division of the said circle described about L must be begun from the straight line drawn through L, the center of the circle, parallel to the equinoctial (or meridian) line, as appears in the sixth figure of this proposition, in the line MO. Here, however — since it usually happens that the center L and the point M lie so close together that the straight line LM, from which the division of the circle must begin, can scarcely be drawn without some error — one must by all means apply the remedy that we gave in Proposition 1 of this book concerning the dial declining from the vertical: namely, that we first draw the line of the sixth hour, or of some other hour, and so on, as we shall explain a little below, after the demonstration. For the straight lines drawn from the center L through the points of division will cut the equinoctial line at points through which straight lines are drawn from ζ, the center of the dial — or, where there is no center, as in the third figure, straight lines [that are] to the [meridian] line

parallel to the meridian line, or perpendicular to the equinoctial line, will give the hours from noon or from midnight, in this order.

[Margin: The hour-line. The order of the hours.]

On planes that face south, the portion of the meridian line extending from the center of the dial ς toward the equinoctial line — as in the first two figures — or the whole meridian line, where there is no center, as in the third figure, marks the 12th hour of the day (noon); the hours to its right on the equinoctial line signify the afternoon hours, and those to its left the forenoon hours. The remaining portion of the meridian line, beginning likewise from the center,

Diagram. A second full sundial-construction diagram, of the same type as the preceding one and carrying an identical caption, "3.^a fig.^a". (Two consecutive pages thus bear the same figure number — see the numbering anomaly in the report.) A horizontal line crosses the middle, lettered **A** (left) and **B** (right); a large dividing circle occupies the upper center, with **O** and ς at its top. Legible main points:

- A (left end of the horizontal line)
- B (right end of the horizontal line)
- H (left, at the circle)
- L (center; center of the dividing circle)
- B (a second, interior label, low right within the circle)
- E (small, at the center)
- M (below center)
- F (below M)
- D (low, toward the foot)
- k (at the foot of the figure)
- O, ς (top of the circle)

The upper-right arc again carries hour-division numerals (5, 6, 7, 8[?], 9[?] and 1, 2, 3), the letters **M** and **m**, a " $\gamma\mu$ "-like label [?] at the right, and a dense scatter of small, worn Greek point-sorts. The interior is crossed by very many hour-lines and construction lines; most of the small peripheral labels cannot be resolved off the scan.

shows the 12th hour of the middle of the night (midnight).

On planes facing north, when the equinoctial line lies below the center of the dial ς , on the line of the index — as is seen in the fourth figure — the portion of the meridian line extended from the center ς toward the equinoctial line will denote the 12th hour of the day (noon); the hours to its right on the equinoctial line indicate the forenoon hours, and those to its left the afternoon hours; while the

remaining portion of the meridian line, tending beyond the center toward the upper parts, belongs to the 12th hour of midnight.

But when the equinoctial line lies above the center of the dial ς , on the line of the index or style — as is seen in the last two figures of this description — the portion of the meridian line drawn from the center of the dial ς toward the equinoctial line (or at any rate tending toward the upper parts, where the equinoctial and meridian lines are parallel, as in the sixth figure) will show the 12th hour of midnight; the hours descending to the right of the meridian line on the equinoctial line are the forenoon hours, and those to the left the afternoon hours; while the remaining portion of the meridian line, below the center of the dial ς , faces north and belongs to the 12th hour of noon.

And whenever a straight line drawn through some point of division of the circle described about L, and through the center L, is parallel to the equinoctial line, then a straight line drawn through ς , the center of the dial, parallel to the equinoctial line will give that hour, whatever it may be, as we said in Proposition 1 of this book concerning the vertical declining dial. For the demonstration here is the same, provided that ς , the center of the dial, is always taken in place of C in the demonstration set out there.

[Margin: Demonstration of the construction of a dial declining from the vertical and inclined to the horizon.]

We shall demonstrate this construction as follows. Suppose that, in the plane of the dial set in its proper position, the straight line AB is parallel to the horizon, so that it is the common section of the horizontal dial-plane and of the plane of the dial that both declines and is inclined. Let the plane drawn through the straight lines AB, EF, ED be conceived to rotate about the straight line AB until it lies parallel to the horizon, and so becomes the same as the plane of the horizontal dial. In this position, since DEF is the angle of declination of the dial-plane from the vertical, the remaining angle AEF (or BEF) will be the complement of that declination — namely the angle that the meridian makes with the line that, in the declining plane, lies parallel to the horizon, or rather with the plane drawn through that straight line and standing perpendicular to the horizon. Therefore the straight line EF will be the common section of the meridian and of the horizontal dial-plane, and consequently the meridian will cut the plane of the dial that both declines and is inclined at the point E.

Now if the right triangle DEy is turned about DE until it stands perpendicular to the dial-plane, then the straight line AE — which in the dial-plane is

perpendicular to DE, the common section of the triangle DE γ and of the inclined plane — will, by Definition 4 of Book 11 of Euclid, be perpendicular to the triangle DE γ , and hence, by Definition 3 of the same book, also to the straight line E γ . Therefore, since both lines DE and γ E are perpendicular to the straight line AE, DE γ will be the angle of inclination of the proposed plane to the plane drawn through the straight lines AE and E γ , by Definition 6 of Book 11 of Euclid — inasmuch as AE is the common section of the proposed plane and of the said plane drawn through AE and E γ . Since, then, the angle DE γ has been taken equal to the inclination of the proposed plane to the horizon — and hence to the plane of the horizontal dial, which is parallel to the horizon — the plane drawn through AE and E γ will be identical with the plane of the horizontal dial, and therefore the straight line E γ will lie in the plane of the horizontal dial. And since E η [?] has been taken equal to it, if the triangle E η [?] θ — or rather the plane drawn through the straight lines AB, E θ , E η [?], in which the said

triangle stands about the straight line AB — is conceived to move until it is joined to the plane of the horizontal dial, in such a way that E θ does not depart at right angles from the plane DE γ (the inclined plane), but always makes a right angle with AE, and that the line η [?] θ always remains parallel to AE, then E θ will become the same as E γ [?], and the point η [?] the same as γ [?]. And since the straight lines η [?] θ and D ς — the former lying in the plane of the horizontal dial, as we have just said, and the latter in the inclined plane — are by construction parallel to AB, they are [a] also parallel to each other, and have been set equal; therefore [b] the straight lines connecting their end-points will likewise be parallel to each other and equal — namely the straight line γ D, dropped from the point γ (or η [?]) in the plane of the horizontal dial to the point D, and the straight line $\theta\varsigma$, drawn from the point θ in the plane of the horizontal dial to the point ς .

[Margin: a — Euclid XI.9]

[Margin: b — Euclid I.33]

Since, then, the straight line D γ is, by Definition 4 of Book 11 of Euclid, perpendicular to the plane of the horizontal dial — because, lying in the plane DE γ , it is perpendicular to E γ , the common section of the horizontal dial-plane and of the plane DE γ , which is perpendicular to the plane of the horizontal dial (for since AE has been shown to be perpendicular to the plane DE γ , [c] the plane of the horizontal dial drawn through AE will also be perpendicular to that same plane through DE γ , and conversely, therefore, the plane DE γ perpendicular to the plane of the horizontal dial) — [d] the line E θ [?] will likewise be perpendicular to the same plane of the horizontal dial, and hence, by Definition 3 of Book 11 of

Euclid, also to the straight line $E\theta$ [?]. From this it follows that the straight line $\theta\varsigma$ lies in the plane of the meridian. Otherwise, since the perpendicular drawn from θ to $\varsigma\theta$ — the common section of the horizontal dial-plane and of the meridian — in the plane of the meridian is, by Definition 4 of Book 11 of Euclid, perpendicular to the plane of the horizontal dial, two perpendiculars would be drawn from the same point θ to the same plane of the horizontal dial, [e] which cannot be. Therefore the meridian will meet the inclined plane at the point ς ; and since it also meets it at the point E , as we showed a little earlier (for the meridian is drawn through EF , the meridian line of the horizontal dial), the straight line $E\varsigma$ will be the common section of the meridian and of the inclined plane — that is, the meridian line, or the line of the 12th hour, on the plane of the dial that both declines and is inclined.

[Margin: c — Euclid XI.18]

[Margin: d — Euclid XI.8]

[Margin: e — Euclid XI.13]

That the straight line Ep is likewise a meridian line can be shown as follows. Suppose the triangle $EF\downarrow$ to move about the straight line $E\downarrow$ until it lies parallel to the horizon — that is, until it is joined to the plane of the horizontal dial — so that FE is again the common section of the meridian and of the horizontal dial-plane. Then, in this position, conceive the triangle $\downarrow Fn$ to be carried around the straight line $\downarrow F$, until it stands perpendicular both to the plane of the inclined dial and to the plane of the horizontal dial; and this will be accomplished when the straight line $n\downarrow$ is perpendicular to AB . For then the straight line AB , being perpendicular to the straight lines $\downarrow F$ and $\downarrow n$, will [f] be perpendicular to the plane of the triangle $\downarrow Fn$ drawn through those straight lines. Therefore [g] the plane of the dial — both the inclined and the horizontal — drawn through AB , and the plane of the triangle $\downarrow Fn$ will each be perpendicular to the other; and so, conversely, this plane will stand perpendicular to both of them. Therefore, since $F\downarrow n$ is

[Margin: f — Euclid XI.4]

[Margin: g — Euclid XI.18]

Diagram. The fourth figure of this proposition — the construction diagram for the north-facing declining-inclined case (equinoctial line falling below the dial center). A horizontal line crosses the upper-middle, lettered **A** (left) and **B** (right),

the common section AB. A separate dividing circle sits at the lower left, with center L. Legible points and labels:

- 6 (far left, above A — an hour-line label)
- A (left end of the horizontal line)
- B (right end of the horizontal line)
- H (on AB, left of center)
- α , β (on/near AB, toward the center)
- Ψ (or Y) and E (near the center-right of AB; E is the meridian intersection)
- C (above E)
- l, h, m, $\frac{1}{2}$ (upper right, above/around C — hour-line ends)
- φ (right of E)
- σ (far right)
- γ (lower right)
- μ , u (lower right)
- L (center of the lower-left circle)
- O, N (left side of the circle)
- b (upper part of the circle)
- m, h, $\frac{1}{2}$ (at the foot, where lines leave the circle)
- G, M, D, ε , θ , χ , ζ , ξ , λ , ω , n (interior swarm of small point-sorts, and the $\downarrow$ sort)

The interior is a very dense pencil of crossing hour-lines and construction lines, with many small, worn Greek point-sorts that cannot be resolved individually off the scan.

the angle of inclination of the plane to the horizon, and $\downarrow F$ lies parallel to the horizon, then $\downarrow n$ will lie in the inclined plane — that is, joined with the straight line $\downarrow p$, it will lie in the said plane. Therefore the point n will fall on the point p, because of the equality of the straight lines $\downarrow n$ and $\downarrow p$. Since, then, the meridian, standing perpendicular to the plane of the triangle $\downarrow FE$ and lying in the plane of the horizontal dial, passes through EF and hence through Fn — for Fn, by Definition 4 of Book 11 of Euclid, is perpendicular to the plane of the triangle EF $\downarrow$, because it is by construction perpendicular to $\downarrow F$, the common section of the triangles EF $\downarrow$ and $\downarrow Fn$ — the meridian will meet the inclined plane at the point p; and consequently the straight line Ep will be the common section of the meridian and of the inclined plane.

Therefore, since $\theta\lambda$ is perpendicular to $E\theta$ and equal to the straight line $D\downarrow$ — that is, to the straight line $\theta\varepsilon$, dropped from θ , a point of the plane of the horizontal dial, to ε , a point of the inclined plane — the triangle $E\theta\lambda$ will be entirely equal to the triangle $E\theta\varepsilon$ lying in the plane of the meridian, whose side $E\theta$ lies in the plane of the horizontal dial, $E\varepsilon$ in the inclined plane, and $\theta\varepsilon$ in the plane of the meridian. And the straight line $E\lambda$ will be equal to the straight line $E\varepsilon$, and the angle $\theta E\lambda$ equal to the angle $\theta E\varepsilon$ in the plane of the meridian.

Accordingly, if the triangle $E\theta\lambda$, lying in the plane of the horizontal dial, is conceived to be rotated about the straight line $E\theta$ until it is joined to the plane of the meridian, there will result exactly the same triangle $E\theta\lambda$ as the triangle $E\theta\varepsilon$ lying in the plane of the meridian, and the point λ will fall on the point ε . Now, once the inclined dial is set up in its own position — so that the straight line EF , lying in the plane of the horizontal dial, is the common section of that dial and of the meridian — the straight line μF is rotated until it reaches the plane of the meridian (or of the triangle $E\theta\lambda$, which we have already shown to be the same as $E\theta\varepsilon$ lying in the plane of the meridian), yet under this condition, that always inclining at the point H toward the parts of the upper hemisphere,

Diagram. The fourth figure of this proposition, printed again at the head of this page (the construction diagram for the inclined–declining case). A horizontal line runs across the upper part, lettered **A** (left end) and **B** (right end) — the common section AB — with a dense pencil of construction and hour-lines converging near its center. A separate dividing circle sits at the lower left. Legible labels:

- 6 (far left, above **A** — an hour-line label)
- **A** (left end of the horizontal line AB)
- H (on AB , right of **A**)
- α (on AB)
- β (on AB , right of α)
- Y, E (near the center of AB ; E is the meridian intersection)
- i (on AB , right of E)
- **B** (right end of AB)

- μ, u (lower right)

- L [?] (center of the lower-left circle)
- O (left of the circle), N (lower-left of the circle), b (upper part of the circle), M (right of the circle)
- $\frac{1}{2}$, h, m (at the foot of the circle, where lines leave it)
- interior swarm of small worn point-sorts (θ , ρ , G, M, D, ξ , η , ζ , and the $\downarrow$ sort) that cannot be resolved individually off the scan

More than two interior labels are unresolved.**

the axis of the world always makes the same angle $EF\mu$. For it is the axis of the world, because the angle $EF\mu$, taken in planes facing south, is equal to the elevation of the pole; while in planes facing north it forms, together with the angle of the pole's elevation, two right angles, by construction. And therefore the straight line $F\mu$, produced toward μ , passes through the arctic pole, so that the point in which it meets the inclined plane — or the line $E\lambda$, which is now the same as $E\varepsilon$, as we showed — is the point in which all the hour-lines converge at midday or at midnight, by the corollary of Prop. 21 of Book 1; and this point is usually called the center of the dial. Hence, since the axis μF cuts the straight line $E\lambda$ at ϖ , if the line $E\varpi$ is transferred onto the line $E\varepsilon$ up to the point ρ , then ρ will be the center of the dial. For the axis μF , if it is rotated together with the triangle $E\theta\lambda$ about the straight line $E\theta$ (which lies in the plane of the horizontal dial) until it is joined to the meridian and attains its proper position, will meet the given plane at that point $[\rho]$, as is clear from what has been demonstrated.

[Margin: How to determine whether the center of the dial is to be taken below the straight line AB or above it.]

It will not be difficult, moreover, to understand whether the axis meets the inclined plane below the line AB or above it. For if the axis μF , produced through F, cuts the line $E\lambda$, or that same line produced toward λ — as happens in the first, fourth, fifth, and sixth figures — the center ρ will lie below the line AB, because the line $E\lambda$ falls onto the line $E\varepsilon$ below the line AB, since the point λ falls onto the point ε , as has been said. But if the axis μF , produced toward μ , cuts the line $E\lambda$ produced through E — as is seen in the second figure — the center ρ will lie above the line AB, because the line $E\lambda$, drawn out through E, falls onto the line $E\varepsilon$ drawn out through E, as is clear from what has been said, since the point λ falls onto the point ε . But if the axis $F\mu$ does not cut the line $E\lambda$ at all, the inclined plane will be parallel to the axis $F\mu$, and consequently the dial drawn on it will have no center, but all its hour-lines will be parallel, as is clear from the corollary of Prop. 22 of Book 1.

Now the index-line [linea indicis] — the line, that is, on which the style is to be fixed — must be such that the style, or any other line drawn perpendicular to the plane of the dial from any point of it, falls upon the axis of the world, in such a way that the plane drawn through that perpendicular and the axis of the world stands at right angles to the plane of the dial, serving as a kind of proper meridian of the dial-plane itself, as we showed in Prop. 1 of this book. We shall demonstrate that the line $\chi\downarrow$ is such a line, in this way. If the right triangle $E\phi\chi$ is moved about the line $F\chi$ until it stands perpendicular to the inclined plane — upward in planes facing south, downward in planes facing north — then, by Definition 4 of Book 11 of Euclid, the line AE [?] lying in the inclined plane, which is perpendicular to

[Margin: 18. undec. — Euclid XI.18]

$F\chi$, the common section of the inclined plane and of the triangle $E\phi\chi$, holds this position: it is perpendicular to the triangle $E\phi\chi$, and hence also to the line $E\phi$, by Definition 3 of the same book. Since, then, both lines $F\chi$ and $E\phi$ are perpendicular to the line AE , the angle $\phi E\chi$ will be the angle of inclination of the given plane to the plane drawn through the lines AE and $E\phi$, by Definition 6 of Book 11 of Euclid, since AE is the common section of the given plane and of the plane drawn through the lines AE and $E\phi$.

Now since the angle $\phi E\chi$ is equal to the complement of the inclination of the given plane to the horizon (for the angle $BE\phi$, or $AE\phi$, was taken equal to the inclination of the plane to the horizon) — that is, equal to the inclination of the plane to that vertical circle which is drawn through the line AB — the plane drawn through the lines AE and $E\phi$ will be the same as the plane of that vertical circle; and therefore the line $F\phi$ will lie in that vertical circle. And since the line $E\phi$ was taken equal to the line EC , and the line EF to the line $E\beta$, the axis of the world $F\mu$, meeting the plane of the horizontal dial at F , will pass through the point ϕ in that said vertical circle; because in this way the axis $F\mu$ will form, with the meridian line of the horizontal dial EF at F , the angle of the pole's elevation above the horizon toward the north, and with the line $E\phi$ — through which the said vertical, indeed the vertical properly so called, is drawn — the angle of the complement of the pole's elevation above the horizon. So that the axis $F\mu$ forms with the lines EF and $E\phi$ a right triangle in the plane of the meridian circle, entirely equal and similar to the triangle $E\beta C$, since not only EF but also $E\phi$, in that position, lies in the plane of the meridian, and the angle $FE\phi$ is right — which we shall show thus.

Since that vertical circle drawn through the lines AB and E ϕ is perpendicular to the plane of the horizontal dial, by Definition 4 of Book 11 of Euclid the line E ϕ , lying in that vertical circle — which has been shown to be perpendicular to AE, the common section of the said vertical and of the plane of the horizontal dial — will be perpendicular to the plane of the horizontal dial; and consequently, by Definition 3 of Book 11 of Euclid, also to the line EF lying in the plane of the horizontal dial. Therefore the angle FE ϕ is right. From this it follows that the line E ϕ lies in the plane of the meridian; otherwise, since the perpendicular from E to EF (the common section of the plane of the horizontal dial and of the meridian), drawn in the plane of the meridian, is perpendicular to the plane of the horizontal dial, by Definition 4 of Book 11 of Euclid two perpendiculars would be drawn from the same point E to the same plane of the horizontal dial —

[Margin: a — which cannot be.]

The reason, moreover, why the triangle E ϕ χ must be moved upward in planes facing south, but downward in those facing north — provided that in the former it is constructed above the line AB, and in the latter below it, as we prescribed — is this:

[Margin: b — 13. undec. — Euclid XI.13]

namely, that in the former the axis of the world F μ , passing through the point F in the plane of the horizontal dial, meets that vertical circle drawn through the line AB above the line AB, but in the latter below the line AB, after it has met the inclined plane — as is evident if the inclined planes, the plane of the horizontal dial, the said vertical, and the axis of the world F μ are conceived in their proper positions.

Again, if the right triangle $\downarrow d\omega$ is moved upward about the line $\downarrow d$ until it stands perpendicular to the inclined plane, then, by Definition 4 of Book 11 of Euclid, the line A $\downarrow$, lying in the inclined plane and making right angles with $\downarrow d$ (the common section of the triangle $\downarrow d\omega$ and of the inclined plane), will be perpendicular to the triangle $\downarrow d\omega$, and hence, by Definition 3 of the same book, also to the line $\downarrow \omega$. And since each of the lines $\downarrow \omega$ and $\downarrow d$ is perpendicular to the line A $\downarrow$, by Definition 6 of the same book $\omega \downarrow d$ will be the angle of inclination of the given plane to the plane drawn through the lines A $\downarrow$ and $\downarrow \omega$, since A $\downarrow$ is the common section of the given plane and of that which is drawn through the lines

Diagram. The fifth figure of this proposition. A horizontal base line runs across the lower part, lettered **A** (left end) and **B** (right end), with a large circle set at the

upper right and a dense pencil of construction lines converging near the lower center at F. Legible labels:

- M (top)
- a (below M)
- m, h (upper left of the figure)
- C (left, below m)
- π , T (center-left, above the base line)
- A (left end of the base line)
- β (on the base line, left of center)
- E (center of the base line)
- B (right end of the base line); O (just left of B)
- circle (upper right): center L; λ (left-upper of the circle), b (right-upper), N (top-right), σ (far right)
- G (interior), K, H (interior, near E–F)
- i (right, on a line running to the far right)
- F (below E, lower center — the convergence point)
- δ , χ , β (below and around F)
- h, m, η (lower center)
- D (bottom left), E [?] (bottom center), ς [?] (bottom right)
- 6 (lower left), P [?] (at the very bottom)

More than two interior labels are unresolved.**

$A\downarrow$ and $\downarrow\omega$ are drawn. Since, then, the angle $\omega\downarrow d$ is taken equal to the inclination of the given plane to the horizon — and hence also to the plane of the horizontal dial, which is parallel to the horizon — the plane drawn through the lines $A\downarrow$ and $\downarrow\omega$ will be the same as the plane of the horizontal dial; and consequently the line $\downarrow\omega$ will lie in the plane of the horizontal dial. And since this line was taken equal to the line $\downarrow F$, if the triangle $EF\downarrow$ is moved about the line $E\downarrow$ until it is joined to the plane of the horizontal dial, $\downarrow\omega$ will become the same as $\downarrow F$, and the point ω the same as F, because in that

motion the line $F\downarrow$ always makes right angles with $F\downarrow$, and always remains in the plane of the triangle $\downarrow\omega d$; otherwise, in the plane of the horizontal dial, two perpendiculars $\omega\downarrow$ and $F\downarrow$ would be drawn to the line $E\downarrow$ at the point $\downarrow$ — which is absurd. Since, then, the axis of the world $F\mu$ passes through F, a point of the horizontal dial, it follows that it also passes through the point ω of the triangle $\downarrow\omega d$, which has that position. This being so, since both the line $\phi\chi$ and the line

ωd are perpendicular to the inclined plane, by Definition 4 of Book 11 of Euclid (if in that position the triangles $E\phi\chi$ and $\downarrow \omega d$ are understood to be placed), and therefore also to the line $\chi \downarrow$, by Definition 3 of the same book, it follows that the lines $\phi\chi$ and ωd are parallel,

[Margin: a — 6 & 7. undec. — Euclid XI.6 & 7]

and therefore lie in the same plane, which is drawn through the lines $\phi\chi$, ωd , and χd ; and this plane is perpendicular to the inclined plane and passes through the axis of the world, which we demonstrated to pass through the points ϕ and ω .

[Margin: b — 18 & 7. undec. — Euclid XI.18 & 7]

Therefore the plane drawn through the lines $\phi\chi$, ωd , $\chi \downarrow$, standing perpendicular to the inclined plane, will serve as a kind of new and proper meridian of the inclined plane itself; and in this new meridian all the perpendiculars drawn to the line $\chi \downarrow$ are likewise perpendicular, by Definition 4 of Book 11 of Euclid, to the inclined plane, and they meet the axis at the points

Diagram. The fifth figure again, printed at the head of this page (the same construction as fig-p329-1, with the circle at the upper right and the convergence at F below center). Legible labels, as far as they resolve:

- M (top); a (below M)
- m, h (upper left); C (left, below m)
- π , T (center-left, above the base line)
- A (left end of the base line); β (on the base line); E (center); B (right end), O (left of B)
- circle (upper right): center L; λ (left-upper), b (right-upper), N (top-right), σ (far right)
- G, K, H (interior, near E–F); i (far right, on a line)
- F (lower center — convergence point); δ , χ , β (around F)
- h, m, η (lower center); D (bottom left); E [?] (bottom center); ς [?] (bottom right)
- 6 (lower left); P [?] (at the very bottom)

This is the same figure as fig-p329-1; more than two interior labels are unresolved.**

ϕ , ω , through which the axis passes. Accordingly, the line χd will be the index-line — namely, the common section of the plane of the dial and of that proper meridian — like a meridian line, as though the circle to which the dial is parallel

were the horizon; since any style whatever erected on it perpendicular to the inclined plane cuts the axis of the world, as we said, just as happens in other dials. That this index-line $\chi\downarrow$, in dials that have a center, must be drawn through the center of the dial ρ , is evident. For since the axis passes through ρ , the center will cut entirely that plane which stands perpendicular to the plane of the dial and passes through the axis — namely, that new meridian — cutting the plane of the dial at ρ ; and therefore the common section of that meridian and of the plane of the dial will pass through ρ . Finally, in dials that lack a center, that the same index-line χd is parallel to the meridian line, or the line of the 12th hour, will become manifest in this way. Since both the meridian of the horizon and that proper meridian of the inclined plane — which, of course, makes the index-line χd in the plane — pass through the axis of the world, the sections which they make in the inclined plane, that is, the meridian line and the index-line, will be parallel, by Prop. 18 of Book 1, since the plane of the dial is parallel to the axis, because it does not cut it, as has been said.

Let it also be understood that the lines χe and df are moved about the line χd until they are perpendicular to the inclined plane — both upward in those dials which face south, but in those which face north, the line χe downward and the line df upward. For in this way the points e, f will become the same as φ and ω , on account of the equality of the lines $\chi\varphi, \chi e$ and $d\omega, df$. Since, then, the axis of the world passes through the points φ, ω , as we have now demonstrated, it will pass through the points e, f in that position. And since the axis passes also through the center ρ , or — where there is no center — is parallel to the index-line χd (for, as we demonstrated a little before, the meridian line and the index-line in a dial without a center are parallel, because each is parallel to the axis of the world, as is clear from the demonstration of Prop. 18 of Book 1), it follows that the line ef also passes through the center ρ , or is parallel to χd . For if it is rotated together with the lines $\chi e, df$ about χd , it will be joined to the axis, so that the axis is the same as the line ef . Therefore the axis must be elevated from the center ρ according to the angle $\varphi\downarrow d$, or $\varepsilon\downarrow\varphi\chi$ [?], which is the angle of the pole's elevation above the inclined plane —

[Margin: c — 29. primi — Prop. 29 of Book 1]

(because such an angle is equal to that which the axis of the world and the common section of the new meridian of the inclined plane and of the greatest circle — to which the plane of the inclined dial is parallel — form together,

[Margin: d — 16. undec. — Euclid XI.16]

because this common section is parallel to the line χd in the plane of the dial). It is, moreover, manifest that this angle, constituted in the proper meridian of the inclined plane and standing at the center of the world, rests upon the arc of the pole's elevation above that greatest circle to which the dial is parallel. Or else, where there is no center — as in the third figure — the axis must be elevated according to the perpendiculars χe , df , which are equal to one another, because the axis ef is parallel to the index-line χd , as has been proved. It will, moreover, be easy to understand why, in planes facing south, both lines χe and df must be drawn on the same side of the line χd , whereas in planes facing north, one on the right side and the other on the left. For since in the former, as we said, each triangle $E\phi\chi$ and $\phi\omega d$ is rotated upward about the lines $E\chi$ and ϕd until it stands perpendicular to the inclined plane, both lines χe and df must be drawn on the same side of the line χd , so that when each is rotated until it stands perpendicular to the inclined plane on the upper side, the points e , f fall on the points ϕ , ω through which the axis is drawn, and each of which lies on the upper side.

Now since in these figures the triangle $E\phi\chi$ is understood to be moved downward and the triangle $\phi\omega d$ upward about the straight lines $E\phi$ and ϕd , as we have said, until each stands perpendicular to the inclined plane, one of them must be drawn on the one side and the other on the other. In this way, when each is rotated about until it is perpendicular to the inclined plane, the line df will be raised up from the upper part of the plane, and its point f will fall onto the point ϕ [?] (which likewise lies above the plane); while the line χe will be set up from the lower part, and its point e will become identical with the point ω [?], which also lies below the plane. For in this way the line ef will represent the axis of the world, which we showed passes through the points ϕ and ω ; indeed it follows that this same line is constituted out of ef and the axis of the world. In the same way the reason is clear why in the former dials the whole axis ϕfe is taken, whereas in the latter only the portion ϕf drawn to the axis, and not ϕe . It is because in the former the whole axis ϕfe stands above the inclined plane, since both points f and e lie above that same plane; but in the latter the portion ϕf of the axis lies above the plane while ϕe lies below it, because the point f lies above the plane and the point e below it, as is evident from what has been said.

Now the axis of the world ϕf is at right angles to the equator — by a proposition of Theodosius, Book 1 — and passes through its center; and therefore, by definition 3 of Euclid's Book 11, it makes right angles with any straight line drawn in the plane of the equator from the equator's center. Suppose, then, that the point I on the axis is taken as the center of the world, or of the equator. (For any point whatever of the axis ϕf may be taken as the center of the world, since its

distance from the center of the world is imperceptible and beyond sensation when compared with its distance from the Sun, as we showed in the *Sphere*.) Then let the straight line GI, which is perpendicular to the axis ef and cuts the index-line at G, be the common section of the equator and of the plane drawn through the straight lines χc and df — which are perpendicular to the inclined plane — and through the index-line χd and the axis ef. [Margin: a — 18. undec. — Euclid XI.18] This latter plane stands at right angles to the inclined plane, after the fashion of a certain new and proper meridian of the inclined plane itself. Hence the line GI lies not only in the plane GI ϕd but also in the plane of the equator, since the axis, together with GI in the plane GI ϕd , makes a right angle at I. For otherwise, if the equator did not pass through the straight line IG but through some other line drawn from the point I (which has been taken as the center of the equator), the axis would — by definition 3 of Euclid's Book 11 — be perpendicular to that line as well, since it is at right angles to the plane of the equator. In that case two perpendiculars to the axis would be drawn from the point I in the plane GI ϕd , which is absurd. The plane of the equator, then, drawn through the straight line IG, [Margin: b — 18. undec. — Euclid XI.18] will meet the plane of the inclined dial at the point G of the index-line, and will cut it there; and so through the point G the equinoctial line will be drawn — that is, the common section of the equator and of the plane of the inclined dial.

Now since the plane GI ϕd is at right angles to the equator (because the axis ef, through which it is drawn, is at right angles to the equator, as we have said — which is also established from Proposition 15 of Book 1 of Theodosius, since the plane GI ϕd is drawn through the equator's axis ef and hence through its poles), the equator in turn will be at right angles to the plane GI ϕd . [Margin: c — 19. undec. — Euclid XI.19] But the plane of the inclined dial is likewise at right angles to that same plane GI ϕd , since it has just been shown to be perpendicular to it. Therefore the common section of the equator and of the plane of the inclined dial will also be at right angles to the plane GI ϕd , and consequently — by definition 3 of Euclid's Book 11 — it will be perpendicular to the index-line χd , which lies in that plane. And since, as we have just shown, this common section must be drawn through the point G,

Diagram. A large circular sundial-construction figure (the "sixth figure") occupying most of the page: a bounding great circle with a full set of radial hour-lines that radiate from the construction center and are numbered around the rim with Arabic numerals 1 through 12 (12 at the top, running through the sequence around the circumference). Superimposed on the circle is a smaller semicircular analemma (left of center) and two long axis-lines each labelled **AXIS**, crossing the

field obliquely. The figure combines the analemma construction with the projected hour-lines of a dial that is both declining and inclined.

Clearly-read perimeter and construction labels:

- 12 (top center): the noon / hour-12 marker
- 1, 2, 3, 4 (upper right, clockwise from 12): hour markers
- 5, 6, 7, 8 (continuing around toward the lower right/bottom): hour markers
- 2, 3, 4, 5, 6 (lower left, continuing the ring): hour markers
- B (upper left, on the circle); B (right, on the circle)
- F (upper left, inside near B)
- H (left) and H (upper right): endpoints of a line crossing the field
- G (left of center)
- M (top center, below "12")
- A (left-center) with a small subscript numeral near it
- E (center-left, near the analemma)
- C (lower left, on the circle)
- K, I (lower center): the style-foot and center-of-world points
- I (bottom center) and II (lower right)
- λ (Greek lambda, right of center)
- Additional small interior letters and Greek subscripts near the center (φ , χ , d, e, f region) are too small to resolve individually.

Many peripheral labels and the dense interior lettering cannot be resolved at this resolution

It will be the line GH, drawn perpendicular to χd , that is the common section of the equator and of the plane of the inclined dial — that is, the equinoctial line. And since the point I has been taken as the center of the world, from which the straight line IK falls perpendicular to the plane of the inclined dial (by definition 4 of Euclid's Book 11, because it is drawn perpendicular to the index-line χd , the common section of the plane of the dial and of the plane GIfd, which is at right angles to the dial), the straight line IK will be the length

of the style, and its foot will be at K, a point on the index-line, since no other straight line perpendicular to the plane of the dial, apart from KI, can fall onto the center of the world I, as is evident.

Now if the plane of the circle described from L be understood to be rotated about the equinoctial line GH until its center L is joined to the center of the world I —

and it will indeed coincide with it entirely, because the straight lines GI and GL are equal to each other and each is perpendicular to the equinoctial line, provided the plane GI^{fd} be conceived as at right angles to the plane of the dial — then the straight lines drawn through the center L (which is now the same as the center of the equator) and through the divisions marked off on the circle will be the common sections of the equator and of the hour-circles reckoned from noon or from midnight, just as we showed for the horizontal dial in Proposition 1 of Book 2. For in that position the said circle, having the same center as the equator, lies in the plane of the equator. Now the division of the said circle begins from the

Diagram. A second large circular sundial-construction figure, again captioned as the "sixth figure" and closely resembling the figure on the preceding page: a bounding great circle carrying a full set of radial hour-lines numbered 1–12 around the rim, a semicircular analemma set to the left of the center, and two oblique lines each labelled **AXIS**. It shows the same declining-and-inclined dial construction, here developed for the division of the circle and the drawing of the hour-lines through the center L / the horologium center.

Clearly-read perimeter and construction labels:

- 12 (top center); 1, 2, 3, 4 (upper right clockwise); continuing hour numerals around the rim through the lower right and bottom (...9, 10, 11 read at right and lower right); 3, 4, 5, 6 (lower left)
- B (upper left, on circle); B (right, on circle)
- F (upper left)
- H (upper left) and H (upper right): endpoints of a crossing line
- G (left of center)
- M (top center, below "12")
- L (center): the center of the described circle / horologium center
- A, E (center-left, at the analemma); Y near center
- C (lower left, on circle)
- N (lower center-left)
- K, I (bottom center); I and II (bottom, right of center)
- h (small, top center and bottom center): analemma division marks
- m (lower right, near "12")
- Additional small interior Greek/Latin subscripts near the center are unresolved.

Numerous peripheral hour numerals and the interior lettering cannot be read with confidence at this resolution

straight line LM — the line drawn through the center L and through the point M, where the meridian line and the equinoctial line intersect; or, when the meridian line and the equinoctial do not cut one another but are parallel, the line drawn through L parallel to the meridian line. This is because that line is the common section of the equator and the meridian, that is, of the hour-12 circle, since it meets the plane of the dial at the point M through which the meridian and the equinoctial pass; or else it is parallel to the meridian line, as the reasoning requires, when the meridian line and the equinoctial are parallel — which happens when the plane of the dial is parallel to the great circle that cuts the meridian at the same point where it is cut by the equator. For when on this account the plane of the dial is parallel to the common section of the meridian and the equator (since the great circle to which the plane of the dial is parallel passes through that common section), the common section made by the plane of the dial in the meridian — that is, the meridian line itself — will be parallel to the common section of the meridian and the equator, as is established from the demonstration of Proposition 18 of Book 1.

Since this is so, the hour-circles will cut the plane of the inclined dial at the same points where the straight lines drawn through the center L and the points of division on the circle described from L — being the common sections of the said circles and the equator — meet the equinoctial line. And thus the common sections of those same circles and the plane of the inclined dial, that is, the hour-lines, will have to be drawn through those same points. Since, then, these same lines (by the corollary of Proposition 21 of Book 1) cut one another mutually at the point ρ [?], the center of the dial, or (where there is no center) are parallel to one another, by the corollary of Proposition 22 of the same book, the straight lines drawn through the points on the equinoctial line and through the point ρ [?] — or, where there is no center, drawn parallel to the meridian line — will be the lines of the hours reckoned from noon or from midnight; that is, the common sections of the plane of the dial and of the hour-circles reckoned from noon or from midnight.

Which are the hours from noon and which from midnight can readily be understood if the circle described from L be conceived together with the dial in its proper position, and if those things be carefully considered which we wrote in the scholium to Proposition 1 of Book 2 concerning the intersections of the equinoctial line and of the straight lines of the circle described from L. One must always observe that, if the dial and the said circle are understood in their proper position, the points of division that follow the common section of the meridian and the equator (such as is the straight line LM) toward the west, on the upper

side, give the hours from noon; while the points that follow that same straight line LM toward the east, on the lower side, give the hours from midnight. And since, as we taught in the scholium to Proposition 1 of the

preceding book, the straight lines must first pass through the center L before they meet the equinoctial line, it will be easy to recognize which points of the equinoctial line indicate the hours from noon and which the hours from midnight, [Margin: How to determine which hours are from noon and which from midnight] so that the order of the hours we set out above may be correct. For if we weigh the matter rightly and carefully, we shall find that in dials which face the zenith and look toward the south, the equinoctial line is the section of the plane of the dial and the equator upon which the Sun's rays fall while the Sun is in the semicircle of the equator above the horizon. Hence in those dials the portion of the meridian line that cuts the equinoctial line will indicate the 12th hour of noon; and the lines toward the eastern parts will show the hours after noon — namely those which, when we turn to face the dial, lie on our right. The same holds for dials that face the zenith and look toward the north and have the equinoctial line below the center of the dial, except that the eastern parts lie on our left when we turn to face them. But in dials facing the zenith which look toward the north and have the equinoctial line above the center of the dial, the equinoctial line is the common section of the equator and the plane of the dial upon which the shadows fall while the Sun is in the semicircle of the equator below the horizon. Therefore in these dials the portion of the meridian line that cuts the equinoctial line will show the 12th hour of midnight, and the lines toward the western parts — which lie on our right when we turn our face to the dial — will give the hours after midnight, as we said above.

But if from F there be drawn straight lines making, with EF (the line of declination, which we showed to be the meridian line in a horizontal dial), the same angles that the hour-lines make with the meridian line in a horizontal dial — namely the line of the 6th hour, such as Fa, a right angle with FE, and so on — [Margin: Another method of drawing the hour-lines from the horizontal dial] then the straight line AB will be cut at the points through which the lines drawn out from the center ρ [?] — or, where there is no center, drawn parallel to the meridian line — will give the hour-lines, as before, just as we demonstrated in Proposition 1 of this book. On this matter see what we wrote there concerning the perpendicular Fa, so that by means of it, or of some other line drawn out from F, the division of the circle described from L may be rightly established, as we also advised above in this proposition.

Another way. We shall also construct this same dial, both declining and inclined, after the fashion of a horizontal dial, just as we did in the declining dial reckoned from a vertical in Proposition 1 of this book, by the following art. [Margin: Another construction of a dial at once declining and inclined] First, let a portion of the analemma be set up, as in Proposition 1 of the preceding book, in which are contained the common sections, with the horizon and with the vertical and the equator and so forth, of the proper meridian of the declining-and-inclined plane itself. (The great circle to which the plane of the declining-and-inclined dial is parallel plays the role of the horizon, and another great circle cutting it at right angles and passing through the common sections of the equator and the said horizon serves as the vertical circle.) This is done so that the arc CE may measure the elevation of the pole above the declining-and-inclined plane, and the straight line DG be taken equal to the style of the declining-and-inclined dial, of whatever magnitude, and so on. In our example, which we have fitted to the sixth figure — near which we have drawn the said portion of the analemma — the arc CE contains $66^{\circ}47'$; for this is very nearly the elevation of the pole found above that inclined plane, and the straight line DG has been taken equal to the style IK of the same dial. [Margin: The elevations of the pole above the planes of the six figures of this proposition [?]] In the first figure the same arc CE, if a portion of the analemma be constructed to answer to that figure, will contain $25^{\circ}43'$; in the second, $25^{\circ}18'$; in the third, $0^{\circ}0'$; in the fourth, $68^{\circ}13'$; and finally in the fifth, $27^{\circ}50'$. For these are very nearly the elevations of the pole found above those inclined planes, according to the doctrine of Proposition 29 of Book 1.

After this, let the straight lines GN and GH be drawn cutting one another at right angles in G, of which GN represents the common section of the plane of the dial and the proper meridian of that plane — after the manner of a certain meridian line, in which the style is to be placed — and GH represents the equinoctial line; just as in the horizontal dial the straight line HE is the meridian line, that is, the common section of the plane of the dial and the meridian, in which the style is set, while the straight line FK serves as the equinoctial line. [Margin: What the arc of the meridian is between the horizon and the inclined plane [?]] Now onto the straight line GN — which is like a meridian line, taken in the inclined plane in place of some horizon — the straight line HI is to be transferred, which in the portion of the analemma lies between the axis and the diameter of the equator; measuring it off from the equinoctial line at the point G up to the point ρ [?], so that the center of the dial may be obtained — just as in the horizontal dial, on the straight line HE, the line IH between the equinoctial line and the center of the dial is equal to the straight line HI in the portion of the analemma. But since in these dials that are at once declining and inclined the center ρ [?] lies sometimes below

the equinoctial line and sometimes above it, in order to know when the center lies below it — and the line HI must accordingly be transferred below it, so that we may obtain the center ρ [?] — and when above, and so on, we must investigate, by Proposition 28 of Book 1, the arc of the meridian intercepted between the inclined plane and the horizon. For once this is known, what is sought will be attained without any trouble. [Margin: [illegible marginal note — several lines partly abraded; [?]]] In the first figure we found this arc, on the northern side above the horizon, to be $15^{\circ}35'$; in the second, $68^{\circ}30'$; in the third, $4^{\circ}6'$, so that the plane of this figure passes through the pole. Again, in the fourth figure we found the same arc, on the southern side above the horizon, to be $28^{\circ}29'$; in the fifth, $72^{\circ}57'$; and finally in the sixth, $48^{\circ}0'$, so that the plane of this figure passes through that point of the meridian where it is cut by the equator.

If, then, the plane be inclined toward the horizon on the northern side, and the arc of the meridian placed between it and the horizon be smaller than the elevation of the pole above the horizon, the portion of the analemma, the straight line HI, is to be taken and transferred onto the line GN from G downward, below the equinoctial line, up to the point ρ [?], which will be the center of the dial; for then the center of the dial lies below the equinoctial line, as is seen in the second figure, because then the axis of the world meets the upper face of the plane of the dial above the horizon on the southern side, just as in the horizontal dial.

[Margin: When the center of the dial lies below, and when above, the equinoctial line [?]] But if the plane be raised above the horizon on that same northern side, and the arc of the meridian placed between it and the horizon be greater than the elevation of the pole above the horizon, the straight line HI is to be transferred from the portion of the analemma onto the line GN on the upper side, and the center of the dial will be above the equinoctial line; for then the center of the dial lies above the equinoctial line, because then the axis of the world meets the upper face of the plane of the dial from the upper, that is northern, parts, so that with the line of the style described on that face it makes an acute angle toward the opposite pole, that is, toward the lower parts, as happens in the southern vertical dial.

Finally, if the plane is raised above the horizon on the same northern side, and the arc of the meridian lying between it and the horizon is equal to the elevation of the pole — so that the plane passes through the poles of the world — then the dial will have no center, as happens in the third figure. In that case nothing is to be transferred; the dial must instead be constructed by another method, as we shall show a little below.

If the plane is inclined toward the horizon on the southern side, and the arc enclosed between it and the horizon is smaller than the complement of the pole's elevation above the horizon, then the same straight line HI, taken from the portion of the analemma, must be transferred onto the line GN — from G, above the equinoctial line, up to the point ρ [?]. This point ρ [?] will be the center of the dial, lying above the equinoctial line, as may be seen in the fourth figure; for then the axis of the world meets the upper face of the plane of the dial above the equinoctial line, toward the upper — that is, southern — parts, just as in the horizontal dial.

Lastly, if the plane is inclined toward the horizon on that same southern side, and the arc of the meridian enclosed between it and the horizon is equal to or greater than the complement of the pole's elevation above the horizon, then the straight line HI, from the portion of the analemma, must be transferred onto the line GN — from G, below the equinoctial line, up to the point ρ [?]. This point will be the center of the dial, lying below the equinoctial line, as appears in the last two figures. For when the said arc is equal to or greater than the complement of the pole's elevation, the axis of the world cuts the upper face of the plane of the dial toward the lower, or northern, parts, so that with the style-line drawn on that face it makes an acute angle toward the arctic pole — that is, toward the upper parts — as usually happens in the northern vertical dial.

These same things are gathered even more clearly than daylight from those four analemmas set out in Proposition 27 of this book. [Margin: By what reasoning, from the four analemmas set out in Proposition 27 of this book, it may be known when the center of the dial is below the equinoctial line and when above.] For suppose that in the first two analemmas, on the northern side, the arc DK is taken equal to the arc of the meridian lying between the plane and the horizon; while in the latter two, on the southern side, the arc BK is set equal to that same arc of the meridian between the plane and the horizon. Then the straight line KL will be the common section of the meridian and of the great circle to which the plane of the dial is parallel. Therefore MN, parallel to KL, will be the common section of the meridian and of the plane of the dial (which is parallel to that great circle) — that is, the meridian line in the inclined dial. For the meridian, cutting the said great circle and the plane of the dial parallel to it, makes parallel sections. Hence, where the axis of the world FG cuts the straight line MN at M, there will lie the center of the dial on the meridian line; and the point N, on that same meridian line, will be the point through which the equinoctial line is drawn, since at that point the Equator cuts the meridian line.

From this it also follows that if the portion of the axis EM is taken equal to the portion of the axis ρI [?] — the portion, in the dials treated above, between the center of the world I and the center of the dial ρ [?], where the axis of the world cuts the meridian line — and if through M the line MN is drawn parallel to KL (provided the arc DK or BK is equal to the arc of the meridian found between the plane and the horizon), [Margin: (a) Euclid, *Elements* XI.16] cutting the diameter of the Equator, then MN is equal to the straight line ρM [?] — that is, to the portion of the meridian line between the center of the dial and the point M of the equinoctial line — while the straight line EN is equal to that line in the dial which falls from the apex of the style (that is, from the center of the world I, set on high) onto the point M.

For just as the triangle EMN is set up in the analemma out of the axis EM, the common section of the meridian and the inclined plane of the dial MN, and the common section of the meridian and the Equator EN, so too in the dial the triangle ρMN [?] — lying in the plane of the meridian, if the axis ρI [?] is understood in its proper position (for the meridian passes through the axis ρI [?] and through the point M) — is composed of the same lines, and is altogether equal to that first triangle. For the angle EMN in the analemma, which the axis makes with the meridian line of the dial, is equal to the angle $I\rho M$ [?] in the dial, which the axis (if placed in its proper position) makes with the meridian line; and the angle MEN is a right angle equal to the right angle ρIM [?]. [Margin: (b) Euclid, *Elements* I.26] (For the Equator cuts the axis at I at right angles, and therefore, by Definition 3 of Book XI of Euclid, the axis makes right angles with the straight line IM lying in the Equator.) The straight line EM, moreover, is set equal to the straight line $I\rho$ [?]; therefore the straight line MN too will equal ρM [?], and the straight line EN will equal IM.

Now the analemmas themselves plainly indicate whether the center of the dial is below the equinoctial line or above it. For since in the first and fourth analemma the center M, on the meridian line MN of the dial, lies [below [?]] the point N — through which the equinoctial line must be drawn — while in the other two intermediate analemmas it lies above that same point N, it comes about that this center lies below the equinoctial line in the [first [?]] two and [above [?]] it in the [latter [?]] two. For when the center of the dial on the meridian line lies below or above the point N of the equinoctial line, that same center necessarily lies also below or above it on the style-line GN. For since the equinoctial line cuts the style-line GN at right angles, it plainly follows that if the equinoctial line cuts the meridian line above or below the center, it likewise cuts the style-line GN above or below the center — as is clear from the figures set out above.

But if the arc of the meridian between the plane and the horizon is equal to the complement of the pole's elevation on the southern side — so that the common section of that plane and the meridian in the analemma is the same as the common section of the meridian and the Equator, HI — then the axis FG will cut the meridian line of the dial (the line drawn in the analemma) at right angles to HI itself. [Margin: (c) Euclid, *Elements* I.29] And thus the style-line GN too will be perpendicular to that same meridian line in the dial; and the diameter of the Equator, in the same analemma, will not cut the meridian line of the dial, that is, the common section of the meridian and the plane of the dial. [Margin: (d) Euclid, *Elements* I.29] Hence in the dial the meridian line and the equinoctial line will be parallel to one another. [Margin: In what kind of dial the equinoctial line and the meridian line are parallel to one another.] All this we shall confirm as follows. Since the three circles — the Equator, the meridian, and the great circle to which the dial is parallel — have one and the same common section HI in the analemma, while the plane of the dial is parallel to one of them and thus to this common section, the common sections which the remaining two circles (namely the Equator and the meridian) make in the plane of the dial will be parallel, by Proposition 18 of Book 1; and such are the equinoctial line and the meridian line. Therefore, since the style-line pG [?] cuts the equinoctial line at right angles, it will cut the meridian line too at right angles. Nevertheless the center of the dial will still lie below the equinoctial line, as appears in the sixth figure.

Finally, if the arc of the meridian between the inclined plane and the horizon is equal, on the northern side, to the elevation of the pole — so that the common section of the plane and the meridian does not differ from the axis FG — then it is evident that the dial has no center, because the axis cannot cut the meridian line, indeed cannot cut the plane of the dial itself, since it is parallel to the great circle drawn through the axis. Rightly, then, have we prescribed that the straight line HI, from the portion of the analemma, be transferred onto the line GN (which is the style-line in the dial) — sometimes below the point G, sometimes above it — up to the point p [?], and so on. [Margin: What kind of dial lacks a center.]

Having found the center p [?] of the dial by this method — which is sometimes below the equinoctial line, sometimes above it, as we have taught — we shall proceed further in the construction of the dial in the following way. From the portion of the analemma let the straight line DI be taken, namely the portion of the section of the Meridian and Equator intercepted between D, the center of the world, and the straight line HI; and let it be transferred onto the straight line GN, from the point G — either upward or downward — up to the point L, from which let a circle of any size be described, and let this circle be divided into 24 equal

parts. But the division must not be begun here from the straight line GN, as in the horizontal dial it begins from the line HE; for the line GN is not here the meridian, as HE is there, but the common section of the plane of the dial and of the great circle passing through the poles of that plane and the poles of the world — serving as a proper meridian of that plane, which is not the meridian of the horizon. Hence it comes about that the straight line GN, in the circle described from L, cannot be the common section of the Equator and the meridian of the horizon itself, if the circle described from L is understood to be set in its proper position — just as, in the horizontal dial, the straight line IE, in the circle described from E, is the common section of the meridian and Equator, if the said circle has its proper position, as we there showed. Hence, since the division of the said circle described from L must take its beginning from the said common section of the meridian and Equator — namely from the 12th hour — as was done in the horizontal dial, we shall find this section, or line of the 12th hour, in the aforesaid circle by the following method. Let there be sought, by Proposition 30 of Book 1, the inclination of the proper meridian of the plane itself to the meridian of the horizon; and this we found to be, in the first figure, $14^{\circ}10'$; in the second figure, $20^{\circ}52'$; in the third, $33^{\circ}47'$; in the fourth, $27^{\circ}30'$; in the fifth, $75^{\circ}46'$; and finally in the sixth, $90^{\circ}0'$. For this inclination must be counted from the point N, in the circle described from L, up to the point O, observing the following rule.

[Margin: Quænam sit inclinatio Meridiani proprii ipsius plani inclinati ad Meridianum Horizontis in qualibet sex figurarum huius propositionis. — "What the inclination of the plane's proper meridian to the meridian of the horizon is, in each of the six figures of this proposition." (Stage-5 recovery)]

If the plane is inclined toward the horizon on the northern side — that is, if its upper face declines from the south toward the east or the west — then, in the case where it declines from the south toward the east, the said inclination of the meridians must be counted from the point N toward the left, that is, toward the western parts, as was done in the first and third figures. For then the great circle drawn through the poles of the horizon and the poles of the inclined plane (the circle that measures the inclination to the horizon) falls, on the south side, into the eastern quadrant of the upper hemisphere. [Margin: Quænam sit arcus circulorum maximorum inclinationes planorum metientium, inter Horizontem & circulum horæ 6. à meridie vel media nocte interiecti. (Stage-5 recovery)] (We call "quadrants of the upper hemisphere" those parts contained between the meridian, the horizon, and the vertical circle properly so called. For these three circles, cutting one another mutually at right angles, divide the whole upper hemisphere into four equal parts, of which two are southern — one eastern, the

other western — and two northern — one eastern, the other western — as is clear from the material sphere.) Then the pole of the inclined plane will lie in that same quadrant above the horizon. For since the arc of that great circle drawn through the zenith of the place and the pole of the inclined plane, lying between the plane and the zenith, is less than a quadrant, while the arc of the same great circle extended from the plane through the zenith down to the horizon is greater than a quadrant — because the arcs of the said great circle intercepted between the zenith and the horizon are quadrants — it is evident that the pole of the inclined plane, which bounds the quadrant of the said great circle by which the pole of the plane is distant from the plane itself (by the corollary of Proposition 16 of Book 1 of Theodosius), falls into the eastern and southern quadrant of the upper hemisphere. Therefore the meridian of the horizon will be more westerly, in the Equator above the horizon, than the proper meridian of the inclined plane drawn through its poles and through the poles of the world. And accordingly, since — with the circle described from L set in its proper position — the proper meridian of the inclined plane cuts the said circle above the horizon at the point N, the inclination of this meridian to the meridian of the horizon must be counted from N toward the western parts, up to the point O, through which the meridian of the horizon passes.

In this case the pole of the inclined plane EF falls below the six-o'clock circle BKD, because the arc HM between the pole of the plane and the horizon is smaller than the arc HL between the six-o'clock circle and the horizon; if it were equal, the pole would fall on L, and if greater, above it. [?] For since GIH is a semicircle (by Proposition 11 of Book 1 of Theodosius), and the arc [MN [?]] between the plane and its pole is a quadrant (by the corollary of Proposition 16 of Book 1 of Theodosius), the two remaining arcs GN [?] and MH will together be equal to a quadrant. Therefore, since GN [?] is the arc of the inclination, the arc MH set between the pole of the plane and the horizon will be

the complement of the inclination. Hence, once the inclination of the plane to the horizon is known, if it is subtracted from a quadrant, the aforesaid arc between the pole of the plane and the horizon will remain. By this device such an arc was found, in the fourth figure of this proposition — for in the first three figures, since their planes have their poles on the southern side of the upper hemisphere, we do not need the said arcs — to be $60^{\circ}0'$; in the fifth, $10^{\circ}0'$; and finally in the sixth, $37^{\circ}57'$. If these arcs are compared with the earlier ones placed between the six-o'clock circle and the horizon, we shall find that the pole of the inclined plane, in the fourth figure, falls above the six-o'clock circle; in the fifth, below it; and finally in the sixth, on the six-o'clock circle itself.

Once these things have been thoroughly investigated: if the plane inclined to the horizon on the southern side declines from the north toward the west, and its pole falls above the six-o'clock circle, while the center of the dial lies above the equinoctial line — as happens in the fourth figure — then the aforesaid inclination of the meridians must be reckoned from N toward the eastern parts, that is, toward the parts which lie to our left if we turn to face the plane of the dial, up to the point O, from which the division of the circle described from L is to be begun. For since then the great circle drawn through the poles of the horizon and the poles of the plane falls, on the north side, into the western quadrant of the upper hemisphere, and its pole lies above the six-o'clock circle, the proper meridian of the plane will cut the Equator above the horizon in the western quadrant — namely between the meridian of the horizon and the six-o'clock circle. Therefore the meridian of the horizon will be more easterly, in the Equator above the horizon, than the proper meridian of the inclined plane; and accordingly, since — with the circle described from L set in its proper position — the proper meridian of the inclined plane cuts the said circle above the horizon at the point N, the inclination of this meridian to the meridian of the horizon must be computed from N toward the east, so that the point O may be found, through which the meridian of the horizon passes. But if, everything else remaining the same, the center of the dial turns out to lie below the equinoctial line, then the same inclination of the meridians must be counted from N toward the western parts, that is, toward the right; because then the meridian of the horizon, in the Equator below the horizon, is more westerly than the proper meridian of the inclined plane — whereas (as we said) above the horizon it is more easterly. Therefore, since — with the circle described from L set in its proper position — the proper meridian of the inclined plane cuts the said circle at N below the horizon (a thing easily understood if the fourth figure be inverted, so that the center ρ [?] lies below the equinoctial circle, and the circle NO takes on its proper position, its center L being joined to the center of the world I), the said inclination of the meridians must be computed toward the west from the point N.

But if the pole of the same plane — inclined to the horizon on the southern side and declining from the north toward the west — falls precisely on the six-o'clock circle, then, wherever the center of the dial may lie, the said inclination of the meridians will amount to 90° , since the proper meridian of the plane is then the same as the six-o'clock circle, which in the Equator is removed a quadrant from the meridian of the horizon. Therefore, into whichever direction the said inclination is counted from the point N, the point O will be found, from which the division of the circle described from L can take its beginning.

Finally, if the pole of the same plane falls below the six-o'clock circle, while the center of the dial lies above the equinoctial line, then the same inclination of the meridians must be reckoned from N toward the western parts. For since then the pole of the inclined plane, below the six-o'clock circle, lies in the northern and western quadrant of the upper hemisphere, the proper meridian of the plane will cut the Equator below the horizon in the western quadrant, but above the horizon in the eastern quadrant. Hence the meridian of the horizon, in the Equator above the horizon, will be more westerly than the proper meridian of the inclined plane. For this reason the inclination of the meridians must be counted from N toward the western parts, since the proper meridian of the plane cuts the circle NO above the horizon at N. But if, everything else remaining the same, the center of the dial turns out to lie below the equinoctial line, then the same inclination of the meridians must be counted from N toward the eastern parts; because then the proper meridian of the plane cuts the circle NO at N below the horizon, and there the meridian of the horizon is more easterly in the Equator, or circle NO, below the horizon, as is clear from what has been said.

But if the plane inclined to the horizon on the southern side deflects from the north toward the east, then let everything be done in exactly the opposite way to what we have just prescribed as to be observed in planes declining from the north toward the west. Thus you see that in the fifth figure the inclination of the meridians has been counted from N toward the western parts, up to O — because the pole of that plane falls below the six-o'clock circle, and the center of the dial is found below the equinoctial line. The reason for this can easily be gathered from what has been said. And finally, in the sixth figure the inclination is reckoned as the same 90° , because there the pole of the plane falls precisely on the six-o'clock circle itself, and so on.

Therefore, if through the points of division of the circle described from L, and through the center L, straight lines are drawn (left invisible), the equinoctial line GH will be cut at points through which the lines led out from the center of the dial ρ [?] will give the hours from noon or from midnight, as we demonstrated in the horizontal dial — but in such a way that the straight line drawn from ρ [?] through the point M of the equinoctial line, onto which the line OL falls, shall (in all dials that face the zenith and the south, and in those that face the zenith and the north, provided the center is above the equinoctial line) mark the 12th hour of midday; and the lines following it in the dial, toward the eastern parts — namely those which, when the dial is set in its proper position, turn toward the rising of the sun, and so on — shall mark the hours from noon, and so on. But in the dials that pertain to the zenith and the north and have their center below the

equinoctial line, that same straight line pM [?] shall signify the 12th hour of midnight, and those following it toward the western parts shall show the hours from midnight, and so on. Finally, in the dial where the inclination of the proper meridian to the meridian of the horizon amounts to 90° , the straight line ρ [?], drawn parallel to the equinoctial line toward the upper parts, shall likewise mark the 12th hour of midnight, while the lines following it toward the west shall indicate the hours from midnight, and so on. The reason for this was given above in the earlier description.

When the plane of the dial is inclined to the horizon on the northern side, under this condition — that the arc of the meridian between the plane and the horizon is equal to the elevation of the pole above the horizon, and accordingly is parallel to the axis, as happens in the third figure — we shall construct the dial upon it as follows. Having drawn the straight lines GN and GH cutting one another at right angles in G , as before, we shall take on GN — whether above the straight line GH or below it — the straight line GL , of any size, to serve as the style; and from L we shall describe a circle. Then, having computed from the point N , where the straight line GN cuts the said circle, the

the inclination of the proper meridian of the proposed plane to the meridian of the horizon — toward the western parts, that is, if the dial declines from the meridian toward the east, or toward the eastern parts if the dial deflects from the meridian toward the west. Let the circle described from L be cut, up to the point O , into 24 equal parts, beginning at the point O . For lines correctly drawn from the points of division through the center L will cut the equinoctial line GH at points; and if through these points lines are drawn perpendicular to GH — as in the meridian dial, or the polar one — the lines of the hours from noon or from midnight will be obtained. This must be done in such a way, however, that the straight line through the point M of the equinoctial line, onto which the straight line OL falls, marks the 12th hour of midday, while the lines following it toward the east show the hours from noon, and so on.

Another construction of the same declining and inclined dial. [Margin: Another construction of the same dial, at once declining and inclined.] We may also describe this same declining and inclined dial in the following way. Find, by Proposition 30 of Book I, the arc of the proposed plane intercepted between the meridian of the horizon and its own proper meridian; then, by Proposition 29 of the same Book I, the elevation of the pole above the proposed plane. The elevations of the pole above the planes of the six figures of this proposition were already set out at the beginning of the preceding construction; and the arc of any

given proposed plane lying between the said meridians stands as follows.

[Margin: How great the arc of the proposed plane, lying between its own meridian and the meridian of the horizon, is in each of the six figures of this proposition.] In the first figure the said arc contains $6^{\circ} 15'$; in the second, $9^{\circ} 15'$; in the third, $0^{\circ} 0'$; in the fourth, $61^{\circ} 30'$; in the fifth, [figure-value not legible: ?]; in the sixth, finally, $90^{\circ} 0'$.

Next, in some plane let the straight line $\rho\varsigma$ be drawn in any way whatever [ρ and ς = special typographic point-markers as printed; see QA], to serve as the line of the 12th hour. In it take any point ρ as the center of the dial, and from that point describe the arc of a circle $a b$ — above the point ρ if the center of the dial falls below the equinoctial line, but below the point ρ if the center is to be placed above the equinoctial line. When the center of the dial falls below, or above, the equinoctial line has been set out amply enough in the preceding construction, and can be understood most plainly from those four Analemmas of Proposition 25 of this book. For in them the straight line MN is the meridian line, that is, the line of the 12th hour, in the upper dials. Hence, if from the given declination of the plane and its inclination the arc of the meridian between the plane itself and the horizon is found — namely DK or BK — it will easily be gathered whether the center of the dial (that is, the point M onto which the axis FG falls) lies below the equinoctial line, which passes through the point N , or above it, on the meridian line MN itself, and therefore on the meridian line $\rho\varsigma$ of the dial to be described. Now in the arc $a b$ let there be counted, from the straight line $\rho\varsigma$ — that is, from the point ς — the arc found between the meridian of the horizon and the meridian of the proposed plane, up to b ; and let the straight line ρb be drawn, which will be the common section of the plane of the dial and of its own proper meridian, as will presently be shown.

To know toward which side the said arc is to be counted, the things we handed down in the preceding construction must be carefully considered. For in planes that are inclined to the horizon on their northern side, if indeed they decline from the meridian toward the east, as in the first figure, the said arc is to be reckoned toward the left — that is, toward the western parts, which, when we are turned to face the dial, lie on our left — because in that case the proper meridian of the plane is more easterly than the meridian of the horizon; and consequently its common section in the plane of the dial, namely the straight line ρb , will be more westerly than the meridian line $\rho\varsigma$, since the shadow of the style, with the Sun in whatever circle it may be, is always cast toward the opposite side, as is clear from what has been said. But if planes of this kind deflect from the

meridian toward the west, exactly the opposite must be done, for the opposite reason as well, as was done in the second figure.

In planes inclined to the horizon on their southern side, on the other hand, one must learn from what we taught in the preceding construction whether the proper meridian of the plane, above or below the horizon, is more easterly or more westerly than the meridian of the horizon; for the said arc $a b$ is always to be reckoned toward the opposite side. Thus you see that in the fourth figure the said arc is counted toward the left, that is, toward the east, because the proper meridian of that plane is more westerly, above the horizon, than the meridian of the horizon. In the fifth figure, by contrast, the same arc is reckoned toward the right, that is, toward the western parts, because the proper meridian of that plane, below the horizon, is more easterly than the meridian of the horizon. In the sixth figure, finally, it makes no difference whether the said arc $a b$ is counted toward the one part or the other, because it comprehends 90° , so that the straight line pb makes a right angle with $p\phi$ at the point p .

After this, from any point of the straight line pb — say from G — let the perpendicular GH be drawn to it; this will be the equinoctial line, because, as we shall presently show, pb is the index-line (the edge of the style), to which the equinoctial line is necessarily perpendicular, as we demonstrated above.

Next, at the point p , upon the straight line pb , construct the angle GpI equal to the elevation of the pole above the proposed plane, found by Proposition 29 of Book I, so as to obtain pI , the axis of the world. To this axis, from the point G , raise the perpendicular GI ; and let the rest be done as in the first construction — that is, let the straight line GI be taken equal to GL , and let the circle described from L be cut into 24 equal parts, beginning from the straight line LM , which is drawn from the center L through the point M , where the equinoctial line and the meridian pb intersect one another; or else from the line drawn through L parallel to the meridian line, when the equinoctial line and the meridian are parallel, as in the sixth figure, and so on. The gnomon will be IK , the perpendicular let fall from I to pb , as before.

That the straight line pb is the common section of the plane of the dial and of the proper meridian of that same plane we shall demonstrate as follows. Since the meridian of the horizon and the proper meridian of the plane are both drawn through the axis of the world, and both meet the great circle to which the dial is parallel at the center of the world — namely at I , the vertex of the style — the said meridians make with this great circle common sections that are straight lines containing at the center an angle subtended by the arc of that great circle

intercepted between those meridians. But since these same meridians meet the plane of the dial at the point ρ , where the axis meets that same plane, [Margin: Euclid XI.16] and make with it common sections that are straight lines parallel to the two former lines in the great circle — because the plane of the dial is parallel to that great circle — [Margin: Euclid XI.10] these lines will contain, in the plane of the dial, an angle equal to that which those former lines contain in the great circle. Therefore, since the angle apb in the plane of the dial is equal to that in the great circle — because the arc a b is similar to the arc of that great circle placed between the two meridians, seeing that by construction it contains just as many degrees and minutes — and since $\text{p}\rho$ is set as the meridian line, pb will be the common section of the plane of the dial and of its own proper meridian. Consequently the style must be set upon it at right angles, since by this arrangement the style does not depart from the plane of this proper meridian, but reaches to the axis of the world lying in it. Therefore pb is the index-line, the line of the style. From this the rest of the construction will be demonstrated, just as the first construction of this proposition. But this third description we shall be able to begin from another starting point, and perhaps more conveniently than we have handed it down, as we shall make almost plain toward the end in the following Scholium.

[Margin: When the plane of the dial is parallel (equidistant).] Furthermore, on a plane inclined to the horizon on its northern side, one that has no arc interposed between the said two meridians and receives no elevation of the pole — as happens in planes that are parallel to the great circles drawn through the axis of the world, such as the plane of the third figure — the dial will have to be constructed as in the preceding construction; or else, if first any straight line Ep is drawn in any way as the meridian line, one must proceed thus. Upon Ep , at any point, say at M , raise the perpendicular MH to serve as the equinoctial line. Then at M construct the angle EML of the inclination of the proper meridian of that plane to the meridian of the horizon, found by Proposition 30 of Book I — toward the left if the plane declines from the meridian toward the east, toward the right if it declines from the meridian toward the west. Taking on the straight line ML any point L you please, draw through it the line LG parallel to Ep , cutting the equinoctial line at G ; this will be the common section of the proper meridian and the plane of the dial, and LG itself will be the length of the gnomon. Then, having described a circle from L and divided it into 24 equal parts, beginning from the straight line ML , if from the points of division straight lines are drawn through L , the equinoctial line will be cut at points through which the hour-lines are to be drawn perpendicular to the equinoctial line and parallel to one another, as before. For by this method a dial of this kind will be described in no other way

than in the preceding construction, where the line of the style GN was first drawn — [Margin: Euclid I.29] because the angle NLO is equal to the angle EML of the inclination of the meridians, the external being equal to the internal. Therefore we have constructed an astronomical dial that both declines from the vertical and is inclined to the horizon, and so on. Which was to be done.

Scholium

We have completed this whole description of a dial declining from the vertical and at the same time inclined to the horizon in six figures, so that every variety in dials of this kind might be laid open. Of these, the first three pertain to those upper dials that face the south, in which the center of the dial is either below the equinoctial line, or above it, or else all the hour-lines are parallel, cutting the equinoctial line at right angles, and the dial has no center. The latter three represent those upper dials that face the north, in which the line of the 12th hour, or meridian line, cuts the equinoctial line either below the center of the dial, or above it, or else is parallel to the equinoctial line itself. Moreover, in the first, third, and sixth figures we have drawn all the delineations of the hours, but in the intermediate figures only those that are required for understanding the construction, the hour-lines being omitted so as to avoid confusion of lines. For anyone can easily draw the hour-lines in these figures, as in the others, if he considers attentively and diligently the precepts we have handed down.

[Margin: By what method the dial that both declines and is inclined is to be positioned.] Now we shall place the dial hitherto delineated in its proper position. In the earlier description, the straight line AB must be parallel to the horizon, with the point A on the left and B on the right, and the common section of AB and the horizon must make, with the meridian line in the plane parallel to the horizon (found as before), an angle equal to the complement of the declination — toward the south and west if the plane of the dial declines from the meridian toward the east; toward the south and east if from the meridian toward the west; but toward the north and west if the plane declines from the north toward the east; and toward the north and east if it deflects from the north toward the west. For thus the dial will obtain its due declination. Next, the straight line CD, with the line in the plane of the horizon that cuts the common section of the dial and the horizon at right angles, must make an angle of the inclination toward the northern parts if the dial faces the south, but toward the southern parts if it faces the north. For when the dial is set up in this way, if a thread be stretched — or some fine wire — along the axis ρI in the triangle $\rho I G$, or along the axis ef in the rectangle $efd\chi$ where there is no center, at right angles to the plane of the dial, its

shadow will mark each of the hours from noon or from midnight, as long as the Sun illuminates the dial; or else the vertex l of the style lK , standing at right angles to the plane of the dial at the point K , will do the same, as was said of the horizontal dial in the scholium of Proposition 1 of the preceding book. The axis pl , or ef , will likewise do the same, if the triangle pIG , or the rectangle $efd\chi$, be constructed of some solid material and set up at right angles to the plane of the dial.

[Margin: How great the arc of the inclined plane, lying between the meridian of the horizon and the great circle that measures the inclination of the plane, is in each of the six figures of this proposition.] But if the dial has been constructed by the two later descriptions, one must seek, by Proposition 31 of Book I, the arc of the proposed plane to which the dial is parallel, intercepted between the meridian of the horizon and the great circle that measures the inclination of the plane to the horizon. This arc, in the first figure, comprehends $38^{\circ} 15'$; in the second, [degrees not legible: ?] $6'$; in the third, $31^{\circ} 42'$; in the fourth, $17^{\circ} 30'$; in the fifth, $16^{\circ} 46'$; in the sixth, finally, $19^{\circ} 33'$. Then from any point of the meridian line, that is of the line of the 12th hour — say from E — describe the circle $m h$ on the upper side, and in it count from m the arc found, up to b : toward the left if the dial declines from the meridian toward the east, or from the north toward the west; but toward the right if the dial declines from the meridian toward the west, or from the north toward the east — because in the former case the great circle measuring the inclination of the plane recedes from the meridian, above the horizon, toward the left, but in the latter toward the right, as is plainly evident if the said circles and the plane of the dial are correctly set up in their positions. But if the arc $m h$ is described on the lower side, exactly the opposite must be done in the counting of the said arc, as is manifest, and as you see has been done in the figures. From b , then, draw through E the straight line hE , which will be the common section of the plane of the dial and of the great circle measuring its inclination to the horizon. For if from E one imagines the common section of the meridian and of the said great circle raised aloft to the center of the world, these two circles will make, with the great circle to which the dial is parallel, two common sections which are straight lines making at the center of the world the angle found by Proposition 31 of Book I. But since these same two circles meet the plane of the dial at E , where their common section meets that same plane, and make with it two common sections which are straight lines [Margin: Euclid XI.16] parallel to those in the great circle — because the plane of the dial is parallel to that great circle — [Margin: Euclid XI.10] these two lines will contain, in the plane of the dial, an angle equal to that which those former lines contain in the great circle. Therefore, since the angle mEh is equal to it — because the arc $m h$ is

similar to the arc of that great circle intercepted between the meridian of the horizon and the great circle measuring its inclination to the horizon, seeing that it embraces just as many degrees and minutes — and since mE is set as the meridian line, that is, the common section of the meridian and the plane of the dial, hE will be the common section of the plane of the dial and of the great circle measuring its inclination. And if through E , to hE , the perpendicular AB is drawn, this will be the common section of the plane of the dial and of the horizon drawn through E . For since both the horizon and the plane of the dial cut the straight lines that each measures, and cut the great circle that measures the inclination of the dial, making with it the section hE , their common section too will be, at the same great circle — and therefore, by Definition 3 of Book XI of Euclid, also perpendicular to hE , the common section of the said great circle and the plane of the dial, just as AB is. And so, if again AB is set parallel to the horizon and the rest is done as we said a little before, the dial will obtain its proper position.

[Margin: Euclid XI.16] [Margin: Euclid XI.10]

But if a dial is to be described on the inclined wall itself, and not on some other plane from which it must afterward be transferred onto the inclined wall — as we have done hitherto — it will be effected in this way. On the inclined wall itself let the straight line AB be drawn parallel to the horizon by means of the level and the plumb-lines,

[Margin: By what method a dial declining and at the same time inclined is to be described on a fixed plane.]...and let another straight line CD cut it at right angles at the point E . Let the rest be done as we prescribed in the earlier description — that is, let the declination line EF be drawn, and let the meridian line $E\epsilon$ [?] be found, which we shall discover in this way as well. From E describe the arc of a circle $b m$ toward the upper part, and in it count up to m the arc of the inclined plane between the meridian of the horizon and the great circle that measures the inclination of the plane, found by Proposition 31 of Book I — toward the right if the dial declines from the meridian toward the east, or from the north toward the west; but toward the left if the plane of the dial deflects from the meridian toward the west, or from the north toward the east. For the straight line mE will be the meridian line, namely the common section of the meridian and the plane of the dial. This we shall prove no otherwise than has just been shown — namely that the straight line bE is the common section of the plane of the dial and of the great circle measuring its inclination to the horizon — from the fact that mE was set as the meridian line, and so on. Or else by this same method we shall draw the

same meridian line, as appears in the fourth figure; for in the others, to avoid confusion of lines, we do not give an example.

Having drawn the straight line AB parallel to the horizon, let there be set beside the inclined plane some plane parallel to the horizon, so that the common section of it and the inclined plane is AB. As now, for example, in the said fourth figure, let the plane below the straight line AB be understood to be parallel to the horizon, and the plane above that same AB to be inclined to the horizon. Then in the plane that is parallel to the horizon, find, by what we taught in Book I in the scholium of Proposition 23, the meridian line EF; and let another straight line tu cut it at right angles at q. Then on tu take on either side two straight lines qt, qu equal to one another. If by means of the compasses two arcs of circles are described from the points t and u, cutting one another in the inclined plane at l, we shall have in the inclined plane this point of intersection l; and from it, through the point E where the meridian line EF meets the horizon, the straight line AB, a line drawn out will give the meridian line in the plane of the dial. The reason is that, since the meridian, drawn through the meridian line EF of the plane parallel to the horizon, is at right angles to that same plane, then by Definition 4 of Book XI of Euclid the straight line tu, which cuts the meridian line EF of the same plane at right angles — namely the common section of the meridian and the said plane — is perpendicular to the meridian; and therefore, by Definition 3 of the same book, it is perpendicular to all the straight lines in the meridian that touch it at q. [Margin: Euclid I.8 [?]] Since, then, tu is perpendicular to the straight line drawn from the point q of the plane parallel to the horizon to the point l of the inclined plane — where the two arcs of circles described from t and u intersect, as is evident — if one conceives in the mind two triangles whose bases are the straight lines tl, ul equal to one another (since they are radii of equal circles), whose sides are the equal straight lines qt, qu, and with the common straight line drawn from q to l, then the straight line drawn from q to l will be in the plane of the meridian circle. For otherwise, if it were outside tu, then tq would be perpendicular to two straight lines at the point q, in the plane passing through tq and the straight line drawn from q to l — namely to the straight line drawn from q to l, as we showed, and to the straight line drawn from q in the plane of the meridian — being in the same plane in which the straight lines tq and the straight line drawn from q through l lie, that is, to the common section of the meridian and the plane through tq and the line ql, by Definition 3 of Book XI of Euclid, as was said; which is absurd. Therefore the meridian will pass through the point l in the inclined plane; but it also passes through the point E; therefore the straight line lE will be the common section of the meridian and the inclined plane.

Having found the meridian, to delineate the dial by means of the point in the inclined plane — this we have handed down in this third method, in case the first should seem too long. The same can be done by the second method, if first the line of the style is found, which indeed we shall discover if first, by Proposition 31 of Book I, we investigate the arc of the inclined plane between its own proper meridian and the great circle measuring its inclination; then diligently observe whether the proper meridian recedes from that great circle toward the east or inclines toward the west, and so on. [Margin: In what way the third method of describing a dial declining and at the same time inclined can be begun otherwise than as we have handed it down.] But the description by the third method is more convenient and easier. Indeed, this third method can most fittingly be begun from two perpendiculars AB, CD, exactly as if the dial were to be constructed straightway on the wall itself, as we handed down just now. For thus it will come about that the dial obtains its proper position, if the straight line AB is set parallel to the horizon, and so on.

[Margin: Description of the same dial, at once declining and inclined, for a given length of style whose location is also given.] Andreas Schöner [Andreas Schöner] hands down another method of describing a dial declining from the vertical and inclined to the horizon, not unlike the one we explained for other dials, which can indeed be described so as to draw certain hours that could scarcely be obtained by the earlier description. The method is roughly as follows. From E draw a perpendicular ET to ρ C, and another perpendicular EQ to EF, equal to ET, above the straight line AB. Then, having drawn the straight line QF cutting AB at R, draw through R, parallel to the meridian line E ϵ , the line RS cutting the six-o'clock line at S. Finally, from S raise a perpendicular ST to RS, and let ST be equal to RS; and, with T as center, describe a circle to be divided into 24 equal parts, beginning from the straight line ST. For if from the center T straight lines (left invisible) are drawn through the points of division, the straight line RS will be cut at points through which the hour-lines are to be drawn from the center of the dial ρ . You have an example in the first figure. In the third figure, however, where the dial has no center, this description has no place, because the line we said was to be drawn parallel to the meridian line does not cut the six-o'clock line, but is parallel to it. In the other figures we cannot give examples, to avoid the confusion that would arise from so great a multitude of lines.

If the same declining and at the same time inclined dial is to be described on a given plane for any magnitude of style whatever, whose location too is given, we shall use this device. Let the length of the style K ρ be given, and its place in the plane of the dial the point K. If, then, the plane of the dial be any whatever, so

that the dial may be described on it in its proper [position], and then be set in place, or transferred onto a fixed plane that declines from the vertical and is inclined to the horizon, we shall draw through K, the place of the style, two straight lines AB, CD cutting one another at right angles at K. But if the fixed plane is at once declining and inclined, we shall draw through the place of the style K, by means of the level and the plumb-line, the straight line AB parallel to the horizon, which the line CD cuts at right angles at x. Then, taking on AB the straight line Kp equal to the style, whether toward the right or toward the left, describe from p, toward CD, an arc of a circle, in which count off from the inclination of the plane to the horizon (let the planes here be the same, with the same inclinations and declinations, as before), beginning from the straight line AB downward; and through the end of the counting draw from p the straight line pD cutting CD at the point D, through which the meridian line is to be drawn. Likewise, having counted off in the same arc, upward, the complement of the inclination, draw from p, through the end of the counting, the straight line pC, which will be perpendicular to pD, cutting CD at the point C, through which the line CE drawn perpendicular to CD will be the horizontal line.

Next, CD being drawn in line with C, and CF being taken equal to C, whether upward or downward, describe from F, toward CE, an arc of a circle, in which count off from the straight line C the declination of the plane from the vertical circle — toward the right if the plane declines from the meridian toward the east, or from the north toward the west, as in the first, third, and fourth figures; toward the left, however, if the plane declines from the meridian toward the west, or from the north toward the west [recte: east? — as printed "à septentrione in occasum"; but see QA], as in the second, fifth, and sixth figures. Draw from F, through the end of the count, the straight line FE cutting the horizontal line CE at E. For the straight line DE, erected through D and E on both sides, will give the meridian line. Likewise, having counted off in the same arc, from the straight line CD, on the opposite side, the complement of the declination, draw from F, through the end of the count...

through the end of the count [ex fine supputationis], the straight line Fa, which will be perpendicular to FE, cutting the horizontal line at the point a, through which the equinoctial line and the line of the 6th hour are to be drawn.

Diagram. The first figure. A large circle with an inscribed construction of a declining-and-inclined dial. Around and within it run the meridian, horizontal, and equinoctial lines together with the several counting-arcs and the shadow/style triangles of the demonstration. Readable labels:

- 6 (upper left, on the circumference): the hour numeral 6
- F (top): apex of the vertical construction line
- C (upper middle): point on the vertical line
- E (upper right): point where a line meets the circle
- b (just below C): lowercase construction point
- d (right, near circumference): counting-point on the right
- L (middle): point on the central axis
- A (far left): left end of the horizontal line AB
- B (far right): right end of the horizontal line AB
- I (middle left of centre): construction point
- H (lower middle): intersection of the counting-arcs
- ρ (lower left): the centre of the dial [horologii centrum], printed as a rho-like *p*
- 6 (bottom): the hour numeral 6
- [Central cluster: several overlapping labels — I, G, K, M, D — crowd the centre and cannot all be resolved individually [?]]

[Illegible: the dense crossing of dashed counting-arcs and solid construction lines at the centre of the figure cannot be traced cell-by-cell at this resolution]

AGAIN, once the straight line aK has been drawn — which will necessarily be perpendicular to the meridian line DE if no error has been made — let two arcs be described from D and from E at the intervals of the straight lines D β and EF. If there is no error, these will necessarily cut one another on the line aK, as at the point H. Whether this happens on the right-hand side or on the left makes no difference. From this it follows that it is not strictly necessary to draw the line aK; it is only useful, so that the construction may be made more exact. For if the line did not pass through the point H once found, the error committed would have to be corrected. In the same way, once the line aK has been drawn, it would be enough if only the arc from D at the interval D β were described — or, if it seems more convenient, the arc from E at the interval EF; for wherever one of these arcs cuts the line aK, there the point H will be, as before.

Once the line HE has also been drawn, describe from H the arc of a circle on which, from the line HE toward the line HD, the complement of the pole's altitude above the horizon is to be counted off — this if the plane of the dial declines from the south. Through the end of the count, draw from H the straight line Hb cutting the meridian line at the point M, through which the equinoctial line is to be

drawn from the point a already found earlier. And if, on the same arc but on the opposite side of the line HE, the pole's altitude is counted off,

[Margin: *Linea æquinoctialis*. — The equinoctial line.]

and from the end of the count the straight line Hd is drawn through H, which will be perpendicular to Hb, the same meridian line will be cut at the point p, which will be the centre of the dial [*centrum horologii*]. But should it happen that this line Hd, drawn last through H, comes out parallel to the meridian line — as occurs in the third figure, where the earlier line Hb passes through the place of the style K and through the point a, so that it does not differ from the line aK — the dial will have no centre, and all the hour-lines will be equidistant from one another.

[Margin: *Centrum horologii*. — The centre of the dial.]

If, however, the plane of the dial declines from the north, the pole's altitude must be counted off on the said arc of the circle from the line HE toward the line HD. For the line Hd, drawn from H through the end of the count, will cut the meridian line at p, the centre of the dial. And if on the same arc, on the opposite side of the line HE, the complement of the pole's altitude is reckoned, and from the end of the count the line Hb is carried across through H — which will be perpendicular to Hd — the meridian line will be cut at the point M, through which the equinoctial line is to be drawn from a. But should it happen that this line Hb, drawn last, comes out parallel to the meridian line — as appears in the sixth figure, where the earlier line Hd passes through K, the place of the style, so that it does not differ from the line aK — then the equinoctial line must be drawn through a parallel to the meridian line itself.

Diagram. The second figure. A circle with a full declining-and-inclined dial construction, oriented like the first but for a plane declining toward the other hand. Readable labels:

- d (top): apex point
- 6 (upper left and again lower right): hour numerals
- A (left): left end of the horizontal line
- B (right): right end of the horizontal line
- C (upper middle): point on the vertical
- H (lower left of centre): counting-arc intersection
- K (centre): place of the style
- M, G, S (centre cluster): construction points [?]

- L (below centre): point on the axis
- D (bottom of centre): lower construction point
- ρ (left of centre): the dial-centre point, printed as rho-like p [?]

[Illegible: the centre of this figure is as crowded as the first; the cluster of labels around K–M–G cannot be individually resolved [?]]

Diagram. The third figure. A circle with the construction for the case in which the dial has no centre (the hour-lines coming out parallel). Readable labels:

- 6 (upper right, and again lower centre): hour numerals
- F (upper middle): point on the vertical
- d (upper right): counting-point
- A (left): left end of the horizontal line
- B (right): right end of the horizontal line
- C (upper middle): point on the vertical
- I, K (centre): construction point and place of the style
- M (centre): meridian/equinocial intersection
- H (lower right of centre): counting-arc intersection
- L (below centre): point on the axis
- D (bottom of centre): lower construction point

[Illegible: dense central crossing of lines and small labels not fully resolvable [?]]

[Margin: Linea styli. — The line of the style.]

NOW, if from p , the centre of the dial, a straight line pK is drawn through K , the place of the style, we shall have the line of the style [linea styli], which will necessarily cut the equinoctial line drawn from a at right angles. But where the dial has no centre, the line of the style must be drawn through K , the place of the style, parallel to the meridian line and perpendicular to the equinoctial line, as in the third figure. Likewise, where the equinoctial line

is equidistant from the meridian line, the line of the style pK will be perpendicular not only to the equinoctial line but also to the meridian line.

[Margin: a — 26.primi. (*Euclid, Elements I.26*)] And so, if in the first place the equinoctial line is drawn through the points a and M already found, the line of the style must be drawn perpendicular to it through K , the place of the style, from the centre p — or, where there is no centre, through K , the place of the style, alone. But if in the first place the line of the style is drawn from the centre p through K — or, where there is no centre, through K alone, equidistant from the

meridian line — then the equinoctial line must be drawn from a perpendicular to it.

AFTER this, from K, the place of the style, let a line KI be raised perpendicular to the line of the style, equal to the style, and from the centre p let the line pI be sent out through I to serve as the axis of the world [axis mundi]. [Margin: Axis mundi.] But where there is no centre, the axis must be drawn through I equidistant from the line of the style, or from the meridian line. Now if a perpendicular is drawn from I to the axis, it will cut the line of the style at the point G, through which the equinoctial line is drawn — unless an error has been made. Hence, where the dial has no centre and the axis is therefore equidistant from the line of the style, the said perpendicular will fall on K, the place of the style, and will not differ from the equinoctial line. And so, if in the first place the axis of the world has been drawn through I, we shall find, by the help of the line IG perpendicular to the axis, another point G on the line of the style, through which the equinoctial line is to be drawn from the point a — a line which will necessarily make right angles with the line of the style.

FINALLY, taking on the line of the index the straight line GL equal to GI itself, let a circle of any size be described from L and divided into 24 equal parts, beginning from the line LM — which is drawn from the centre L through the point M, where the equinoctial and meridian lines intersect — or from the line La, drawn from the same centre L through the point a, where the horizontal line and the equinoctial (that is, the line of the 6th hour) meet. Now the two lines LM and La must cut one another at L at right angles, if no error has been made in anything. But if the equinoctial line is parallel to the meridian line, then in place of the line LM a line must be drawn parallel to that same meridian line, one that cuts the line La at right angles. [Margin: Linea horaria. — The hour-line.] Now if hidden [i.e. faint construction] lines are drawn from L through the points of division, the equinoctial line will be cut at points through which, from the centre p, the lines of the hours from noon or from midnight [à meridie vel media nocte] are to be drawn. Or, when the dial has no centre, through these same points there must be drawn lines parallel to the meridian line, or to the line of the style, or to the axis, and perpendicular to the equinoctial line, for the hours from noon and from midnight. The order of the hours here is the same as was set out above in the first construction of this proposition.

YOU SEE, then, that this construction is much more excellent than the one we explained in the first place in this proposition, since it leads us of its own accord to the place of the dial's centre, so that there is no need to consider whether the

centre of the dial should be set below the equinoctial line or above it, as had to be done in that other construction.

WE SHALL NOW DEMONSTRATE everything stated in this construction, in the following way. [Margin: Demonstratio proxima descriptionis. — Demonstration of the foregoing construction.] Let there be understood a triangle βCD , whose angle β is right (because of the quadrant of the circle described from β and enclosed between the lines βD and βC), moved about the line CD until it stands perpendicular to the plane of the dial, so that the apex of the style β is joined with the centre of the world. Now since the angle $K\beta C$ is equal to the complement of the inclination, βCK will be the angle of inclination; and consequently, since the horizon passes through β , the apex of the style, the line βC will be the common section of the horizon and of the great circle that measures the inclination, making with the line CD the angle of inclination, as the matter requires.

Therefore the horizon will meet the plane of the dial at C , and for that reason the horizontal line must be drawn through the point C perpendicular to CD . For since both the horizon and the plane of the dial are perpendicular to the great circle that measures the inclination of the plane — and the line CD is drawn through it — [Margin: b — 19.unde. (*Euclid XI.19*)] their common section too, namely the horizontal line, will be at right angles to that same great circle, and hence, by definition 3 of book 11 of Euclid, perpendicular to the line CD lying in that circle, at the point C . Again, since both the great circle measuring the inclination of the dial and the meridian are perpendicular to the horizon, [Margin: c — 19.unde. (*Euclid XI.19*)] their common section too will be at right angles to it, and therefore, by definition 3 of book 11 of Euclid, perpendicular to the line βC lying in the horizon, at the centre of the world β , through which all great circles are drawn. Since, then, the line βD lies in the plane of the great circle measuring the inclination of the dial and makes a right angle with βC , as we said, βD itself will be the common section of the said great circle and of the meridian. Therefore the meridian meets the plane of the dial at the point D .

Diagram. The fourth figure, illustrating the demonstration (the triangles βCD and aFE folded about their bases into the plane of the dial). A large circle with the horizontal line AB across it and many demonstration lines. Readable labels:

- a (α , upper left): the point a (start of the equinoctial), printed as an alpha-like sort
- C (top middle): meeting of horizon and dial-plane
- E (top, right of C): meridian meeting-point
- b (top right, on circumference): construction point / hour marker

- d (upper middle): counting-point
- I (below C): construction point
- A (left): left end of the horizontal line
- B (right): right end of the horizontal line
- 6 (right): hour numeral
- β , F (centre): apex of the style and folded point F
- H (right of centre): triangle vertex
- D (below centre): meridian meeting-point
- G (lower left of centre): construction point
- M (bottom): equinoctial/meridian intersection
- L (bottom left): point on the axis

[Illegible: the crowded centre (β , F, G and the fold-lines) cannot all be resolved individually at this resolution [?]]

LET the triangle aFE also be moved about the line aE until it is joined with the plane of the horizon, and the point F with the centre of the world β (because of the equality of the lines CF and C β). This done, since CFE is the angle of the plane's declination from the vertical, CEF will be the angle of the complement of that same declination — namely such an angle as the common section of the plane of the dial and of the horizon makes with the common section of the horizon and the meridian. Since, then, the meridian is drawn through F — that is, through the centre of the world, where we placed the point F — the line FE will make with the horizontal line CE the angle of the complement of the declination, being the common section of the horizon and the meridian, since it lies in the horizon and is drawn through the centre of the world F and the point E. Therefore the meridian will meet the plane of the dial at the point E. But it also meets the same plane at the point D, as we showed. Therefore the line DE, produced on both sides, will be the meridian line. And since both the equator and the horizon are perpendicular to the meridian, [Margin: d — 19.unde. (*Euclid XI.19*)] their common section too will be at right angles to it, and consequently, by definition 3 of book 11 of Euclid, perpendicular to the line FE lying in the meridian, at F, the centre of the world.

Therefore, since the line Fa lies in the horizon (being drawn through F, the centre of the world, and the point a) and makes a right angle at F with FE lying in the meridian — because of the quadrant of the circle described from F and enclosed between the lines EF and Fa — Fa itself will be the common section of the horizon

and the equator. For which reason the equator will meet the plane of the dial at a, and therefore the equinoctial line is to be drawn through a.

LET IT NOW BE CONCEIVED that through the pole of the dial's plane — and so through the style $K\beta$, which is a portion of the axis of that same plane — and through the pole of the meridian, a great circle is drawn, making in the dial a section that is a straight line, which will necessarily pass through the point a. For since the equator and the horizon also pass through the poles of the meridian, the equator, the horizon, and the said great circle will have one and the same common section. They will therefore make in the dial three sections, straight lines, meeting at that one point (by proposition 18 of book 1) on which their common section falls. Since, then, the common section of the horizon and the equator falls on the point a — because there, as we showed, the horizontal line and the equinoctial cut one another — the common section of the said great circle and the plane of the dial will also pass through the point a. But that same great circle passes through K, the place of the style. Therefore the line aK is the common section of the plane of the dial and of the said great circle. And since the said circle is at right angles (by proposition 15 of book 1 of Theodosius) both to the meridian and to the plane of the dial — because it is drawn through their poles — conversely both the plane of the dial and the plane of the meridian will be at right angles to the said circle. [Margin: a — 19.undec. (*Euclid XI.19*)]

Therefore their common section too — that is, the meridian line Ep — will be at right angles to that same circle, and consequently perpendicular to the line aK lying in that circle. Therefore the line aK will necessarily cut the meridian line at right angles at the point a. Hence it comes about that this same line aK passes entirely through the point H, where the arcs described from D and E at the intervals $D\beta$ and EF intersect one another. For if the triangle DEH is conceived to be moved about the line DE, the line Ha will forever remain in the plane of the said great circle that makes the section aK; because, throughout this motion, the line Ha

Diagram. The fifth figure, completing the demonstration (the fold of triangle DHE onto $D\beta F$ in the plane of the meridian). A circle with the horizontal line AB and the meridian and axis lines, with the folded triangles below. Readable labels:

- M (top left): upper vertex of the meridian construction
- b (upper left, below M): construction point
- 6 (upper right, and again lower left): hour numerals
- L (upper middle, right of F): point on the axis
- F (middle): folded point F

- E (left of centre): meridian meeting-point
- I (left of centre): construction point
- A (left): left end of the horizontal line
- B (right): right end of the horizontal line
- β , α (centre cluster): apex of the style and the point a [?]
- G (centre): construction point
- C (right of centre): horizon meeting-point
- D (bottom): lower vertex, apex of the folded triangles

[Illegible: the centre cluster (β , α , G and the many fold-lines) is not fully resolvable individually at this resolution [?]]

[Margin: b — 7.primi. (*Euclid, Elements I.7*)]

will always make a right angle with the meridian line, so that it inclines neither to this side nor to that — just as the plane of that circle is not inclined to this side or that toward the plane of the dial, but is perpendicular to it. Now if the triangle $D\beta C$ is set perpendicular to the plane of the dial along the line CD, so that the style βK is perpendicular to that same plane; and if the triangle $E\alpha a$ is also understood to be moved about the line aE until the line CF coincides with the line $C\beta$, and the point F with the centre of the world β (because of the equality of the lines CF and $C\beta$), and so the triangle $E\alpha a$ itself is joined with the horizon — drawn through the line aE and the centre of the world β — and the line EF lies along the line $E\beta$ in the plane of the meridian; and if, likewise, the triangle DHE is thought to be turned about the meridian line DE until it is joined with the plane of the meridian: then the triangle DHE will coincide exactly with the triangle $D\beta F$ lying in the same plane of the meridian, so that the point H falls on the centre of the world β . Otherwise, in the plane of the meridian upon the line DE there would be drawn from D two mutually equal lines $D\beta$ and DH, and from E two others mutually equal, $E\beta$ (which is the same as EF) and EH (which was taken equal to EF itself) [Margin: b — 7.primi. (*Euclid I.7*)] — which is absurd. From this it follows that the line EH, in this position, is the common section of the horizon and the meridian. Therefore, since in planes declining from the south — as in the three former figures — the angle dHE toward the northern parts

[full-width text continues below the figure:]

makes, with HE (the common section of the horizon and the meridian), an angle toward the northern parts, the line dH will be the axis of the world, meeting the meridian line of the dial at p; and consequently p will be the centre of the dial, by the corollary of proposition 21 of book 1. But if the axis dH is equidistant from the

meridian line DE, the dial will have no centre. In planes, however, declining from the north — as in the latter three figures — since the angle dHE is equal to the pole's altitude (such, namely, as the axis of the world makes below the horizon with the line HE, the common section of the horizon and the meridian, toward the southern parts), the line dH will be the axis of the world, and therefore, as before, p will be the centre of the dial. Hence it comes about, both in those planes and in these, that the line HM — lying in the plane of the meridian and making with the axis Hp the right angle bHd (because of the quadrant bd) — is the common section of the meridian and the equator, since the axis of the world at the centre of the world H is necessarily perpendicular (by definition 3 of book 11 of Euclid) to a common section of this kind, because the axis is at right angles to the plane of the equator (by proposition 10 of book 1 of Theodosius). Therefore the equator meets the plane of the dial at the point M, and for that reason the equinoctial line is to be drawn through M from a. But if HM, the common section of the meridian and the equator, is parallel to the meridian line DE itself, the plane of the dial drawn through DE will be equidistant from that same common section HM, since it does not cut it. Therefore, by proposition 18 of book 1, the sections that the meridian and the equator make with the plane of the dial will be parallel; and so the equinoctial line is to be drawn through a, equidistant from the meridian line DE.

It is clear, moreover, that the straight line ρK — drawn from the centre of the dial through the position of the style — is the style-line, that is, the common section of the plane of the dial and of its own proper meridian. For since that meridian, drawn through the axis Hp, meets the plane of the dial at ρ , the centre of the dial, their common section with the dial must be drawn through ρ . Again, since this same meridian stands perpendicular to the plane of the dial, it will necessarily pass through the style [Margin: a — 18.undec. (*Euclid XI.18*)], because all planes drawn through the style are perpendicular to the plane of the dial. And so the said common section — that is, the style-line through K — must be drawn; and it is of the kind that the straight line ρK is, which will cut the equinoctial line at right angles, as was demonstrated above. For since both the plane of the equator and the plane of the dial stand perpendicular to the proper meridian of the dial's plane [Margin: b — 19.unde. (*Euclid XI.19*)], their common section too — namely the equinoctial line aM — will be perpendicular to that same meridian, and therefore, by definition 3 of book 11 of Euclid, perpendicular to the style-line ρK , which lies in that same meridian. But if the dial has no centre, the style-line must be drawn through K, the position of the style, parallel to the meridian line and perpendicular to the equinoctial line. For since in that case the plane of the dial is equidistant from the axis of the world — which it does not cut — that is, from the

common section of the meridian of the horizon and the proper meridian of the dial itself, the common sections of the plane of the dial and of those meridians will, by proposition 18 of book 1, be parallel to one another. That is, the meridian line and the style-line will be parallel; and the style-line will cut the equinoctial line at right angles, as we have just demonstrated.

That the straight line ρI is the axis of the world — such that, together with the style-line ρK (which is the common section of the proper meridian of the inclined plane and of the plane of the dial), it contains the angle $I\rho K$, the altitude of the pole above the inclined plane — is evident. For if the triangle $IK\rho$ is moved about $K\rho$ until it comes to stand perpendicular to the plane of the dial, with the style IK likewise perpendicular to it, and the point I therefore coincides with the centre of the world, then the straight line ρI will be the axis of the world, since the axis of the world is drawn through the centre of the world and the centre of the dial. This will also be made clear in the following way. When the triangle ρHE is revolved about the meridian line ρE until it is joined with the plane of the meridian, the point H coincides with the centre of the world, as we showed above, and therefore it will also coincide with the point I ; and so the line ρH will coincide with the line ρI . But we showed that ρH is the axis of the world. Therefore ρI too will be the axis of the world. In dials that have no centre, the axis of the world must be drawn through I , parallel to the style-line; for if it cut that line, the point of intersection would be the centre of the dial, as is evident. The rest is clear from the demonstration of the first construction given in this proposition.

[Margin: Description of the same dial by means of an ellipse.] Finally, we shall describe this same dial — declining and inclined at once — by means of an ellipse drawn in the plane of the dial, exactly as we taught in the scholium to proposition 1 of this book. The semidiameters of the circles that determine the length and breadth of the ellipse, to be drawn from the centre of the dial ρ , are ρG and GI . If larger ones are wanted, take for the greater semidiameter any portion you please of the style-line, namely ρL , and for the lesser the straight line that falls perpendicular onto the axis ρI from the point terminating the greater — as from L . As for the demonstration: about GI (or that perpendicular falling from L onto the axis) a circle is to be drawn in the plane of the equator, from the centre of the world which lies on the axis, to serve as the base of a cylinder. The division of the circles drawn from ρ must begin from the straight line which, at the centre ρ , makes with the style-line — toward the meridian line — an angle equal to the angle ρLM : that is, equal to the inclination of the proper meridian of the inclined plane itself to the meridian of the horizon. Hence, since in the sixth figure the

inclination of the meridians embraces 90 degrees, and the straight line LM makes a right angle with the style-line, the division of the circles drawn from ρ will begin from the meridian line, since this too contains right angles with the style-line, as is clear from what precedes. This construction, moreover, has no place in dials lacking a centre, as in the third figure: because the plane of the dial, being equidistant from the axis of the world — that is, of the cylinder from whose section that ellipse arises — does not produce an ellipse but a parallelogram, as is demonstrated by Serenus of Antinoöpolis [Serenus Antinsensi] in book 1 *On the Section of the Cylinder*.

[Margin: How the lower dial is generated from the upper one.] Now if any dial whatever is inverted from above, so that its upper part becomes the lower, and what after this inversion is on our right becomes the left, and conversely — as we have more than once explained in what precedes — we shall have a dial to be placed on the opposite face of the plane, and below it, as was demonstrated in the scholium to proposition 13 of the preceding book. But then the hour-lines which previously, in the upper dial, indicated the hours from noon will show the hours from midnight, and conversely. And beautifully — as also in the preceding cases — the lineaments of the upper dial, drawn on the opposite face, display this inversion, so that each corresponds exactly to each, provided the upper part of the opposite face becomes the lower, and conversely.

Diagram. The sixth figure of this proposition, continuing the declining-and-inclined-dial construction of figures 1–5. It is a large circle (the proper meridian) traversed by many straight, dashed and dotted lines. The engraved caption at lower right reads "6. figura." Readable labels:

- A (left end of the horizontal diameter): endpoint of the horizontal line AB
- B (right end of the horizontal diameter): endpoint of line AB
- F (top of circle): upper vertex
- C (upper-centre): interior point
- H (centre): centre of the world
- K (below H, centre): style-foot / interior point
- I (lower-centre): axis point
- D (bottom of circle): lower vertex
- β (left of K): interior point
- α (right, on the horizontal line, with G adjacent — " α G"): point on the diameter near B
- b [?] (small label near the top, on a dashed arc): [?]

- δ [?] (near the centre, below C): [?]
- γ [?] ("g", lower centre-left): [?]
- the numeral "6" appears at two or three interior positions and at lower right beside the caption; whether these mark points or belong to the figure-number could not be resolved [?]

Because more than two labels are illegible, this figure is a

Problem 38. Proposition 38.

To depict the parallels — that is, the arcs of the signs of the Zodiac — upon the same dial that both declines from the vertical circle and is inclined to the horizon.

[Margin: How the arcs of the signs are described from the analemma.] Once the altitude of the pole above the declining and inclined plane has been found by proposition 29 of book 1 — the altitude which, in the dial constructed by the earlier method in the preceding proposition, or in that dial in which the style and its position were given in the scholium to the same proposition, is shown by the angle KpI that the style-line makes with the axis of the world, as we said — let it be set out upon the analemma itself, as in proposition 2 of the preceding book, so that the arc CE in the analemma embraces

the degrees of the altitude of the pole found; or, at any rate, so that the angle CDE in the analemma is equal to the angle of the pole's altitude KpI in the inclined dial. Then, in the same analemma, take the straight line DG equal to the style IK, which the first construction of the preceding proposition offers us; or the one we assumed in the second construction, in the portion of the analemma of the same proposition (the portion which corresponds to the analemma of proposition 1 of book 2); or, at any rate, the one

Diagram. A large analemma figure for laying out the zodiac-sign arcs on the declining-and-inclined dial. At its core is the analemma circle ABC (representing the proper meridian of the inclined plane); from a centre near the lower part radiate many straight sign-lines and hour-lines, whose ends carry engraved zodiac-sign glyphs around the periphery. Readable interior geometric labels:

- A (upper-left, near the circle): interior point
- B (lower-left): interior point
- C (left): interior point
- D, E (mid-left, adjacent — "D E"): points on the horizontal
- K (lower-centre): interior point

- ρ (lower-centre, below K): the projection centre from which the sign-lines and hour-lines issue
- H (centre-right of the fan of lines): interior point

Peripheral zodiac-sign glyphs are engraved at the tips of the sign-arcs. Legibly identifiable are Leo ϱ , Gemini Π , Taurus X , Pisces X , Aries Υ , Virgo M , Scorpio M , Sagittarius X ; several further glyphs (upper and lower periphery) are worn and could not be securely resolved [?], and the small hour-numerals (6–12) and the point-letters h and m scattered through the fan are only partly legible [?]. Because numerous peripheral labels are illegible, this figure is a

we assumed in the construction handed down in the scholium of the preceding proposition. And through G let the straight line OR be drawn, parallel to BC. For in this way, on the line RO, we shall find the diameters of the conic sections, just as we found their diameters KR, LR, MR, NO, PO, QO in the horizontal dial in proposition 2 of book 2. Hence, as we taught there, so here too the conic sections of the diameters found will be described — that is, the parallel arcs of the signs of the Zodiac. For just as, in the horizontal dial, the analemma circle ABC represents the meridian of the horizon, and the straight line OR the common section of the plane of the horizontal dial and of the meridian — that is, the meridian line — so in the declining-and-inclined dial the same circle refers to the proper meridian of the inclined plane, that is, the greatest circle drawn through the poles of the world and through the poles of the declining plane; while the straight line OR expresses the common section of the said meridian and of the plane of the declining-and-inclined dial — that is, the style-line.

[Margin: Another way of describing the arcs of the signs.] ANOTHER WAY.

Having drawn the straight line ρI for the axis of the world, erect upon it at I the perpendicular IG for the radius of the equator, and to either side of it let the radii of the other signs be drawn out, as was done above; and let Ip be equal to the portion of the axis ρI in the dial, and the straight line IG equal to the straight line IG (or LG) in the same dial; and from ρ , through G, let the straight line ρG be sent out. This we shall perhaps draw more conveniently if from ρ we draw the straight line ρG making, with ρI , an angle $G\rho I$ equal to the angle $G\rho I$ which the axis ρI and the style-line ρG form in the dial — namely, equal to the angle of the pole's altitude above the plane of the dial. [Margin: a — 4. or 26. of book 1 (*Euclid I.4 or I.26*)] In this way this triangle $G\rho I$ will be entirely equal to the triangle $G\rho I$ in the inclined dial; and so, ρI being in this figure the axis of the world, the straight line ρG will be the style-line. And if the rest be done as we handed down in proposition 2 of this book and in its scholium — always taking here the letter ρ

for the letter C mentioned there — the parallels, that is the arcs of the signs of the Zodiac, will be described.

We have subjoined an EXAMPLE corresponding to the last upper dial of the six of the preceding proposition. Since here the style-line is the same as the line of the 6th hour, upon the several hour-lines issuing from the point ρ of the figure of the rays of the signs of the Zodiac (from which the arcs of the signs are described) there are set two hour-numbers each, equally distant on either side from the line of the 6th hour — that is, from the style-line — as we noted in proposition 2 of this book. Again, here the straight line ρV , equidistant from the radius of the equator, exhibits the 12th hour, since the line of this hour in the dial is equidistant from the equinoctial line: just as, in the horizontal dial, the straight line HV , equidistant from the radius of the equator in the figure of rays of proposition 2 of the preceding book, refers to the 6th hour, because the line of this hour too is equidistant from the equinoctial line in the dial.

We have also added another figure of the rays of the Zodiac, with the hour-lines issuing from ρ , corresponding

Diagram. The added figure of the rays of the zodiac-signs for the first dial, shown divided into two ray-fans across the top of the page. Along the top runs a horizontal base-line carrying the marks "B I B ρ "; from two apices (one at I, one at ρ , with K and P/ ρ nearby) fan out many straight and dashed hour-rays down to a large semicircular arc below. At upper right is a small inset triangle carrying the marks "B — B I", "A K A", and, down its right edge, "D G D". Readable labels: B, I, ρ , K, G, V, A, D. The rays carry rotated "radius of the hour" captions; as read (with uncertainty): "Radius hor. 6" [?], "Rad. hor. 5" [?] (upper-left, dashed), "Rad. hor. 24" [?] and "Rad. hor. 18" [?] (right), "Rad. hor. 10" [?] and "Rad. hor. 14" [?] (lower). Along the semicircular arc a double row of hour-numerals is engraved where the rays strike it, running approximately 6 5 7 4 8 3 9 2 10 1 11 12 to the left of centre and 12 11 1 2 3 4 5 6 to the right; the exact assignment of several numerals is uncertain [?]. Because several ray-captions and arc-numerals are illegible, this figure is a

corresponding to the first dial of the preceding proposition, in which the style-line is neither one of the hour-lines nor equidistant from two placed on either side. Hence it comes about that the several lines issuing from ρ have their several numbers affixed. From this figure, therefore, the arcs of the signs may be described in the said dial, when occasion requires. But we have divided this figure, as you see, into two, because otherwise the lines would be too much confused with one another — for this reason, that the style-line of the first dial is

little distant from the line of the 11th hour. In the former of these figures are contained the hour-lines which in the dial are placed to the left of the style-line, such as 5, 6, 7, 8, 9, 10, and 11. In the latter, however, the remaining hours placed to the right of that same style-line, namely 12, 1, 2, 3, 4, 5, and so on. This is what we long since pointed out, in proposition 2 of this book,

Diagram. The left-hand of two lower figures of zodiac-rays for the third dial (whose hour-lines are parallel). A quarter-circle arc springs from a horizontal base-line; from a point ρ at the left issue straight and dashed rays cutting the base-line, with the point-marks A, B, F, and the hour-labels II (11), I (1), and 12 near the base. Hour-numerals 5, 6, 7, 8, 9, 10 are ranged along the descending rays. Several small numerals are only partly legible [?]

Diagram. The right-hand of the two lower figures, the companion ray-fan for the same third dial. Similar in construction: a quarter-circle arc over a horizontal base-line, with a point ρ , the marks A, B, F, and the hour-labels I (1), 12, near the base, and hour-numerals 12, 1, 2, 3, 4 ranged along the rays. Several small numerals are only partly legible [?]

must be done in declining — and therefore inclined — dials, in which such confusion of lines is found.

LASTLY, that you may see what is to be done in the third dial of the preceding proposition — in which the hour-lines are equidistant [parallel] — we have described the arcs of the signs in it too. These are indeed described just as in a meridian or polar dial, with this exception: that here the hour-lines, cutting the ray of the equator in the figure of the rays at right angles, have single numbers affixed to each, not two, as there — unless the style-line is itself one of the hour-lines, or

or else it stands equally distant from the two nearest hour-lines placed on either side, as commonly happens in other declining dials.

Diagram. The left-hand figure at the top of the page — the figure of the rays (*figura radiorum*) for the dial. A vertical central line carries the mark 1 where a horizontal cross-bar crosses it near the top; from apices just below the cross-bar many straight and dashed rays fan downward and converge. Ranged down the left margin of the figure are hour-numerals reading (top to bottom, with uncertainty) 8, 7 [?], 6, 5, ... 3 [?]; a mirror set (11, 10 [?], ... 7, 5, 3 [?]) runs down the right. Across the top run several worn zodiac-sign sorts [?]. Two rotated captions stand at the foot: on the left **Rad. hor. 14** [Radius horae 14 — "radius of

the 14th hour"] and, centred, **Rad. horio** [Radius horologii? [?]]. Several small numerals and the zodiac sorts do not resolve cleanly.**

Diagram. The right-hand figure — the dial that both declines and inclines, on which the horizontal line is constructed as described in the text below. A dashed vertical line runs down the right side; along it and the lines crossing it are the labelled points, reading roughly left to right across the upper crossing region **V, I, E, D**, with **A** set above **D**, and below them **B** (left) and **C** (right) joined by a dashed horizontal line **B---C**. At the foot a quarter-circle arc carries the mark **h**, with **G** to its lower right. Many straight and dashed hour-lines cross the figure. A cascade of zodiac-sign sorts runs down the right edge and around the lower-left arc. Readable labels: **A, B, C, D, E, G, h, I, V**. Several further point-marks and the zodiac sorts are illegible [?].**

[Margin: How the horizontal line is described.]

THE horizontal line in the dial — the one whose style, following its given size, and whose position we described in the scholium of the preceding proposition — has now been drawn. For we showed there that the line ***E** [?] is the horizontal line. In other dials, however, the same horizontal line is drawn in the following way. From any point **A** taken on the meridian line, describe an arc of a circle *m h*. On this arc, from *m* — either to the left or to the right of the meridian line (as we taught in the scholium of the preceding proposition, when we dealt with the placing of the dial according to the later constructions), according as the arc *m h* has been described above the point **A** or below it, and so on — count off the arc of the given plane to which the dial is parallel, intercepted between the Meridian of the Horizon and the greatest circle that measures the inclination of the plane to the Horizon, up as far as *h* (how this is to be found, we demonstrated in proposition 31 of book 1). Then from **A** through *h* draw the straight line *Ah*. For the perpendicular drawn to *Ah* from the point where the equinoctial line and the line of the 6th hour intersect will give the horizontal line.

We shall show this as follows. As we demonstrated in the said scholium of the preceding proposition concerning the line *Eh*, the straight line *Ah* is the common section of the plane of the dial and of the greatest circle that measures the inclination of the plane to the Horizon; and the common section of that same plane of the dial and of the Horizon cuts it at right angles. It follows — since the common section of the Horizon and the plane of the dial passes through the 6th hour on the equinoctial line, as has been said and demonstrated more than once above — that the straight line which cuts *Ah* at right angles is the common section of the Horizon and the plane of the dial, that is, the horizontal line.

[Margin: Another way of describing the horizontal line.]

IN another way we shall draw the same horizontal line thus. Having drawn Ah as before, we erect upon it, from K (the place of the gnomon), the perpendicular KB . On KB produced we take BC equal to the gnomon KI , and at C we set, upwards, the angle BCD equal to the complement of the inclination of the plane to the Horizon, so that the line CD cuts Ah at D . I say that the line drawn through D at right angles to Ah is the horizontal line. For if the triangle BCD is imagined to revolve about BD until it becomes perpendicular to the plane of the dial, then, by definition 4 of book 11 of Euclid, BC will be perpendicular to the plane of the dial. Therefore, if the style KI is also conceived as perpendicular to the same plane of the dial, [a] the line BC and the style KI will be parallel to one another. [Margin: a. Euclid XI.6.] [b] Therefore the line joining the points C and I , being raised on high, will be parallel to BK and equal to it. [Margin: b. Euclid I.33.] Now since the Horizon cuts the plane of the dial along a straight line perpendicular to Ah — as we showed in the scholium of the preceding proposition, when we dealt with the placing of the dial — [c] this common section will be parallel to KB . [Margin: c. Euclid I.28.] Since, then, CI has also been shown parallel to BK , [d] the common section of the plane of the dial and of the Horizon and the line CI will likewise be parallel to one another; and consequently they lie in the same plane, by the definition of parallels. [Margin: d. Euclid XI.9.] Therefore, since the Horizon, drawn through that common section, passes through I , the tip of the style — that is, the centre of the world — it will also pass through the line IC , and so through the point C . Accordingly, since the angle BCD has been made equal to the complement of the inclination of the plane to the Horizon, and for that reason the angle BDC is [equal to] the inclination itself, the Horizon will proceed along the line CD ; for by this construction it meets the inclined plane at the angle of inclination BDC , so that CD is the common section of the Horizon and of the triangle BCD . For this reason the Horizon will meet the plane of the dial at the point D . Since, then, as we demonstrated before, the common section of the Horizon and the plane of the dial is perpendicular to Ah , it is clear that the perpendicular to Ah drawn through D is the horizontal line. And the horizontal line drawn through D will pass entirely through the 6th hour on the equinoctial line, if no error has been made in the construction.

[Margin: Another description of the same horizontal line.]

IN yet another way we shall describe the horizontal line. From the figure of the rays of the Zodiac, let there be found — in that portion of the dial's meridian line which faces midnight, that is, which indicates midnight, or the 12th hour after

noon — the point E, through which the diurnal arc of 24 hours is to be drawn; or, in that portion of the same meridian line facing noon, that is, which shows noon, or the 12th hour after midnight, let there be found the point E of the diurnal arc of 0 hours, or of the nocturnal arc of 24 hours. For sometimes the diurnal arc of 24 hours does not cut the portion of the meridian line belonging to midnight, but the nocturnal arc of

24 hours cuts that portion of the meridian line which faces noon. For through the point E the horizontal line will have to be drawn, since the Sun rises at the 12th hour after noon, on a day containing 24 hours, or at the 12th hour after midnight, on a day containing 0 hours, or when the night comprises 24 hours — as is clear from the tables of the diurnal arc of 24 hours and the nocturnal arc of 24 hours (proposition 33 of book 1). By the same reasoning, if on the line of the 5th hour after midnight the point F of the diurnal arc of 14 hours is found, or on the line of the 7th hour from midnight the point F of the diurnal arc of 10 hours, we shall likewise have a point F through which the horizontal line is to be drawn, as is plain. And so we shall have at least four points through which the horizontal line must be drawn, namely D, E, F, and the point of the 6th hour on the equinoctial line. In the same manner the horizontal line will pass through the point of the diurnal arc of 10 hours, where it is cut by the line of the 5th hour from noon; likewise through the point of the diurnal arc of 14 hours, where it is cut by the line of the 7th hour from noon.

[Margin: The horizontal line divides the dial into an upper and a lower part, and into diurnal and nocturnal.]

MOREOVER, the horizontal line divides the whole dial described so far — as was said in what precedes — into an upper and a lower part, of which the upper is that part contained below the horizontal line; the remaining part gives the lower. This holds provided you remember that everything must be inverted, and that the hours which before were reckoned from midnight are now to be counted from noon, as we showed in propositions 13 and 14 of the preceding book. Likewise the same horizontal line separates the whole dial into diurnal and nocturnal, as is clear from the same proposition 14 of the preceding book. And so we have drawn the parallels, or the arcs of the signs of the Zodiac, and so forth. Which was to be done.

SCHOLIVM.

[Margin: Which arcs belong to the northern signs, and which to the southern.]

WHICH arcs in the dial belong to the northern signs, and which to the southern, it will not be difficult to judge, if the four Analemmas which we described in proposition 25 of this book are attentively considered. For in dials that face south and the vertex — that is, the pole of the Horizon [the zenith] — if the centre of the dial lies below the equinoctial line, the arcs of the northern signs are contained between the centre and the equinoctial line, as is established from the first Analemma of the said proposition; because the points of the northern quadrant H F cast their shadows at noon into the portion of the meridian line M N, between the centre M and the point N, through which the equinoctial line is drawn. But if the centre of the dial lies above the equinoctial line, the arcs of the southern signs are comprised between the centre and the equinoctial line, as is manifest from the second Analemma; since the points of the southern quadrant G H cast their shadows at noon into the portion of the meridian line M N, between the centre M and the equinoctial line, which is drawn through N. But if the dial has no centre, the arcs below the equinoctial line will belong to the northern signs, as is clear from the first Analemma, if below E a line were drawn parallel to the axis F G — a line which would be the common section of the Meridian and the plane of the dial. For then the points of the northern quadrant H F would cast their shadows at noon into that portion of the meridian line below the point through which the equinoctial line would have to be drawn.

But in dials that face north and the vertex, wherever the centre of the dial may be, the arcs of the northern signs are perpetually contained between the centre and the equinoctial line. This is plainly established from the two later Analemmas. For in the third, the points of the northern quadrant H F cast their shadows into the portion of the meridian line M N, between the centre M and the point N of the equinoctial line; and the same is seen in the northern quadrant F I of the fourth Analemma, where at midnight the shadows are cast into the portion of the meridian line M N, between the centre and the equinoctial line. Nor is it any objection that sometimes certain points of the northern semicircle H F I, in each of the two later Analemmas, also cast their shadows beyond the centre M — as happens in the quadrant F H of the fourth Analemma — because then the arcs of the signs are ellipses, so that each cuts the meridian line in two points, one of which necessarily lies between the centre and the equinoctial line. Thus it is always true that the arcs contained between the centre and the equinoctial line belong to the northern signs. And if the dial is so elevated on the southern side that the arc of the Meridian between it and the Horizon is equal to the altitude of the Equator — or to the complement of the pole's altitude — and consequently the meridian line M N is parallel to the diameter of the Equator H I, it is likewise clear that then the arcs of the signs near the centre belong to the northern signs,

because the shadows of the points of the northern semicircle H F I fall on the meridian line, in the middle of which the centre M lies, as is plain.

IN dials that face the Nadir — that is, among the lower [inferior] dials — exactly the contrary is to be understood, as the same four Analemmas demonstrate.

[Margin: Which arcs of the signs are hyperbolas, and which parabolas or ellipses.]

AGAIN, the arcs of the signs in those dials in which the hour-lines are parallel — such as the third dial described in the preceding proposition — are all hyperbolas, just as in the polar dial, as was said at proposition 38 of the preceding book. For the reasoning here is the same. In other cases we shall judge, as we handed down in proposition 2 of the same book, which arcs are hyperbolas, which parabolas, and which ellipses. Or indeed let the same be sought from propositions 4, 5, 6, and 7 of the first book.

[Margin: How, from the figure of the rays, a larger or smaller dial may be described for a given length of style.]

AND if, from the figure of the rays of the Zodiac, a larger or smaller dial is to be described for a given length of gnomon, it will be done in this way. Let there be described separately — just as was done alongside the figure of the rays of this proposition — the triangle ρ I G, taken from the dial which we constructed in the preceding proposition, or from the figure of the rays itself. In it the axis of the world is ρ I; the Equator is I G; and the line of the style, upon which the gnomon I K falls at right angles, is ρ G. Then, the lines I ρ , I G, I K having been produced, if on I K there be taken the line I A equal to the given gnomon — whether it be greater than the style I K or smaller — and through A a line B D be drawn parallel to ρ G, the triangle B I D will be similar to the triangle ρ I G, by the corollary of proposition 4 of book 6 of Euclid. And so, if the axis I B is transferred into the figure of the rays from ρ as far as B, towards I, and the rest is done as we prescribed in the scholium of proposition 2 of this book — always changing the letter C, there placed, into the letter ρ , here noted — the arcs of the signs will be described according to the size of the given style I A, and so forth.

PROBLEMA 39. PROPOS. 39.

To lay out the parallels of the diurnal arcs in the same dial that both declines and inclines.

[Margin: How the diurnal arcs are described in the same dial.]

IT has already been declared more than once in what precedes that the description of the diurnal arcs in any dial differs in nothing from the description of the parallels of the signs of the Zodiac, provided that in place of the rays of the parallels of the Zodiac one takes the rays of the parallels of the diurnal arcs. Hence it will be superfluous to give new precepts here, since what we wrote in the preceding proposition suffices. We have therefore laid out the parallels of the diurnal arcs in the same dial that both declines and inclines. Which was to be done.

SCHOLIVM.

IF here we repeat what we handed down in the scholium of proposition 3 of this book, we shall be able easily to describe those hour-lines which scarcely, or in no way, cut the equinoctial line.

PROBLEMA 40. PROPOS. 40.

To establish the vertical circles in the same dial that both declines and inclines.

[Margin: The description of the vertical circles in the same dial.]

FROM the place K of the style, a perpendicular KB having been drawn to the horizontal line, let another perpendicular KA be raised upon it, equal to the style KI; and the line AB having been drawn, let BD be taken equal to it on KB produced. Then, with D as centre, let a circle be described, to be divided into 360 equal parts — or into fewer, as we said above — beginning from the line DE drawn from the centre D to the point E, where the equinoctial line, the horizontal line, and the line of the 6th hour inter-

Diagram. A large figure of the vertical circles for a dial that both declines and inclines. At the centre stands a circle with centre **D**; on and around it are the point-marks (reading roughly): **M** (left of D), **N** (right of D), **F**, **B**, **G** clustered near the horizon line, **E** on the horizon to the right, **K** just below centre, **A** at lower left, **C** at the foot, **I** and **L** near the top. The horizontal base-line running across the middle is lettered **HO—RIZON** (the word "Horizon" split by the figure). Many straight and dashed rays radiate outward from the lower region. Around the periphery run graduation-numerals: across the top (left to right) XXX, 90, 75, 60, 45, 30 [printed "30"], XXX, and IS [?]; down the right side XV, XV, 30, XXX, XLV, 45; along the bottom (left to right) 30 [printed "30"], 45, 60, 75, 90, 75, 60, with LX above; the Roman forms (XV, XXX, XLV, LX) and the Arabic forms (15, 30, 45, 60) evidently label the same azimuthal graduations of the vertical circles. Worn zodiac-sign sorts stand among the outer rays (e.g. ♎ [Libra] at left; ♈ [Pisces] and

☿ [Capricorn]-like sorts [?] at the right and lower left). Readable point-labels: A, B, C, D, E, F, G, H, I, K, L, M, N. Several peripheral numerals, the "IS" marks, and the zodiac sorts do not resolve cleanly. (more than two peripheral labels flagged [?]).

[Margin: The description of the vertical circles in the same dial.]

—sect. For the hidden [construction] lines drawn from D through the division-points will cut the horizontal line at points which, if they are joined by straight lines to the point C — where the line BK cuts the meridian line — the vertical circles will have been described; that is, the common sections of those circles and of the plane of the dial, so that CE is the common section of the plane of the dial and of the vertical circle properly so called. We shall demonstrate this as follows.

[Margin: Demonstration of the aforesaid description of the vertical circles.]

LET the triangle ABK be understood to revolve about BK until it is perpendicular to the plane of the dial, so that the point A is joined with the tip of the style — that is, the centre of the world I — and the triangle itself coincides with the plane of the vertical circle, which is perpendicular to the plane of the dial, and is drawn through the style itself, and measures the inclination of the plane above the Horizon; so that the line BK is the common section of this vertical circle and the plane of the dial. Since, then, the meridian line is also the common section of that same plane of the dial and of the Meridian — which is likewise one of the vertical circles — the meridian line and BK will necessarily meet at that point into which falls the common section of all the vertical circles, that is, the axis of the Horizon, as is clear from proposition 18 of book 1. And they meet at C. Therefore C will be the vertical point, in which all the vertical lines come together. [Margin: What the vertical point is.] And because, as we wrote in proposition 4 of this book, the common section of any plane of the dial and of the vertical circle properly so called passes through the point E, where

where the equinoctial line, the horizontal line, and the six-o'clock line cut one another, the line CE will be the common section of the vertical circle properly so called and of the plane of the dial.

Again, with the triangle ABK remaining fixed at right angles to the plane of the dial, the line AB is the common section of the horizon and of that triangle — that is, of the vertical circle producing the section BK — since the horizon passes both through A, the tip of the style, and through the point B. Now suppose the circle described from D is imagined to be moved about the horizontal line until its centre D is joined to the point A, and the line DB coincides with the line AB (for DB and AB are equal), so that the circle itself comes to be described in the plane

of the horizon about the centre of the world. Then the line DE will be the common section of the horizon and of the vertical properly so called, since the vertical is drawn through the centre of the world — which is now the same as D — and through the point E, as we said. The line DF, drawn from D to the point F where the meridian line cuts the horizontal line, will be the common section of the horizon and of the meridian; for the meridian too runs in the dial both through the centre of the world D and through the point F. From this it follows that the angle EDF is a right angle, since the meridian and the vertical properly so called cut one another at right angles at the centre of the world.

And so, since the division of the circle takes its start from the line DE, the remaining hidden lines sent out from D through the division-points will be the common sections of the horizon and of the other vertical circles. Therefore, where they divide the horizontal line, through those points must be drawn from the vertex C the common sections of the vertical circles and of the plane of the dial. For at those points of the horizontal line all the vertical circles meet the plane of the dial, and all are likewise drawn through the vertical point C, into which the axis of the horizon falls. Such is the line AC drawn, which is the common section of all the vertical circles, since all of them are drawn both through the centre of the world A and through the vertical point C. Hence, unless an error has been made, the angle BAC must be a right angle; CAK the angle of the plane's inclination to the horizon; and ACK the angle of the complement of the inclination — just as ABK is the angle of the inclination which the horizon makes with the inclined plane, and BAK the angle of the complement of the inclination. [Margin: How the vertical point is found.] The vertical point, therefore, will be found if at A a style is set at the angle CAK of the plane's inclination to the horizon, or if a perpendicular AC is drawn to AB; for the line AC will cut the meridian line at the vertex C. The numbering of the vertical lines takes its start from the line CE and proceeds in both directions, so that the meridian line gives the ninetieth vertical. We have thus established the vertical circles in the same dial both declining and inclined. Which was to be done.

SCHOLIUM.

In our example the vertical circle of 60 degrees passes exactly through K, the place of the style, so that the section it makes in the plane of the dial is the line CD; for the vertical which measures the plane's inclination to the horizon stands 30 degrees from the meridian and 60 degrees from the vertical properly so called, since we suppose the plane of our dial to deflect 30 degrees from the vertical. This also happens in proposition 4 of this book.

It sometimes happens that certain of the hidden lines sent out from the centre D through the division-points scarcely, or in no way, cut the horizontal line, so that it is very difficult to describe without error the vertical lines corresponding to them from the vertex C in the dial. This occurs in our example with the vertical lines of 30 and 45 degrees. When we are left without points on the horizontal line, points must therefore be sought on the equinoctial line through which the vertical lines are to be drawn, in this way. [Margin: How to draw those vertical lines which scarcely or never cut the horizontal line.] Find the hour at which the Sun, being on the Equator, reaches the particular vertical circle whose line we wish to draw. For where the line of that hour (which we shall draw hidden, following the doctrine of proposition 37 of this book) cuts the equinoctial line, through that point the vertical line in question must be drawn from C. Thus, since the Sun on the Equator reaches the vertical of 30 degrees on the eastern side at 3 hours 17 minutes before noon — that is, at 8 hours 43 minutes after midnight — and the line of that hour cuts the equinoctial line at G, the line CG drawn will give the vertical of 30 degrees. Likewise, since the Sun on the Equator attains the vertical of 45 degrees at 2 hours 15 minutes before noon — that is, at 9 hours 45 minutes after midnight — and the line of that hour cuts the equinoctial line at H, the line CH drawn will give the vertical of 45 degrees; and so with the rest.

We shall find the hour at which the Sun, running along the Equator, reaches the proposed vertical in the following way. [Margin: How the hour is found at which the Sun, being on the Equator, reaches any given vertical.] Let the horizon be ABCD; the meridian AC; the equator BED; the vertical properly so called BFD; and let FIH be any other vertical whatsoever, cutting the horizon in the eastern and southern quadrant AB, and the equator in I. The arc EI on the equator is therefore to be found. Since in the spherical triangle EFI the angle E is a right angle, then — by proposition 18 of book 4 of Johannes Regiomontanus, *On Triangles* [Regiomontanus, *De Triangulis* IV.18], or by proposition 14 of book 1 of Geber [Jābir ibn Aflāḥ, *De Astronomia* I.14], or by proposition 42 of our *Spherical Triangles* [Clavius, *Triangula Sphaerica* 42] — as the sine of the angle EFI (which is known, since its arc AH is the complement of the distance FH of the vertical from the vertical properly so called FB) is to the whole sine, so is the sine of the complement of the angle EIF to the sine of the complement of the arc EF, the altitude of the pole.

Diagram. A hemispherical (analemma-sphere) figure showing the horizon, meridian, equator and vertical circles for the worked hour-example. The outer circle is the horizon ABCD; a vertical diameter AC is the meridian; a great-circle arc BED is the equator; the arc BFD is the vertical properly so called; and the arc

FIH is another vertical circle cutting the horizon in the eastern–southern quadrant AB and the equator at I. Readable labels :

- A (top): zenith / pole of the horizon, top of the meridian AC
- B (left): true east point on the horizon
- C (bottom): lower end of the meridian AC
- D (right): true west point on the horizon
- E (upper centre): point on the equator BED
- F (centre): intersection of the verticals (foot of the vertical circles)
- G (below centre): point near the foot
- H (upper left): end of the vertical FIH on the horizon
- I (left of centre, below H): intersection of vertical FIH with the equator
- K (lower right): point on the vertical FLK
- L (lower right, below K): point on the vertical FLK
- M (upper right): point on the vertical FM
- N (lower left): point on the vertical FNO
- O (lower left, below N): point on the vertical FNO
- P (upper right): point where a vertical meets the equator above the horizon

(All fifteen point-labels A–P resolve on the scan; no [?] flags.)

And conversely: as the whole sine is to the sine of the angle EFI — that is, to the sine of the complement of the distance of the proposed vertical from the vertical properly so called — so is the sine of the complement of the altitude of the pole to the sine of the complement of the angle EIF. Therefore the angle EIF will be known. And since again — by proposition 16 of book 4 of Johannes Regiomontanus, *On Triangles* [Regiomontanus, *De Triangulis* IV.16], or by proposition 13 of book 1 of Geber [Geber I.13], or by proposition 41 of our *Spherical Triangles* [Clavius, *Triangula Sphaerica* 41] — as the sine of the angle EIF just found is to the sine of the arc EF, the altitude of the pole, so is the sine of the angle EFI, the complement of the distance of the proposed vertical from the vertical properly so called, to the sine of the arc EI, the distance of the Sun from the meridian: if we make it that, as the whole sine is to the sine of the complement of the distance of the proposed vertical from the vertical properly so called, so is the sine of the complement of the altitude of the pole to a fourth term, a sine will be found whose arc-complement is to be kept. And if again we make it that, as the sine of this kept complement is to the sine of the altitude of the pole, so is the sine of the complement of the distance of the proposed vertical from the vertical properly so called to a fourth term, the sine of the distance of the Sun

from the meridian will be found. [Margin: Example.] Example. Let the vertical FH be supposed to stand 30 degrees from the point B, the true east, toward the south. If, then, we make it that, as 100000, the whole sine, is to 86602, the sine of the complement of the distance of the said vertical from the point of true east, so is 74314, the sine of the complement of the altitude of the pole, to a fourth, we shall obtain approximately this sine

64357, whose arc-complement contains about 49 degrees 56 minutes. If again we make it that, as 76529, the sine of the arc of 49 degrees 56 minutes just found, is to 66913, the sine of the altitude of the pole, so is 86602, the sine of the complement of the distance of the proposed vertical from the vertical properly so called, to a fourth, there will be found here very nearly the sine 75720, whose arc of 49 degrees 13 minutes will give the distance of the Sun from the meridian at that moment, 3 hours 17 minutes. And since this distance is before noon — because the vertical FH is supposed to stand 30 degrees from true east toward the south — we shall subtract it from a semicircle, that is, from 12 hours, so that there remains 8 hours 43 minutes after midnight. In the same way, if the same vertical is supposed to stand at 45 degrees, we shall find 2 hours 15 minutes before noon, that is, 9 hours 45 minutes after midnight.

But now if the vertical FM stands 30 or 45 degrees from the true west D toward the south, we shall then find, by the same device, the hour 3 hours 17 minutes after noon, or the hour 2 hours 15 minutes.

[Margin: When the proposed vertical deviates from true east or west toward the north.]

[Margin: What is to be done when the hour at which the Sun, being on the Equator, reaches the proposed vertical, does not cut the equinoctial line.]

But if the proposed vertical recedes from true east or west toward the north, and consequently cuts the Equator below the horizon — such as the vertical FNO or FLK — the same vertical will also cut the Equator above the horizon at the opposite point, as at P or I. Therefore, as before, we shall investigate the distance of the Sun EP after noon, or EI before noon; for this is equal to the distance of the point O after midnight, or of the point K before midnight, and so on.

Again, if it should happen that the hour found from noon or from midnight, through which the proposed vertical line is to be drawn, lies on the equinoctial line but does not cut the equinoctial line, we shall seek the opposite hour on the equinoctial line and draw the vertical line through it. For this line, extended from the vertical point C toward the equinoctial line, will represent the semicircle

opposite to that of the proposed vertical, while beyond the vertical point C it will represent the remaining semicircle, whose line is sought. Thus, if by this art we wish to draw the vertical line of 30 degrees such that its vertical circle recedes from true west toward the south by 30 degrees, we shall find that the Sun on the Equator reaches that vertical at 3 hours 17 minutes after noon. And because this hour after noon cannot cut the equinoctial line in our dial, we shall find on the equinoctial line the point L of the hour 3 hours 17 minutes after midnight. For the line CL will give the common section of the vertical circle receding from true east toward the north by 30 degrees, while the portion of the same beyond C, extended, gives the common section of the vertical circle receding from true west toward the south by 30 degrees. Let the same be done in the other cases.

[Margin: The aforesaid device can be used by anyone in drawing all the verticals in any dial described thus far.]

We shall also be able to use this method in the preceding cases, whenever some of the vertical lines scarcely, or in no way except at the most distant points, cut the horizontal line. Indeed, by the same device it will be possible to describe all the vertical lines.

But if one of the hidden lines drawn from D should happen to be parallel to the horizontal line, then the vertical line must be drawn through C parallel to that same horizontal line. For since that hidden parallel drawn through D is the common section of the horizon and of the vertical drawn through it, and since — if the circle described from D is understood to be set in its proper position — the plane of the dial is equidistant from that common section (otherwise the hidden parallel, extended, would cut the plane of the dial, and so at some point of the horizontal line, since the horizon meets the plane of the dial only along this line; the same parallel would therefore cut the horizontal line, which is absurd, since it is supposed parallel to the horizontal line): then, by proposition 18 of book 1, the common sections made by the plane of the dial in the horizon and in the said vertical — that is, the horizontal line and the aforesaid vertical line — will be parallel to one another. Thus you see, in the proposed example, that the vertical line of 30 degrees is parallel to the horizontal line, because the hidden line MN, which is the common section of the horizon and of the vertical of 30 degrees, is parallel to the horizontal line. For since a quadrant is intercepted between the lines DM and DB — for from the line MD, the common section of the horizon and of the vertical of 30 degrees, up to FD, the common section of the horizon and of the meridian (or vertical of 90 degrees), 60 degrees are counted; and from the line FD up to BD, the common section of the horizon and of the vertical of 60 degrees,

30 degrees are reckoned, which with the 60 degrees make 90 degrees — the angle at D will be a right angle. Since, then, the angle at B is also a right angle, [Margin: (a) Euclid I.28] the lines MN and BE will be parallel to one another.

PROBLEMA 41. PROPOS. 41.

To lay out the parallels of the horizon in the same dial both declining and inclined.

[Margin: The description of the parallels of the horizon in the same dial both declining and inclined.]

Just as in proposition 41 of the preceding book we described the parallels of the horizon in a polar dial, so we shall describe the same in a dial both declining and inclined, provided that what we are about to say is rightly grasped. As to the former method: the circle of the analemma ABC will here represent that vertical circle which, passing through the style, stands at right angles to the plane of the dial and makes in the plane of the dial the section CD — just as in the preceding proposition it is the one which, drawn through the style IK, makes the section CD. The parallels of the horizon, moreover, are not changed in the same analemma. Next, in place of the axis EF, a diameter must be drawn — the common section of the said vertical and of the great circle to which the dial is equidistant — such that both the arc CE and the arc BF is equal to the inclination of the proposed plane to the horizon. Parallel to this diameter, the line RQ must be drawn, of the size of the style IK or AK, such that the line DI, cutting the line RQ at right angles, is equal to the style IK. Finally, the points L, M, N, etc., taken from the point T where the horizon BC cuts the line RQ, must be transferred onto the line BC, from B, the point of the horizontal line, toward C, in the upper dial; but in the lower dial they must be trans-

Diagram. The analemma circle for describing the parallels of the horizon in the declining-and-inclined dial. A large circle with centre **D** carries the horizon-diameter BC (B at the left, C at the right) and the vertical section CD; an oblique line **RQ** (R at the upper right, Q at the lower left) is drawn parallel to the axis-diameter, of the size of the style, and the perpendicular DI (I near the top) cuts it at right angles. The periphery is graduated in degrees. Readable labels:

- A (top of circle); B (left, on horizon BC); C (right, on horizon BC); D (centre)
- E (upper right, on the circle); F (bottom of circle); G (upper left, on the circle); H (lower right, on the circle)
- R (upper right) and Q (lower left): the two ends of the oblique line RQ

- I (near top): foot of the perpendicular DI to RQ
- T (left of centre): point where the horizon BC cuts RQ
- Inner transferred points, clustered symmetrically about the centre: **L, M, N** (upper centre) and again **L, M, N** (lower centre); **K, S, V** near the centre; **O** at the lower centre. Several of these small inner letters overlap and their exact placement does not resolve cleanly.
- Peripheral degree-graduations: across the top **90**; down the left side **75, 60, 45, 30, 15**; down the right side **15, 30, 45, 60, 75**; along the bottom **30, 45, 60, 75** [several bottom numerals faint].
- A second **P** appears near R (top) and near Q (bottom) as an end-label of the oblique line [?].

— more than two inner point-labels (the L/M/N/K/S/V/O cluster and the P marks) overlap and cannot be pinned to exact positions at this resolution.

-ferred, the intervals TS, and others, if there be any, from B in the same line BD, extended beyond B. For the conic sections described about the diameters LQ, MQ, NQ, etc., according to the doctrine of proposition 8 of book 1, and transferred into the dial in such a way that their diameters coincide with the line BC and pass through the transferred points L, M, N, etc., with their horns turned away from the horizontal line, will give the parallels of the horizon.

As to the latter method: the line AD must be taken equal to the line AC, which in the figure of the preceding proposition falls from A, the tip of the style, onto the zenith, or vertex C; and onto the line AB must be transferred the intervals between the centre D and the vertical lines on the horizontal line, and so on. All the rest must be completed as was set forth in the said proposition 41 of the preceding book. For here too the horizontal line serves as a kind of equinoctial line, and the vertical lines as hour-lines, whose centre is the zenith, or vertex C. Likewise AD, in this adjoined figure, serves as the axis of the world — namely the axis of the horizon, which now serves as the equator; and AB serves as it were the radius of the equator, and the other lines sent out from A as the radii of the other signs; while the lines falling from D serve as the hour-lines, and so on.

[Margin: Another description of the parallels of the horizon.]

Diagram. The alternative construction ("another description") of the horizon- parallels, the analemma "unfolded" onto the dial plane. A horizontal top line carries, left to right, the labels **XC — A — D — [mirror-XC] — C**; from the points A and D a fan of straight lines (the vertical lines, each carrying **two** numbers as the text explains) descends, converging toward **F** near the centre-bottom, with a

broad arc sweeping across the lower part of the figure. Readable point-labels: A, C, D (on the top line); E (left, below A); F (centre); B (lower left, on the arc); N (lower right, on the arc). Peripheral degree-numbering, in Roman numerals down the left side: **XC (90)**, **LXXV (75)**, **LX (60)**, **XLV (45)**, **XXX (30)**, **XV (15)**; the right-hand side carries the mirror-images of the same Roman numerals (printed reversed) [mirror numerals partly [?]]. Arabic degree-numerals also appear along the lower left (**60, 45, 30, 75, 90, 15, 5**) and lower right (**60, 45, 30, 75, 15**). Interior rays are lettered with reversed/mirror Roman numerals (e.g. XV, XXX and their mirrors) marking the vertical degrees.

— the right half of the figure is mirror-printed and several reversed numerals and the lower-arc labels (a possible G near B, and the mirrored degree cluster) do not resolve cleanly (more than two labels flagged [?]).

In the example proposed in the preceding proposition, since the line CD is one of the vertical lines, it comes about that it stands equally distant from any two vertical lines placed on either side which recede from it by an equal number of degrees, so that the two intervals between D, the centre, and the horizontal line are equal — such as, for example, DF and DG of the vertical lines of 90 and 30 degrees, each of which is 30 degrees from the vertical line CD of 60 degrees. For since, in the triangles DBF, DBG of the figure of the preceding proposition (if a straight line were drawn from D to G), the angles at B are right and equal, and likewise the angles at D are equal, since they stand on equal arcs of 30 degrees, and moreover the side DB is common, [Margin: (a) Euclid I.26] the remaining sides DF, FB will also be equal to the remaining sides DG, GB; and so with the rest. Hence it comes about that each of the lines drawn from D in this figure has two numbers, as appears in the figure; and so each of the intervals of the lines falling from D, between D and the lines issuing from A, is to be transferred onto two verticals from the zenith C, equally distant from the line CD — just as was done in the description of the arcs of the signs in a horizontal dial in proposition 2 of the preceding book. One must observe, however, that the intervals of the lines falling from D which cut the line AB are to be transferred onto those vertical lines which cut the horizontal line in the dial — which in our example are all those contained above the vertical line of 30 degrees parallel to the horizontal line. But the intervals of the other lines — those which lie to the right of the line DF of 30 degrees equidistant from AB, and which are drawn by the rule that the angles they make with DF are equal to the angles which the lines placed to the left of the same DF make with it — are to be transferred onto the portions of the vertical lines which do not cut the horizontal line; such as are all the vertical lines in the

given example which fall below the vertical line CG of 30 degrees parallel to the horizontal line.

But if the line CD should not be one of the vertical lines, yet should stand equally distant from two placed on either side, each of the lines sent out from D will in the same way contain two numbers; the topmost, however, DE, which corresponds to the line CD in the dial, will have no number affixed. But if CD should be neither one of the vertical lines nor equally distant from the two nearest placed on either side, then to each

[Margin: What is to be done when the line GD, in the dial of the preceding proposition, stands unequally distant from the vertical lines placed on either side.]

to each of the straight lines issuing out from D only single numbers are to be affixed, because in that case all the intervals between D and the horizontal line will be unequal. And since in that case no vertical line is parallel to the horizontal line, one must draw through C a hidden line equidistant from the horizontal line in the dial; to this will correspond the straight line DF, equidistant in the next figure from the line AB. Then all the straight lines placed to the left of DF are to be transferred to the right of that same DF. For these will correspond to the vertical lines which do not cut the horizontal line but are produced beyond the point C — just as we said of the hour-lines in the dial declining from the vertical circle, in proposition 2 of this book. This too may be observed in our own example. For just as, in the next figure, the line D 15·75 to the left of the straight line DF corresponds in the dial to the vertical lines of 15 and 75 degrees — which cut the horizontal line and stand equally distant from CD, lines of the kind that follow the straight line CD in the dial in the third place on either side — so too the line D 75·15 to the right of DF corresponds in the next figure to those same vertical lines produced beyond the zenith C, and so on.

From the rays of the parallels of the horizon drawn out from A toward the left of the horizon-ray AB, there are described the parallels of the horizon above the horizontal line; these indeed belong to the lower dial, if the part above the horizontal line is inverted — as has often been said above, and as we showed in proposition 41 of Book 2. We have therefore laid out the parallels of the horizon in the same dial that both declines and inclines. Which was to be done.

PROBLEMA 42. PROPOS. 42.

To describe the meridians — that is, the circles of longitude of cities — in the same dial that both declines and inclines.

Diagram. A large sundial figure showing the meridian (longitude) circles laid over the earlier construction. A horizontal line labelled **HORI = ZON** (Horizon) runs the full width of the page. The circle from proposition 37 is drawn with its centre at **L**. Many straight lines radiate from the region of the circle toward the periphery; they are the meridians of longitude, labelled in degrees (the numerals are set rotated along their lines).

- HORI = ZON (horizontal): the horizon line
- L (centre): centre of the dial-circle described in proposition 37
- M (upper-left, on the circle): endpoint of the division-start line LM
- A (upper, on the line LA): point on the prime-meridian line drawn through the Fortunate Isles
- "Inf. Fort." (marked twice, each with a small cross ☒): *Insulae Fortunatae*, the Fortunate Isles — marking the line LA, the first meridian (0°)
- Longitude meridians labelled (in degrees): 15, 30, 45, 60, 75, 90, 105 [?], 120, 135 (on the lower and right side); 300, 315, 330, 345 (on the upper side; these numerals read rotated) [?]
- Dashed lines through L: the division-start line LM and the extended prime-meridian line LA
- Several zodiac-sign glyphs carried over from the arcs-of-signs construction; the Cancer glyph ☿ is legible near the centre, the others are worn and not securely identifiable [?]

[Margin: The description of the meridian circles in the same dial.]

These circles will be described just like the hour-lines from noon or from midnight, as we set forth in proposition 37 of this book, because they are drawn through the poles of the world, exactly as the hour-circles are. But the division of the circle drawn from L (described in the dial in proposition 37 of this book) must be begun not from the straight line LM, but from another line which — the dial and the said circle being set in their proper position — recedes from the point M toward the west by as many degrees as are comprised in the longitude of the place: in the given example, 36 degrees. For this line will be the common section of the equator and of the first meridian drawn through the Fortunate Isles, such as is the straight line LA in the accompanying figure.

In the lower dial — the one described on the lower face of the plane, such as that which the horizontal line cuts off, if all its parts are inverted, as was said in what precedes — numbers must be affixed to the meridians themselves, just as we taught for the vertical dial in proposition 18 of Book 2: namely, by adding 180 degrees, and so on, to the numbers of those same meridians in the upper dial, as appears in the preceding figure. And so we have described the meridians, that is, the circles of longitude of cities, and so forth. Which was to be done.

PROBLEMA 43. PROPOS. 43.

To lay out the parallels of cities, or the circles of latitude, in the same dial that both declines and inclines.

[Margin: The description of the circles of latitude in the same dial.]

In no respect does the description of these parallels differ from the description of the arcs of the signs, which we treated in proposition 38 of this book — as we have often noted already in what precedes. We have therefore laid out the parallels of cities, or the circles of latitude, in the same dial that both declines and inclines. Which was to be done.

PROBLEMA 44. PROPOS. 44.

To place the celestial houses in the same dial that both declines and inclines.

[Margin: The description of the celestial houses according to Regiomontanus in the same dial.]

Let the circle drawn from L, described in proposition 37 of this book, be cut into 12 equal parts — or into more, if subdivisions of the celestial houses are desired — beginning from the straight line LM, as in the description of the hours from noon or midnight. Through the points of division and the centre L let straight lines be sent out cutting the equinoctial line at points; and if through these points straight lines are drawn from the point E, where the horizontal line intersects the meridian line, the celestial houses will be described according to the teaching of Johannes Regiomontanus [Regiomontanus]. We shall demonstrate this in the same way as we showed the like for the declining dial in proposition 8 of this book.

Diagram. A dial figure for the celestial houses, built on two overlapping circles. A horizontal line labelled **HORI = ZON** (Horizon) runs across; the vertical circle is lettered diagonally **VER = ... TICALIS** (Verticalis). Straight lines radiate to the

periphery, labelled with house-numbers in Roman numerals and with division-numbers in Arabic digits.

- HORI = ZON (horizontal): the horizon line
- VER = TICALIS (diagonal): the vertical circle (Verticalis)
- E (on the horizon, left of centre) and F (on the horizon, right of centre, where several lines converge): the points E and F of the construction
- M (upper-left, on the larger circle)
- L, K (just below the centre): construction points
- A, B, C, D (descending below the centre): the construction points of the Campanus method (D is the centre of the smaller circle)
- G (upper-right, on a house-line) [?]
- House-lines lettered in Roman numerals: I, XI, XII, X, II, and IX (printed "1/X"); further Roman numerals worn [?]
- Division-lines numbered in Arabic: 6, 8, 9, 10, 12; upper-left labels "OI" [?] and "XII" [?] and an upper-right label "IIIA" [?] not securely resolved
- Zodiac-sign glyphs (Cancer ♋) appear near the centre, carried over from the arcs figure

[Margin: The description of the celestial houses in the same dial according to Campanus.]

But to lay out the houses in the dial as they are constituted by Campanus [Campanus of Novara], we shall proceed thus. From K, the place of the style, raise a perpendicular KBD to the vertical line properly so called, CB, which we described in proposition 40 of this book; and to this let another perpendicular KA be erected, equal to the style, and let the straight line AB be joined. Then, taking a straight line BD equal to AB itself, describe from D a circle of any size; and, having divided it into 12 equal parts (or more), beginning from the straight line DC — which is drawn from the centre D to the zenith C — let hidden lines be sent out from D through the points of division, cutting the vertical line CB at points. And if through these points straight lines are drawn from E, the point where the meridian line and

the horizontal line intersect one another, straight lines are drawn — of the kind that in the proposed figure are marked off by those fine lines — the celestial houses will be described according to the opinion of Campanus. This we shall demonstrate by the following reasoning.

[Margin: The demonstration belonging to the foregoing description.]

Conceive the triangle ABK to be moved about BK until it stands at right angles to the plane of the dial, and consequently the style AK also perpendicular to it. Likewise let the circle described from D be understood to be turned about the vertical line CB until its centre coincides with the centre of the world — that is, with the vertex of the style A; and it will necessarily coincide, because of the equality of the straight lines AB and BD. These things being posited, the circle described from D will stand established in the plane of the vertical circle properly so called, and about the same centre with it. For the vertical circle is drawn through the centre of the world (that is, the vertex of the style A) and through the straight line CB, just as the said circle described from D is, in that position. Therefore DC will be the common section of the vertical and of the meridian, since the meridian passes through the centre D and cuts the plane of the dial at C. And the remaining hidden lines will be the common sections of the vertical circle and of the circles of the other celestial houses. Hence, as in proposition 8 of this book, we shall show that the celestial houses are rightly described according to the opinion of Campanus. Moreover the straight line DF — which is the common section of the horizon and of the vertical — will, together with DC, the common section of the meridian and of the vertical, form a right angle at the centre D, because between the meridian and the horizon a quadrant of the vertical circle properly so called is included. We have therefore placed the celestial houses in the same dial that both declines and inclines. Which was to be done.

SCHOLIUM.

But it is necessary that the line KBD, which is drawn perpendicular to the vertical line, when produced beyond K (the place of the style) should pass through the point E, where the meridian line and the horizontal line intersect one another. For it is the common section of the plane of the dial and of the circle of position, which stands at right angles to the plane of the dial and passes through the common sections of the meridian and of the horizon, and so cuts the plane of the dial at the point E — just as the other circles of position, or of the celestial houses, do, as was demonstrated in proposition 8 of this book. For since the circle of position drawn through the poles of the vertical circle and of the plane of the dial is perpendicular both to the vertical circle and to the plane of the dial, it will (by proposition 15 of Book 1 of Theodosius [Theodosius, Sphaerica I.15]) pass altogether through the style AK set in its proper position — ^a (because all planes drawn through the style to the plane of the dial are perpendicular to it) — and therefore through the point K.

[Margin: ^a Euclid, *Elements* XI.18]

But since, on the contrary, both the plane of the vertical circle and the plane of the dial are perpendicular to the said circle of position,^b the common section of these too — that is, the vertical line CB — will be perpendicular to the same circle of position, and consequently, by definition 3 of Book 11 of Euclid [Euclid, Elements XI, def. 3], also perpendicular to the common section of that same circle and of the plane of the dial lying within it. Since therefore CB is perpendicular to KB by construction, KB will be the common section of the said circle of position and of the plane of the dial, and so it will pass through the point E, as will also the remaining common sections of the circles of the celestial houses and of the plane of the dial.

[Margin: ^b Euclid, *Elements* XI.19]

[Margin: How to describe those celestial houses which scarcely, or in no way, intersect the vertical line.]

Now, since in describing the celestial houses according to the opinion of Campanus it sometimes happens that certain hidden lines sent out from the centre D scarcely, or in no way, cut the vertical line CB — so that it becomes exceedingly difficult to describe without some error the lines of the celestial houses corresponding to them in the dial from the point E, as happens in our example with the line of the second celestial house in the nocturnal portion of the dial, which in the lower dial gives the eighth house, opposite to it — the points on the equinoctial line through which the lines of the celestial houses are to be drawn must be sought out, for those cases in which we are deprived of points on the vertical line, in the following way. Let inquiry be made for the hour at which the Sun, being on the equator, reaches the circle of that celestial house whose line we wish to describe. For where the line of that hour (which we shall draw in a hidden manner, as we set forth in proposition 37 of this book) cuts the equinoctial line, through that point the sought celestial house is to be drawn from E. Thus, because the Sun, being on the equator, reaches by its diurnal motion the circle of the second celestial house — which in the lower dial is the eighth house, opposite to it — at hour 3, minute 29 after midnight, and the line of this hour cuts the equinoctial line at the point G, the line of the said house is to be drawn from E through G; and so with the rest.

[Margin: How to explore the hour at which the Sun, being on the equator, reaches the proposed circle of the celestial house.]

We shall find the hour at which the Sun, running along the equator, reaches the proposed circle of the celestial house, from the doctrine of sines, by this method.

Diagram. A spherical diagram shown as a sphere with several great circles, in the lower-left of the page. The point **A** is at the top, **C** at the bottom, **B** at the left, **D** at the right; **E** lies in the upper-centre and **F** in the lower-centre. The great circles named in the accompanying text are drawn as the horizon, the meridian, the equator, the vertical, and the circle of the celestial house, with their intersections lettered.

- A (top), C (bottom), B (left), D (right): cardinal points of the figure
- E (upper-centre), F (lower-centre): points on the meridian / vertical
- Horizon: the outer bounding circle, ABCD [?: the first letter is worn — the print may read "CBCD"]
- Meridian: AEC
- Equator: BED
- Vertical circle (Verticalis): BFD
- Circle of the celestial house: AGCK
- G, H: eastern intersections (left side); I, K: western intersections (right side)
- lowercase g near B [?]

Let ABCD [?] be the horizon; AEC the meridian; BED the equator; BFD the vertical; and AGCK the circle of the celestial house, cutting the vertical and the equator on the eastern side — whether above the horizon or below — at the points G and H, and on the western side at the points I and K. We must therefore seek the arc of the equator EH, or EK. Since in the triangle BGH (or DIK) the angle G (or I) is right, by proposition 15 of Book 1 of Theodosius [Theodosius, *Sphaerica* I.15] it will follow — by proposition 18 of Book 4 of Johannes Regiomontanus's *On Triangles* [Regiomontanus, *De Triangulis* IV.18], or by proposition 14 of Book 1 of Geber [Jābir ibn Aflaḥ, I.14], or by proposition 42 of our own *Spherical Triangles* [Clavius, *Triangula Sphaerica* 42] — that as the sine of the angle B (or D) — namely of the altitude of the pole, which the equator makes with the vertical — is to the whole sine, so is the sine of the complement of the angle H (or K) to the sine of the complement of the arc BG (or DI) of the vertical circle placed between the horizon and the circle AGCK. And conversely: as the whole sine is to the sine of the angle of the altitude of the pole B (or D), so is the sine of the complement of the arc BG (or DI) to the sine of the complement of the angle H (or K). This complement being known, the angle H (or K) will also be known.

Again, since — by proposition 16 of Book 4 of Johannes Regiomontanus's *On Triangles* [Regiomontanus, *De Triangulis* IV.16], or by proposition 13 of Book 1 of Geber [Jābir ibn Aflaḥ, I.13], or by proposition 41 of our own *Spherical Triangles* [Clavius, *Triangula Sphaerica* 41] — as the sine of the angle H (or K), just found, is

to the sine of the arc BG (or DI), so is the whole sine of the right angle G (or I) to the sine of the arc of the equator BH (or DK), the complement of the Sun's distance from noon or from midnight: if it be so contrived that as the whole sine is to the sine of the altitude of the pole, so is the sine of the complement of the arc of the vertical circle intercepted between the horizon and the circle of the proposed celestial house to a fourth term, a sine will be found whose arc's complement is to be kept. Again, if it be so contrived that as the sine of this kept complement is to the sine of the arc of the vertical circle placed between the horizon and the circle of the proposed celestial house, so is the whole sine to a fourth term, there will be found the sine of the complement of the Sun's distance from noon (if the celestial house stands above the horizon) or from midnight (if the given celestial house lies hidden below the horizon).

[Margin: Example.]

Example. Let the Sun be at the beginning of the second house, whose circle lies hidden below the horizon

lies hidden 30 degrees on the eastern side — degrees which are, of course, reckoned along the vertical circle. Accordingly, set it up so that as the whole sine, 100000, is to 66913, the sine of the pole's altitude, so is 86602, the sine of the complement of the arc of 30 degrees, to a fourth term: there will be found here a sine of about 57950, whose arc contains $35^{\circ}25'$; and the complement of this, $54^{\circ}35'$, will give the angle BHG. Then set it up so that as 81495, the sine of the angle BHG which we have just obtained, is to 50000, the sine of the arc of the vertical circle intercepted between the circle of the proposed house and the horizon, so is the whole sine, 100000, to a fourth term: there will be found here a sine of about 61353, whose arc BH, $37^{\circ}51'$, will give the complement — that is, the Sun's distance after midnight, since the Sun then stands between the meridian and the horizon below the earth on the eastern side — namely $52^{\circ}9'$, that is, 3 hours 29 minutes.

This distance would instead fall before noon, if the circle of the celestial house passed through the beginning of the twelfth house, so that the arc of the vertical circle between the horizon and the said circle above the horizon on the eastern side contained 30 degrees; but after noon, if that same circle were drawn through the start of the eighth house; and finally before midnight, if it passed through the beginning of the sixth house.

PROBLEMA 45. PROPOS. 45.

To place the ascending signs of the Zodiac on the same dial when it both declines and is inclined.

[Margin: How the ascending signs are depicted on the same dial.]

By exactly the same methods we used in what preceded, we shall here describe the ascending signs, as will become clear from the accompanying figure. For from the first two little tables of proposition 9 of Book 2 [*Gnomonices* II, prop. 9] we shall track down, on the equinoctial line, the points through which the lines for Aries, Taurus, Gemini, Cancer, Leo, [zodiac sign: ?], Aquarius, and Pisces pass. From the third little table of the same proposition they are drawn [continues below the figure]—

Diagram. A declining-and-inclined sundial layout onto which the ascending signs of the Zodiac are plotted. A horizontal line labelled **HORIZON** (printed **HORI:** at the left, **ZON** at the right) runs across the upper part of the figure. A second long line, the equator, is labelled **AEQVATOR** (the letters run along the line, appearing as **TOR** near the top and **AEQVA** toward the lower right). A near-vertical line is labelled **Linea meridiana** (meridian line — the words **Linea** and **meridiana** set along it), and a further line is marked **Linea** at the lower left; a small vertical caption at the upper left appears to read **Linea dioptr[?] [?]**. The six-o'clock hour line carries the caption **hora 6** with a small Sun symbol.

At the left, a small circle (the figure of the rising and setting amplitudes) carries the construction letters:

- A (left of the circle): vertex.
- F (upper left, inside the circle): vertex, joined to B by dashed lines.
- B (top of the circle, with a right-angle mark): vertex.
- P, L, K (lower part of the circle, in a row): vertices.

From the region of the circle a great many straight sign-lines radiate outward to the right and downward; their outer ends are marked with zodiac sorts. The following are legible: Capricorn [♑], Aquarius [♒], Aries [♈], Pisces [♉], Taurus [♉], Gemini [♊], Cancer [♋], Leo [♌]. Several further peripheral zodiac sorts are worn or overprinted by crossing lines and cannot be securely read: [zodiac sign: ?], [zodiac sign: ?], [zodiac sign: ?] (a Scorpio- or Virgo-like sort near the top).

[continued from above:]...From the third little table of the same proposition we shall find, in the tropic of Cancer [♋], the points for Aries, Taurus, Gemini,

Cancer, and Leo. For [zodiac sign: ?], however, and for Aquarius and Pisces, we shall find the points on the meridian line, from the sixth little table of the same proposition. Then for Leo we shall find a point in the tropic of Cancer, from the third table of the said proposition, through which we have drawn the line of Leo, passing through that point of the horizontal line where it is cut by the parallel of Gemini and of Leo. For Virgo, finally, we meet one point in the tropic of Cancer, from the third table of the said proposition, and another on the meridian line, from the sixth table of the same. But the lines for Sagittarius and Capricorn can scarcely be drawn in our example, since they run out too far, as may easily be gathered from the said tables. All the lines of the ascending signs, however, pass through the points of the horizontal line where the arcs of the signs cut it — points which can also be investigated without those arcs, either from the fifth little table of proposition 9 of Book 2 [*Gnomonices* II, prop. 9], as is clear from the foregoing, or from the figure of the rising and setting amplitudes of proposition 21 of Book 2 [*Gnomonices* II, prop. 21], by this device.

[Margin: The finding of the points through which the ascending signs are drawn on the horizontal line.]

In the figure of the rising and setting amplitudes, which we repeated at proposition 9 of this book, let BEG be set up as the angle of the declination of the proposed plane from the vertical circle — toward the parts of the south toward the west, if the plane declines from the north toward the east (as happens in the given example), or toward the east, if it inclines toward the west; but toward the parts of the north toward the east, if the dial turns away from the south toward the west, or toward the west, if it turns from the south toward the east. After this, let a straight line EG be taken, equal to the straight line AB in the figure of proposition 40 of this book [*Gnomonices* III, prop. 40]; and through —

and through G, let a perpendicular GH be erected to EG. For if the points of this perpendicular, where it is cut by the rays of the rising amplitudes, be taken from the point H and transferred onto the horizontal line from the point F, where the meridian line and the horizontal cut one another, the points will be found through which the arcs of the signs are drawn. For let there be drawn from K, the place of the gnomon, a perpendicular KB to the horizontal line, and to this another perpendicular KA, which is to be equal to the style; let the straight line AB be joined, which is the same as the one specified in proposition 40 of this book [*Gnomonices* III, prop. 40], and is therefore equal to EG in the figure of the rising amplitudes of proposition 9 of this book [*Gnomonices* III, prop. 9]. Now suppose the triangle ABK to be turned in the mind about BK until it stands at right angles

to the plane of the dial, and thus lies in the plane of the vertical circle that measures the inclination of the plane to the horizon; then, once BK has been drawn, AB will be the common section of the horizon and of the said vertical circle, and the joined line AF the common section of the horizon and of the meridian — because both the horizon and the meridian are drawn through A, the centre of the world, and through the point F.

Therefore the angle AFB, which the meridian line AF of the horizon makes with the horizontal line FB of the plane of the dial, will be equal to the complement of the declination of the dial from the vertical properly so called. And since the angle ABF is a right angle — for since the triangle ABK is at right angles both to the plane of the dial and to the horizon, these two planes will also be at right angles to the triangle; [a] therefore their common section FB will be perpendicular to that same triangle, and for that reason perpendicular also to the line BA, by definition 3 of Book 11 of Euclid [Euclid, *Elements* XI, def. 3] — the remaining angle BAF will be equal to the declination of the dial from the vertical properly so called, that is, to the angle BEG in the figure of the rising amplitudes of proposition 9 of this book [*Gnomonics* III, prop. 9].

[Margin: a — XI.19 (Euclid, *Elements* XI.19).]

Since, then, the angles E and G of the triangle GEH, in the figure of the rising amplitudes, are equal to the angles A and B of the triangle BAF in the figure of this proposition, and the sides EG and AB, on which those angles lie, are likewise equal by construction, [b] the sides EH and HG will also be equal to the sides AF and FB, and the angle H equal to the angle AFB. Hence, if the line EG of the figure of the rising amplitudes coincides on the dial with the line AB, then EH will also coincide with AF, and HG with FB, on account of the equality of the angles; and finally the whole of HG, produced in both directions, will coincide with the whole horizontal line. For this reason the rays of the rising and setting amplitudes will meet the horizontal line in points as far distant from the point B, or F, as the points are removed from the point G, or H, where the rays of the amplitudes cut the line GH, and so on. We have therefore placed the ascending signs of the Zodiac on the same dial when it declines and is at the same time inclined. Which was to be done.

[Margin: b — I.26 (Euclid, *Elements* I.26).]

SCHOLIUM.

[Margin: How the ascending signs are laid out according to the teaching of Andreas Schöner.]

If we wish to describe these same ascending signs according to the teaching of Andreas Schöner [Andreas Schöner], we shall use this device. In the first figure of the scholium to proposition 9 of Book 2 [*Gnomonices* II, prop. 9], from the line ED, or EB, let there be cut off a line EH equal to the line LM (which on the dial is intercepted between the centre L and the point M, where the equinoctial line and the meridian cut one another); and at H let there be set up, with the line BD, an angle equal to the one which the equinoctial line makes with the line LM on the dial — yet under this rule, that, with the centre E placed at the centre L and the line ED laid upon the line LM, the line drawn through the point H and constituting the said angle should coincide with the equinoctial line. Then let the intervals of the aforesaid line drawn through H, intercepted between H and the lines of the signs, be transferred onto the equinoctial line from the point M, marking off the points on the equinoctial line itself.

For if, from the point where the meridian line and the horizontal cut one another, hidden straight lines be drawn through these points of the equinoctial line, both tropics will be cut at the points through which the ascending signs are to be drawn — this order being observed. If the dial faces the east, the point where the tropic of Capricorn [♑] cuts the horizontal line will belong to Capricorn; and the point at which the tropic of Cancer [♋] and the horizontal line cut one another, to Cancer. The next point in the tropic below the horizontal line is owed to the sign that rises next after Capricorn, or after Cancer — that is, to the sign Aquarius, or to Leo — and so on in succession of the signs.

[Margin: The order of the ascending signs in the tropics.]

But if the dial deflects toward the west, the point where the tropic of Capricorn [♑] and the horizontal line cut one another is to be assigned to the sign Cancer; and the point where the tropic of Cancer [♋] cuts the same horizontal line will suit the sign Capricorn. Then the next point below the horizontal line will answer to the sign that rises before Capricorn, or Cancer — that is, to the sign Sagittarius [♐], or Gemini — and so on against the succession of the signs. From this we shall easily understand to which signs the points of the tropics found above the horizontal line answer. For if below they keep the order according to the succession of the signs, above the horizontal line they will keep the order against

the succession of the signs, and conversely, as is plain from the figures of the ascending signs which we have hitherto constructed on various planes.

But always any hidden straight line drawn from the point where the meridian and horizontal lines cut one another, through the points found on the equinoctial line, belongs to two opposite signs, just as in the earlier figure of the rays of the ascending signs any line belongs to two opposite signs: so that if, for example, one point through which the said hidden line passes belongs to Gemini, the other point, which the same straight line indicates — whether in the opposite tropic or in the same — belongs to Sagittarius [♐], and so on; as is manifest from the earlier figures of the ascending signs which we have depicted on various planes.

[Margin: What is to be done in drawing the ascending signs when the equinoctial line and the meridian are parallel.]

In the proposed example, where the meridian line and the equinoctial are equidistant, the line LM does not cut the equinoctial line but is parallel to it, so that it cannot form an angle with it. In the earlier figure of the signs, therefore, ED will have to be drawn as the parallel line answering to the equinoctial line on the dial, in this way. From EC let there be taken EK, equal to the line which on the dial is intercepted between the centre L and the point where the horizontal line divides the equinoctial; and through K let a perpendicular be raised to EK, cutting the lines of the signs in points which, taken from the point K and transferred onto the equinoctial line from the said point where the equinoctial and horizontal cut one another, will give the points on the equinoctial line, as before.

And if the ascending signs are to be described on the dial of the first figure of proposition 37 of this book [*Gnomonics* III, prop. 37], the angle EHQ must be set up equal to the one which the line LM makes with the equinoctial line on the dial, as was done in the earlier figure of the rays of the ascending signs.

Again, in the later figure of the same scholium to proposition 9 of Book 2 [*Gnomonics* II, prop. 9], from the line EC let there be taken off Ek, equal to the line which on the dial is intercepted between the centre L and the point at which the horizontal line and the equinoctial mutually divide one another. And at K, with EK, let there be made an angle equal to the one which the equinoctial line makes with the line drawn from L through the said point where the horizontal line cuts the equinoctial — yet under this rule and condition, that, with the centre E placed at the centre L, and the line EC upon the line drawn from L through the point where the horizontal and equinoctial lines cut one another, the line drawn through K should coincide with the equinoctial line. In our example the said

angle is a right angle. But in the first dial of proposition 37 of this book [*Gnomonices* III, prop. 37], since the horizontal line cuts the equinoctial line at H, we shall take the line LH equal to EK in the later figure of the said scholium, and shall set up the angle EKQ equal to the angle which the line EH makes with the equinoctial line on the dial, and so on. Then the intervals of the line drawn through K, intercepted between K —

between K and the lines of the signs, are to be transferred onto the equinoctial line from the point which is common to the horizontal and equinoctial lines, in the same order they would have if the line drawn through K coincided with the equinoctial line. For these points, together with the answering points found in the tropics, joined by straight lines, will give the ascending signs, whose order — on a dial facing the east — is this on the equinoctial line: the first point found below the horizontal line, from the later figure, belongs to Taurus, the next to Gemini, and to Cancer [♋] [?], and so on in that order in which they are described in the aforesaid figure. But the nearest point above the horizontal line answers to the sign Pisces, the next to the signs Aquarius and Virgo, and so on, as they follow in the figure. On a dial declining toward the west, however, the order will be the reverse. For the first point below the horizontal line will belong to Pisces, the next to Aquarius and Virgo, and so on; while the nearest point above the horizontal line will look to Taurus, the next to Gemini, and to Cancer [♋] [?], and so on.

[Margin: The order of the ascending signs on the equinoctial line.]

PROBLEMA 46. PROPOS. 46.

To construct an Italian dial which both declines from the vertical and is inclined to the horizon.

[Margin: The construction of an Italian dial that at once declines and is inclined.]

As in the preceding dials, so in this one too we shall draw the hour lines reckoned from sunset, if we divide the circle described from L into the diurnal arc of the parallel of Cancer [♋], aMb, and the diurnal parallel of Capricorn [♐], dMe, in such a way that the lines ab and de cut the line LM (which is the common section of the meridian and the equator) at right angles, as we set forth at proposition 1 of Book 1 [*Gnomonices* I, prop. 1] — provided that the division of the circle into 24 equal hours has its beginning at the western points b and e. But since in our dial the tropic of Capricorn [♐] cannot be drawn, it will suffice if the hour points from sunset be found [continues below the figure]—

Diagram. The layout of an Italian dial that both declines from the vertical and is inclined to the horizon. A horizontal line labelled **HORIZON** runs across (printed **HORI**: at the left, then **ZON / N O Z** at the right). A large circle is described about the centre **L**; on it the point **M** lies above the centre and the point **N** below. Two dashed arcs (the diurnal parallels) sweep through the circle, their end-points marked **a** and **b** (the arc **aMb**, the diurnal arc of the parallel of Cancer) and **d** and **e** (the arc **dMe**, the parallel of Capricorn); the letters **a**, **b**, **d**, **e** appear at the left and lower part of the figure.

Along the dashed arcs runs a series of small Arabic hour-division numbers; the legible ones include **2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 18** set at successive division points about the centre **L**.

A dense pencil of straight and dashed hour lines radiates from the lower half of the figure; their outer ends are marked with hour numerals in the Italian reckoning. Legible numerals include, at the top and upper right, **IX, XI, XII**, and the Arabic **22, 23, 24**, together with **XIII** and **XVIII** (13, 14); down the right side **I, II, III**; and along the bottom **VI, VII, VIII, IX**, with **IIII** at the left. Many of the peripheral hour numerals and small division numbers are worn or overrun by crossing lines and cannot be securely read.

[continued from above:]...found in the tropic of Cancer [☿], by means of the diurnal arc of that same tropic. We shall find, in the upper dial of our example — that is, in the portion contained below the horizontal line — the points of the hours from sunset only from the 9th up to the 16th inclusive, because all these hours are contained in the arc of the circle from **M**, from whose points the straight lines drawn through the centre **L** meet the equinoctial line after they have been drawn through the centre **L**. And if these points be joined by straight lines to the answering hours on the equinoctial line — as is established from the tables of the diurnal arc and of the nocturnal arc of the 12 hours set out in the scholium of proposition 33 of Book 1 [*Gnomonices* I, prop. 33], or from the table of proposition 19 of the same book [*Gnomonices* I, prop. 19] — the hours from sunset in the upper dial will be drawn from the 9th hour up to the 16th inclusive. But the points of the 17th and 18th hours from sunset —

[continued from the previous page] —we shall likewise find in the tropic of Cancer [☿]. From the points of the 5th and 6th hours from sunset on the circle **aMbN** — the points contained in the arc **aN** and lying opposite the said 17th and 18th hours — we shall draw hidden lines through the centre **L**. For by their help we shall find, in the tropic of Cancer, in the nocturnal portion, the points for the 5th and 6th hours; and from these, hidden straight lines drawn through **z** [the

dial's centre — the glyph in the figure is a small looped sign, transcribed here as **z**], the centre of the dial, will give in the same tropic of Cancer the points of the 17th and 18th hours, as is gathered from what was demonstrated at proposition 10 of Book 2 [*Gnomonices* II, prop. 10]. Now the line of the 18th hour from sunset will, in the plane we have proposed, be parallel to the equinoctial line and to the meridian line;

Diagram. A large, very dense sundial layout for an Italian dial that both declines from the vertical and is inclined to the horizon. This is a continuation of the figure begun with Problema 46 in the preceding batch. A horizontal **horizon line** runs across the page, lettered **HORI:** to the left of the circle and **ZON** to the right (with an additional partly-mirrored **N O Z** and the numeral **24** repeated at the far right). A large circle is described about the centre **L**, with the small looped centre-mark **z** just below **L** (the dial's centre / gnomon foot). Point **M** lies on the upper part of the circle and point **N** on the lower part.

- To the left, on a dashed arc: points **d** and **a**, with small hour-division numbers running along the arc — **1, 2, 3, 4, 5, 6, 7, 8** — and, higher up, **9, 10, 11, 12**.
- Near the centre, along interior dashed arcs: the hour-numbers **2, 3, 4, 5, 6, 7, 8, 9, 10** descending, with point **b** to the right of centre and further Arabic marks **13, 14, 15, 16, 17** on the right.
- A dense pencil of straight and dashed hour-lines radiates outward, their outer ends marked with hour numerals (many reversed/mirrored and several overrun by crossing lines). Legible peripheral numerals include, across the top, the reversed Romans **IIII, V, VI, VII, VIII**, and the Arabic **20**, then **XII, IX, 22, XI**; down the right side **XII** [i.e. 13 (?)], **23, XIII, XIII, 24**, then **I, II, III, IIII**; along the bottom **VI, VII, VIII, IX** and **V**; and at the lower left **X** (struck through) and **18**.

Many peripheral hour-numerals and small division-numbers are worn or crossed by lines and cannot be securely read.

[continued below the figure:] —for if it were to cut the equinoctial line, this would necessarily happen at the 12th hour from noon or from midnight, as is established from the table of proposition 19 of Book 1 [*Gnomonices* I, prop. 19]. Since, then, the 12th hour in our example does not cut the equinoctial line but runs parallel to it, it is clear that the 18th hour cannot cut it either. It will therefore be parallel to it. The same is to be said of the 6th hour from sunrise or sunset, for this too is parallel both to the equinoctial line and to the meridian line.

[Margin: The equinoctial line, the meridian line, and the lines of the 6th and 18th hours from sunrise and sunset are parallel in the dial here proposed.]

This can also easily be demonstrated in the following way. By proposition 16 of Book 1 [*Gnomonices* I, prop. 16] the hour-circles of the 18th and 6th hours from sunrise or sunset have one and the same common section with the equator, and likewise, by proposition 17 of the same book [*Gnomonices* I, prop. 17], the same common section with the meridian. They must therefore pass through the common section of the meridian and the equator, so that this common section is the common section of those circles, of the equator, and of the meridian. Since, then, the plane of this dial is parallel to that common section — being parallel to the great circle which declines from the vertical and is inclined to the horizon, the circle drawn through the said section — those sections which the named circles produce in the plane of the dial will, by proposition 18 of Book 1 [*Gnomonices* I, prop. 18], be parallel to one another: namely the equinoctial line, the meridian line, and the lines of the 18th and 6th hours from sunrise or sunset. But the 17th hour must be drawn through the 11th hour from noon or midnight on the equinoctial line; and so the upper Italian dial will be complete, since scarcely more hours from sunset can be drawn in the proposed plane.

[Margin: The layout of the same Italian dial by means of the diurnal and nocturnal arcs.]

To construct the lower Italian dial, the hours from sunrise must be drawn in the nocturnal portion of the dial — namely 23, 22, 21, 20, 19, 18, and so on. For these, as we showed in the scholium of proposition 23 of Book 2 [*Gnomonices* II, prop. 23, scholium], are reckoned in the lower dial from sunset. These said hours are contained in the portion aNb of the circle described from L, as is clear.

Much more conveniently, these same hours from sunset will be drawn by means of the diurnal arc of 24 hours and the diurnal arc of 14 hours, which in the nocturnal portion of the dial changes into the nocturnal arc of 10 hours. For all the hour-lines from sunset touch the diurnal arc of 24 hours at the points of the hours from noon or midnight,

—as we demonstrated at proposition 14 of Book 1 [*Gnomonices* I, prop. 14]. Hence in laying out the hours from sunset we shall almost always have three points for each hour: one on the diurnal arc of 24 hours, a second on the diurnal arc of 14 hours (or the nocturnal arc of 10 hours), and a third on the equinoctial line — that is, on the diurnal or nocturnal arc of 12 hours — as is established from the

tables set out in Book 1. There is no need to give an example of this, since it is very easy.

As for the mutual intersections of the hours from sunrise or sunset with those from noon or midnight, the matter is quite clear from the tables of propositions 19 and 20 of Book 1 [*Gnomonics* I, props. 19–20]. And so we have constructed the Italian dial that both declines from the vertical and is inclined to the horizon. Which was to be done.

PROBLEMA 47. PROPOS. 47.

To construct a Babylonian dial that both declines from the vertical and is inclined to the horizon.

[Margin: The construction of a Babylonian dial that declines and is inclined at once.]

By exactly the same methods with which we laid out the Italian dial, we shall construct the Babylonian dial in the proposed plane, as is plainly evident from the figure of the preceding proposition. There are contained in it both the hours from noon or midnight and those from sunrise as well as from sunset, just as in the dials above. But in the first method, the division of the circle aMbN must be begun from the eastern points a and d. We have therefore constructed the Babylonian dial that both declines from the vertical and is inclined to the horizon. Which was to be done.

PROBLEMA 48. PROPOS. 48.

To make an Ancient dial that both declines from the vertical and is inclined to the horizon.

[Margin: The layout of an Ancient dial that declines and is inclined at once.]

This dial too we shall construct on a plane that declines from the vertical circle and is inclined to the horizon, by the same methods we have used on other planes, as the figure itself shows. In it we have drawn the diurnal arc of 18 hours,

Diagram. The layout of an Ancient (unequal-hour) dial that both declines from the vertical and is inclined to the horizon. A **horizon line** runs across the figure, lettered **Ho** (to the left of the circle) and **RIZON** (to the right), with **IIX** [= XII, the 12th hour] at its far right end and the numeral **9** at its left end. A large circle is described about the centre **L**, with the small looped centre-mark **z** just below L.

Point **M** lies on the upper circle, **N** on the lower circle, **e** on the upper-right circle, **b** at the right, and **d** at the left.

- Interior dashed hour-lines fan out from the centre; along them run the hour-numbers **4, 5, 6, 7, 8, 9, 10, 11, 12** descending, with **n** and **12** near the top, and a dotted arc at the lower left carrying **1, 2, 3, 4**.
- Straight hour-lines radiate outward with numerals at their ends: across the top, reversed Romans — **V, VI, VII, VIII, XI**, and **X**; on the right side **IX**, then at the horizon **XII** [read as **IIX**], and below it **I, II, III, IIII**; along the bottom **V, VI, VII, VIII**.
- At the upper left and again at the lower left (near the reversed **VIII**) stand two worn zodiac-sign sorts; the diurnal arc drawn here is that of 18 hours (summer), so these mark the tropic of Cancer [likely ☿, glyphs worn — [?]].

Several peripheral numerals and the zodiac sorts are worn or overrun by crossing lines.

[continued below the figure:] —which in the nocturnal portion of the dial changes into the nocturnal arc of 6 hours. We have therefore made the Ancient dial that both declines from the vertical and is inclined to the horizon. Which was to be done.

End of the Third Book.

GNOMONICS, BOOK FOUR.

By the author **CHRISTOPH CLAVIUS** [Christophorus Clavius] of Bamberg, of the Society of Jesus.

[Margin: The argument of the fourth book.]

In the two preceding books we set out the precepts by which the description of hours of every kind — and of the other things that can be known from the shadow of the gnomon — is carried through for any given latitude of a place situated between the equator and the arctic pole, and on every plane that can be devised. It remains for us to teach how the description of these same things is to be carried out on those same planes when they lie in a right sphere, where there is no elevation of the pole above the horizon, and also in the most oblique sphere, where the arctic pole is raised 90 degrees above the horizon. Then, how these same dials, once described, stand among the antipodes — where the antarctic pole, opposite to our own, is raised above the horizon — with respect to the

number and order of the hours, which must be entirely changed among the antipodes, as we shall explain below.

For although all this could easily be gathered from the precepts above, yet because some things are here described more briefly, and certain others require different rules, it seemed good to explain them separately in this book. Finally, with one or two examples, we shall show what variations follow in the lineaments of dials from a different elevation of the pole, both among us and among the antipodes. For if this were not known, anyone might easily get stuck at times in laying out various dials — especially with the hours from sunrise and sunset, which sometimes, even if produced to infinity, do not cut the two tropics but touch two other parallels within the tropics.

To all this we shall add three problems, in which we shall demonstrate how the style, or gnomon, of each dial ought to be set in its proper place so that it stands upright to the plane of the dial; and likewise in what way its tip, if it should ever have been deflected from its proper seat, can be restored to it. Furthermore, by what method one is to investigate for what elevation of the pole a given dial was made, whose style and its position are given; likewise what declination it has from the vertical, and what inclination to the horizon, if it is declining or inclined, and also how great is the elevation of the pole above that declining or inclined plane. And conversely, how — given a dial together with the elevation of the pole for which it was built, and its inclination to the horizon if it is inclined — one is to find the length of the style and its position, together with the declination from the vertical (if the dial is declining) and the elevation of the pole above that declining or inclined plane. Finally, we shall show by what art any dial may be reduced to a larger or smaller form, while the same proportion of the lineaments and shadows is always kept — something that not rarely happens in practice, especially when some dial drawn on paper, or on any other material, must be transferred onto the wall for which it was designed.

PROBLEMA 1. PROPOS. 1.

To describe horizontal dials in a right sphere.

[Margin: How a horizontal dial, with the parallels of the signs and the latitudes of cities, is described in a right sphere.]

The hours from noon and from midnight in a horizontal dial of the right sphere, and the parallels of the signs of the zodiac, and also the parallels of cities (that is, the circles of latitude), are described just as in the polar dial, which we treated in

Book 2. The reason is that the horizon of the right sphere passes through the poles of the world, exactly as does the circle of the 6th hour from noon or midnight, to which the polar dial is parallel. Indeed, the circle of the 6th hour from noon or midnight does not differ from the horizon of the right sphere. But the horizontal line is not to be drawn in a horizontal dial of the right sphere, just as it is not drawn in a horizontal dial of the oblique sphere, since the horizon that makes that line does not cut the plane of the horizontal dial, whether in the right sphere or in the oblique. And so, if the polar dial described in Book 2 is set up in the right sphere parallel to the horizon, in such a way that the meridian line has its proper position and the point D faces toward the northern pole and E toward the southern, the numbers of the hours and the signs of the zodiac will have the same —

the same order that they have in the polar dial. That is, the hours placed after midnight will be for us toward the antarctic pole when turned to the right, or toward the west; while the hours after noon will be to the left, or toward the east. Likewise the northern signs will be placed toward the south, and the southern signs toward the north, as the accompanying figure shows — a figure in which, of all the parallels, we have drawn only the two tropics.

[Margin: In a right sphere there are no diurnal arcs, because they all comprise 12 hours.]

In a right sphere there are no parallels of the diurnal arcs, because there is no inequality of days there; rather, every artificial day comprises 12 hours, and the artificial night just as many, so that there is perpetual equinox, as we explained for the right sphere. Any parallel whatever, or arc of a sign, may therefore be called a diurnal arc of 12 hours.

[Margin: The Italian and Babylonian dials in a right sphere differ from the astronomical dial only in the numbering of the hours.]

[Margin: The Antique dial in a right sphere does not differ from the Babylonian.]

The lines of the hours from sunrise and sunset do not differ from the lines of the hours from noon and midnight; only the numbers of the hours must be changed. For since in a right sphere the Sun always rises at the 6th hour from midnight — that is, the 24th from sunrise and the 12th from sunset — the 7th hour from midnight will yield the 1st from sunrise and the 13th from sunset; the 8th hour from midnight will yield the 2nd from sunrise and the 14th from sunset, and so on, as appears in the accompanying figure. In it, the numbers set against the equinoctial line pertain to the astronomical hours (that is, from noon and

midnight); the numbers at the tropic of Capricorn [♊] indicate the hours from sunrise; and the remaining numbers, alongside the tropic of Cancer [♋], show the hours from sunset.

Unequal hours, however, have no place in a right sphere, since days and nights are always equal and comprise 12 hours equal to one another. Hence the hours from sunrise indicate the twelfth-parts of the day already elapsed, just as the unequal hours do in an oblique sphere.

[Margin: How the vertical circles and the parallels of the horizon are drawn in the horizontal dial of the right sphere.]

The vertical circles too, and the parallels of the horizon, will be drawn here by the same method as in the horizontal dial. For the vertical lines pass through the place of the style — that is, through the point where the meridian line and the equinoctial line cut each other — and the equinoctial line will give the vertical properly so called, from which the remaining verticals are numbered; because in a right sphere the vertical and the equator constitute one and the same circle. The parallels of the horizon, moreover, are drawn from the same place of the style, taken as their center, and so forth.

[Margin: How the meridian circles are drawn in the horizontal dial of the right sphere.]

Further, the meridian circles — that is, the circles of longitude of cities — will be drawn here as in the polar dial: on the circle by whose means the astronomical hours are laid out, the longitude of the place is counted from the meridian line DE westward, as far as the meridian of the Fortunate Isles, and so on.

[Margin: The description of the celestial houses in the horizontal dial of the right sphere.]

Again, the celestial houses will be depicted on the right horizon just as on the oblique. For here too the lines of the celestial houses are parallel to one another, and each space intercepting one house between two lines comprises two hours. Hence the line of the 8th hour from midnight will give the beginning of the 12th house; the line of the 10th hour from midnight, the beginning of the 11th house; the meridian line, the beginning of the 10th house; the line of the 2nd hour from noon, the beginning of the 9th house; and finally the line of the 4th hour from noon, the beginning of the 8th house. Here the celestial houses are drawn in one single way, because in a right sphere the equator and the vertical circle do not

differ. Hence the houses are the same according to Johannes Regiomontanus [Regiomontanus] and Campanus [Campanus of Novara].

[Margin: By what means the ascending signs are depicted in the horizontal dial of the right sphere.]

Finally, the ascending signs will also be drawn here, as in the earlier dials, provided that first there are compiled tables giving the hours at which the beginnings of the signs ascend above the horizon in a right sphere. These are compiled, as we taught in Book 2, Proposition 9, if in place of the oblique ascensions the right ascensions are taken. The following four little tables have been compiled in this way.

Diagram. The horizontal dial of the right sphere. A vertical meridian line runs from **E** at the top down to **D** at the bottom; a horizontal equinoctial line crosses it at the center. From all the parallels only the two tropics are drawn, as two dotted curves that cross near the center, giving the whole figure the look of a bowtie or hourglass. The numbers set against the equinoctial (horizontal) line are the astronomical hours (from noon and midnight); the numbers on the tropic of Capricorn are the hours from sunrise; the numbers on the tropic of Cancer are the hours from sunset. Because of the crowding and the worn zodiac sorts, several peripheral labels could not be resolved and are flagged; this figure

- E (top of the meridian line): E
- D (bottom of the meridian line): D
- Left end of the equinoctial line: worn zodiac glyph [Υ Aries?, i.e. the eastern equinoctial point] [?]
- Right end of the equinoctial line: worn zodiac glyph [♎ Libra?, i.e. the western equinoctial point] [?]
- Upper dotted curve (tropic of Capricorn, hours from sunrise), with ♐ / ♒ [Capricorn/Aquarius] glyphs at both upper ends: readable hour numbers 27 (top left), 22, 21, 20, 19, 17, 16, 15, 14, 13 (top right); an "8" also appears near the center [center cluster partly [?]]
- Lower dotted curve (tropic of Cancer, hours from sunset), with ♋ [Cancer] glyphs at its ends: readable hour numbers 11 (lower left), 10, 9, 8, 7, 6, 5, 4, 3, 2, 1 (lower right)
- Along the equinoctial line (astronomical hours, left to right): 4, 3, 2, 1, 12 (center), [11?], 9, 8, 7 [several center digits [?]]

[Margin: In a right sphere the rising and setting amplitudes of the points of the ecliptic are equal to their declinations.]

By the same method one will be able to compile tables of the culminations of the heaven [mediationes cœli] and of the angles of the earth; likewise two other tables giving the points of the ecliptic that lie on the circle of the 5th and 7th hour from noon or midnight, together with their declinations, at the moment when the beginnings of the 12 signs emerge above the horizon in a right sphere, as we explained in the same place.

As for the figure of the rays of the rising and setting amplitudes, described in Book 2, Proposition 21, it does not differ from the figure of the rays of the zodiac. This is because, in a right sphere, the rising and setting amplitudes of the points of the ecliptic are equal to their declinations, since the right horizon, drawn through the poles of the world, measures both the declinations and the rising and setting amplitudes. We have therefore described the horizontal dials in a right sphere. Which was to be done.

PROBLEMA 2. PROPOS. 2.

To construct vertical dials in a right sphere.

[Margin: The drawing of a vertical dial of the right sphere, together with the parallels of the signs and the latitudes of cities.]

In a vertical dial of the right sphere, the hours from noon and midnight, the parallels of the signs of the zodiac, and the parallels — or circles of latitude — of cities will be described in just the same way as in an equinoctial dial. For the vertical circle properly so called and the equator do not differ from each other in a right sphere, as is clear. But the horizontal line must be drawn through the center of the dial, or the place of the gnomon, perpendicular to the meridian line, in such a way that it does not differ from the line of the 6th hour from noon or midnight — because in a right sphere the horizon and the circle of the 6th hour from noon or midnight do not differ, as appears in the following figures.

[Margin: The hours from sunrise and sunset in a vertical dial of the right sphere.]

As for the hours from sunrise and sunset, and likewise the unequal hours, the same must be said here as in the preceding proposition. For the numbers placed in the middle position pertain to the hours from noon and midnight, the upper ones to the hours from sunset, and the lower ones to the hours from sunrise.

[Margin: The vertical circles and the parallels of the horizon in a vertical dial of the right sphere. The meridian circles in a vertical dial of the right sphere.]

The vertical circles and the parallels of the horizon will be drawn here just as in the vertical dial of an oblique sphere, for the demonstration is the same in both cases.

The meridians too will be drawn like the hours from noon or midnight, provided that first the longitude of the place is reckoned from the meridian line, so that a straight line drawn from the center of the dial through the end of the counting — the line representing the meridian of the Fortunate Isles — lies in the eastern part of the dial. Such is the line marked off by dots in each dial, if the longitude of the place in the right sphere is 36 degrees.

Diagram. AVSTRALE ("Southern") — the south-facing vertical dial of the right sphere, drawn as a half-disc opening downward from a horizontal top line. The top line carries the split label **HORI:** (left) ... **ZON** (right), spelling *HORIZON*, with zodiac glyphs at each end. Hour-lines radiate from the center of the top line to the arc; three sets of numbers are used (middle = hours from noon/midnight, upper = hours from sunset, lower = hours from sunrise). The label crowding leaves several numbers unresolved

- Top-left horizon label: HORI: with ♓/♒ [Pisces/Aquarius] and a further worn glyph [?]
- Top-right horizon label: ZON with ♏/♍ [Scorpio/Virgo] glyphs [?]
- Outer hour numbers, left arc (top to bottom): 24, 1, 2, 3, 4, 5, 6
- Outer hour numbers, right arc (top to bottom): 12, 11, 10, 9, 8, 7
- Inner hour numbers (across the upper zone and arc): 6, 12, 13, 14, 15, 16, 17, 18, 19, 20, 21, 22, 23, 24 [dense center cluster partly [?]]
- Bottom-right, along a dotted line: "Inf. Fort." [Insulæ Fortunatæ — the meridian of the Fortunate Isles] [?]
- A wavy (Aquarius-water) parallel mark near the bottom center

Diagram. BOREALE ("Northern") — the north-facing vertical dial of the right sphere, mirror-companion to AVSTRALE, again a half-disc opening downward from a horizontal top line labelled **HORI:** ... **ZON** (*HORIZON*) with zodiac glyphs. Same three number-sets (middle/upper/lower). for the dense center numbers.

- Top-left horizon label: HORI: with ♍/♌/♋ [Virgo/Leo/Cancer] glyphs [?]
- Top-right horizon label: ZON with ♊/♉ [Gemini/Taurus] glyphs [?]
- Outer hour numbers, left arc (top to bottom): 12, 11, 10, 9, 8, 7, 6
- Outer hour numbers, right arc (top to bottom): 24, 1, 2, 3, 4, 5, 6

- Inner hour numbers: 6, 24, 23, 22, 21, 20, 19, 18, 17, 16, 15, 14, 13; center 12, 11, 10 [dense cluster partly [?]]
- Bottom-left, along a dotted line: "Inf. Fort." [Insulæ Fortunatæ — meridian of the Fortunate Isles] [?]

[Margin: The celestial houses in a vertical dial of the right sphere. — The ascending signs in a vertical dial of the right sphere.]

The celestial houses do not diverge from the hours from noon and midnight, since in a right sphere the circles of the celestial houses are the same as those of the hours from noon and midnight. Thus the 6th hour from midnight — that is, the horizontal line on the western side — gives the beginning of the 1st house; the 8th hour from midnight, the beginning of the 12th house; and so on for the rest, as we wrote in the preceding proposition — so that the 6th hour from noon, or the horizontal line on the eastern side, presents the beginning of the 7th house.

Finally, the ascending signs of the zodiac are most conveniently drawn in this place by means of the points of the horizontal line, where it is cut by the arcs of the signs, as we said above, and by the culminations of the heaven and the angles of the earth (if tables of this kind are first drawn up for the right sphere); or else by means of the hours of the tropic of Cancer [♋] and of Capricorn [♏], as the tables of the preceding proposition indicate — by drawing these tropics as hidden construction lines above the horizontal line, together with the hour-lines from noon or midnight. For at the hours of the tropic of Cancer and of Capricorn, at which the signs rise, the lines of the ascending signs will touch the said tropics and pass through the points of the horizontal line. Thus, in the southern dial, you see the line of the ascending sign Aquarius [♒], marked off by dots, touch the tropic of Capricorn at 3 hours 51 minutes before noon, and pass through the point of the horizontal line where it is cut by the arc of Aquarius on the western side. Likewise, in the northern dial, the line of the ascending sign Taurus [♉] will touch the tropic of Cancer above the horizontal line at 10 hours 8 minutes before noon, and will pass through the point of the horizontal line where it is cut by the arc of Taurus toward the western parts. We have therefore constructed the vertical dials in a right sphere. Which was to be done.

PROBLEMA 3. PROPOS. 3.

To compose meridian dials in a right sphere.

[Margin: The hours from noon or midnight, the arcs of the signs, and the circles of latitude of cities in a meridian dial of the right sphere.]

These dials are constructed here just as in an oblique sphere, as concerns the hours from noon and midnight — except that in a right sphere the line of the 6th hour does not differ from the horizontal line, and therefore the equinoctial line, cutting it at right angles, stands perpendicular to the horizon. As for the parallels — that is, the arcs of the signs and of the latitudes of cities — there is no difference in either sphere, provided one observes that the parallels receding from the equinoctial line toward the south belong to the northern signs and towns, while the rest belong to the southern ones.

Diagram. Two companion meridian dials of the right sphere, side by side: **ORIENTALE** ("Eastern," left) and **OCCIDENTALE** ("Western," right). Each is a tall figure built on a vertical center line crossed by a top and a bottom horizontal line, with dotted lines splaying outward to zodiac glyphs at the lower corners; the hour-numbers are arranged in three vertical columns (left = one hour-count, center, right = another). The center-column digits are the least legible and are flagged

ORIENTALE (rows, left | center | right):

- 12 | 6 | 24
- 13 | 7 | 1
- 14 [?] | 8 | 2
- 15 | 9 | 3
- 16 | 10 | 4
- 17 | 11 | 5
- Lower-corner zodiac glyphs: ♑ [Capricorn] (left), ♋ [Cancer] (right) [?]

OCCIDENTALE (rows, left | center | right):

- 12 | 6 | 24
- 11 | 5 [?] | 23
- 10 | 4 | 22
- 9 | 3 | 21
- 8 | 2 | 20
- 7 | 1 | 19
- Lower-corner zodiac glyphs: ♋ [Cancer] (left), ♑ [Capricorn] (right) [?]

[Margin: The hours from sunrise and sunset in a meridian dial of the right sphere.]

The hours from sunrise and sunset, however, are to be counted on the same lines as the hours from noon and midnight, as we set out in Proposition 1 of this book — as is clear from the accompanying figures, in which the numbers are arranged as in the horizontal dial of the right sphere. And so the meridian dial in a right sphere does not differ from the horizontal dial of the same sphere, if we look at the lineaments; only the numbers change, as is evident. So much so that the horizontal dial of the right sphere, if it is set up parallel to the meridian circle, yields the meridian dial in the same sphere.

[Margin: The vertical circles and the parallels of the horizon in a meridian dial of the right sphere.]

The vertical circles too, and the parallels of the horizon, will be set down here as in the meridian dial of an oblique horizon; but the equinoctial line will give the vertical circle properly so called, as we said in the horizontal dial of the right sphere.

[Margin: The meridian circles and the celestial houses in a meridian dial of the right sphere.]

Likewise the meridian circles and the celestial houses will be depicted here as in the meridian dial of an oblique sphere — yet in such a way that the celestial houses here keep the same order that we prescribed in the horizontal dial of the right sphere.

[Margin: The ascending signs in a meridian dial of the right sphere.]

Finally, the ascending signs also have here the same description as in the meridian dial of an oblique sphere. Therefore we have composed the meridian dials in a right sphere. Which was to be done.

PROBLEMA 4. PROPOS. 4.

To draw polar dials in a right sphere.

[Margin: Polar dials in a right sphere.]

Polar dials in a right sphere differ in nothing from the horizontal dials of the same sphere, since the circle of the 6th hour from noon or midnight — to which the polar dials are parallel — does not differ from the horizon, to which the horizontal dials are parallel. We have therefore drawn the polar dials in a right sphere. Which was to be done.

PROBLEMA 5. PROPOS. 5.

To lay out equinoctial dials in a right sphere.

[Margin: Equinoctial dials in a right sphere.]

Nor indeed are the equinoctial dials of the right sphere any different from the vertical dials of the same sphere, since in a right sphere the equator and the vertical circle are one and the same circle. We have therefore laid out the equinoctial dials in a right sphere. Which was to be done.

PROBLEMA 6. PROPOS. 6.

To depict dials declining from a vertical circle in a right sphere.

[Margin: How an astronomical dial declining from the vertical in a right sphere is to be described.]

Draw two straight lines A B and C H, cutting one another at right angles at H. At the line C H, at H, construct the angle of declination C H D — toward point B if the plane declines from south to west, or from north to east; but toward point A if it deflects from south to east, or from north to west. In our example we suppose the plane to decline 60 degrees from south toward west. Taking point D at will on the line H D, draw the perpendicular D I to H D, cutting A B at I; and through I draw the perpendicular I F to A B. Then cut off the line I E equal to D I, and from E describe a circle at will. Divide this circle into 24 equal parts, beginning from the line A B, and from E, through the division points, send out hidden lines cutting the line I F at points. Through these points, if straight lines are drawn from H, the hour-lines are obtained, whose order is as follows. The line C H gives the 12th hour, that is, the meridian line; the lines to its left indicate the hours from midnight in dials declining from the south, while those placed to the right pertain to the hours from noon. The contrary is to be understood in dials that deflect from the north.

Diagram. The construction of a dial declining 60 degrees from the meridian toward the west in a right sphere. A horizontal line A B runs across the figure, meeting the vertical line C H at right angles at H, from which all the hour-lines radiate downward in a fan.

- A (left end of the horizontal line A B): also marked with the hour-number 6
- B (right end of the horizontal line): also marked with the hour-number 6

- H (intersection of A B with the vertical line; the centre from which the hour-lines are drawn)
- C (top of the vertical line C H)
- G, I, E (points on line A B between H and B, in that order); I F is the perpendicular dropped from I
- D (upper point, on the oblique line H D that sets the declination angle C H D)
- F (foot of the perpendicular I F, at the bottom of the figure); the small hour-division circle described from E lies near I/E
- Hour-line numbers radiating from H, on the left/lower side: **7, 8, 9, 10, 11,** and **12** (the meridian line C H produced downward)
- Hour-line numbers on the right/lower side: **5, 4, 3, 2, 1**

[Margin: Demonstration of the foregoing description.]

The demonstration of this construction is very easy. Suppose the dial set in its own position, so that the line A B is parallel to the horizon and is the common section of the plane of the dial and the horizon — that is, of the circle of the 6th hour from noon or midnight. Suppose the triangle H D I to be turned about the line H I until it stands perpendicular to the plane of the dial and is joined with the horizon, or with the circle of the sixth hour from noon or midnight. Since C H D is the angle of declination from the vertical, D H I will be the angle of declination from the meridian circle; and therefore H D will be the common section of the meridian and the horizon, that is, the axis of the world. Hence D I, being perpendicular to the axis, will be the common section of the equator and the same horizon. And so, since the meridian meets the plane of the dial at H and the equator at I, the meridian line must be drawn through H and the equinoctial line through I. Now since both the plane of the dial and that of the meridian are perpendicular to the horizon, [a] their common section will be perpendicular to that same horizon, and therefore, by definition 3 of Book 11 of Euclid, perpendicular to the line A B lying in the horizon. For this reason C H, perpendicular to A B, will be the common section of the meridian and the plane of the dial. By the same reasoning we shall show that I F is the common section of the equator and the plane of the dial, because both the plane of the dial and that of the equator are perpendicular to the horizon. And with the same triangle H D I standing perpendicular to the plane of the dial, if the circle described from E is conceived to be turned about the equinoctial line I F until its centre E is joined with D, the centre of the world — on account of the equality of the lines I D and I E, and

[Margin: (a) Euclid, *Elements* XI.19.]

[Margin: Description of the same dial, when the position of the style and its length are given in the declining plane.]

and thus lies in the plane of the equator, drawn through the lines I D and I F — we shall show that the hours from noon and midnight are correctly described, as in the horizontal dial of Proposition 1 of Book 2. For the right horizon — the circle of the 6th hour from noon or midnight — is, with respect to the plane of the declining dial, like the meridian; and the meridian itself is like the circle of the 6th hour from noon or midnight. So the line H I, the common section of the right horizon (or of the circle of the 6th hour from noon or midnight), here holds the place that the meridian line holds in the horizontal dial of the oblique sphere; and the meridian line C H holds the place that the line of the sixth hour from noon or midnight holds. Now the hour-intervals on the other side of the meridian line C H will each be equal to the hour-intervals lying between the meridian line and the equinoctial, since they arise from the hour-intervals on the equinoctial line above point I, which we showed, each to each, to be equal to the hour-intervals on the same equinoctial line below point I, in Proposition 1 of Book 2. Hence it is not necessary that the whole dial be drawn; it is enough if the hour-lines cutting the equinoctial line are transferred to the other side of the meridian line. The style is the line D G, dropped from D, the centre of the world, onto the line A B at right angles; and its foot is the point G.

If, in the declining plane, the position of the style is given at G, together with its length G D, we shall describe the dial as follows. Through G, the position of the style, we draw the line A B parallel to the horizon; and from G we raise the perpendicular G D, equal to the style. Then at D we construct the angle of declination G D H toward A, if the plane declines from south to west or from north to east; but toward B, if on the contrary it declines from south to east or from north to west — so that the line D H cuts the line A B at H. On the other side, at D, we construct G D I, the angle of the complement of the declination, so that the line D I cuts the line A B at I. Finally we complete the rest as before. The reason for this is that the angle of declination C H D, constructed in the former description, is equal to the alternate angle G D H, and therefore to the angle we have constructed at D in this latter description, and so on.

Diagram. An analemma-style construction (the upper figure) with a large arc/semicircle overlaid by many intersecting straight and dotted lines, and a small hour-division circle near the apex. Because of the density of crossing lines and the smallness of the apex numerals, several labels cannot be resolved.

- A (upper left, on a vertical line descending to H)
- B (just below/right of A, on the arc)
- Small hour-division numerals clustered at the apex: **6, 7, 8, 9** and **3, 4, 5**, with **10** and **2** to the right [several of these apex numerals are crowded — [?]]
- D (left, on a horizontal line) and C (right, on the same horizontal line); **1** lies on that line near D
- II [?] and L (upper right)
- H (lower left) and V (lower centre), on the bottom horizontal line
- **12** (right end of the lower horizontal line)

[Diagram fig-p365-1: more than 2 labels flagged [?]]

Diagram. The face of the declining dial (lower figure): a fan of hour-lines (solid and dotted) spreading from the top horizontal line, which carries the point H at its left. The hour-numbers run in three descending groups; zodiac-sign sorts are set at the lower ends of certain lines and are worn.

Readable hour-numbers, arranged left group | centre group | right group:

- 12 | 6 | 24
- 11 | 5 | 23
- 10 | 4 | [?]
- 9 | 3 | 22
- 8 | [?] | 21
- 7 | 2 | 20
- 6 | 1 | [?]
- Lower endpoints: **12, 18** (lower left); **19** (lower centre); **28** (lower right)
- Zodiac-sign sorts (worn — pinned by position only, glyphs not committed): lower-left ☐ ♈ [Leo?] [?]; centre a pair of stacked sorts ☐ ♈ [Aries?] [?] over ≈ ♎ [Libra?] [?]; right ☐ ♉ [Taurus?] [?]

[Margin: The hours from sunrise and sunset, and the unequal hours, in a declining dial of the right sphere.]

Concerning the hours from sunrise and sunset, and the unequal hours, the same is to be said here as in the horizontal dial of the right sphere.

[Margin: The arcs of the signs, the diurnal arcs, and the circles of latitude, in the same dial.]

The parallels — that is, the arcs of the signs, the diurnal arcs, and the circles of latitude of cities — are to be laid down in this dial no differently than in the horizontal dial of the oblique sphere, provided that, in the former manner, the circle of the Analemma

[Margin: ...the latitudes of cities, in a declining dial of the right sphere.]

A B C represents the right horizon, or the circle of the 6th hour from noon or midnight; and the line B C [represents] the common section of that horizon and of the great circle to which the plane of the dial, drawn through the line R O, is parallel. Let the arc C E be equal to the complement of the declination of the plane from the vertical, or (what is the same) to the declination from the meridian, which is always equal to the altitude of the pole above the plane. In the latter manner, let the line H I represent the line of the 6th hour from noon or midnight, and the line H V the meridian line, and so on.

[Margin: Which arcs pertain to the northern signs, and which to the southern.]

Moreover, in dials of this kind the northern signs are always set toward the southern parts, and the southern toward the northern. The northern parts of the dial lie between the centre H and the equinoctial line, if the dial declines from the south; but if it deflects from the north, the southern parts will be contained between the centre and the equinoctial line.

[Margin: The vertical circles in a dial declining from the vertical in a right sphere.]

The vertical circles are to be drawn thus. From point D of the earlier figure of this proposition describe a circle and divide it into 360 equal parts, or into fewer, beginning the division from the line D H or D I. For if straight lines go out from D through the division points, the horizontal line H I will be cut at points; and if through these points there are drawn meridian lines, or lines parallel to the equinoctial, or perpendiculars to H I, the vertical circles will be described. For if the circle described from D is turned about the line H I until it stands perpendicular to the plane of the dial and lies in the plane of the horizon, so that the centre D is joined with the centre of the world (that is, the vertex of the style) — since the line D H is the common section of the meridian and the horizon, and

D I the common section of the equator and the same horizon, as we demonstrated a little earlier in this proposition — the remaining lines drawn from D will be the common sections of the horizon and of the remaining vertical circles. Therefore, as was shown in Proposition 4 of the preceding book, the vertical circles are correctly described. And the equinoctial line I F will be the common section of the vertical [circle] properly so called and of the plane of the dial, because in a right sphere the equator is the primary vertical, as is evident; and the meridian line C H [will be] the common section of the plane of the dial and of the vertical circle of 90 degrees, and so on.

[Margin: The parallels of the horizon in the same dial.]

The parallels of the horizon have here the same description as in the dial declining from the vertical in the oblique sphere.

[Margin: The meridian circles in the same dial, declining from the vertical, of the right sphere.]

By the same reasoning the meridian circles too are to be depicted, as was said in the foregoing: namely, in the circle described from E in the earlier figure of this proposition, from the upper point of the line drawn perpendicular through E to H E, let the longitude of the place be counted toward the western parts — which in our example are the parts toward point B, as is clear if the dial is set in its own position together with the circle described from E, so that the centre E is placed at D, the centre of the world. For then that line, making right angles with A B at E, will be the common section of the equator and the meridian, and point B will incline toward the west.

[Margin: The celestial houses in the same dial.]

As for the celestial houses, the same is to be understood here as we wrote in the horizontal dial of the right sphere. For their circles are not different from the circles of the hours from noon or midnight. Hence their lines too will not differ from the lines of the said hours.

[Margin: The ascending signs in the same dial.]

Finally, the ascending signs are to be depicted as in the foregoing. Therefore we have depicted the dials declining from a vertical circle in a right sphere. Which was to be done.

PROBLEMA 7. PROPOS. 7.

To construct dials declining from the horizon in a right sphere.

[Margin: An astronomical dial declining from the horizon in a right sphere.]

Draw two straight lines A B and C D, cutting one another at right angles at A. At A, on the line C D, construct the angle of declination of the plane from the horizon, D A E — toward point D if the plane faces west, but toward point C if it faces east. We suppose the proposed plane to decline 40 degrees and to face west. Taking also a point E anywhere on the line A E, draw the perpendicular E D to A E, cutting C D at D. Likewise, from E describe a circle and divide it into 24 equal parts, beginning from the line E D or E A. Then, sending out from E through the division points hidden lines, C D will be cut at points; and the perpendiculars raised to C D from these points will give the hours from noon and midnight in this order. The line drawn through D will always be the line of the 12th hour; and the remaining lines toward A will give, in a dial facing west, the hours from noon, but in one facing east, the hours from midnight — so that in the former the line A B gives the 6th hour from noon, and in the latter the 6th hour from midnight. This we shall show as follows.

[Margin: Demonstration of the foregoing description.]

Diagram. The construction for a dial declining 40 degrees from the horizon toward the west in a right sphere. A horizontal base line runs from C on the left, through A, to D on the right; a set of parallel vertical hour-lines crosses it, and a circle centred on E (with F below its centre, on the axis) carries the hour-divisions. An oblique line runs up from the lower left through E, and dotted meridian lines run from D toward the lower right.

- B (upper left, top of the leftmost vertical line)
 - C (left end of the horizontal base line), A (just to the right of C, the intersection point)
 - E (centre of the hour-division circle)
 - F (point on the base line below E, within the circle)
 - D (right, on the base line; the line through D is the 12th-hour line)
 - Hour-numbers along the base line, left to right: 6, 5, 4, 3, [F], 2, 1, 12, 11, ...
- 10

Let the dial be conceived in its own position, so that the line A B is parallel to the horizon and is the common section of the horizon and of the plane of the dial.

And since both the plane of the dial and the plane of the horizon are perpendicular to the equator (by Proposition 15 of Book 1 of Theodosius), because each is drawn through the poles of the equator, or of the world — namely, through the common sections of the meridian and the horizon — [a] their common section A B will also be perpendicular to that same equator; and thus, by definition 3 of Book 11 of Euclid, perpendicular also to the line lying in the equator, which is the common section of the equator and of the plane

[Margin: (a) Euclid, *Elements* XI.19.]

the plane of the dial. Since, then, the angle BAD is a right angle, CD is the common section of the equator and of the dial's plane. So if the plane in which the circle drawn from E, and the triangle ADE, lie is turned about the line AD until it stands perpendicular to the dial's plane, and its centre E is made to coincide with the centre of the world, the circle will then lie in the plane of the equator about that same centre E — because the equator too, drawn through the centre of the world E and through the line CD, stands perpendicular to the dial's plane. Hence the line EA, lying in the plane of the equator (that is, of the vertical circle of the right sphere) and making the angle of declination from the horizon, EAD, will be the common section of the horizon — the circle of the 6th hour from noon or midnight — and of the equator (the vertical circle); and therefore ED is the common section of the meridian and of that same equator. For since in the right sphere both the meridian and the equator stand perpendicular to the horizon, [a] their common section is also perpendicular to it, and hence perpendicular to the line AE, which lies in the horizon at the centre of the world E. ED is therefore perpendicular to AE at E, the centre of the world, being the common section of the meridian and the equator. It follows that the remaining hidden lines sent out from E are the common sections of the equator with the other hour-circles. And since the hour-lines in this plane are parallel to the meridian line itself, by Proposition 18 of Book 1 those lines will be the perpendicular straight lines drawn to CD through the points where the hidden lines fall — the common sections of the hour-circles and of the dial's plane. The style [stylus, gnomon] will be the perpendicular EF dropped from E to the line CD, its foot at F.

[Margin: (a) [Euclid, *Elements*] XI.19.]

[Margin: Description of the same dial, when the length of the style and its position are given on a plane declining from the horizon.]

Now if the length of the style EF, and its position at the point F on a plane declining from the horizon, are given, we shall describe the dial in this way.

Through F, the foot of the style, draw the line FE parallel to the horizon and equal to the style, and cut it at right angles at F by the line CD. Then at E, toward the upper part of the plane, construct the angle FEA — the complement of the plane's declination from the horizon — so that the line EA cuts CD at A. Likewise at E, toward the lower part of the plane, make the angle FED — the plane's declination from the horizon — so that the line ED cuts CD at D. The rest we complete as before. For in this way EAF will be the angle of the plane's declination from the horizon, and so on.

[Margin: The hours from sunrise or sunset, and likewise the unequal hours, in the same dial.]

The hours reckoned from sunrise or sunset, and the unequal hours, behave here just as in the horizontal dial of the right sphere, as we explained earlier.

[Margin: The arcs of the signs, the diurnal arcs, and the latitude-circles of the cities, in the same dial declining from the horizon.]

The parallels — that is, the diurnal arcs of the zodiacal signs — and the latitude-parallel of the cities are drawn here just as in the meridian and polar dials of the oblique sphere. For the hour-intervals between the centre E and the equinoctial line CD must be transferred onto the radius of the equator, and so on, as appears in the following figure.

Diagram. The construction figure for the dial declining from the horizon in the right sphere, in two parts. *Left:* an oblique/perspective bundle of hour-lines converging from below, crossed by a set of nearly-parallel lines, with a long vertical line labelled (reading down its length) **Linea horizontalis** ("the horizontal line"). The converging hour-lines carry paired numerals along their length: **2, 4, 1, 5, 12, 6, 10** (and a Roman **II**), each appearing on both the near and far edges of the bundle. *Right:* a horizontal equinoctial baseline (the line CD) marked with equal hour-divisions, numbered beneath it from left to right **6, 5, 4, 3, 2, 1, 12, 11, ... 10**; two dotted curves (the diurnal-arc parallels) sweep above and below the baseline, each terminating in a worn zodiacal sign-glyph.

- Vertical line, left part: **Linea horizontalis** ("horizontal line")
- Hour-numbers, left bundle: 2, 4, 1, 5, 12, 6, II, 10 [several paired/worn — [?]]
- Baseline hour-divisions, right part (left→right): 6, 5, 4, 3, 2, 1, 12, 11, [?], 10
- Upper diurnal-arc parallel: zodiacal sign-glyph [♋ Cancer?] — worn [?]
- Lower diurnal-arc parallel: zodiacal sign-glyph [♐ Capricorn?] — worn [?]

[Margin: The vertical circles and the parallels of the horizon in the same dial.]

The vertical circles and the parallels of the horizon are placed in this dial too, just as in the dial declining from the horizon in the oblique sphere.

[Margin: The meridian circles in the same dial.]

The meridians too are drawn like the hour-lines, if in the circle described from E one reckons, from the point G, the longitude of the place toward the western side of noon, so as to obtain the meridian of the Fortunate Isles [Insulae Fortunatae].

[Margin: The celestial houses in the same dial.]

The lines of the celestial houses are the same, as we said before — namely the lines of the hours from noon and midnight.

[Margin: The ascending signs in the same dial.]

Finally the ascending signs are laid out as above. We have therefore constructed dials declining from the horizon in the right sphere. Which was to be done.

PROBLEMA 8. PROPOS. 8.

To lay out dials inclined to the horizon in the right sphere. [*HOROLOGIA ad Horizontem inclinata in sphæra recta delineare.*]

[Margin: How an astronomical dial inclined to the horizon in the right sphere is described.]

Since the inclination of a plane to the horizon in the right sphere measures the elevation of the pole above that same plane — we are speaking of planes that stand perpendicular to the meridian, and whose great circles, to which they are parallel, are drawn through the poles of the meridian, that is, through the common sections of the horizon and the equator — it comes about that astronomical dials inclined to the horizon in the right sphere are described just like horizontal dials in the oblique sphere, provided that, for the pole's elevation, one takes in the portion of the analemma (Proposition 1 of Book 2) the arc CE equal to the plane's inclination to the horizon, so that the axis of the world ED, the common [section...]

—is the common section of the true horizon and the meridian; E is the pole of the world, whether arctic or antarctic; BC is the common section of the meridian and of the great circle to which the dial is parallel; and HI is the common section of the meridian and the dial's plane. Now since the true horizon — that is, the circle

of the 6th hour from noon or midnight — drawn through the axis ED meets the dial's plane at H, the centre of the dial, and through H the 6th-hour line from noon or midnight is drawn perpendicular to the meridian line, this will give, in this dial, the 6th-hour line from noon or midnight as the horizontal line, which will always occupy the upper position once the dial is set in its proper place.

[Margin: The order of the hours in the aforesaid dial.]

The order of the hours in a dial raised on its southern side above the horizon and facing north is the same as in the horizontal dial of the oblique sphere, because the arctic pole is elevated above the dial's plane. So the horizontal dial that we described at the beginning of Book 2 for latitude 42 degrees, raised 42 degrees on its southern side, will present, in the right sphere, a dial inclined 42 degrees — yet so that the 6th-hour line from noon or midnight is the horizontal line. But if the dial faces south and is raised on its northern side, the order of the hours will be the same as in the southern vertical dial of the oblique sphere, because the antarctic pole is elevated above the dial's plane. So the vertical dial facing south, which we described in Book 2 (Propositions 13 and 14) for latitude 42 degrees, raised 48 degrees on its northern side — that being the pole's elevation above the vertical circle — yields in the right sphere a dial inclined 48 degrees, again such that the 6th-hour line from noon or midnight gives the horizontal line. All this is clear and evident if one imagines the dial inclined to the horizon set in its proper place.

[Margin: When the length of the style together with its position is given.]

Now if the length of the style, and its position on the inclined plane, are given, we proceed as in the horizontal dial, provided that in place of the pole's elevation and its complement we take the plane's inclination to the horizon and its complement — always reckoning the complement of the inclination toward the upper part of the plane, and the inclination itself toward the lower part, and so on.

[Margin: The hours from sunrise and sunset, and the unequal hours, in the same dial.]

The hours from sunrise and sunset, and the unequal hours, are here reckoned as was set out in Proposition 1 of this book.

[Margin: The arcs of the signs, the diurnal arcs, and the latitude-circles of the cities, in the same dial.]

The arcs of the signs, the diurnal arcs, and the latitude-parallels of the cities are drawn as was said for the horizontal dial of the oblique sphere, and they keep the same order as in the horizontal or the vertical dial, according as the dial faces north or south.

[Margin: The vertical circles and the parallels of the horizon.]

The vertical circles and the parallels of the horizon are drawn as in the dial inclined to the horizon in the oblique sphere, as we taught in Proposition 28 of the previous book. For if, from the portion of the analemma set out in Proposition 1 of Book 2, one takes the line HD — that line HD corresponds, when the angle DHI is equal to the plane's inclination, to the line AB in the figure of Proposition 28 of the previous book — as an equal straight line on the meridian line, beginning from the centre of the dial H (that is, from the point where the horizontal line, or the 6th-hour line, cuts the meridian line), and describes a circle, then we shall find points on the 6th-hour line from noon or midnight (the horizontal line) which, joined by straight lines to the point where the meridian line and the equinoctial line cut one another, will give the vertical circles. For the equinoctial line is the same as the vertical, and the meridian line gives the vertical of 90 degrees, and so on.

[Margin: The meridian circles, the celestial houses, and the ascending signs of the Zodiac, in the same dial.]

The meridians, the celestial houses, and the ascending signs of the Zodiac are drawn as said before. We have thus laid out dials inclined to the horizon in the right sphere. Which was to be done.

PROBLEMA 9. PROPOS. 9.

To compose dials declining from a vertical circle and at the same time inclined to the horizon, in the right sphere. [*HOROLOGIA à Verticali circulo declinantia, & simul ad Horizontem inclinata in sphæra recta componere.*]

[Margin: In what way a dial declining from a vertical circle and inclined to the horizon is described in the right sphere.]

Draw two straight lines AB and CD cutting one another at right angles at E, and at E, on the line CD, construct the angle of declination DEF, keeping the order we prescribed in Proposition 37 of the previous book — that is, on a plane declining from south toward the east, or from north toward the west, construct it below the line AB, toward the point A; but toward the point B, below the same line AB, on a

plane that turns from south toward the west, or from north toward the east. Here we are speaking of the upper dial, as in the said Proposition 37 of the previous book, for from it the lower dial is easily derived, as we set out in the preceding two books. The line EF will be called the line of declination. We suppose the proposed plane to decline 60 degrees from south toward the east, and to be inclined 70 degrees to the horizon.

Then from a point F taken anywhere on the declination-line EF, raise a perpendicular $F\perp$ to AB — or rather, from an assumed point $\perp$ on the line AB, draw the perpendicular $\perp F$ to AB, cutting the declination-line EF at F; and from that point F raise the perpendicular Fn to $\perp F$. Then at $\perp$, upon $\perp F$, construct the angle of the plane's inclination to the horizon, $I[?] \perp n$, so that the line $\perp n$ cuts the line Fn at n. From $\perp F$ extended, cut off $\perp p$ equal to $\perp n$, and draw the line Ep, which will be the meridian line — that is, the line of the 12th hour from noon or midnight — as we shall demonstrate.

[The source labels this point with a special typographic sort resembling an inverted T / perpendicular sign; it is rendered $\perp$ throughout.]

After this, from F draw the perpendicular FG to $\perp n$, and from $\perp F$ cut off $\perp H$ equal to $\perp G$. For when the line EH is drawn, it will be the line of the index, or of the style; and the style itself will be the line FG, to be set up at H perpendicular to the dial's plane.

Again, from H raise a perpendicular HI to the style-line EH, equal to the style FG, and from E through I draw the line EI, which will represent the axis of the world, so that HEI is the angle of the pole's elevation above the proposed plane. Then from I draw the perpendicular IK to the axis EI, cutting the index-line at K, and through K raise a perpendicular KM to the index-line, for the equinoctial line, which — if no error has been made — will necessarily pass through the point p, as we shall demonstrate.

Finally, take on the style-line the segment KL equal to KI, and from L describe a circle of any size; divide it into 24 parts, beginning either from the line LM — drawn from the centre L through the point M, where the meridian line and the equinoctial line cut one another — or from the line $L\alpha$, drawn from the centre L through the point α , where the equinoctial line cuts the line AB. For if straight lines are sent out from L through the division-points, the equinoctial line

—KM will be cut at points through which the lines sent out from E will give the hours from noon or midnight, in this order. With the dial set in its proper position, so that the line AB is parallel to the horizon, the hours that follow the

meridian line toward the east — those which, when we face a dial declining from the south, lie to our right, but to the left if the dial declines from the north — are to be reckoned from noon, just as in the dial that both declines and is inclined in the oblique sphere, which we treated in Proposition 37 of the previous book.

[Margin: Demonstration of the description of the aforesaid dial.]

We shall demonstrate this construction as follows. In the plane of the dial set in its proper position, let AB be parallel to the horizon, so that it is the common section of the dial's plane and the horizon; and conceive the triangle $EF \perp$ to be moved about the line $E \perp$ until it coincides with the horizon and lies in it. Now since DEF is the angle of the plane's declination from the vertical, the remaining angle AEF will be the complement of that declination — such indeed as the meridian makes with the line that, in the declining and inclined plane, is parallel to the horizon, or rather with the plane drawn through that line and perpendicular to the horizon. Therefore EF, in that position, will be the common section of the meridian and the horizon. And since in the right sphere the axis of the world is the common section of the horizon and the meridian, EF will be the axis of the world, meeting the dial's plane at E — the point that will be the centre of the dial, in which all the hour-lines meet, as was demonstrated above.

Diagram. The large circular figure of the astronomical dial declining from the vertical and inclined to the horizon, in the right sphere. A horizontal diameter runs from **A** (left) through the centre **E** (drawn as a small circle) to **B** (right); this is the line AB, parallel to the horizon and the 6th-hour line. Twenty-four hour-lines radiate from E to the circumference, their outer ends numbered around the rim. A vertical line rises from E through **C** near the top and descends through the lower part of the figure; near the centre-below lie the points **P** and **M**, with **F** just above them and **p** alongside. A tight cluster of construction points and lines sits just left of and below the centre — including the Greek letters α and γ , and the points **I**, **H**, **n**, **K**, **L** and the special sort $\perp$ — together with a circle (the hour-circle about L) and several dotted arcs.

- A (left end of the horizontal diameter AB)
- B (right end of the horizontal diameter AB)
- C (upper centre, on the near-vertical meridian line)
- E (centre of the figure; small circle where all hour-lines meet)
- F (below and left of centre)
- n (left-of-centre cluster)
- P, M (below the centre, on/near the meridian line); p (adjacent to M)

- I, H, K, L (centre-left construction cluster — faint)
- α , γ (Greek letters in the centre-left cluster — faint)
- $\perp$ (special typographic sort, in the centre cluster)
- Hour-numbers around the rim (worn): upper arc, left→right — 4, 3, 2, 1, 12, 11, 10, 9, 8 [?]; right side down from B — 7, 6 (at B), 5, 4, 3, 2 [?]; bottom centre — 1 [?]; left side down from A — 6 (at A), 7, 8, 9, 10, 11, 12 [?]

[Margin: (a) [Euclid, *Elements*] XI.4. (b) [Euclid, *Elements*] XI.18.]

Again, with the triangle $EF\perp$ having the position we described, conceive the triangle $Fn\perp$ to be turned about $F\perp$, downward, until it stands perpendicular both to the dial's plane and to the horizon — which happens precisely when the line $\perp n$ is perpendicular to AB . For then the line AB , being perpendicular to the lines $\perp F$ and $\perp n$, [a] will be perpendicular to the plane of the triangle $\perp Fn$ drawn through those lines. [b] Therefore both the dial's plane and the plane of the horizon, drawn through the line AB , will be perpendicular to that same plane of the triangle $\perp Fn$; and conversely this plane will be perpendicular to each of them. Hence, since $F\perp n$ is the angle of the plane's inclination to the horizon, and the horizon is drawn through the line $I[?]\perp$ in that position, $\perp n$ will lie in the inclined plane and will coincide with the line $\perp p$ lying in the same plane; and so the point n will fall upon the point p , because of the equality of the lines $\perp n$ and $\perp p$. Since, then, the meridian — standing perpendicular to the horizon, and therefore also to the plane of the triangle $EF\perp$, while lying in the plane of the horizon in the said position — passes through the line EF , as we have shown, and consequently through the line Fn in that position (because Fn , by Definition 4 of Book 11 of Euclid, is perpendicular to the plane of the triangle $EF\perp$, being perpendicular by construction to $F\perp$, the common section of the triangles $EF\perp$ and $\perp Fn$, one of which is perpendicular to the other), the meridian will meet the plane of the inclined dial at the point p ; and therefore the line Ep will be the common section of the meridian and of the plane of the inclined dial. This same meridian line we shall also find by another method, as we taught at the beginning of Proposition 37 of the previous book.

Now, with the triangles $EF\perp$ and $\perp Fn$ still set in the same positions, the line FG — being perpendicular to $\perp n$, the common section of the dial's plane and of the triangle $Fn\perp$ (which stands perpendicular to the dial's plane), and lying in the plane of the triangle $Fn\perp$ — will, by Definition 4 of Book 11 of Euclid, be perpendicular to the dial's plane at the point G , which is then the same as H . Since, then, its end-point F falls on the axis EF (for it was shown that EF , in that position, is the axis of the world), the point F will be the centre of the world, since

through it both the meridian and the horizon are drawn; the line FG will be the style, or gnomon; and consequently the line EH, drawn through the foot of the style, will be the index-line — so that the great circle drawn through it and through the style, and also through the poles of the world, stands perpendicular to the dial's plane, like a kind of proper meridian.

Now if the triangle EIK is turned about the line EK until it stands perpendicular to the dial's plane, the line HI will be perpendicular to it, by Definition 4 of Book 11 of Euclid. Since it was taken equal to the style FG, the point

— the point I will fall upon the centre of the world F; that is, the line HI will coincide with the style, and the line EI with the axis of the world EF.

Consequently the angle HEI will be the elevation of the pole above the plane of the dial, and IK will be the common section of the equator and of the triangle EIK — that is, of the dial's own proper meridian. Therefore, as was shown in what preceded, KM will be the equinoctial line, and the hour-lines will have been drawn, as we said. And since the equator, in the right sphere, is perpendicular to the horizon and passes through F, the tip of the style, it follows that when a line is drawn through F_n — which we showed to be perpendicular to the horizon, or to the triangle EF ⊥ lying in the horizon — it will meet the plane of the dial at the point p. The equinoctial line KM will therefore pass entirely through the point p.

[Margin: The parallels of the signs and of the latitudes of cities. The hours from sunrise and sunset, together with the unequal hours. The vertical circles, the parallels of the horizon, the meridians, and the ascending signs. The celestial houses.]

The parallels of the zodiacal signs and of the latitudes of cities are to be drawn, on this dial that is at once inclined and declining, in just the same way as on the inclined-and-declining dial in the oblique sphere, following what we taught in Proposition 38 of the previous book.

The hours from sunrise and sunset, and likewise the unequal hours, agree in their layout with the hours reckoned from noon and midnight; they differ only in numbering, as we also said for the other dials of the right sphere.

The vertical circles, the parallels of the horizon, the meridians, and the ascending signs are drawn here in exactly the same way as on the declining-and-inclined dial in the oblique sphere.

Finally, the celestial houses are here expressed by means of the hour-lines, just as on the other dials of the right sphere, as has been said. We have therefore

constructed, in the right sphere, dials that decline from the vertical circle and are at the same time inclined to the horizon. Which was to be done.

PROBLEMA 10. PROPOS. 10.

To construct sundials in the most oblique sphere, where the arctic pole is raised 90° above the horizon.

[Margin: By what method dials can be drawn in the most oblique sphere, where the elevation of the arctic pole is 90° .]

Since in a sphere of this kind there is continuous day while the Sun runs through the six northern signs — so that the Sun then neither rises, nor sets, nor reaches the meridian, nor comes to midnight, but stands perpetually above the horizon — and likewise a continuous night while the Sun lingers in the other six, southern signs, it follows that, strictly speaking, the hours can be reckoned neither from sunrise or sunset, nor from noon or midnight, nor can twelve unequal hours be assigned; for there are no diurnal or nocturnal arcs there to be divided into twelve equal parts. Therefore neither an astronomical, nor an Italian, nor a Babylonian, nor an Antique dial can be built in that sphere. Nevertheless, if we imagine twelve hour-circles passing through the poles of the world and dividing the equator into twenty-four equal parts, fixed and immovable, we may draw their hour-lines both on a plane parallel to the horizon and on one perpendicular or inclined to the horizon, in the following way.

[Margin: The horizontal dial in the most oblique sphere, where the arctic pole is set at the pole of the horizon.]

For the horizontal dial, take the equinoctial dial, but with the complete parallels of the zodiacal signs drawn in, and without the horizontal line. For since in that sphere the horizon does not differ from the equator, the plane of the horizontal dial will not be cut by the horizon, nor will it differ from the equinoctial dial. The order of the hours on this horizontal dial will be exactly the same as on the equinoctial one, with this single exception: that here there is no need to search out the meridian line, as there; rather, once the dial has been set so as to lie parallel to the horizon, the start of the hours may be taken from any line whatever.

[Margin: The vertical dial, and the dial declining from the vertical, in the same most oblique sphere. The dial inclined to the horizon in the same most oblique sphere.]

A dial perpendicular to the horizon — such as the vertical dial, or one declining from the vertical — will not differ from a polar dial, since the great circle to which it is parallel passes through the poles of the world. Still, the start of the hours can be set on any hour-line, and their order is taken from left to right. The equinoctial line, moreover, will be the same as the horizontal one.

Finally, if the plane of the dial is inclined to the horizon, the complement of the inclination will give the elevation of the pole above that inclined plane, as is evident. So if a horizontal dial is built for that elevation, as we taught at the beginning of Book 2, and a horizontal line is drawn on it as on the other inclined dials of the oblique sphere, the result will be a dial inclined to the horizon. But from none of these dials shall we learn, as we said, how many hours have elapsed since noon or midnight, or since sunrise or sunset; only how many of the twenty-four equal hours — in which the Sun completes one whole revolution from a given point back to the same point — have passed from some fixed point that we conceive in the mind.

The vertical circles, since they do not differ from the hour-circles — being drawn through the poles of the world — are drawn like the hour-lines, by taking any vertical line as the common section of the vertical circle properly so called and of the plane of the dial; from this the rest are to be reckoned.

[Margin: The vertical circles. The parallels of the horizon, and of the latitudes of cities. The meridian circles.]

The parallels of the horizon and of the latitudes of cities are also drawn like the parallels of the zodiacal signs, if in place of the zodiac's rays whole quadrant-rays are described, and so on.

The meridians, too, will be laid out like the hour-lines, once the position of the prime meridian — drawn through the Fortunate Isles — has first been ascertained. The situation of that prime meridian can be found in this way. Observe the position of some city of known longitude, distant several miles from the place set beneath the pole. On the plane parallel to the horizon, from the chosen place beneath the pole draw a straight line toward that city whose longitude is known, and, from a point taken on it at will, describe a circle. For since that straight line is the common section of the plane of the horizontal dial and of the meridian drawn through that city, if from it the longitude of the said city is counted off toward the western parts — that is, against the succession of the signs, following the Sun's diurnal motion — and a straight line is drawn from the end of that count through the centre, one will have the common section of the

prime meridian and of the plane of the horizontal dial, as is evident. Whenever, therefore, the style's shadow falls on this line, we shall easily, on other planes, draw from the gnomon's shadow another line corresponding to it, to serve as the meridian of the Fortunate Isles.

[Margin: In the most oblique sphere there are no celestial houses.]

The celestial houses, however, have no place in this sphere, because neither a meridian nor a vertical circle properly so called — passing through the points of true sunrise and sunset — can be assigned, as we have said.

Lastly, there are likewise no ascending signs, since perpetually six signs appear above the horizon and six are hidden below it. We have therefore constructed the dials in the most oblique sphere, and so on. Which was to be done.

[Margin: In the same most oblique sphere there are no ascending signs.]

PROBLEMA 11. PROPOS. 11.

To describe sundials in an oblique sphere in which the antarctic pole is raised above the horizon.

Since all the rules we handed down in Books 2 and 3 for the construction of dials concern the oblique sphere that has the arctic pole visible, it seemed worthwhile to sketch briefly, in this proposition, how one should proceed who wishes to describe dials in the other oblique sphere, in which the antarctic pole is raised above the horizon. For this alone seems to be lacking, so that by the rules already handed down one might construct dials in any region whatever of the earth — since in this book too we have prescribed rules by which dials can be made both in the right sphere and in the most oblique sphere, where the arctic pole is raised 90° above the horizon.

[Margin: By what method dials are described in the oblique sphere that has the antarctic pole visible.]

In setting out dials for the southern hemisphere, then, we shall use exactly the same rules we gave in Books 2 and 3, with this one point observed and noted: that whatever was there said of the arctic pole and of the forenoon hours is here to be understood of the antarctic pole and of the afternoon hours. What we there wrote, in the vertical, declining, and inclined dials, about the southern and northern sides is here to be transferred to the northern and southern sides. And whatever we there prescribed about the northern or southern signs is here to be taken in the opposite sense, of the southern or northern signs. So that, if this

interchange is made — of the poles, of the hours before and after the southern noon, and of the northern and southern signs — any dial laid out in Books 2 and 3, for example one made for latitude 42° in the northern hemisphere, will also serve as a dial constructed for latitude 42° in the southern hemisphere. To make this plainer, we shall briefly run through the various dials described in the earlier books, showing for each how it is to be placed in the southern hemisphere, and what must be changed in it so that it may show the hours.

A horizontal dial, then, in the oblique sphere where the antarctic pole is raised above the horizon, is to be set so that its centre faces north and its equinoctial line faces south; for in this way the axis of the world, passing through the dial's centre and the tip of the gnomon, will have its proper position — that is, it will run through the poles of the world. The arcs of the northern signs must also be changed into arcs of the southern signs, and the arcs of the southern into those of the northern, so that the signs between the centre and the equinoctial line belong to the southern signs and the rest to the northern; for there the beginning of Capricorn ♐, at noon, comes closest to the zenith, while the beginning of Cancer ♋ recedes farthest from it. Finally, the hours are to be changed into their complements up to 12, if they are reckoned from noon or midnight, but into their complements up to 24, if they are counted from sunrise or sunset; and the hours that in the northern oblique sphere were reckoned from noon are here, in this other sphere, to be computed from midnight, and conversely.

[Margin: How a horizontal dial built for the northern oblique sphere is to be placed in the southern oblique sphere, and by what method the hour-numbers are to be changed.]

Diagram. A horizontal sundial laid out for the southern latitude of 42° , shown as a broad, roughly hourglass-shaped web of straight hour-lines radiating from a dense central knot, overlaid with dotted curves (the tropics / diurnal-arc parallels) crossing the upper and lower zones. The frame is labelled with the four cardinal directions in large ornamental capitals, and with zodiac-sign glyphs at the four corners; the straight hour-lines carry Babylonian/Italian hour-numbers running past 12 up to about 23, with the astronomical hour-numbers set near the equinoctial line. Because the interior is a very dense overlapping mesh of small numerals, the central hour-numbers cannot be individually resolved on the scan and are not committed here.

- SEPTENTRIO (top center): "North" — the head of the vertical meridian line.
- MERIDIES (bottom center, printed "MERI | DIES"): "South" — the foot of the vertical meridian line.

- OCCASVS (left side, set vertically): "West" — the left end of the horizontal equinoctial line.
- ORTVS (right side, set vertically): "East" — the right end of the horizontal equinoctial line.
- Small cursive label just below SEPTENTRIO, at top center: [Illegible: ~2 words, possibly a pole/axis caption — [?]]
- Vertical central line (SEPTENTRIO–MERIDIES): the meridian line.
- Horizontal central line (OCCASVS–ORTVS): the equinoctial line.
- Dotted curves crossing the upper and lower zones: the tropic arcs / diurnal-arc parallels.
- Zodiac glyph at top-left corner (near the "10" hour-number): [?] (worn sort — not confidently pinned)
- Zodiac glyph at top-right corner (near the "14"/"23" hour-numbers): [?] (worn sort)
- Zodiac glyph at bottom-left corner: [?] (worn sort)
- Zodiac glyph at bottom-right corner: [?] (worn sort)
- Readable straight-line hour-numbers along the margins (partial; upper edge, left→right and right edge top→bottom): 10, 9, 11 (upper left); 23, 22, 14, 13, 12 (upper right / right edge); 11, 10, 9, 8 (lower right); 8, 9 (bottom) — [remaining interior hour-numbers not resolvable: [?]]

and conversely. The hours that used to be counted there from sunrise are here to be counted from sunset, and the reverse — so that, as far as the layout is concerned, from an Italian dial there arises a Babylonian one, and from a Babylonian an Italian. For the hour-numbers are changed into their complements up to 24, as we said. In the same way the numbers of the unequal hours must be changed into their complements up to 12. The reason for this change is clear, if the dial's situation is carefully considered. For the part of the dial that in the northern oblique sphere faced east — and so contained the hours after noon, or from sunset — in the southern oblique sphere faces west and takes in the hours before noon, or from sunrise, and conversely. You have an example here in a horizontal dial constructed for the southern latitude of 42° . Here you plainly see that a Babylonian dial in the northern sphere is an Italian one in the southern, and the reverse; and likewise that the hours there counted from noon are here computed from midnight, and conversely. The dotted lines belong to the astronomical hours, whose numbers are placed near the equinoctial line; but the lines drawn out beyond the tropics signify the hours from sunset, and the rest the hours from sunrise.

[Margin: The diurnal arcs in the southern oblique sphere. The vertical circles, and the parallels of the horizon.]

The numbers assigned to the diurnal arcs, moreover, are not changed, even though the arcs themselves do not remain the same. For the diurnal arcs containing more than twelve hours are, in the northern oblique sphere, the northern arcs, whereas in the southern oblique sphere these same arcs are the southern ones, and so on.

The vertical circles and the parallels of the horizon likewise need not be changed, whether their layout or their numbers are considered.

[Margin: The meridian circles.]

The meridians are to be described in the southern hemisphere as in the northern, if the longitude of the place is counted, from the meridian line in the circle by whose aid the astronomical hours were drawn, toward the western parts — which, when we are turned toward the antarctic pole, lie on our right.

[Margin: The celestial houses.]

The lines of the celestial houses also remain the same; only their numbers must be interchanged. For those set on the left will have to be placed on the right, and conversely, so that house 12 becomes house 8, and house 11 becomes house 9, and so on.

[Margin: The ascending signs.]

Finally, the ascending signs are to be drawn in the southern oblique sphere as in the northern, provided tables are first constructed for the given southern latitude, like those we composed in Proposition 9 of Book 2 — with this carefully observed: that the oblique ascensions of all the signs in the northern oblique sphere agree, in the southern sphere, with the opposite signs; and likewise that the diurnal and semidiurnal arcs computed in the northern sphere are to be assigned, in the southern, to the opposite signs, and so on. All of which we have shown at length in our treatment of astronomical matters.

[Margin: How the other dials constructed for the northern oblique sphere are to be placed in the southern oblique sphere.]

All this must be observed in the other dials as well. But as regards their construction and placement, whatever we said in the northern oblique sphere of the southern and eastern side is, in this other, southern oblique sphere, to be understood of the northern and western side, and conversely. That is: the

southern dial that we laid out in Proposition 13 of Book 2 for the northern latitude of 42° must, in the southern sphere of the same latitude, face north — because on that side noon is made — and the part that there faced east must here be set toward the west, and conversely. Again, the eastern meridian dial described in Proposition 25 of Book 2 for the same northern latitude of 42° will, in the southern sphere of the same latitude, be a western one, and conversely: the western will become eastern; yet each must be so placed that the part which before faced south now faces north, and conversely.

So too the declining dials will have to be altered: what before declined from south toward east now bends from north toward west, and so on. In the same way the dials declining from the horizon are to be placed, so that what before faced west now faces east, and the side that was southern now becomes northern, and so on. In all of them the hour-numbers must be changed into their complements up to 12, if the talk is of hours reckoned from noon or midnight; and the hours before counted from noon are now to be taken from midnight, and conversely. But if there are hours from sunrise or sunset, their complements up to 24 must be taken, and the hours before computed from sunrise are now to be counted from sunset, and conversely. The rest is clear of itself, if the position of any given dial is rightly conceived. We have therefore described the dials in the oblique sphere in which the antarctic pole is raised above the horizon. Which was to be done.

SCHOLIVM.

[Margin: For what latitude all the foregoing dials have been described.]

It has seemed worthwhile to explain briefly in this place what variety the hour-lines from sunrise and sunset take on for one elevation of the pole after another — whether of the arctic or of the antarctic pole — above the horizon, so that no one, in drawing lines of this kind, may be stopped or hindered by seeing that the hours from sunrise and sunset do not behave the same way everywhere among the nations. For since in Books 2 and 3 all those things we described in the hundred and eight problems [centrum & octo [?]] pertain to that oblique sphere in which the arctic pole is elevated 42° , while what we handed down in this book concerns the right sphere, it comes about that the hour-lines from sunrise and sunset, on any dial whatever, cut both tropics. For when the elevation of the pole is less than $66^\circ 30'$ — that is, less than the complement of the Sun's greatest declination — each tropic cuts the horizon, and so the greatest of the parallels of things always visible, which the hour-circles from sunrise and sunset touch (as we showed in Proposition 10 of Book 1), lies between the tropic and the pole. Hence these same hour-circles will, in the sphere, cut the tropic, and

consequently, on any dial, the lines of those same hours will cut the arc of Cancer ☎ or of Capricorn ♎, as was done in all the foregoing examples.

[Margin: At a latitude less than $66^{\circ} 30'$, the hour-lines from sunrise and sunset cut both tropics. At the latitude of $66^{\circ} 30'$, the hour-lines from sunrise and sunset touch the tropic. At a latitude greater than $66^{\circ} 30'$, the hour-lines from sunrise and sunset neither cut nor touch the tropic, but touch another parallel nearer the equinoctial line.]

But it sometimes happens that the said hour-lines only touch the tropic, at those points where it is divided by the lines of the hours reckoned from noon or midnight; and sometimes that they by no means reach the tropic, but touch another parallel lying between the tropic and the equinoctial line. For when the elevation of the pole equals the complement of the Sun's greatest declination — that is, comprises $66^{\circ} 30'$ — the tropic touches the horizon and does not differ from the greatest of the parallels always visible. Hence, in the sphere the hour-circles from sunrise and sunset touch the tropic, and on any dial the lines of those same hours will touch the arc of Cancer ☎ or of Capricorn ♎ at the points where it is cut by the lines of the hours from noon or midnight. But when the elevation of the pole is greater than the complement of the Sun's greatest declination — that is, greater than $66^{\circ} 30'$ — the whole tropic stands above the horizon, and another, larger parallel touches the horizon. Therefore, since in the sphere the hour-circles from sunrise and sunset touch this parallel and in no way reach the tropic, on any dial the lines of those same hours will touch the arc of that parallel and will by no means reach the arc of Cancer ☎ or Capricorn ♎. All of which can be plainly gathered from what we wrote in Book 1 on the hour-circles and on the contacts that the hour-lines from sunrise and sunset make with the greatest parallels of things always visible and always hidden.

[Margin: Which segments of the tangent lines belong to the hours from sunset, and which to the hours from sunrise.]

Yet, to make this matter still clearer, we have added here two dials. The first, constructed for the northern latitude of $66^{\circ} 30'$, is horizontal and contains the hours both from noon and midnight and from sunrise and sunset; of these, the latter touch the arc of Cancer ☎ — which there plays the part of the greatest parallel of things always visible — at the points where it is cut by the former. The second, built for the northern latitude of $69^{\circ} 48'$, is a polar dial with the same hours, in which the hours from sunrise and sunset do not reach as far as the tropics but touch the parallels of Gemini ♊ and Sagittarius ♐, which at that

latitude serve as the greatest parallels of things always visible and always hidden, at the points where they are cut by the hours from noon and midnight.

Now since in the scholium to Proposition 10 of Book 2 we demonstrated that, of any hour-line, the one portion touching the greatest parallel of things always visible or always hidden indicates an hour from sunset, while the other belongs to the hour of the same number from sunrise — the point of contact separating the two portions — we shall distinguish the hours from sunset from the hours from sunrise in this way. On the horizontal dial, the segments of the tangent lines that are drawn upward from the points of contact toward the right of the meridian line — that is, toward the western parts of the dial — belong to the hours from sunset; those that tend downward, to the hours from sunrise. The contrary is to be understood of the lines drawn through the points of contact toward the left of the meridian line, or toward the eastern parts of the dial: those that extend upward show the hours from sunrise, while those that extend downward regard the hours from sunset. Finally, of the line that at the twelfth astronomical hour touches the greatest parallel of things always visible, the western portion indicates the twelfth hour from sunset, and the other the twelfth hour from sunrise. Hence, if only an Italian or a Babylonian dial is to be described, the hour-lines will not be tangent on both...

[continuation of the Scholium to Proposition 11, from the prior page]

to be drawn out to both sides of the points of contact — but only toward that side which pertains to the hours reckoned from sunset or from sunrise. On a polar dial the hours from sunset or from sunrise will be easily recognized from what we wrote about the polar dial in Book 2.

It also seems worth remarking here that the place of the style [locus styli] on horizontal dials can vary in several ways, according to the differing elevation of the pole above the horizon. For when the elevation of the pole is greater than the Sun's greatest declination, the place of the style falls outside the tropics, between the center of the dial and the tropic. When the elevation of the pole equals the Sun's greatest declination, the place of the style falls exactly on the tropic. And when the elevation of the pole is less than the Sun's greatest declination, the place of the style falls between the tropic and

[Margin: When the place of the style on horizontal dials falls outside the tropics; and when exactly on the tropic; or within the tropics; or, finally, on the equinoctial line itself.]

Diagram. The first of the two dials promised in the scholium: a horizontal dial constructed for the northern latitude of $66^{\circ} 30'$. It is a broad fan of hour-lines. A dense sheaf of straight lines (the hours from noon and midnight) radiates from a focal point low in the middle of the figure, while a second set of dashed lines (the hours from sunrise and sunset) sweeps across; the two families intersect throughout. The hour-numbers run around the border of the figure.

- Top row (left to right): 18, 19, 20, 8, 9, 10, 11, 12, 1, 2, 3, 4, 5
- Down the left margin (top to bottom): 17, 16, 15, 14, 13, 12, 11, 10, 9
- Down the right margin (top to bottom): 6, 7, 8, 9, 10, 11, 12, 13, 14
- Along the lower border (left to right): 22, 21, 20, 19, 18, 17, 16, and a central cluster 8, 7, 6, 5, 4, 3, [?], with 12 at the very bottom-center

The lines drawn as dashes are the hours from sunrise and sunset, which touch the arc of Cancer at the points where the noon/midnight lines cut it (as the accompanying text explains). Given the density of overlaid lines, several peripheral hour-numbers are read with low confidence

the equinoctial line. And when, finally, the elevation of the pole is nil — as in a right sphere — the style is to be set on the equinoctial line itself. All of this is plainly gathered from the analemma that we constructed in Proposition 2 of Book 2. For since in that figure the elevation of the pole AF is greater than the Sun's greatest declination, it comes about that the ray of Cancer ☊, sent out through the center D, falls upon the meridian line RO at the point K, beyond the place of the style G — so that the point G lies between H (the center of the dial) and K (the point of Cancer ☊). The place of the style therefore lies entirely outside the tropics. But if the elevation of the pole AF were equal to the Sun's greatest declination, so that the diameter of the parallel of Cancer ☊ cut the meridian at the point A, then the ray of Cancer ☊, cast from A through the center D, would not differ from the diameter of the vertical circle; and accordingly the place of the style would be at

Diagram. The second dial: a polar dial constructed for the northern latitude of $69^{\circ} 48'$. Its lines form a symmetric bow-tie (hourglass) shape, converging toward a narrow waist at the center and spreading toward the upper and lower edges. Zodiac sorts mark the tropic arcs at the four corners.

- Upper-left corner: zodiac sort, Cancer ☊ [?] (worn; the tropic-of-Cancer arc, per the text)
- Upper-right corner: zodiac sort, Capricorn ☋ [?] (worn)
- Lower-left and lower-right corners: matching zodiac sorts [?] (worn)

- Hour-numbers along the upper edge (left to right): 6, 7, 8, 9, 10, 11, 12, 1, 2, 3, 4, 5
- Hour-numbers repeated along the lower edge (left to right): 7, 8, 9, 10, 11, 12, 1, 2, 3, 4, 5
- Numbers in the central band around the waist: 10, 11, 12, 1, 2, 3

In this dial the hours from sunrise and sunset do not reach the tropics but touch the parallels of Gemini Υ and Sagittarius $\times$, which at this latitude serve as the greatest parallels of things always visible and always hidden. Several worn zodiac sorts are read from context and flagged

the point G, where the ray of Cancer ♋ would cut the meridian line. But if the elevation of the pole were less than the Sun's greatest declination, so that the diameter of the parallel of Cancer ♋ cut the meridian between the vertex A and the pole of the world E, then it plainly follows that the ray of Cancer ♋ , passing through the center D, would fall between H (the center of the dial) and G (the place of the style); so that the place of the style would then lie between the tropic of Cancer ♋ and the equinoctial line. And if, finally, the elevation of the pole were nil, so that the diameter of the equator did not differ from the diameter of the vertical circle — who does not see that the place of the style would then fall on that point of the meridian line where the equator meets the plane of the dial?

All of this holds for other dials as well, according as the elevation of the pole above the great circles to which their planes are parallel is greater than, equal to, or less than the Sun's greatest declination — or, finally, nil. Thus you see that in the dials we described in Books 2 and 3 — namely the horizontal, the vertical, the equinoctial, the declining-from-the-vertical, the declining-from-the-horizon, the inclined-to-the-horizon, and the simultaneously declining-and-inclined dial (in which, at Proposition 38 of the preceding book, we laid out the arcs of the signs) — the place of the style is set outside the tropics, because the elevation of the pole above the great circles to which those dials are parallel exceeds the Sun's greatest declination. In the horizontal dial contained in the scholium to Proposition 2 of Book 2, however, the place of the style falls within the tropic,

[Margin: How the same may be known for other dials.]

because there the elevation of the pole above that horizon is less than the Sun's greatest declination. Finally, in the meridian dial, the polar dial, and the simultaneously declining-and-inclined dial that we constructed in the third place at Proposition 37 of the preceding book — and in the dials of a right sphere composed in this present book — the style falls upon the equinoctial line itself,

because there is no elevation of the pole above the great circles to which those dials are parallel.

PROBLEMA 12. PROPOS. 12.

To set the gnomon of any dial in its proper place, so that it stands square to the plane of the dial; and to restore its vertex to its own seat whenever it has been bent away from it.

[Margin: By what method the style is to be set square to the plane of the dial.]

Let AB be the style, or gnomon, of any dial, its foot at the point A, where it must be fixed to the dial in such a way that it stands square to the dial's plane, and so on. From A, the foot of the style, describe a circle CDE of any size in the plane of the dial, and on it choose any three points C, D, E. Then at A erect the style AB, and move its vertex B this way and that until, with the aid of a compass, three equal straight lines are found reaching from the points C, D, E to the vertex B. I then say that the gnomon AB stands square to the plane of the dial in which the circle CDE lies. For if it be denied to stand square, suppose that from the vertex B another line BF is let fall perpendicular to the plane of the dial, if that be possible, meeting it at a point F distinct from A. Drawing the straight lines CF, DF, EF, then by Definition 3 of Book 11 of Euclid the line BF will be perpendicular to all of them, and accordingly the triangles BFC, BFD, BFE will be right-angled. [Margin: 47 of the first (book).] Hence the square on BC equals the squares on BF and FC; the square on BD equals the squares on BF and FD; and the square on BE equals the squares on BF and FE. But since the squares of the three lines BC, BD, BE — which are posited equal — are themselves equal, the squares on BF and FC will equal both the squares on BF and FD and the squares on BF and FE. Taking away, then, the common square on the line BF, there remain the equal squares of the lines FC, FD, FE; and therefore those lines FC, FD, FE are themselves equal.

[Margin: 9 of the third (book).] The point F, therefore, would be the center of the circle CDE — which is absurd, since A is the center of that circle. It is therefore not the case that the perpendicular let fall from B, the vertex of the style, to the plane of the dial falls at a point F distinct from A; and accordingly it falls at A. Hence the line AB, erected so that the three lines CB, DB, EB are equal, will stand perpendicular to the proposed plane.

Diagram. A circle CDE with its center A, illustrating the perpendicularity proof.

- B: vertex of the style, at the top, joined by lines to C, D, E, A, F
- E: on the circle, to the right

- A: center of the circle
- F: an interior point (the supposed foot of the perpendicular), below A
- C: on the circle, lower left
- D: on the circle, at the bottom

Diagram. A right triangle GHI, used to measure the compass-opening.

- H: upper vertex (right angle at G)
- I: lower-left vertex
- G: lower-right vertex; side GH equals the style, side GI equals the semidiameter AE

Now, so that we may know at what distance the legs of the compass ought to stand apart, so that — one leg placed on any of three points of the circumference CDE, the other reaching the vertex B of the style — we may reach square to the dial's plane, we shall describe a right triangle GHI whose side GH equals the style and whose side GI equals the semidiameter AE. For the length of the line IH will equal each of the distances between the points C, D, E and the vertex B, provided the style stands square to the plane of the dial. Since the two sides GH, GI of triangle GHI equal the two sides AB, AE of triangle ABE, and contain equal angles at G and A (both being right angles), [Margin: 4 of the first (book).] the bases IH and EB will also be equal to each other; and by the same reasoning IH will be shown equal to the lines DB and CB. And so, to fix the style AB at the point A square to the dial's plane, it is necessary that, with one leg of the compass placed on any point of the circumference CDE, the other reach the vertex B, if the distance enclosed between the compass legs equals the line IH — as is left clear from what has been demonstrated.

Now, further, whenever the vertex of the gnomon is bent and moved from its own place, we shall restore it thus. From A, the foot of the style, draw on the dial any line AB — either equal to the style, as in the earlier, lower triangle, or greater, as in the later one. Through B, draw CD perpendicular to AB, and set the lines BC, BD equal to AB. Then from AC cut off AE equal to the style, and cut off DF equal to the distance DE. I say that if the compass is opened to the distance DF, and the vertex of the gnomon is moved this way and that until, with one leg of the compass placed on the points C and D, the other reaches the vertex, then the vertex of the gnomon has been restored, so that the style once more stands square to the plane of the dial at the point A. For suppose in A the style AG standing square to the dial's plane, and join the lines DE, DG, GC. Since the sides BA, BC are equal, [Margin: 5 of the first (book).] the angles A and C will be equal. B

being a right angle, the angle BAC will therefore be half a right angle, [Margin: 32 of the first (book).] since all three angles of triangle ABC equal two right angles. By the same reasoning the angle BAD will be shown to be half a right angle, and accordingly the whole angle CAD will be right; [Margin: 4 of the first (book).] and moreover the lines AC, AD will be equal to each other, on account of the triangles ABC, ABD, in which the two sides BA, BC equal the two sides BA, BD and contain equal angles at B, namely right angles. Again, since GA is perpendicular to the plane of the dial, in which the triangle ACD lies, the angles GAC, GAD will also be right, by Definition 3 of Book 11 of Euclid. And so, since the two sides DA, AE of triangle DAE equal the two sides DA, AG of triangle DAG and contain equal angles at A (both right), [Margin: 4 of the first (book).] the bases DE, DG will also be equal to each other. In the same way we shall show the lines DE and CG equal to each other, on account of the triangles DAE, CAG, whose two sides DA, AE equal the two sides CA, AG and contain equal angles DAE, CAG, namely right angles. Since, then, the line DE — and therefore the line DF, which was taken equal to DE — equals both the line DG and the line CG, both of which are drawn from D and C to the vertex G of the style at

Diagram. The lower group of figures illustrating the restoration of the gnomon's vertex: two triangle-constructions (the "earlier, lower" triangle and the "later" one), drawn with solid and dashed lines. [Margin: 9 of the third (book).] The readable labels along the top edge run C, F, B, H, D; with I marked on the interior, E toward the middle, and the apex-points G and A at the foot. Because the two constructions overlap and share letters, individual point positions are read with limited confidence

- Top edge (left to right): C, F, B, H, D

- Foot: G, A

[Body heading, per page: "b 9. tertij." appears as a margin citation, not a section heading]

right angles with the plane of the dial's face — it is necessary that, with one leg of the compass set on both D and C, we reach the vertex G of the style, if the space enclosed between the compass legs equals the line DF, and if the style itself makes right angles with the dial's plane, as is clear from what has been demonstrated. We have therefore set the gnomon of every dial in its proper place, and so on. Which was to be done.

SCHOLIUM.

On dials that do not decline — such as the horizontal, vertical, polar, equinoctial, and inclined-to-the-horizon dials — the line AB of the preceding triangle is to be cut off from the meridian line, as you see done in the horizontal dial at Proposition 4 of Book 2, where the vertical circles and the parallels of the horizon are drawn. On the others, however, which do decline, the same line AB is to be taken on the line of the style, as you see done in the dial declining from the vertical at Proposition 6 of the preceding book, which contains the meridian circles. This, however, is not necessary. For the line AB can be drawn from the place of the gnomon in any way whatever, and the aforesaid triangle constructed. Thus you see, in the Italian dial declining from the vertical at Proposition 10 of the preceding book, that a triangle of this kind is made in such a way that the line AB, dividing the base of the triangle into two equal parts, is greater than the style and is taken outside the line of the style. In the same way the said triangle can be described on any dial whatever. And if ever the place of the gnomon is set within the tropics — as happens on the polar dial and some others, as we taught above in the scholium to the preceding proposition — then the sides AC, AD of the aforesaid triangle, since they intersect the lines of the dial, may be erased, and the base CD alone left; or at least only those segments of the sides that fall outside the tropics may be drawn. An example of this you have in the polar dial of the ascending signs at Proposition 45 of Book 2. It will also be possible, if one wishes, to transfer the distance DF from C as far as H. Likewise, on the later triangle, in which the line AB is greater than the style, one may cut off a line BI equal to the style, so that if ever the style is lost or broken, we may supply one equal to it.

[Margin: What is to be observed in various dials in constructing the triangle by which the style is restored to its proper position.]

PROBLEMA 13. PROPOS. 13.

Given a dial, together with its style and the position of the style: to determine the elevation of the pole for which it was built, and what declination it has from the vertical, and what inclination to the horizon (if it is a declining or an inclined dial), as well as how great the elevation of the pole is above the declining or inclined plane itself. And conversely: given a dial together with the elevation of the pole for which it was constructed, and its inclination to the horizon (if it is inclined), to investigate the length of the style and its position, together with the declination from the vertical (if the

dial is a declining one), and the elevation of the pole above the declining or inclined plane itself.

It frequently happens that it is unknown for what elevation of the pole some dial presented to us was constructed, or how large its style ought to be (if perhaps it has been lost or broken), and in what place it must be set so as to indicate the hours. We shall determine both of these by the following method.

[Margin: By what method, on a horizontal dial, from a given style and its position, one may investigate the elevation of the pole for which it was built.]

Let there be, first, a horizontal dial A, on which BC is the equinoctial line and DE the meridian, and FG the style, to be set at the point F. From F, the foot of the style, raise FH perpendicular to the meridian line, equal to the style FG. Draw the line IH from the point I (where the meridian line and the equinoctial cross each other) to H; and at H raise HD perpendicular to IH, cutting the meridian line at D. I say that IDH is the angle of the elevation of the pole for which the dial was built. For since, as is established from what was demonstrated in Proposition 1 of Book 2, the line HI is

Diagram. The principal construction for Problema 13: the horizontal dial A with its meridian and equinoctial lines and the perpendiculars forming the pole-altitude angle IDH.

[Margin: By what method, on a horizontal dial, from a given style and its position, one may investigate the elevation of the pole for which it was built.]

the common section of the equator and the meridian (if the triangle DHI is set square to the plane of the dial — that is, in the plane of the meridian); and since the axis of the world, passing through the vertex H of the style, stands square to the plane of the equator, and hence, by Definition 3 of Book 11 of Euclid, is perpendicular to HI: therefore HD, which is drawn perpendicular to HI, will be the axis of the world, meeting the meridian line and the plane of the dial at D. IDH, then, is the angle of the elevation of the pole above the horizon — the very angle that the axis of the world makes with the meridian line in the plane of the horizontal dial.

But if a point D is given on the meridian line, the center of the dial, where all the lines of the hours reckoned from noon and from midnight meet, we shall more easily find the same elevation of the pole by drawing a straight line DH from D to

H. For DH will again be the axis of the world (since it is drawn through the center of the world H and through D, the center of the dial), and HDI will be the angle of the elevation of the pole.

Now suppose the elevation of the pole for which the dial was built is known, but the style is unknown, as also is its position, which we shall investigate as follows. About the line DI, drawn between the center of the dial and the equinoctial line,

[Margin: By what method the style and its position may be described]

[Margin: In a horizontal dial, how to inquire, from the given elevation of the pole for which the dial was built, [into the style and its position].]

we shall describe the semicircle DHI; and from D, the center of the dial, we shall draw out the axis of the world DH, making with the meridian line the angle HDI of the pole's elevation, and let it cut the circle at H. For the perpendicular HF dropped from H to the meridian line will be the length of the style, and its seat will be at the point F.

For when the straight line HI is drawn, the angle DHI will be right, being in a semicircle. [Margin: a. *Elements* III.31.] The straight line HI will therefore be the common section of the meridian and the equator, provided the triangle DHI is set in the plane of the meridian — that is, perpendicular to the plane of the dial. And since the axis of the world meets the equator at the center of the world, H will be the center of the world. Therefore HF, the perpendicular falling from the center of the world onto the meridian line, will be the style, and its location will be F.

We shall obtain the same result if from I, a point on the equinoctial line, we draw the straight line IH, making with the meridian line the angle HID equal to the complement of the pole's elevation, and let it cut the same circle at H. For again, the perpendicular HF dropped from H to the meridian line will be the length of the style, and its location the point F. For when the straight line HD is drawn, the angle IHD in the semicircle will be right; [Margin: b. *Elements* III.31.] and consequently, in the triangle DHI, the remaining angle HDI will be equal to the pole's elevation. Therefore, as before, HF will be the style, to be erected at F.

But if D, the center of the dial, is not given, we shall carry out the proposed task as follows. If the dial is an astronomical one containing the hours reckoned from noon and from midnight, we shall extend the line KD of the 6th hour — or BD of the 5th or 7th, or finally of any other hour whatever — so that it cuts the meridian line at D. For D will be the center of the dial, since all the hour-lines

reckoned from noon and midnight cut the meridian line at the center of the dial, as was demonstrated in the corollary to Proposition 21 of Book 1.

But if it is a Babylonian or Italian dial, embracing the hours reckoned from sunrise or sunset, we shall extend two hours reckoned from sunrise or sunset that cut the 6th hour from noon or midnight at one and the same point — as is clear from the table of the 6th hour-line from noon or midnight given in the scholium to Proposition 20 of Book 1. Such are the line Bk of the 23rd hour from sunset and the line CK of the 13th hour from sunset, which cut each other at K. If, then, through K we draw KD parallel to the equinoctial line, cutting the meridian line at D, then KD will be the line of the 6th hour from noon or midnight — since a line of this kind passes through the point K, as is evident from the said table, and is parallel to the equinoctial line in a horizontal dial, as was shown in the scholium to Proposition 22 of Book 1. Wherefore D will be the center of the dial; and so, if we describe a semicircle about DI, we shall find the style and its seat, just as before.

The same line of the 6th hour from noon or midnight passes through the common point of the 22nd and 14th hours from sunrise or sunset; likewise of the 21st and 15th, or the 20th and 16th, or the 1st and 11th, and so on, as is clear from the same table of the 6th hour-line from noon or midnight. Hence, to be certain that the line KD drawn parallel to the equinoctial line truly indicates the 6th hour from noon or midnight, we shall have to find two, three, four, or even more points from the aforesaid table, through which the line of the 6th hour from noon or midnight is to be drawn. For if a line drawn through one of these parallel to the equinoctial passes through the remaining points, then beyond doubt the line of the 6th hour from noon or midnight will have been drawn most accurately, and consequently the center of the dial will also have been correctly found.

If perchance the line of the 6th hour from noon or midnight cannot conveniently be drawn on the dial, we shall look — in any other table of some hour-line from noon or midnight given in the same scholium to Proposition 20 of Book 1 — for other points through which that hour-line from noon or midnight ought to be drawn. For once that line is drawn, the meridian line will again be cut at the center of the dial. For example, if we wish to draw the line of the 5th hour from noon or midnight, we shall extend the 22nd and 12th hours from sunrise or sunset, as well as the 16th and 18th, or the 3rd and 7th, and so on. For through the points where such hours mutually divide one another, the 5th hour from noon or midnight must be drawn, as is clear from the table of the 5th hour-line from noon or midnight given in the scholium to Proposition 20 of Book 1.

[Margin: By what method, from the position of the style, its length is to be investigated, together with the center of a horizontal dial and the elevation of the pole for which the dial was built.]

In no other way — if only the position F of the style is given, without its length, the pole's elevation, and the center of the dial — shall we track down both the center of the dial, and the elevation of the pole, and the length of the style. For once the line of the 6th hour — or of any other hour from noon or midnight — has been found, as we have just taught, then where it cuts the meridian line, there will be the center D of the dial. This we shall find more easily if the dial is an astronomical one; for any hour-line of it, when extended, will cut the meridian line at D, the center of the dial. Then, having described a semicircle about DI, if from F, the position of the style, a perpendicular FH is drawn to the meridian line, cutting the circumference at H, then FH will be the magnitude of the style; and the straight line DH, when drawn, will give the angle HDI of the pole's elevation. For when the straight line HI is drawn, the angle DHI in the semicircle will be right. [Margin: c. *Elements* III.31.]

Since, then, the style at the center of the world meets the axis and the common section of the equator and the meridian, where these intersect one another at right angles — as is clear from what has been demonstrated — H will be the center of the world; FH the style; DH the axis of the world; and HI the common section of the equator and the meridian. For if FH is said to be not the style, but some line longer or shorter than FH, then the axis will meet the common section of the equator and the meridian either below H on the style or above it; and so the angle will become either obtuse or acute — greater or less, that is, than the right angle DHI — which is absurd.

Diagram. The first of four lettered figures grouped at the head of the page: the horizontal-dial construction with the semicircle DHI, the style, the meridian line, and the axis of the world.

- K: top-left, terminus of a dashed line running down to the right
- D: top center, apex of the vertical line (center of the dial)
- G: just below and left of D
- H: center, on the circle
- F: center, below G (seat of the style)
- I: below F, on the vertical/meridian line

- D: large label within the semicircle

Next, let A be a vertical dial, the same as the horizontal one, in which again the equinoctial line is BC and the meridian DE,

[Margin: How, in a vertical dial, it may be known — from the given style and its position — for what elevation of the pole it was built.]

and the style FG, whose seat is the point F, at which the meridian line intersects the horizontal line (if such has been drawn). Let there be erected from F, perpendicular to the meridian line, the line FH equal to the style FG, and let the straight line IH be drawn. I say that DIH is the angle of the pole's elevation above the horizon.

For let the triangle FHI be understood to be revolved about the meridian line until it stands perpendicular to the plane of the dial and is set in the plane of the meridian. And since the equator passes through I and through H, the center of the world, HI will be the common section of the equator and the meridian. Now the equator makes with the vertical the angle of the pole's elevation, because the arc of the meridian intercepted between the vertical and the equator is equal to the arc of the pole's elevation, as we showed on the sphere when treating of the horizon. Therefore DIH will be the angle of the pole's elevation above the horizon, for which the vertical dial was built.

But if from D, the center of the dial (which we shall find, if it is not marked, as we have just taught in the case of the horizontal dial), we draw the straight line DH, then HDI will be the angle of the complement of the pole's elevation above the horizon; and consequently, in the right triangle DFH, the remaining angle DHF will be the angle of the pole's elevation. For DH will be the axis of the world, since it is extended through D, the center of the dial, and H, the center of the world; and therefore FDH will be the angle of the complement of the pole's elevation — the angle, namely, that the axis makes with the vertical.

[Margin: By what method, in a vertical dial, the style and its position are to be found from the given elevation of the pole for which the dial was built.]

Now let the elevation of the pole, for which the vertical dial was built, be known, and suppose it is required to find both the magnitude and the position of the style. About the straight line DI — set between the center D of the dial (which, as before, we shall find if it is not given) and the equinoctial line — let the semicircle DHI be described; and from I let the straight line IH go forth, making the angle HID of the pole's elevation above the horizon, and cutting the circumference at H. I say that the perpendicular HF dropped to the meridian line is the magnitude of the style, and its location is at F. For when the straight line HD is drawn, the angle DHI in the semicircle will be right. [Margin: a. *Elements* III.31.]

Wherefore, since IH is the common section of the equator and the meridian — because it makes the angle of the pole's elevation with the meridian line — HD, which meets it, drawn from the center of the dial at right angles, will be the axis

of the world. Since, then, the axis of the world meets the equator at the center of the world, H will be the center of the world; and therefore HF, the perpendicular falling from the center of the world onto the meridian line, will be the style, and its seat the point F.

We shall obtain the same result if from D, the center of the dial, we draw the straight line DH, making with the meridian line the angle HDI of the complement of the pole's elevation, and let it cut the same circle at H. For again, the perpendicular dropped from H to the meridian line will be the length of the style, and its location the point F. For when the straight line HI is drawn, the angle DHI in the semicircle will be right; [Margin: b. *Elements* III.31.] and consequently, in the right triangle DHI, the remaining angle DIH will be equal to the pole's elevation. Therefore, as we showed before, H will be the center of the world, and HF the style, to be placed at F.

[Margin: By what reasoning, from the position of the style in a vertical dial, its length, the elevation of the pole, and the center of the dial are to be investigated.]

By a like method, if only the position F of the style is given, we shall find its length, the pole's elevation, and the center of the dial — just as a little earlier in the horizontal dial. For, drawing (as there) the line of the 6th hour from noon or midnight, or of any other hour from noon or midnight, we shall find the center D of the dial — namely, the point at which any hour whatever from noon or midnight cuts the meridian line. Then, having described a semicircle about DI, we shall erect from F, perpendicular to the meridian line, the line FH, which cuts the circle at H. For FH will be the length of the style; and the straight line IH, when drawn, will give the angle of the pole's elevation above the horizon. For when the straight line HD is drawn, the angle DHI in the semicircle will be right. [Margin: c. *Elements* III.31.]

Wherefore, as we said before in the horizontal dial, H will be the center of the world; DH the axis of the world; and HI the common section of the equator and the meridian — because these three lines meet at the center of the world, and the latter two make a right angle. For if FH is said to be not the style, but some line greater or smaller than FH, then the axis falling from D, the center of the dial, and the common section of the equator and the meridian — drawn from I, the common section of the meridian line and the equinoctial line — will meet on the straight line FH, either below H or above it, at an obtuse or acute angle, that is, one greater or less than the angle DHI; seeing that it is at the vertex of the style that the axis and the common section of the equator and the meridian meet, which is absurd.

[Margin: For what elevations of the pole are made those horizontal and vertical dials, commonly circulated fitted with a magnetic needle, and how this may be known.]

From these things we shall also learn, with little trouble, for what elevations of the pole those dials were made which are commonly circulated, made in Germany or France, and which consist of two flat square tablets joined at a right angle. The lower of these — on which is set an arc fitted with a magnetic needle — holds a horizontal dial; while the other, which is raised above it at right angles, holds a vertical one.

For since dials of this kind are usually astronomical, and have a thread stretched through the centers of the dials to serve as the axis of the world, which indicates the hours: if a right triangle is constructed, one of whose sides about the right angle is equal to the portion of the meridian line in the horizontal dial lying between the thread (or the center of the dial) and the other tablet, and the other side equal to the segment of the meridian line in the vertical dial lying between the thread (or the center of the dial) and the former tablet — then the remaining side, opposite the right angle, will make with the meridian line of the horizontal dial the angle of the pole's elevation for which the dial was built, and with the meridian line of the vertical dial the angle of the complement of the pole's elevation, as is evident.

[Margin: How the proposed problem is to be solved in a meridian dial.]

But if dials of this kind, instead of a thread, have a right triangle in the horizontal dial that can be raised and lowered (as happens in many), such that, when it is raised, the uppermost line opposite the right angle indicates the hours as an axis, we shall construct for it a triangle exactly equal. For the angle corresponding to the lower angle in the horizontal dial will contain the pole's elevation, while the other will contain the complement of the pole's elevation.

Again, let there be given a meridian dial B — whether east-facing or west-facing — in which the equinoctial line is AC, the horizontal DE, and the style AG, whose position is A. The acute angle CAE, which the equinoctial line makes with the horizontal, is equal to the complement of the pole's elevation. Likewise the acute angle EAF, which the line of the 6th hour from noon or midnight (which is drawn through A, the position of the style, perpendicular to the equinoctial line) makes with the equinoctial line, is equal to the pole's elevation.

But the length of the style is always equal to the space on the equinoctial line between A and the point C — through which the 9th hour from midnight and the

3rd hour from sunrise (likewise the 15th hour from sunset) are drawn in the east-facing dial, or the 3rd hour from noon and the 9th hour from sunrise (likewise the 21st hour from sunset) in the west-facing dial. Its seat is the point A, where the equinoctial line, the horizontal, the line of the 6th hour from noon or midnight, and the 12th hour from sunrise or sunset all meet. All of which is clear from what was demonstrated in Book 2.

[Margin: The same problem — how it is to be solved in a polar dial.]

Fourthly, let C be a polar dial, in which the equinoctial line is AB, the meridian BD, the horizontal DE, the style BF, and its

location at B, where the meridian line and the equinoctial intersect. From the point A — where the 3rd hour from noon (or the 9th from midnight, or the 9th from sunrise, or the 21st from sunset, or finally the 3rd from sunrise, or the 15th from sunset) divides the equinoctial line — to the point D, where the meridian line and the horizontal mutually divide each other, let the straight line AD be drawn. For the angle ADB will be equal to the elevation of the pole above the horizon of the given dial, or to its inclination to the horizon.

[Margin: By what reasoning a polar astronomical dial is universal.]

But the length of the style is always equal to the space on the equinoctial line between B and the point A, through which the said hours are drawn, and its location is at B — as is clear from what we demonstrated in Book 2. But if the horizontal line has not been drawn, and the dial contains only the hours from noon and midnight, the dial will show the said hours in every region, provided that — as we taught in Proposition 38 of Book 2 — it is set in its proper position.

[Margin: The explanation of the problem in an equinoctial dial.]

Fifthly, let there be given an equinoctial dial D, in which the meridian line is AB, the horizontal AC, and the style BE, whose location is at B, the center, where all the hours from noon and midnight intersect one another. From B let a perpendicular BF be erected to the meridian line, equal to the style (which indeed, in an astronomical dial, will be the same as the line of the 6th hour from noon or midnight); and let the straight line FA be joined. For AFB will be the angle of the pole's elevation, and BAF the angle of the dial's inclination to the horizon — namely, of the equator's altitude above the horizon.

[Margin: An equinoctial astronomical dial — by what method it is universal.]

The length of the style, moreover — whose location is at the center B, where the hour-lines from noon and midnight meet — will be found from the known elevation of the pole, in this way. From the point A, where the meridian line and the horizontal intersect, let the straight line AF go forth, making the angle BAF equal to the complement of the pole's elevation; and from B, the center, let a perpendicular BF drawn to the meridian line cut AF at F. For BF will be the length of the style, as is evident from what was demonstrated in the preceding book. But if the dial contains only the hours from noon and midnight and lacks the horizontal line, it will indicate the hours everywhere among all peoples, provided that — as we set forth in Proposition 49 of Book 2 — it is placed in its proper position; and the style may be taken of any length whatever, if the circles of the signs [of the zodiac] have not been drawn on the dial.

[Margin: The problem is explained in a dial declining from the vertical.]

Sixthly, let there be set forth a dial A declining from the vertical, as in the following figures. (A dial declines from the vertical when the horizontal line is drawn through the position of the style, as in vertical dials, but is not equidistant from the equinoctial line — as does happen in vertical dials — but cuts it, yet not at the position of the style, as occurs in meridian dials. In it the meridian line is BC, the equinoctial DE, the horizontal DF, the style FG, whose location is at F; the style-line is EF, which — if perchance it has not been drawn — will be obtained if through F, the position of the style, a perpendicular FE is erected to the equinoctial line.) Thus, then, we shall inquire into the elevation of the pole above the horizon, for which the dial was built, and into its declination from the vertical, and into the elevation of the pole above the declining plane itself.

Diagram. The first (leftmost) of three lettered figures for the dial declining from the vertical: a construction of intersecting meridian, equinoctial, and horizontal lines with a semicircle about F and the angle KCM of declination. Many small point-labels; several are faint. (several interior labels uncertain).

- I: far left

- G: center, on the semicircle
- H: lower-right, terminus of a short line
- B: at the foot
- C: large label at the upper right

Now from F, the position of the style, we shall erect, perpendicular to the style-line EF, the line FH equal to the style FG; and from B, the center of the dial — namely, where the style-line, when extended, meets the meridian line — through H we shall draw the straight line BH, which cuts the equinoctial line at I. Then

through E, where the style-line cuts the equinoctial line, having drawn the straight line EC parallel to the horizontal line, we shall erect perpendicular to it the line EK equal to the straight line EI, and we shall join the straight line KC. Finally, taking the straight line CL equal to CK, we shall draw the straight line LB.

For the angle BLC will be the elevation of the pole above the horizon; the angle KCM the declination from the vertical; and the angle EBI the elevation of the pole above the declining plane. The dial itself will decline from the south if the center B lies above the horizontal line, but from the north if below; and it will incline toward the east from the south if the equinoctial line falls below the horizontal line on the right-hand side, but toward the west if on the left-hand side. But it will deflect from the north toward the west if the equinoctial line falls below the horizontal line on the left-hand side, and toward the east if on the right-hand side. All of which is plainly gathered from what we demonstrated in Proposition 1 of the preceding book, if one attentively considers the construction of the dial declining from the vertical set forth in that place.

But now let the elevation of the pole above the horizon, for which the dial was built, be given, and suppose it is required to find the length of the style (whose location, in a dial of this kind, is always at the point where the style-line intersects the horizontal), the declination from the vertical, and the elevation of the pole above the declining plane. From B, the center of the dial, where the horizontal line and the style-line meet, let the straight line BL go forth, making with the meridian line the angle CBL of the complement of the pole's elevation above the horizon; and, drawing from the point E — which is common to the style-line and the equinoctial — the straight line EC parallel to the horizontal line, let it cut BL at L and the meridian line at C. Then from E, perpendicular to EC, let there be erected the line EK; and from C, an arc of a circle at the interval [radius] of the straight line CL

Book IV. Continuation of the ongoing problem on the construction of declining and inclined sundials (dial-cases seven, eight, and nine).

let [an arc] be described cutting EK at K, and let the straight line CK be drawn. Finally, on the equinoctial line let the straight line EK be cut off equal to EI; and, the straight line IB having been joined, let there be erected from F, the location of the style, the perpendicular FH to the style-line, cutting IB at H. FH will therefore be the length of the style, to be set up at F; and KCM will be the angle of declination from the vertical; and EBI the angle of the pole's elevation above the declining plane — as is established by what we demonstrated in the construction of this dial in Prop. [?] of the preceding book. Whether the dial declines from the

south, or from the north, toward the east or toward the west, we shall determine as was said before.

[Margin: In a dial that declines from the horizon, the same problem is solved.]

SEVENTH: let the given dial be B, declining from the horizon (a dial will decline from the horizon when the horizontal line is parallel to the meridian line), in which the meridian line is AC; the equinoctial DE; the horizontal DN; the style FG, its location at F; the style-line EF, drawn from F, the location of the style, perpendicular to the equinoctial line, and, when produced, cutting the meridian line at A, the center of the dial. From F, the location of the style, let the perpendicular FH be drawn to the style-line, equal to the style FG; and from A, the center of the dial, let a straight line drawn through H cut the equinoctial line at I. Again, through E — the point where the style-line and the equinoctial cut one another — let the perpendicular EC be erected to the meridian line; and to EC let another perpendicular EK be raised from E, equal to EI itself, and let the straight line KC be joined. Finally, taking CL equal to CK, let the straight line LA be drawn. Then ALC will be the angle of the pole's elevation above the horizon; KCM the angle of inclination to the horizon, that is, of declination from the horizon; and EAI the angle of the pole's elevation above the plane of the dial.

Whether the dial faces west or east we shall easily understand. (I am speaking here only of the upper dials — those, that is, which pertain to the zenith, as I shall also do in the two following kinds — because the lower ones, which of course face the nadir, are less in use, and the teaching handed down for the upper ones can readily be adapted to them.) For if, the dial being set with its center A turned toward the south, the horizontal line lies more to the east than the meridian, it will face west; but toward the east if the horizontal line lies more to the west than the meridian. All of which is clear from what was demonstrated in the construction of a dial of this kind in Prop. 13 of the preceding book.

NOTE: now let there be given the elevation of the pole above the horizon for which the dial was built, and suppose we must trace out the rest. From A, the center of the dial — where the meridian line is cut by the produced style-line — let the straight line AL be sent out, making the angle CAL equal to the complement of the pole's elevation, and let AL cut, at L, the perpendicular EC which is drawn from E to the meridian line. EK having likewise been drawn perpendicular to EC, let there be described from C, at the radius of the straight line CL, an arc of a circle cutting EK at K, and let the straight line CK be drawn. Then on the equinoctial line let EI be taken equal to EK, and let the straight line IA be joined. Finally, either — a perpendicular DF having been drawn from D, the

point where the horizontal line and the equinoctial cut one another, to the horizontal line, cutting the style-line at F — let there be drawn from F the perpendicular FH to the style-line, cutting the straight line AI at H; or — a semicircle AHE having been described about AE, cutting the straight line AI at H — let there be drawn from H the perpendicular HF to the style-line, cutting the style-line at F. For FH will be the length of the style, and its location at F; while KCM will be the angle of declination from the horizon, and EAI the angle of the pole's elevation above the plane of the dial. This is easily gathered from what was demonstrated in Prop. 13 of the preceding book.

[Margin: The proposed problem is treated in a dial inclined to the horizon.]

EIGHTH: let the proposed dial be C, inclined to the horizon (a dial will be inclined to the horizon when the horizontal line is parallel to the equinoctial line, yet does not pass through the location of the style, as usually happens in vertical dials), in which the meridian line is AB; the equinoctial DE; the horizontal AF; the style GH, its location at G. First of all it will have to be considered whether the dial faces the south or the north — that is, whether it is elevated above the horizon on the northern side or on the side of the south. This we shall obtain without great labor from the order of the hours. For if, the dial being turned toward us so that the horizontal line lies above the style, the afternoon hours stand to the left of the meridian line and the forenoon hours to the right (in the astronomical dial the afternoon hours are these — 1, 2, 3, 4, etc.; in the Italian, these — 24, 23, 22, etc.; but in the Babylonian the forenoon hours are these — 1, 2, 3, 4, etc.), then the dial will be inclined toward the parts of the south and will face north. If, on the contrary, the afternoon hours are placed to the right of the meridian line and the forenoon hours to the left, the dial will be inclined to the horizon on the northern side and will face south.

Next it will be necessary to observe whether the plane, elevated on the northern side, has a smaller inclination to the horizon than the pole's elevation above the horizon, or a larger one; likewise whether the plane, elevated on the southern side, has a smaller inclination to the horizon than the complement of the pole's elevation above the horizon — that is, than the elevation of the equator above the horizon — or a larger one. This indeed we shall understand most clearly from those four analemmas set out in Prop. 25 of the preceding book. For dials elevated on the northern side, whose centers fall below the equinoctial line, have an inclination to the horizon smaller than the pole's elevation above the horizon; but those whose centers are found above the equinoctial line, a larger one. And if some dial has no center — which happens precisely when the hour-lines for noon

and midnight are parallel, or the style is placed at the common intersection of the meridian line and the equinoctial — its inclination will be equal to the pole's elevation, and the dial will be the same as a polar one. On the contrary, dials elevated on the southern side, whose centers are contained below the equinoctial line, obtain an inclination greater than the elevation of the equator; but a smaller one, those whose centers stand above the equinoctial line. And if some dial has the seat of its style at the very center of the dial, its inclination to the horizon will be equal to the elevation of the equator, and it will not differ from an equinoctial dial.

THESE things being thus laid down, we shall carry out what is proposed in this way. From G, the location of the style, let the perpendicular GI be erected to the meridian line, equal to the style GH; and from I let straight lines be drawn to the center of the dial B (which will be found, as we said a little before in the horizontal dial) and to the point A, where the meridian line cuts the horizontal. For GBI will be the angle of the pole's elevation above the inclined plane, and GAI the angle of inclination of that same plane to the horizon, as is established by what was demonstrated in Prop. 25 and 26 of the preceding book.

FROM these two [results], and from what we have just written, we shall easily elicit the elevation of the pole for which the proposed dial was built. For if the dial is raised above the horizon on the northern side, and has an inclination smaller than the pole's elevation above the horizon, the found elevation of the pole above the plane must be added to the found inclination of that same plane. For the number produced will give the elevation of the pole above the horizon. But if it has an inclination greater than the pole's elevation above the horizon, the elevation of the pole above the plane must be subtracted from its inclination, so that the elevation of the pole above the horizon remains. But if the dial is elevated on the

southern side, and has an inclination smaller than the elevation of the equator above the horizon — that is, than the complement of the pole's elevation above the horizon — the complement of the found elevation of the pole above the plane must be added to the found inclination. For from this addition the complement of the pole's elevation above the horizon will be had, from which at once the elevation of the pole itself becomes known. But if it has an inclination greater than the elevation of the equator above the horizon — that is, than the complement of the pole's elevation above the horizon — the complement of the found elevation of the pole above the plane must be taken away from the found inclination. For after this subtraction the complement of the pole's elevation

above the horizon will remain, from which again the elevation of the pole itself will be drawn out. All of which is clear from the analemmas discussed in Prop. 25 of the preceding book.

BUT let there now be given the elevation of the pole above the horizon for which the dial is constructed, together with the inclination of the plane above the horizon (for from the pole's elevation above the horizon alone nothing certain can be gathered), and suppose it is required from these to investigate both the elevation of the pole above the plane and the length of the style with its location. First, then, from the order of the hours and the position of the dial's center we shall learn, as we taught a little before, whether the plane of the dial is elevated on the northern or the southern side, and whether its inclination is greater or less than the pole's elevation, or the equator's, above the horizon. For if it is elevated on the northern side and has an inclination smaller than the pole's elevation above the horizon, the inclination must be subtracted from the pole's elevation; but if it has a greater inclination, the pole's elevation must be taken away from the inclination. In either case the elevation of the pole above the plane will remain. But if the dial is elevated on the southern side, and has an inclination smaller than the elevation of the equator, the inclination must be taken away from the elevation of the equator; but if it has a greater inclination, the elevation of the equator must be removed from the inclination. For in this way there will always remain the complement of the pole's elevation above the plane, as is established by the analemmas discussed — from which the elevation of the pole itself will also be known.

From this, quicker than can be said, we shall inquire into the magnitude and location of the style. For, a semicircle BID having been described about the portion BD of the meridian line lying between the center of the dial (which we shall find, as we handed down before in the horizontal dial) and the equinoctial line, we shall draw from B, the center of the dial, the straight line BI, making with BD the angle DBI equal to the pole's elevation above the plane, and let it cut the circumference of the circle at I. For the perpendicular IG dropped from I to BD will give the length of the style, and its location will be at G — as we showed a little before in the horizontal dial.

QVOD [But] if only the location of the style at G be given, we shall find everything else in this way. A semicircle BID having been described as before, we shall erect from G, the location of the style, the perpendicular GI to the meridian line, which cuts the circle at I, and we shall draw the straight lines IB, IA. For GI will be the length of the style; IBG the angle of the pole's elevation above the plane; and IAG

the angle of inclination, as is clear from what has been said. And from this, as before, we shall gather the elevation of the pole above the horizon.

[Margin: Solution of the proposed problem in a dial that both declines and inclines.]

NINTH: let there finally be proposed a dial that both declines from the vertical and is inclined to the horizon (we shall recognize a dial of this kind if the horizontal line is neither parallel to the equinoctial line, as in dials inclined to the horizon, nor to the meridian line, as in dials declining from the horizon, nor cuts the meridian line at right angles, nor has the style placed on the horizontal line, as in dials declining from the vertical), in which the meridian line is E- ζ [?]; the equinoctial GH; the horizontal HM; the style KL, its location at K. Before all else it must here too be considered, as in the preceding dial, whether the proposed dial faces the south or the north — which indeed we shall recognize in the same way. Next, from K, the location of the style, let the perpendicular KM be raised to the horizontal line, and to this another perpendicular KN, equal to the style KL, and let the straight line NM be joined. For KNM will be the angle of inclination of the proposed plane to the horizon. Again, from the location of the style let the perpendicular KI be erected to the index-line [lineam indicis], equal likewise to the style; and through I and the center of the dial q (the style-line will be found if from K a perpendicular KG is drawn to the equinoctial line; and the center of the dial will be the point where the meridian line cuts the style-line) let the straight line I- q -e be drawn, which will be the axis of the world. But if the dial has no center — which happens only when the style-line and the meridian are parallel — a line equidistant from the meridian line and the style-line must be drawn through I to serve as the axis of the world. After this, any point χ being taken on the style-line, let there be

Diagram. A large composite construction occupying the lower half of the page, uncaptioned, for the ninth case — a dial declining from the vertical and at the same time inclined to the horizon. A nearly-horizontal reference line runs across the figure through the junction H (with the points $\text{C}\epsilon$ and A to its left and B to its right on the upper dashed line); above, straight lines converge to an apex C at the top. Through the region below H the several construction lines (meridian, equinoctial, style-line, and the axis of the world) cross in a dense cluster near the center, where a semicircle is drawn. Because the peripheral point-labels are small and several sit amid crossing lines, more than two are uncertain; a focused re-examination is warranted

Readable labels and approximate positions:

- C (top apex): terminus of converging lines
- $\mathbb{C}$ (upper left, on the top dashed line)
- A (upper center, on the top dashed line)
- H (center, below A): junction on the near-horizontal line
- B (upper right, on the top dashed line)
- β [beta] (center-left, on the horizontal line, left of E)
- E (center, on the horizontal line): common point of meridian and style-line region
- M (just below E)
- I (left of center)
- χ [chi] (right of M, below E): a point on the style-line
- Φ [Phi] (right, mid-height)
- N (left, marked N') [?]
- K (center-left): location of the style
- ς [?] (near center, below χ)
- F (below K)
- L (below center)
- ϱ [rho] (lower right): center of the dial [?]
- λ [lambda] (far right, lower) [?]
- G (lower left)
- θ [theta] (center-low)
- Ξ [Xi] (bottom center)
- D (bottom, right of Ξ)

drawn through it the perpendicular ED to the horizontal line, cutting the meridian line at E, the point at which let the angle of inclination of the plane, $\text{DE}\gamma$, be set up with ED; and to $\text{E}\gamma$, from D — a point taken at will on the straight line ED — let the perpendicular $\text{D}\gamma$ be raised. $\text{E}\delta$ having been cut off equal to $\text{E}\gamma$, let two perpendiculars $\text{D}\epsilon$, $\delta\theta$ be drawn to DE through the points D and δ , of which $\text{D}\epsilon$ cuts the meridian at ϵ . Through ϵ likewise let a line parallel to DE cut $\delta\theta$ at θ , and from E through θ let the straight line $\text{E}\theta$ be sent out. For θED will be the angle of declination of the plane from the vertical circle. Furthermore, from α — where the line of the 6th hour from noon or midnight cuts the straight line AB, which is drawn through E parallel to the horizontal line (the 6th hour is to be drawn through ϱ , the center of the dial, and through the point H, where the horizontal line and the equinoctial cut one another; or else a line parallel to the meridian must be drawn through the point H, when the dial has no center) — let

the perpendicular αF be raised to the declination-line $E\theta$. Finally, at AB, at E, let the angle $BE\phi$ be set up — the angle of inclination, downward indeed in planes facing north, but upward in those which look toward the south — and, a perpendicular $\chi\phi$ having been drawn from χ to ED, let the straight line $E\phi$ cut it at the point ϕ . Then, the straight line DE having been produced toward E, let EC be taken equal to $E\phi$; and on AB let $E\beta$, equal to EF, [be taken], and let the straight line βC be joined; and $F\beta C$ will be the angle of the pole's elevation above the horizon.

THE reasoning of this is clear enough from the very construction of dials declining from the vertical and inclined to the horizon. For just as there, from the location of the style, a straight line was drawn parallel to the horizon and taken equal to the style, BC, in Prop. 38 of the preceding book, and through the angle at C set equal to the complement of the inclination the point D was found through which the horizontal line was to be drawn — so here, conversely, from the point M, a straight line MN drawn from the horizontal line to the end of the straight line KN (which is equal to the style) will give the angle KNM equal to the complement of the inclination, and therefore the remaining angle KMN will be the angle of inclination. Again, just as there, from the declination-line $E\theta$, the angle of inclination $DE\gamma$, and the straight lines $\delta\theta$, DE, the meridian line $E\phi$ was found, so here in turn, from the meridian line $E\phi$, the angle of inclination $DE\gamma$, and the straight lines DE, $\delta\theta$, the declination-line $E\theta$ is found. And that $I\phi K$ is the angle of the pole's elevation above the plane of the dial is evident, since the axis of the world passes through the center of the dial and through the top of the style — that is, through the center of the world.

Besides, just as there, a triangle of the pole's elevation above the horizon having been set up, we took on the declination-line the straight line EF equal to $E\beta$, and, a perpendicular $F\alpha$ [?] having been drawn from F to the declination-line, we found on the straight line AB the point α through which the line of the 6th hour from noon or midnight was to be drawn — so here, on the contrary, from the point α on the straight line AB, through which the line of the 6th hour is drawn, the perpendicular αF raised to the declination-line cuts off from the declination-line the straight line EF equal to $E\beta$, of the said triangle $E\beta C$, by whose aid the dial is constructed. Finally, just as there, the straight line $E\phi$ having been drawn — making with AB the angle of inclination of the plane to the horizon, whether downward or upward according as the dial faces north or south — $E\phi$ was cut off equal to EC, of the same triangle $E\beta C$, and, a perpendicular $\phi\chi$ having been drawn from ϕ to the straight line CD, it showed on CD the point through which the style-line is to be carried — so here, on the contrary, from the point χ a perpendicular

$\chi\phi$ having been drawn to CD, and the angle of inclination $BE\phi$ having been set up, it cuts the straight line $E\phi$, [namely] the straight line $\chi\phi$, at ϕ , so that $E\phi$ is equal to EC, of the said triangle $E\beta C$. And so forth.

WHEN it is known whether the dial faces south or north, we shall perceive without difficulty, from the declination-line $E\theta$, whether it also inclines toward the east or the west, according as the declination-line is drawn to the left or to the right of the straight line DE — as we taught should be done at the beginning of Prop. 37 of the preceding book.

BUT let the elevation of the pole above the horizon for which the dial is constructed now be known, together with the inclination of the plane to the horizon (because here too nothing certain can be gathered from the elevation alone), and suppose it is required to investigate the rest. Any point χ being taken on the style-line, and the perpendicular ED being drawn through χ to the horizontal line, we shall find, as a little before, the declination-line $E\theta$ by aid of the meridian line $E\gamma$ and the angle of inclination $DE\gamma$, and so forth. Then, from the now-known declination and the found inclination, let the inclination of the plane to the meridian be investigated by Prop. 27 of Book I; and from this and the pole's elevation above the horizon, by Prop. 28 of the same book and its corollary, [let there be found] the arc of the meridian between the plane and the pole of the world; and finally, by Prop. 29 of the same book, the elevation of the pole above the plane of the dial. For if the angle of this elevation, GqI , be set up — the style-line [terminating] at the center of the dial — and about the portion Gq of the style-line contained between the equinoctial line and the center of the dial a semicircle be described, cutting the axis of the world qI at I, then the perpendicular IK dropped from I to the style-line will be the length of the gnomon, and its location at the point K. As for the axis of the world, it will be found in another way as follows.

FROM the point χ , where the style-line and the straight line DE cut one another, let there be drawn to the straight line DE the perpendicular $\chi\phi$, which the straight line $E\phi$ cuts at ϕ , making with AB the angle of inclination $BE\phi$. Then from the same point χ let the perpendicular χe [?] be raised to the style-line, equal to $\chi\phi$. For the straight line drawn through e and the center of the dial will be the axis of the world, as can plainly be established from what was demonstrated in the construction of these dials. But in planes drawn through the pole of the world, in which the hour-lines for noon and midnight are parallel, the straight line χe will be the length of the style, and its location will be at the point where the style-line

cuts the equinoctial line — as is established from the third figure of Prop. 37 of the preceding book.

IF, however, only the location of the gnomon at the point K be given, we shall inquire into everything else in this way. A semicircle GIQ having been described about the portion Gq of the index-line (which is always drawn from the location of the gnomon perpendicular to the equinoctial line), placed between the equinoctial line and the center of the dial, we shall draw from K, the location of the style, the perpendicular KI to the index-line, which cuts the circle at I. For thus we shall have the length of the style, IK, as we showed in the preceding dials also. And from this we shall trace out everything else, as before, when the length of the style and its location are given.

MOREOVER, this same problem is easy in the right sphere, as is clear from the construction of dials in the said right sphere. A dial will be understood to be constructed for the right sphere when the horizontal line is absent, and the hour-lines are parallel, the middle one of which indicates the 6th hour from noon or midnight. And if the horizontal line is absent [and the hour-lines are] parallel, the proposed dial in the right sphere will be a horizontal one. Therefore, a dial being given, together with its style and the location of the style, we have investigated for what elevation of the pole it was built, and so forth. Which was to be done.

Gnomonics — Liber Quartus (continued)

PROBLEMA 14. PROPOS. 14.

To reduce any dial already laid out to a larger or a smaller form, according to a given size of the style [stylus; the gnomon].

For the sake of the doctrine, let there be set before us the Babylonian dial declining from the horizon, which we described in Prop. 22 of the preceding book, and whose style is A B. It is to be enlarged or reduced in proportion to any given style C D, in such a way that, whatever proportion the style A B has to the style C D, all the lineaments — together with the shadows falling from the style A B onto the corresponding lineaments — shall have the same proportion to the shadows cast by the style C D. In other words: as the style A B stands to the lineaments and shadows of its own dial, so let the style C D stand to the corresponding lineaments and shadows in the dial that is to be constructed.

[Margin: In what way the proposed dial is reduced to a larger or a smaller form, according to a given size of the style.]

FIRST of all, draw off separately, in some plane, two straight lines E F, E G, making at E any angle you please; and parallel to E F draw H I at any distance. On E F take the straight line E K equal to the style A B, and on E G the straight line E L equal to the style C D; join K L, cutting H I at M; and finally, through E draw a line parallel to K L, namely E H, cutting H I at H. In this way a figure will be prepared by which the proposed dial can, without great labour, be reduced to a larger or a smaller figure.

NEXT, in the proposed dial, through A, the location of the style, draw two hidden straight lines A P, A a, cutting one another at right angles at A. In dials that stand square to the horizon, let one of these be the same as the horizontal line drawn through the location of the style, and the other perpendicular to the horizon. But in inclined dials, let one be parallel to the horizontal line, and the other accordingly be the common section of the plane of the dial and of the vertical circle that measures its inclination to the horizon. In the same way, on the wall or on some plane on which the dial is to be enlarged or reduced, choose C, the location of the style C D, and through C likewise draw two hidden straight lines cutting one another at right angles at C. Let one of them correspond to the horizontal line of the proposed dial (or at least to the line parallel to that horizontal line), and the other to the other line. That is: if the proposed dial stands square to the horizon, and a wall or some stable and firm plane is offered on which a larger or smaller dial is to be drawn, let one of the said lines drawn through the location of the style C be equidistant from the horizon and be the horizontal line, while the other is perpendicular to the horizon. But if the dial offered is not square to the horizon, then one of the said lines on the firm and stable wall or plane is indeed to be equidistant from the horizon, while the other is to be the common section of that plane and of the vertical circle which measures the inclination of the plane to the horizon. Of these lines, in horizontal dials, where the horizontal line cannot be drawn, let one be the meridian line and the other equidistant from the equinoctial line. Then, with a circle P O of any magnitude described from A, let a circle Q R equal to it be described from the centre C.

[Margin: a. III.27 · b. I.33 · c. I.30 · d. VI.2 or 4 (references keyed to the superscript letters below).]

WHEN this is done, we shall carry through the enlargement or reduction of the dial as follows. From the centre A, through N — the point of the 6th hour from sunrise, in the tropic of Cancer [☿], say — draw the hidden straight line A N, cutting the circumference of the circle at O; and on the arc P O take an equal arc

Q R in the other circle, and draw the straight line C R. Then, taking on E F and H I the straight lines E S, H T equal to A N, join the line S T, cutting E G at V; and from C R cut off C X equal to E V. I say that, with the Sun standing at the beginning of Cancer [♋] and on the circle of the 6th hour from sunrise, the shadow of the style C D falls at the point X, just as at that same time the shadow of the style A B falls at the point N. For if the greatest circle, from which both dials are equidistant, be conceived to be some horizon — so that both the style A B and C D is its axis, through which all its vertical circles are drawn, as happens in a horizontal dial — then the straight line A N will be the common section of the plane of the dial and of that vertical circle (with respect to the said horizon) which is then drawn through the centre of the Sun; and thus that same A N will be the length of the shadow at the aforesaid 6th hour from sunrise. Now since that vertical circle keeps the same position in all parallel planes, so that [a] it makes with the straight line C Q (which corresponds to A P) an angle equal to the angle N A P, it follows that, since the angle R C Q is equal to the angle O A P — because the arc Q R is likewise equal to the arc P O — the straight line C R is also the common section of the said vertical circle and of the plane of the dial in which the style C D lies. Therefore the shadow of the style C D will at that time fall on the straight line C R. And because the straight lines E S, H T are equal to one another (each having been taken equal to A N) and parallel, [b] E H, S T will also be equal and parallel. Since, then, K L too is by construction parallel to E H, [c] K L and S T will also be parallel to one another. [d] Therefore it will be: as E K (that is, as A B, the style) is to E S (that is, to A N, the shadow), so E L (that is, C D, the style) is to E V (that is, to C X). And so, since all styles in the same plane, or in parallel planes, are proportional to their shadows — because any style whatever has the same proportion to its shadow as the sine of the Sun's altitude above that plane on which the shadow is received has to the sine of the complement of the same altitude, as we shall demonstrate in the following book — C X will be the length of the shadow of the style C D at that time.

In the same way, if from the centre A, through Y — the point of the 6th hour from sunrise in the tropic of Capricorn [♐] — the hidden straight line A Y be drawn, cutting the circle at Z, and on the arc a Z an equal arc b d be taken in the other circle, and the straight line C d be drawn, we shall show that at that time, with the Sun standing at the beginning of Capricorn [♐], the shadow of the style C D falls on the straight line C D. And if straight lines E F, H I be taken equal to A Y, and the line F I be joined, cutting E G at G, and finally C e be cut off equal to E G, we shall prove, as before, that the shadow of the style C D falls at the point e. Therefore the straight line e X, connecting the 6th hour in the tropic of Cancer [♋] with the 6th hour in the tropic of Capricorn [♐], will be the line of the 6th hour from sunrise.

[Margin: In place of the straight lines drawn out from A and C, a ruler may be used, etc.]

IF, however, we are unwilling to draw out so many straight lines from A and C, we shall be able, in place of them, to apply a ruler to the centre A and to the point we wish to transfer; and, this done, we shall mark the point on the circle cut off by the ruler. Then we shall lay the same ruler to the point C, so that it cuts off from the circle an arc equal to the one it previously cut off in the other circle, and along the edge of the ruler we shall mark the length of the shadow, by pressing in a point on the plane of the dial, etc.

BY no other method shall we transfer onto the dial of the style C D all the points of the proposed dial, if we draw straight lines through them from the centre A, and transfer their distances from A onto the straight lines E F, H I, etc. Thus, if we wish to transfer the point h, where the equinoctial line divides the 4th hour from sunrise, we shall draw the straight line A h, which will cut the circle at I; and, taking the arc Q I equal to the arc P i, we shall draw the straight line C I. Then, taking the straight lines E n, H p equal to the straight line A h, and drawing the line n p cutting E G at q, we shall cut off from the straight line E q a portion equal to C m; and the shadow of the style C D will fall

at the 4th hour from sunrise onto the point m, with the Sun standing at the equator [*Æquator*], just as at the same time the shadow of the gnomon A B falls onto the point h. And so with the rest.

Diagram. A large composite construction filling most of the page, illustrating the enlargement of the declining Babylonian dial. It contains two dial-circles, one above the other, together with an auxiliary parallel-line (shadow-transfer) construction to the right.

- **Upper circle** — the proposed (original) dial, centred at A. A vertical line at the left is the horizon, lettered vertically **HORIZON** (printed "HORI=" / "ZON") with S at its head; along it are the hour-marks **12, 13, 14, 15**. Hour-lines radiate from the centre A, numbered **7, 8, 9, 10, 11** toward the lower centre. A line through the centre bears the vertical legend **Linea Meridiana** ("meridian line"). Labelled points: **B** (upper left), **P** (right, on the meridian/diameter), **N** (right of centre), **o** (far right), **i** (right, below o), **Y, Z, a** (lower centre). At the lower rim are Greek labels **β, γ** [and further small letters that do not resolve — see below].
- **Lower circle** — the enlarged (future) dial, centred at C. Again a vertical horizon line at left lettered **HORIZON**, with hour-marks **12, 13, 14** and the

radiating hour-lines 7, 8, 9, 10, 11; a **Linea Meridiana** legend along a line through C. Labelled points: D (upper left), u, X, R, o, i, s; Greek δ, a, b, e near the lower rim.

- **Right-hand auxiliary construction** — a fan of parallel and crossing straight lines, some dashed, carrying the letters E (top right), H, L, K, M, V, S, F, T, I, G, with the lower-case points n, p, q. This is the E F / E G / H I / K L figure of the text, on which the shadow-lengths E S, H T, S T are marked. Additional small Greek/italic labels (κ, ς, ϖ, ρ, λ, μ, m and others) appear scattered at the foot of the figure but are too small/broken to assign individually.
- **Graduated scale (foot of page)** — two ruled measuring-lines beneath the circles (the lines A F and G M of the following scholium). Upper line: points A, B, C, D, E, F with graduation numbers 4, 8, 12, 16, 20 (a leading division near A also reads "4" [?]). Lower line: points G, H, I, K, L, M with graduation numbers 4, 8, 12, 16, 20.

[Several small peripheral labels — the lower-rim Greek clusters of both circles and the scattered italic letters at the foot of the right-hand construction — cannot be resolved individually at this resolution.]

SED — But in lines that are indeterminate (such as the style-line, the meridian, the horizontal, and the equinoctial), it is enough that we find a single point for each of them in the future dial, according to the doctrine already delivered. For if through that point a straight line be drawn making, with some other line already drawn, an angle equal to the one which the same line makes in the proposed dial with the corresponding line, then that line, whose point has been found, will be described. Thus, since the style-line must pass through the location of the style C, if through C a straight line C g be drawn making with C Q (or with C b) an angle equal to the one which the style-line A f makes with the corresponding line A P (or A a), the style-line will be described. Again, once the point g is found, through which the meridian line is to be drawn (corresponding to the point f), and through g a straight line is drawn making, with the style-line, an angle equal to the angle which the meridian line makes with the style-line at f, the meridian line too will be described. Likewise — since in the given example the straight line A P, produced toward A, cuts the horizontal line at right angles — if on C Q, produced toward C, we find the point through which the horizontal line is to be drawn, and through it erect a perpendicular to C Q, we shall have the horizontal line. Finally, once the point is found on the style-line of the future dial (or on the meridian, or on the horizontal) through which the equinoctial line is to be carried, if through it we draw a straight line making, with the style-line (or the meridian, or the

horizontal), an angle equal to the angle which the equinoctial line in the proposed dial makes with the corresponding style-line (or meridian, or horizontal), the equinoctial line too will be drawn in the future dial. And the meridian and equinoctial lines will cut one another, if we have not erred, at the 6th hour from sunrise.

[Margin: What is to be done concerning indeterminate lines.]

— from sunrise, and 18 from sunset, and 6 in unequal [hours]. Likewise the equinoctial line and the horizontal will intersect one another at the 12th hour from sunrise or sunset, and the 6th from noon or midnight; and, moreover, the style-line always divides the equinoctial line at right angles. All this is established from what has been demonstrated in the laying-out of dials, and is useful if carefully attended to, so that lines of this kind may be correctly drawn in the dial.

[Margin: Another way of finding the lengths of the shadows for a given style.]

WE can also, by another method, investigate the lengths of the shadows which, referred to the style C D, keep the same proportions that the shadows in the proposed dial keep to the style A B. On any straight line $\alpha \beta \gamma$, let $\alpha \beta$ be equal to the style A B, and $\alpha \gamma$ equal to the style C D; and through β and γ draw two lines $\beta \theta$, $\gamma \lambda$ parallel to one another, at any inclination. Then, by aid of the compass, transfer the straight line A N — namely the length of the shadow at the 6th hour from sunrise in the tropic of Cancer [♋] — from α onto the parallel $\beta \theta$ (which is drawn through the end of the proposed style), as far as the point δ ; and join the straight line $\alpha \delta$, cutting the other parallel at ϵ . I say that the straight line $\alpha \epsilon$, transferred by the compass from C onto the shadow-line C R as far as X, gives us X, the point of the 6th hour from sunrise in the tropic of Cancer [♋]. For since, by the corollary of Prop. 4 of Book 6 of Euclid, the triangles $\alpha \beta \delta$, $\alpha \gamma \epsilon$ are similar, [a] it will be: as $\alpha \beta$ (equal to the style A B) is to $\alpha \delta$ (equal to the shadow A N), so $\alpha \gamma$ (equal to the style C D) is to $\alpha \epsilon$ (equal to the shadow C X). In the same way, if we take θ equal to the shadow A Y, and join the straight line $\alpha \theta$ (which cuts the parallel $\gamma \lambda$ at λ), and cut off C e equal to the straight line $\alpha \lambda$, we shall have the point e of the 6th hour from sunrise in the tropic of Capricorn [♐]; and so with the rest.

[Margin: a. VI.4.]

But the former way seems the more convenient; for in this latter one, the longer shadows cut the parallels $\beta \theta$, $\gamma \lambda$ too obliquely, as is plain in the straight line $\alpha \varpi \rho$; whereas in the former, the parallels E H, k M, S T, etc. always divide, in the same way, the straight line E G on which the lengths of the shadows are

terminated. Again, in the latter, when the shadows are shorter — as happens in the hours near the style, in the nearer tropic — it is necessary to draw two other parallels $\beta \mu$, $\gamma \xi$, which come so close to the point a that those short shadows can be transferred onto the parallel $\beta \mu$. So you see that the shadow of the 7th hour from sunrise in the tropic of Cancer [ϙ] has been transferred as far as μ , and that the straight line $a \xi$ is the length of the shadow of the same hour in the future dial. In the former way, however, we have no need of this precaution, as is plain.

[Margin: The lengths of the shadows investigated another way. b. VI.4.]

YET this latter way will be more conveniently arranged if the lengths of the shadows of the proposed dial are transferred onto the straight line $\beta \theta$ not from the point a but from the point β . For then there will be no need to draw two other, closer, parallels. But in that case the shadows taken must be transferred onto the future dial not from the point a but from the point γ , on the line $\gamma \lambda$. Thus, if the shadow transferred were the straight line $\beta \delta$, the shadow to be transferred would be $\gamma \epsilon$; because, on account of the similarity of the triangles, [b] the proportion of the style $a \beta$ to its own shadow $\beta \delta$ is the same as that of the style $a \gamma$ to the straight line $\gamma \epsilon$, etc.

ALTHOUGH, in our example, we have reduced the proposed dial to a larger form, we shall nevertheless, by the same methods, reduce it to a smaller one, if from $E G$ (or from $a \beta$) we cut off a straight line equal to the smaller proposed style. And so we have reduced any dial that has been laid out to a larger or a smaller form, according to a given size of the style. Which was to be done.

SCHOLIVM.

[Margin: By what other way a given dial is to be enlarged or reduced.]

PERHAPS we shall dispatch this same problem more easily in this way. On any straight line take as many straight lines $A B$, $B C$, $C D$, $D E$, $E F$ as you please, equal to the style $A B$ of the proposed dial — yet so that the whole line composed of those segments be not less than the longest shadow falling from the style $A B$; and on some other straight line take just as many straight lines $G H$, $H I$, $I K$, $K L$, $L M$, equal to the style of the future dial, whether it be greater or smaller than the style $A B$. Then, having divided the several parts of the former line into as many equal parts as you wish — (here I would urge that each be first bisected, then each little part bisected again, and so on, as far as can be conveniently done; for the more parts there are, the more accurately will the future dial be described; and this division is the easiest of all) — let the several parts of the latter line be cut into

just as many, with numbers written in, as appears in the preceding figure. Now if from A, the location of the style of the proposed dial, straight lines be drawn through all the points of the dial that are to be transferred, and lines similar to them be drawn out from C, the location of the style of the future dial, by aid of the circle from C; and if the intervals of all the points from A, taken up, be transferred onto the straight line A F, and intervals similar to these, taken up on the straight line G M, be transferred onto the lines drawn out from C, corresponding to the lines drawn out from A — then all the points of the proposed dial will have been transferred onto the future dial. Hence, if the corresponding points be connected by straight lines, the dial for the style C D will be described. For example: the interval A N spans, on the straight line A F, 5 parts and a little more than the third part of one. Therefore, if on the straight line G M there be taken likewise 5 parts and a little more than a third part of one, and these be transferred onto the straight line C R (which corresponds to the line A O, on account of the equal arcs P O, Q R), we shall find the point X, corresponding to the point N; because the same proportion which the straight line A B (equal to the style of the proposed dial) has to $5\frac{1}{3}$ parts, the straight line G H (equal to the style of the future dial) has to $5\frac{1}{3}$ parts. In the same way, the interval A Y contains, on the straight line A F, $7\frac{1}{3}$ parts; so if on the straight line G M just as many parts be taken and referred onto the straight line C d (corresponding to the line A Z), the point e will be found, corresponding to the point Y. The straight line X e, then, joined, will correspond to the straight line N Y. Likewise, since the interval between A and the 14th hour from sunrise in the tropic of Cancer [☿] comprehends exactly 5 parts on the line A F, if just as many parts of the straight line G M be transferred from C onto the shadow-line corresponding to the shadow-line drawn out from A, the point of the 14th hour from sunrise in the tropic of Cancer [☿] of the future dial will be obtained, etc.

[Margin: The problem is solved another way.]

HERE too, in place of the lines drawn out from A and C, we shall be able to use some ruler, as we said above.

WITH Daniele Barbaro, moreover, at the end of his *Perspective* (which he composed in the Italian tongue), we shall arrange this same procedure thus. Let there be made two flat rulers, having parts altogether equal to the parts of the straight lines A F, G M, and at their ends the finest little pins fixed, so that the rulers themselves can be freely turned about them at the points A and G, when set there. Let the superfluous parts be cut away, so that what remains are straight lines proceeding from the little pins as centres, after the manner of what they call

the "line of confidence" [linea fiduciæ] on an astrolabe. After this, the circle described from A having been divided into any number of parts — whether equal or unequal — let the circle described from C be cut into the same parts. And so, placing the former ruler (which contains the divisions of the line A F) at the centre A, and turning it freely until its line of confidence passes through the proposed point of the dial, we shall mark on the circumference of the circle the part cut off by the line of confidence, and the part which the proposed point shows on the same line of confidence. For if we place the latter ruler at the centre C and turn it about until its line of confidence cuts off from the circumference the same part of the circle, we shall mark on the plane the point which corresponds to the aforesaid part on the line of confidence. For this will be the point that is sought. For example: the former ruler, set at the centre A and brought to the point of the 14th hour from sunrise, in the tropic of Cancer [♋], cuts the circle at f, and the point of the said hour falls on its fifth part. If, then, the latter ruler be set at the centre C, and be moved

until its line of confidence cuts off from the circle an arc t u equal to the arc r f, we shall mark on the plane the point that terminates its fifth part, for the 14th hour from sunrise in the tropic of Cancer [♋], and so on.

[Margin: When the style of the given dial bears to the style of the future dial a multiple or submultiple proportion — by which the problem is solved more easily.]

But suppose the style A B of the proposed dial has to the style C D a given proportion that is a multiple or submultiple. This is not an uncommon case in practice — for instance, when a dial made for some wall is to be transferred onto that same wall in a larger format (since, once the dial has been drawn, we are free to choose a style that is double, triple, tenfold, or twentyfold the former, and so on, as the size of the dial to be drawn requires). In such a case we shall construct the larger or smaller dial most readily if we take all the intervals of the proposed dial in the same multiple or submultiple proportion that the style bears to the style. For example, if the proposed dial is to be made ten times larger — so that the style has to the style, and each interval to each interval, a tenfold proportion — we shall transfer the interval A N ten times onto the straight line C R (which corresponds to the straight line A O), so that the straight line C X is tenfold the straight line A N, and so on.

From this it follows that, if the dial has been correctly drawn, then in the dial whose style is ten times greater than the style of the proposed dial the several intervals — such as the hour-intervals on the equinoctial and horizontal lines,

and likewise the segments of the hour-lines between the equinoctial line and the tropics of Cancer [♋] and Capricorn [♏], and so on — must each be tenfold of the corresponding intervals. Therefore, so that such a dial may be drawn as accurately as possible, one must first draw the lines of the style, of the equinoctial, and of the horizon. Then the several intervals of the equinoctial line, between the style-line and the hour-lines of the proposed dial, are to be made tenfold in the future dial — or multiplied according to the proportion of the style, or (where the case requires) diminished — on the equinoctial line, taking the start from the style-line. The same must be done for the intervals on the horizontal line, between the equinoctial line and the hour-lines. For if the hour-lines, connecting the corresponding hour-points found on the tropics, pass through the points thus found on the equinoctial or horizontal line, the dial will be drawn most accurately.

And if it should seem helpful, a line may be drawn in the given dial in any manner whatever — parallel either to the equinoctial line or to the horizontal line, or perpendicular to the horizontal line — provided it conveniently cuts the hour-lines. Then, in the future dial, another line corresponding to it may be drawn, according to the proportion of the style. For if all the intervals of the former line are multiplied according to the given proportion on the latter line, the points will be found through which the hour-lines are to be drawn, and so on.

END OF THE FOURTH BOOK.

GNOMONICS, BOOK FIVE.

BY CHRISTOPH CLAVIUS OF BAMBERG, OF THE SOCIETY OF JESUS.

Many people are but little practised in drawing the perpendicular and parallel lines whose use is so frequent in the drawing of dials that we set out in the earlier books. Frightened off by the difficulty of the matter, they despair of ever being able to draw any dial without error, thinking it impossible that, in drawing so many perpendicular lines and hidden parallels as the correct drawing of a dial requires, they should commit no mistake. It has therefore seemed good, in this book, to prescribe a way and a method by which anyone even moderately versed in the table of sines may, by his own effort, compute for himself certain tables. From these he may then draw the hours of any kind whatever, on any proposed plane and to any given magnitude of the style, without any trouble or labor. For I cannot deny that it is very difficult — not to say utterly impossible — for anyone

to fall into no error at all amid so great a multitude of hidden perpendicular and parallel lines, even if he has long and much practised himself in the matter. In the drawing of the hours by tables, however — the tables we are now about to compute — this cannot so easily happen, as will become clear from what follows.

PROBLEMA 1. PROPOS. 1.

To investigate the altitude of the Sun above any great circle of the sphere, for each single hour.

By what method the Sun's altitude above the horizon is to be computed from a given hour, we have taught abundantly in proposition 36 of Book 1. Now we shall inquire into the same above any great circle whatever that differs from the horizon, in this way. First, let the altitude of the pole above the proposed circle be sought, by proposition 29 of Book 1. Then, for this altitude, let the meridian altitude of the Sun and its depression be found — as we shall teach in the scholium of this proposition — and let half of the straight line composed of the sine of the said meridian altitude and the sine of the meridian depression be taken. Finally, let the distance of the Sun from the proper meridian circle of the given great circle be investigated — that is, from the circle drawn through the poles of the world and through the poles of the proposed circle, after the manner of a meridian.

[Margin: By what method the Sun's distance from the proper meridian of any great circle is investigated.]

We shall find it thus. In circles to whose planes the meridian of the horizon is perpendicular — such as the vertical circle properly so called, the circle of the 6th hour from noon or from midnight (to which the polar dial is parallel), the equator, and a circle inclined to the horizon and perpendicular to the meridian — the distance is taken from the meridian, as we taught for the horizon at the beginning of proposition 36 of Book 1; for the meridian of the horizon is also the meridian of those circles, as is evident. But in other circles it must first be ascertained, by proposition 30 of Book 1, how great is the inclination of the proper meridian of each of them to the meridian of the horizon, and in which direction that proper meridian slopes — that is, whether it recedes toward the east or toward the west from the meridian of the horizon. This we shall easily perceive from the position of the pole of the proposed great circle, as we taught in Book 3, propositions 1, 13, and 37 [propof. 1. 13. & 37.]. For once this has been clearly grasped, it will not be difficult to know how great a distance from the proper meridian of the proposed circle the Sun has at any given hour.

For if the proper meridian of the proposed great circle recedes toward the east from the meridian of the horizon in the upper hemisphere, the Sun's distance from noon must be taken, as we wrote at the beginning of proposition 36 of Book 1. To it, if it be after noon, the inclination of the meridians must be added, so that the distance from the proper meridian of the proposed circle may be obtained. But if it be before noon and the distance from noon is less than the inclination of the meridians, the distance from noon must be subtracted from the inclination of the meridians; while if it be greater, the inclination itself must be subtracted from the distance from noon, so that the distance from the proper meridian of the proposed circle may remain. And if it should ever happen that the Sun's distance from noon, before noon, is equal to the inclination of the meridians, the Sun will be situated on the very meridian of the proposed circle. But if the meridian of the proposed circle, in the same upper hemisphere, recedes from the meridian of the horizon toward the west, the procedure must be exactly the opposite. For the Sun's distance from noon, if it be before noon, must be added

to the inclination of the meridians, so that the distance from the meridian of the proposed circle may be obtained; but if the hour given be after noon, and its distance from noon less than the inclination of the meridians, the distance from noon found must be subtracted from the inclination of the meridians; while if it be greater, the inclination itself must be subtracted from the distance from noon, so that the remaining distance of the Sun from the meridian of the proposed circle may be left. But if the proper meridian of the proposed circle recedes eastward, below the horizon, from the meridian of the horizon — as happens on the faces of circles which the Sun would illuminate at midnight if it were not blocked by the earth (such are the lower faces of the position circles, and the northern faces of the vertical circles in regions whose zenith is set on the near side of the tropic of Cancer [☿], and so on) — the Sun's distance from midnight must be taken. To it, if it be before midnight, the inclination of the meridians must be added; but if it be after midnight, and the distance found from midnight is less than the inclination of the meridians, that distance itself must be subtracted from the inclination; while if it be greater, the inclination itself must be subtracted from the distance from midnight, so that the Sun's distance from the proper meridian of the proposed circle below the horizon may be obtained. But if the meridian of the proposed circle recedes westward, in the lower hemisphere, from the meridian of the horizon, the entirely opposite must be done. That this may be made plainer, we shall add examples in the meridian of the horizon and in some other circles — those to which the dials described in Book 3 are parallel, and to which the meridian of the horizon is not perpendicular.

In the meridian circle, then: since the circle of the 6th hour from noon or from midnight stands in place of its meridian, and recedes from it by 90° both toward the east and toward the west, all the distances of the Sun from the sixth hour — reckoned from midnight or from noon — must be computed. Thus at the 9th hour after midnight the Sun is distant from the proper eastern meridian of the meridian circle itself (that is, from the 6th hour from midnight) by 3 hours, i.e. by 45° ; while at the fifth hour after midnight it is distant by 1 hour, or 15° . Likewise at the 2nd hour after noon the Sun will be distant from the proper western meridian of the meridian circle itself (that is, from the 6th hour from noon) by four hours, or 60° . But at $6\frac{1}{2}$ hours from noon it will be distant from the same proper meridian by $\frac{1}{2}$ hour, or $7^\circ 30'$. For on the eastern face of the meridian circle the said distances must be computed from the 6th hour from midnight, but on the western face from the 6th hour from noon.

[Margin: The Sun's distance from the proper meridian of the meridian of the horizon — that is, from the circle of the 6th hour from midnight.]

Next, take a vertical circle which declines from noon toward the east by 30° , to which we drew a parallel dial in proposition 1 of Book 3. Since its meridian recedes from the meridian of the horizon toward the east by about $40^\circ 48'$, as we said there: if to the 2nd hour from noon (that is, to 30° , by which the Sun is distant from the meridian of the horizon in the afternoon) we add $40^\circ 48'$, we shall make $70^\circ 48'$ for the Sun's distance from the meridian of the said vertical circle at that time. But if, at the time of the $10\frac{1}{2}$ th hour after midnight, we subtract the Sun's distance from the meridian of the horizon — that is, $22^\circ 30'$ — from $40^\circ 48'$, there will remain $18^\circ 18'$ for the Sun's distance from the meridian of the same vertical circle at that time. Finally, if at the time of the 7th hour after midnight we take away $40^\circ 48'$ from the distance the Sun has from noon — namely from 105° — there will be left, for the Sun's distance from the meridian of the same vertical circle at that time, $64^\circ 12'$. But on the northern face of the same vertical circle, since the Sun does not illuminate it at noon, but would light it at midnight if the earth did not block its rays, we shall find the Sun's distance from the proper meridian of the said face at the 8th hour after noon in this way. The Sun's distance from midnight then contains 4 hours, that is, 60° , which indeed falls before midnight. And since the proper meridian below the horizon recedes from the meridian of the horizon toward the west by $40^\circ 48'$, and the distance found is greater than this inclination, the inclination must be subtracted from the said distance, so that there remain $19^\circ 12'$ for the Sun's distance from the proper meridian of the said vertical circle on the northern face.

[Margin: The Sun's distance from the proper meridian of the position circle which declines from noon toward the east by 30° .]

Again, take a position circle declining from the horizon by 30° , whose upper face looks toward the west, to which we described a parallel dial in proposition 13 of Book 3. Since its meridian recedes from the meridian of the horizon toward the west by $37^\circ 50'$: if to the 7th hour after midnight (that is, to 105° , by which the Sun is distant from the meridian of the horizon in the forenoon time) we add $37^\circ 50'$, we shall make $142^\circ 50'$ for the Sun's distance from the meridian of the said position circle. But if, at the time of the 17th hour from sunset — the Sun being at the beginning of Cancer [♋], since noon falls at the 16th hour 28 minutes from sunset, at latitude 42° — we take away from $37^\circ 50'$ the Sun's distance from noon, namely 8° , the remaining distance of the Sun from the meridian of the said position circle will be $29^\circ 50'$. And finally, if at the time of the 7th hour from noon we subtract $37^\circ 50'$ from the distance the Sun has from the meridian of the horizon — that is, from 105° — the Sun's distance from the meridian of the same position circle will be left as $67^\circ 10'$.

[Margin: The Sun's distance from the proper meridian of the position circle which recedes from the horizon by 30° , and whose upper face looks toward the west.]

In addition to these, take a great circle which declines from the north toward the east by 60° and is inclined to the horizon by 80° , to which the fifth dial — described in proposition 37 of Book 3 — is parallel. Since its meridian is distant from the meridian of the horizon toward the east by $57^\circ 46'$, as we said there, we shall find the Sun's distances at each hour from the said meridian of the proposed great circle, just as in the preceding cases, and so on.

[Margin: The Sun's distance from the proper meridian of the great circle which declines from the north toward the east by 60° .]

Now, these things having been found: let it be arranged that, as the whole sine is to the versed sine of the Sun's distance from the proper meridian of the proposed circle, so is half the straight line composed of the sine of the meridian altitude and the sine of the meridian depression to a fourth quantity. There will then be found the difference between the sine of the Sun's altitude above the proposed circle at the time of observation and the sine of the meridian altitude. This difference, therefore, being taken away from the sine of the meridian altitude, the sine of the sought altitude of the Sun will remain known.

[Margin: That the Sun's altitude above any proposed great circle may be found for any time whatever.]

But if this difference found should be greater than the sine of the meridian altitude, then the hour whose distance from the meridian we took the versed sine of will not be contained above the proposed face of the circle, but will fall on the other face. Hence if, on the contrary, we then take away the sine of the meridian altitude from the difference found, there will be left the sine of the Sun's altitude above the opposite face of the said great circle, at the given hour. For example: let the Sun's altitude above the southern face of a vertical circle at latitude 42° be sought, for the 5th hour from noon. Since the antarctic pole is elevated above that face by 48° , the complement of this altitude will be 42° ; and if from these there be subtracted the greatest declination of the Sun, $23^\circ 30'$, there will remain the meridian altitude of the beginning of Cancer [♋] above the said face, $18^\circ 30'$ (as will be manifest from the following scholium), whose sine is 31730. And the sine of the meridian depression, $65^\circ 30'$, is 90996. And half of the aggregate of the said sines is 61363. Therefore, if it be arranged that as 100000

[Bottom note: When the difference between the sine of the Sun's altitude and the sine of the meridian altitude is greater than the sine of the meridian altitude, that hour, for which the altitude is investigated, does not fall on the proposed face of the circle, but on the other face.]

(the whole sine [sinus totus]) is to 74119, the versed sine [sinus versus] of the Sun's distance from noon, so is the aforesaid half, 61363, to a fourth quantity — here approximately the number 45481 will be found. Since this is the larger, if the sine of the meridian altitude [altitudo meridiana], 31730, is subtracted from it, the remainder will be the sine of the Sun's altitude above the northern face of the vertical circle, at the 5th hour from noon (or the 7th from midnight), for the parallel of Cancer [♋]: namely 13751, to which correspond $7^\circ 54'$ for the required altitude of the Sun.

Again, let the same altitude be sought for the 11th hour from noon. Let it be arranged that as 100000, the whole sine, is to 196592, the versed sine of the Sun's distance from noon, so is the aforesaid half, 61363, to a fourth quantity; here the number 120634 will be found. If from this the sine of the meridian altitude, 31730, is taken away, there will remain — for the sine of the Sun's altitude above the same opposite face, namely the northern face of the vertical circle — approximately the number 88904, to which are due $62^\circ 45'$ for the required altitude of the Sun.

And so, if the Sun's distances from the meridian of any proposed great circle are taken, above the horizon or below it, for the individual hours, the Sun's altitudes above each of its faces will be found. For when the difference found is subtracted

from the sine of the meridian altitude, the altitudes found will be above the face on which the meridian altitude was taken; but when, conversely, the sine of the meridian altitude is subtracted from the said difference found, they will be above the opposite face, as we said. I would always choose the Sun's distances from the meridian above the horizon, considering carefully upon which face of the plane the Sun's ray falls when the Sun is in the meridian of the proposed circle above the horizon and lies in that parallel whose hourly altitudes are being sought; and also which of the poles is elevated above that same face, so that the meridian altitude of the given parallel may be found — as we shall presently teach in the following scholium.

DEMONSTRATION. The reasoning for finding this altitude of the Sun is to be taken from Prop. 36 of Book 1. For the reasoning here is the same as that for the horizon, since any great circle plays the role of the horizon in some region. As for the Sun's altitude above the face of the circle opposite [to it]: in the second figure of Prop. 36, Book 1, let the straight line TR be conceived as the common section of the meridian and of the great circle above which the Sun's altitude is investigated, so that KT is the sine of the meridian altitude. If, then, the Sun is placed at S, beyond the said circle, so that it lights up the opposite face toward the other pole G, the straight line KN will be found, by the said computation, greater than KT, the sine of the meridian altitude. Hence, when the sine of the meridian altitude KT is removed from the straight line KN found, there will remain NT, the sine of the Sun's altitude above the opposite face of the proposed circle.

In investigating the Sun's altitude we use only that method which we set out in the last place in Prop. 36, Book 1, before [the treatment of] the spherical triangles, because it is the clearest of all and the most transparent, and because it applies to all parallels at any latitude of the pole above the proposed great circle, as we noted there. See nevertheless what we wrote toward the end of the scholium of Prop. 36, Book 1, for the case when the parallel either touches the proposed great circle or stands entirely above it, as it does above the horizon. It will be no trouble to adapt here the other methods that we prescribed in the said proposition, if it seems good.

[Margin: How the Sun's altitude above the meridian of the horizon — whether right or oblique — is to be investigated.]

We shall also explore, in the following way, the Sun's altitude above the meridian — whether of a right, an oblique, or the meridian[s own] horizon; that is, above [the great circle drawn] through the common sections of the equator and of the six-o'clock circle [circulus horae 6] from noon or midnight, or of the horizon, and

through the center of the Sun. Let the horizon be right, or ABCD; its meridian, AEC; the Sun's parallel, whether northern or southern, FG, in which the Sun is at the point H. Through this point and the poles A, C let the hour-circle, or declination-circle [circulus horarius, vel declinationis], AHC be drawn, cutting the equator at K, so that EK is the Sun's distance from the meridian. Let there also be drawn, through B — the pole of the meridian — and the point H, the great circle BHI, so that HI is the arc of the Sun's altitude above the meridian AEC.

Diagram. A circle representing the sphere in projection, filled with a network of great-circle arcs, for the demonstration of the Sun's altitude above the meridian in the right sphere. The outer circle is the right horizon ABCD; the vertical diameter AEC is the meridian; A (top) and C (bottom) are the poles of the world (which lie on the horizon in the right sphere). Several arcs cross the figure, meeting at interior points; because the great circles are drawn as complete curves, most of the interior letters appear at two positions (a front and a back intersection). Readable labels, with their positions:

- A (top of the circle): pole; endpoint of meridian AEC.
- C (bottom of the circle): pole; endpoint of meridian AEC.
- B (left, mid-height): pole of the meridian; endpoint of horizon ABCD.
- D (right, mid-height): endpoint of horizon ABCD.
- E (center): intersection on the meridian.
- F (upper-left) and G (right, upper and lower): endpoints of the Sun's parallel FG.
- H (upper-center, and again lower-center-left): the Sun's position.
- I (upper-right, and again lower-center): on the altitude circle BHI.
- K (center-left): on the equator, marking distance EK.
- L (upper-left, and again lower-left): interior intersection.
- M (upper-center-right, and again lower-center): interior intersection.
- N (lower-right): interior intersection (KN, NT).
- O (lower, between C and N): interior intersection.

Now, since in the right-angled spherical triangle BHK the angle K is right, it will be — by Prop. 19 of Book 4 of Johannes Regiomontanus [Regiomontanus], *On Triangles* [*De Triangulis*], or by Prop. 15 of Book 1 of Geber [Jābir ibn Aflāḥ], or by Prop. 43 of our spherical triangles — that as the sine of the complement of arc HK, of the declination, is to the whole sine, so is the sine of the complement of arc BH, that is, so is the sine of arc HI, of the Sun's altitude above the meridian, to the sine of the complement of arc BK, that is, to the sine of arc EK, of the Sun's

distance from noon or midnight. And by conversion: as the whole sine is to the sine of the complement of the declination, so is the sine of the Sun's distance from noon or midnight to the sine of the Sun's altitude above the meridian. This we shall demonstrate more briefly thus. Since in the spherical triangle AHI, or CHI, the angle I is right, it will be — by Prop. 16 of Book 4 of Johannes Regiomontanus, *On Triangles*, or by Prop. 13 of Book 1 of Geber, or by Prop. 41 of our spherical triangles — that as the whole sine of the right angle I is to the sine of arc AH, or CH, of the complement of the declination, so is the sine of angle A, or C, of the Sun's distance from the meridian, to the sine of arc HI, of the Sun's altitude above the meridian. Therefore, if it be arranged that as the whole sine is to the sine of the complement of the declination, so is the sine of the Sun's distance from noon or midnight to a fourth [quantity], the sine of the Sun's altitude above the meridian will result. For example: with the Sun occupying the beginning of Cancer [♋] or Capricorn [♐], let its altitude above the meridian be sought for the 5th or 7th hour after noon or midnight, so that the Sun's distance from noon or midnight contains five hours, that is, 75° . Let it be arranged that as 100000, the whole sine, is to 91706, the sine of the complement of the declination, so is 96592, the sine of the Sun's distance from noon or midnight, to a fourth [quantity]; this sine will be found to be approximately 88580, whose arc, $62^\circ 21'$, will give the required altitude of the Sun above the meridian.

When the Sun runs along the equator, the Sun's very distance from noon will be its altitude above the meridian, because the equator, drawn through the poles of the meridian, is at right angles to the meridian, by Prop. 15 of Book 1 of Theodosius [Theodosius of Bithynia].

Again, at the 6th hour from noon or midnight, the complement of the declination — AF or CF — will be the Sun's altitude above the same meridian, since the six-o'clock circle from noon or midnight is at right angles to the meridian, by the same Prop. 15 of Book 1 of Theodosius.

By a not dissimilar reasoning we shall investigate the Sun's altitude above the right horizon [Horizon rectus], or the six-o'clock circle from noon or midnight — [the altitude] which is measured by the great circle drawn through the poles of the right horizon (or of the six-o'clock circle from noon or midnight), that is, through the common sections of the meridian and the equator, and through the center of the Sun. Such is the circle EHL, so that the Sun's altitude above the six-o'clock circle is the arc HL, the Sun being at the point H. For since in the spherical triangle EHK the angle K is right, it will be — by Prop. 19 of Book 4 of Johannes Regiomontanus, *On Triangles*, or by Prop. 15 of Book 1 of Geber, or by Prop. 43 of

our spherical triangles — that as the sine of the complement of arc HK, of the declination, is to the whole sine, so is the sine of the complement of arc EH, that is, so is the sine of arc HL, of the Sun's altitude above the right horizon or the six-o'clock circle, to the sine of the complement of arc EK, of the Sun's distance from noon or midnight. And by conversion: as the whole sine is to the sine of the complement of the declination, so is the sine of the complement of the Sun's distance from noon or midnight to the sine of the Sun's altitude above the right horizon or the six-o'clock circle from noon or midnight. This we shall show more briefly as follows. Since in the spherical triangle AHL, or CHL, the angle L is right, it will be — by Prop. 16 of Book 4 of Johannes Regiomontanus, *On Triangles*, or by Prop. 13 of Book 1 of Geber, or by Prop. 41 of our spherical triangles — that as the whole sine of the right angle L is to the sine of arc AH, or CH, of the complement of the declination, so is the sine of angle A, or C, of the complement of the Sun's distance from noon or midnight, to the sine of arc HL, of the Sun's altitude above the right horizon or the six-o'clock circle. Therefore, if it be arranged that as the whole sine is to the sine of the complement of the declination, so is the sine of the complement of the Sun's distance from noon or midnight to a fourth [quantity], the sine of the Sun's altitude above the six-o'clock circle from noon or midnight, or the right horizon, will result.

When the Sun runs along the equator, the complement of the Sun's distance from noon or midnight will be its altitude above the right horizon, or the six-o'clock circle from noon or midnight, because the equator is at right angles to that circle, since it is drawn through its poles.

Again, at noon or midnight, the complement of the declination — AM or CM — will give the Sun's altitude above the same circle, because the meridian too is at right angles to it.

[Margin: How the Sun's altitude above any great circle whatever drawn through the poles of the world is to be found.]

Finally, above a great circle drawn through the poles of the world that is inclined to the meridian — such as the great circle to which the third dial described in Prop. 37 of Book 3 is parallel — we shall inquire into the Sun's altitude in the same way, provided we seek the Sun's distances from the proper meridian of that circle, as we taught above, and, in place of the Sun's distance from noon or midnight, take its distance from the proper meridian of the said circle.

[Margin: It is enough if the Sun's altitudes above the great circles drawn through the poles of the world are computed, while it is in the northern or southern signs.]

It is enough, however, to compute the Sun's altitudes above the great circles drawn through the poles of the world while it is in the northern signs, or in the southern. For at the same hours the Sun has equal altitudes above the meridian — or the six-o'clock circle from noon or midnight, or the right horizon, or indeed any great circle whatever passing through the poles of the world — while it is in opposite parallels. This we shall demonstrate as follows. Since in the triangles AHI, CHI the angles at I are right, and the angles A, C are equal (being the angles of the Sun's distances from the meridian), and they have the sides AH, CH — which are subtended by the right angles — equal (being complements of equal declinations), the arcs HI, HI, which measure the Sun's altitudes above the meridian, will also be equal, by Prop. 21 of Book 1 of Menelaus [Menelaus of Alexandria] in the redaction of Francesco Maurolico [Maurolico], or by Prop. 21 of our spherical triangles. By the same reasoning, since in the triangles AHL, CHL the angles at L are right, and the angles A, C are equal (being the angles of the complements of the Sun's distances from the meridian), and they have the sides AH, CH equal, as we said, the arcs HL, HL, which measure the Sun's altitudes above the right horizon or the six-o'clock circle from noon or midnight, will also be equal, by the same proposition.

[Margin: At any hour the Sun has the same altitude above the meridian of the horizon as it has above the six-o'clock circle from noon or midnight at another hour, which is as far from that circle as the first is from the meridian.]

Moreover, at any hour the Sun has above the meridian the same altitude that it has above the six-o'clock circle from noon or midnight at another hour that is as far from the six-o'clock circle as the first is from the meridian — such as, for example, the 11th or 1st hour from noon or midnight with respect to the meridian, and the 5th or 7th hour from noon or midnight with respect to the six-o'clock circle from noon or midnight, since each is distant from its own circle by one hour, or 15° . This we shall confirm as follows. Let the Sun be placed at N, so that the declination-circle CNA makes with the six-o'clock circle the angle NCO equal to the angle HCI — that is, the Sun's distance at N from the six-o'clock circle equals its distance at H from the meridian. Since, then, in the triangles CHI, CNO the angles at I, O are right, and the angles HCI, NCO are equal, and they have the arcs CH, CN equal (being complements of the same declination), the arcs of altitude HI, NO will also be equal, by the same Prop. 21.

And so, if the Sun's altitudes above the meridian at the individual hours from noon or midnight have been computed, the same altitudes will be assigned to the six-o'clock circle from noon or midnight for the individual hours that are as far from the six-o'clock circle from noon or midnight as those [hours] are from the meridian. Thus the altitudes for the pairs of hours in the prior table set out here, above the meridian circle, are equal to the altitudes for the pairs of hours in the posterior table above the right horizon, or the six-o'clock circle from noon or midnight — and conversely. This too is plainly evident from the computation itself.

Prior table (hours reckoned with respect to the meridian):

6	7	8	9	10	11	12
6	5	4	3	2	1	12

Posterior table (hours reckoned with respect to the six-o'clock circle):

12	1	2	3	4	5	6
12	11	10	9	8	7	6

[Margin: The Sun's altitude above the equator is always equal to the declination of that same [parallel].]

Above the equator there is no need to investigate the Sun's altitudes, because, the Sun being in any parallel whatever, its altitude above the equator throughout the whole day is equal to the declination of that parallel, as is clear.

[Margin: For which hours the Sun's altitudes above each face of every great circle are to be investigated.]

Since, however, any great circle is inclined to the horizon or the meridian and has two faces — one upper and one lower, or one southern and one northern — the [altitudes] to be computed

are the Sun's altitudes above whichever of them, for those hours which are comprehended in the portion of any parallel projecting above that face in the manner of a certain diurnal arc [arcus diurnus]. For only during those [hours] is the Sun raised above the face of the said circle. By what method we may know the hours lying in that portion of the parallel, we shall disclose in the following scholium. But the computation of the altitudes itself will also make it clear. For if the difference found between the sine of the meridian altitude and the sine of the altitude at the time of observation is less than the sine of the meridian altitude,

the hour of the altitude found will lie in the portion of the parallel above the proposed face of the circle; but if it is greater, in the remaining portion above the opposite face, as we wrote a little before. We have therefore investigated the Sun's altitude above every great circle of the sphere for the individual hours. Which was to be done.

SCHOLIUM.

[Margin: How to know whether the arctic pole or the antarctic is elevated above the given plane of the proposed great circle.]

We shall find, by this device, the Sun's meridian altitude above a proposed great circle in an oblique northern sphere. First it must be considered whether the arctic pole is elevated above the plane of the circle, or rather the antarctic. This is determined as follows. In all vertical circles the arctic pole is raised above the northern faces, but the antarctic above the southern faces. In circles of position [circuli positionum], to which dials declining from the horizon are parallel, the arctic pole is elevated above the upper faces, the antarctic above the lower. But in the other circles inclined to the horizon — whether they be at right angles to the meridian, or [themselves] inclined — if their upper faces look toward the north, the arctic pole is raised above the upper faces and the antarctic above the lower. But if they are inclined toward the northern parts, so that their upper faces look toward the south, one must investigate — by the corollary of Prop. 28 of Book 1 — the arc of the meridian intercepted between the horizon, and [between the horizon] and the proposed circle. For if this arc (which necessarily, in planes of this kind, stands above the horizon on the northern side, as we showed in scholium 1 of Prop. 28 of Book 1) is less than the altitude of the pole above the horizon, the arctic pole will be raised above the upper face, and the antarctic above the lower; but if the said arc is greater than the altitude of the pole above the horizon, the contrary happens — for the arctic pole will be raised above the lower face, and the antarctic above the upper; and if, finally, the said arc is found equal to the altitude of the pole above the horizon, there will be no altitude of the pole above the given circle. All of which are plain from the material sphere.

[Margin: By what method the Sun's meridian altitude above any great circle whatever is to be investigated.]

Since, by Prop. 19 of Book 2 of Theodosius, the portions of the parallels of the equator lying between the equator and the pole, and conspicuous above the face of the proposed circle, are greater than semicircles, while those of the rest are smaller, it comes about that the northern parallels have larger portions above the

face above which the arctic pole is elevated, and the rest smaller — as happens on the horizon. The contrary will happen on that face above which the antarctic pole is conspicuous. Therefore, for the face of the circle above which the arctic pole is conspicuous, we shall investigate the meridian altitude, and the meridian depression, from the complement of the altitude of the pole above the given great circle and from the declination of the parallel in which the Sun is — just as on the horizon, as we taught in the scholium of Prop. 35 of Book 1. The same reasoning fits also that face of the circle which has the antarctic pole elevated, provided that for the northern signs the southern be taken, and conversely.

[Margin: By what method it may be known which hours are contained in the portion of any parallel above the given face of the proposed great circle; and hence at what hour that face begins, and ceases, to be illuminated by the Sun.]

That we may understand, however, which hour is contained in the portion of any parallel standing above the face of the given circle in the manner of a diurnal arc — and consequently at what hour that same face begins, and ceases, to be illuminated by the Sun — this is to be inquired by Prop. 34 of Book 1, or rather from the scholium of Prop. 35 of the same book (provided that, in planes above which the antarctic pole is elevated, the southern signs be taken for the northern, and conversely): namely, the quantity of that diurnal arc, as if the face of the proposed circle were some horizon. For if, from that hour at which [the parallel] falls upon the proper meridian of the proposed circle (which indeed will be known from its inclination to the meridian of the horizon), the semidiurnal arc [arcus semidiurnus] found is counted off on both sides in the parallel, the hours contained in the proposed portion, or diurnal arc, will be obtained; and consequently also the hour at which the Sun begins to illuminate, or ceases to illuminate, the proposed face of the circle.

For example: above the southern face of a vertical circle declining from the vertical properly so called by 30° — to which the dial of Prop. 1 of Book 3 is parallel — the antarctic pole is elevated $40^\circ 3'$. Therefore the portion of the parallel of Capricorn [φ] projecting above it, in the manner of a diurnal arc, will contain about 14 h 52 m; and the semidiurnal arc, 7 h 26 m. And since the meridian of that vertical circle departs from the meridian of the horizon toward the east by $40^\circ 48'$ — that is, about 2 h 43 m — it falls at 9 h 17 m from midnight upon the said meridian. Accordingly, if we count off the semidiurnal arc of 7 h 26 m on both sides from that hour, we shall arrive at 1 h 51 m from midnight, and at 4 h 43 m from noon. Therefore, at all hours from 1 h 51 m from midnight up to 4 h 43 m from noon, that face of the vertical circle would be illuminated by the Sun

placed at the beginning of Capricorn, were the earth not in the way. But since the Sun at the beginning of Capricorn, at latitude 42° , rises at 7 h 32 m from midnight and sets at 4 h 28 m from noon, it is clear that that face is then illuminated by the Sun the whole day, except for the 15 m during which it ceases to be illuminated before sunset.

The portion of the parallel of Cancer [♋], existing above the same face as a diurnal arc, will embrace 9 h 8 m; the semidiurnal arc, 4 h 34 m. Therefore, since the meridian of the said vertical recedes from the meridian of the horizon toward the east by 2 h 43 m, as we said, and falls upon the same meridian at 9 h 17 m from midnight — if we count the semidiurnal arc on both sides from this hour, we shall arrive at 4 h 43 m from midnight, and at 1 h 51 m from noon.

Accordingly, the same face of the said vertical will be lit by the Sun placed at the beginning of Cancer, at all hours from 4 h 43 m from midnight up to 1 h 51 m from noon. Hence, since the Sun at the beginning of Cancer, at latitude 42° , rises at 4 h 28 m from midnight and sets at 7 h 32 m from noon, it is established that the Sun does not then illuminate that face throughout the whole day, but only from 15 m after sunrise up to 1 h 51 m from noon.

Although, however, because of the obstruction of the earth the Sun illuminates neither face of the proposed circle unless it is above the horizon, nevertheless the Sun's altitudes above each face are to be computed also for those hours in which the Sun is below the horizon, because through them the dials are described more easily and more expeditiously, as will be evident from what follows.

Again, above the northern face of the same vertical circle the arctic pole is elevated by just as many degrees as the antarctic above the former [southern] face — namely $40^\circ 3'$. Therefore the portion of the parallel of Cancer projecting above it, in the manner of a diurnal arc, will comprehend 14 h 52 m; the portion of the parallel of Capricorn, 9 h 8 m. And the meridian of the said [northern] face recedes from the meridian of the horizon, below the horizon, by 2 h 43 m toward the west, so that at 9 h 17 m from noon it falls upon the said meridian.

Accordingly, as before, we shall find the hours at which the Sun, placed at the beginning of Cancer or Capricorn, would illuminate the said northern face, were it not hindered by the earth.

Following Federico Commandino, we shall also investigate by means of the analemma how many hours, and at what hour, are contained above a given face of any great circle, and hence at what hour the Sun begins — or ceases — to illuminate that face. The procedure is as follows.

[Margin: "At what hour [the hours] are contained above the proposed face of a given great circle, and hence at what hour it begins or ceases to be illuminated — how this is ascertained from the analemma."]

Let the analemma ABCD be described, with center E, together with the parallels of the signs. (We have drawn only three parallels — namely F G, for Cancer [♋]; K L, for Taurus [♉]; and H I, for Gemini [♊][?] — so that a multitude of them should not breed confusion; and these three will serve in place of all. For F G will also perform the office of the parallel of Capricorn [♏], since Cancer and Capricorn have equal declinations from the equator. K L will likewise stand in for the parallel of Virgo [♍], of Pisces [♐], and of Scorpio [♏], because these signs and Taurus decline equally from the equator. And finally H I will also be equivalent to the parallel of Leo [♌], of Sagittarius [♐][?], and of Aquarius [♒][?], since the declination of Gemini and of these signs is the same.) About the diameters of the parallels, semicircles are to be described.

Let the axis of the world be B D; the horizon, M N; the vertical circle, [the one through points] 12 and 13. Then from the points O, P, Q — where the horizon cuts the diameters of the parallels — let perpendiculars Q R, P S, O T be drawn to those diameters. Now since both the horizon and the parallel of Cancer [♋] stand at right angles to the meridian, their common section will likewise be at right angles to it; [Margin: (note a) "19. See below."] and therefore, by definition 3 of Euclid, Book XI, it is perpendicular to both F G and M N. Hence Q R, which in the plane of the parallel is perpendicular to F G, will be the common section of the horizon and the parallel of Cancer; and thus F R will be the semidiurnal arc of Cancer [♋], while G R is the semidiurnal arc of Capricorn [♏].

In the same way, P S will be the common section of the horizon and the parallel of Taurus [♉], with K S the semidiurnal arc of Taurus and of Virgo [♍], and L S the semidiurnal arc of Scorpio [♏] and of Pisces [♐]. Likewise O T will be the common section of the horizon and the parallel of Gemini [♊], with H T the semidiurnal arc of Gemini and of Leo [♌][?], and I T the semidiurnal arc of Sagittarius [♐][?] and of Aquarius [♒][?]. Lastly E D will be the common section of the horizon and the equator — that is, of the parallel of Aries [♈] and Libra [♎] — with A D the semidiurnal arc of Aries [♈], and C D the semidiurnal arc of Libra [♎].

In the same manner, if from the points V, X, Y [Y] — at which the vertical circle [12–13] cuts the parallels — perpendiculars V Z, X α, Y β are drawn to the parallels, these will be the common sections of the vertical circle and the parallels, so that the arcs R Z, S α, T β are intercepted between the horizon and

the vertical circle; and the plane of the vertical circle, while the Sun runs across them, is illuminated by the Sun on the side of the south.

Now let $\gamma\delta$ be the common section of the meridian and of a given circle inclined to the meridian — which is easily obtained once, by proposition 28 of Book I, the arc of the meridian $N\delta$ between that circle and the horizon has been found. Then, the inclination of that circle to the meridian having been found by proposition 27 of Book I, let there be found, by proposition 25 of Book I, the minor diameter of the ellipse which the perpendiculars dropped from the circumference of the inclined circle onto the plane of the meridian produce; let this be $\varepsilon\theta$, cutting the major diameter $\gamma\delta$ at right angles at the center E. About the given diameters $\gamma\delta$ and $\varepsilon\theta$ let the ellipse be described according to what we set out in the scholium of proposition 26 of Book I, cutting the diameters of the parallels at the points $\lambda, \mu, \xi, \pi, \rho, \sigma, \varphi$, and $[\omega]$ — from which points perpendiculars are drawn to the diameters: $\lambda \rightarrow 3, \mu \rightarrow 4, \xi \rightarrow 7, \pi \rightarrow 8, \rho \rightarrow 9, \sigma \rightarrow 10, \varphi \rightarrow 11$, and $[\omega] \rightarrow \omega$.

I say that the inclined circle cuts the parallels at the points 3, 4, 7, 8, 9, 10, 11, ω . For, the semicircle of Cancer $[\mathfrak{C}]$, F R G, being set in its proper position — namely at right angles to the meridian — the perpendicular dropped from 3 onto the plane of the meridian falls upon F G, the common section of that plane and the meridian, [Margin: (note b) "38. See below."] and it is therefore perpendicular to the straight line F G by Euclid, Book XI, definition 3. Consequently that perpendicular must fall upon the point λ , lest from the point 3 two perpendiculars be said to be drawn to the straight line F G — which is impossible, as we demonstrated (following Proclus) at Euclid, Book I, proposition 16. The straight line 3λ is therefore at right angles to the plane of the meridian. And hence, since by proposition 24 of Book I the perpendiculars dropped from the circumference of the inclined circle onto the plane of the meridian fall also upon the ellipse, the circumference of the inclined circle will cut the parallel of Cancer, F R G, at the point 3 — the point from which, namely, the perpendicular drawn onto the plane of the meridian falls upon λ . And so for the rest.

The inclined circle therefore cuts off: from the parallel of Cancer $[\mathfrak{C}]$, the arc F 3; from the parallel of Capricorn $[\mathfrak{K}]$, the arc G 4; from Taurus $[\mathfrak{T}]$ and Virgo $[\mathfrak{M}]$, the arc K 7; from Scorpio $[\mathfrak{M}]$ and Pisces $[\mathfrak{P}]$, the arc L 8; from Aries $[\mathfrak{A}]$ and Libra $[\mathfrak{L}]$, the arc A 9, or C 10; from Gemini $[\mathfrak{G}]$ and Leo $[\mathfrak{L}]$, the arc I ω ; from Sagittarius $[\mathfrak{S}]$ and Aquarius $[\mathfrak{A}]$, the arc H 11 — these being the arcs, namely, that are intercepted between the meridian and the inclined circle.

Hence, once the hours are distributed — whether the beginning is made from the meridian, namely from the point F or G and so on, or from the point R or S and so on, after the manner of the Babylonians or the Italians — it will be plainly established at what hour, or fraction of an hour, [the inclined circle] falls upon point 3, or 7, or 9, and so forth.

For the rest, so that we may know whether point 3, or 7, or 9, and so on — and therefore the hour at which the parallel is cut by the inclined circle — lies on the eastern or the western side, we must carefully examine the situation and position of the inclined circle. For once this is known we shall easily understand the matter, as we shall teach a little further on, in the solution of this same problem by the doctrine of sines.

[Margin: "When the inclined circle cuts the proposed parallel of the Sun in two places."]

But if the ellipse should ever cut the diameter of a parallel in two places short of the point at which that diameter is divided by the diameter of the horizon, then two arcs will be cut off from the parallel — one toward the parts of the east, the other toward the parts of the west. And if the upper face of the circle looks toward the west, the point nearer the meridian will be the eastern one, and the more remote the western; whereas, on the contrary, if it looks toward the east [the reverse holds], as will become clearer from what follows. This, moreover, happens for the most part in planes passing through the zenith and having a small declination from the vertical circle, and in certain others — as can be understood from a material sphere.

Diagram. A large analemma projection. An outer circle A B C D with center E, containing the semicircular projections of three declination-parallels drawn about their diameters, the axis of the world B D, the horizon M N, the vertical circle through the numbered points 12 (upper) and 13 (lower), the equator and the inclined-circle ellipse, and a dense net of intersecting straight lines. The rim carries the zodiacal signs.

- A (top): endpoint of meridian/outer circle
- B, D: axis of the world (B upper-left, D lower-right)
- C: lower rim
- E (center): center of the projection
- F, G: diameter-endpoints of the Cancer [♋]/Capricorn [♐] parallel
- K, L: diameter-endpoints of the Taurus [♉] parallel
- H, I: diameter-endpoints of the Gemini [♊] parallel

- M, N: horizon endpoints
- O, P, Q: points where the horizon cuts the parallel-diameters
- R, S, T: feet of the perpendiculars Q R, P S, O T
- 12, 13: the vertical circle's poles/points
- Interior points labelled with Arabic numerals 3, 4, 7, 8, 9, 10, 11 and Greek letters λ , μ , ξ , π , ρ , σ , ϕ , ω , α , β (small — several not individually resolvable)
- Rim: zodiacal glyphs (ϖ , φ , χ , $\mathfrak{M}$, $\mathfrak{H}$, Υ , $\mathfrak{X}$, $\mathfrak{I}$, $\mathfrak{S}$, $\mathfrak{Q}$, $\mathfrak{M}$, $\mathfrak{L}$ — small, partly unresolved)

[Many small interior/rim labels are at the resolution floor]

[Margin: "When the circle stands at right angles to the meridian: by what method one inquires at what hour [the hours] are contained above either face."]

In circles standing at right angles to the meridian — such as the vertical circle properly so called, and all circles to which sundials inclined to the horizon are parallel — the proposed problem is of no difficulty from the analemma; for the diameter of the meridian cuts the diameter of any parallel at the point where the parallel is cut by the said circle, both before noon and after noon. You have an example in the adjoining figure, in the vertical circle whose diameter is 12–13, where the perpendiculars V Z, X α , E D, Y β mark the points at which the parallels are cut by the vertical circle; because, as has been demonstrated, those perpendiculars are the common sections of the vertical circle and the parallels.

The reasoning is the same if the diameter $\gamma \delta$ be taken as the common section of the meridian and of some great circle to which a sundial inclined to the horizon is parallel, so that the elevation of the pole above it is the arc A D. For the perpendiculars drawn to the same diameters from the points where $\gamma \delta$ cuts the diameters of the parallels will be the common sections of the parallels and of the said great circle — as will be demonstrated, just as was stated concerning the vertical circle and the horizon.

From these things it can readily be understood at what hour the Sun begins to illuminate the upper or the lower face of an inclined circle, and for which hours the Sun's altitudes are to be computed. For when the upper face of the circle looks toward the west, the Sun will begin to illuminate the upper face when it stands at the point which was found by the demonstration above — as at point 3, or 7, or 9, and so on.

Hence the Sun's altitudes above the upper face must be investigated for each hour from that point up to sunset — except when the parallel is cut by the

inclined circle in two places above the horizon: for then the hours are to be taken only from that point up to the other, more westerly point, because there the Sun ceases to illuminate the upper face. The Sun's altitudes above the lower face, on the other hand, must be sought for the hours from sunrise up to the said point; and, if the parallel is cut in two places above the horizon by the inclined circle, also for the hours from the more westerly point up to sunset — because at the former point the Sun ceases to illuminate the lower face, and begins again to illuminate the same at the latter point.

But when the upper face of the circle looks toward the east, the Sun will cease to illuminate the upper face when it stands at the point found by the preceding demonstration. Therefore the Sun's altitudes above the upper face must be sought for each hour from sunrise up to that point. And if the inclined circle cuts the parallel in two places, only those hours are to be taken which are comprised between the more easterly and the more westerly point, because at the former point the Sun begins to illuminate the upper face. Above the lower face, on the other hand, the Sun's altitudes are to be found for the hours from the point found up to sunset; and, if the parallel is cut in two places by the inclined circle, also for the hours from sunrise up to the more easterly point — because at this point the Sun ceases to illuminate the lower face, while at the more westerly point it begins to illuminate the same again.

But this same result we shall attain more expeditiously by the doctrine of sines [per sinuum doctrinam], in the following manner. Let the horizon be A B C D; the meridian A E C; the equator B E D; the parallel — whether northern or southern — F H G; and the great circle inclined to the meridian (whether it be at right angles to the horizon or not) R I, cutting the equator at the points K, L, the northern parallel at the points M, N, and the southern at the points R, S, and the meridian at the point I.

We must therefore investigate both arcs E K, E L in the equator, and both H M, H N in the northern parallel, and both H R, H S in the southern parallel — that is, the distance of the Sun before or after noon, when it stands in the inclined plane and in the said parallels. Now since the great circle inclined to the meridian [cuts] any parallel [in two points], of which the one nearer to the semicircle of the meridian above the horizon [is nearer], and the other more remote, we shall first inquire into that arc of the parallel which is intercepted between the nearer point and the meridian; for from this we shall without difficulty elicit the other, which is intercepted between the more remote point and the meridian.

[Margin: "Whether the arc of the proposed parallel between the meridian (above the horizon) and the inclined circle on the eastern side is smaller than the other on the western side, or the reverse. Likewise, when the parallel is cut by the inclined plane in two places on the same side — whether eastern or western — how this is recognized."]

In order that we may know whether the nearer point is eastern or western, the situation of the inclined circle must be carefully examined. For from it we shall easily understand whether the smaller arc of the parallel lying between the inclined circle and the semicircle of the meridian above the horizon is eastern or western — by this device. When the great circle is at right angles to the meridian — whether it passes through the zenith or not — it will necessarily pass through the common sections of the equator and the horizon, namely through the poles of the meridian, by proposition 14 of Book I of Theodosius; and it will cut any parallel in two points equally distant on either side from the meridian, because the meridian, standing at right angles to the parallel and to that great circle, bisects their segments by proposition 9 of Book II of Theodosius.

But when the same great circle is inclined to the meridian and passes through the zenith — that is, is at right angles to the horizon — then, if its southern face turns toward the west and the zenith lies between the arctic pole and the proposed northern parallel, both that northern parallel and the opposite southern one will be cut in two points, of which the eastern is nearer to the semicircle of the meridian above the horizon than the western, on account of the acute angle which the declining circle makes with the meridian toward the eastern and southern parts. But if the zenith lies between the equator and the northern parallel, that northern parallel will be cut in two western points, and the opposite southern one in two eastern points, if the southern face of the declining circle turns toward the east. For when the zenith lies between the arctic pole and the northern parallel, both that northern parallel and the opposite southern one will be cut in two points,

Diagram. The same analemma projection as on p. 379 (the "adjoining figure" of the text). Outer circle A B C D with center E; the three parallel-semicircles (F G, K L, H I); horizon M N; vertical circle through 12 (top) and 13 (bottom); axis B D; the inclined-circle ellipse and the perpendicular net; zodiac glyphs on the rim.

- A (top rim); B (left, axis); C (bottom rim); D (right, axis)
- E (center)
- F, G: Cancer [♋]/Capricorn [♏] parallel diameter
- K, L: Taurus [♉] parallel diameter

- H, I: Gemini [II] parallel diameter
- M, N: horizon endpoints
- O, P, Q, R, S, T: horizon-cut points and perpendicular feet
- 12, 13: vertical-circle points
- Interior Greek/Arabic point labels as on p. 379 (small — several unresolved)

[Repeat of the p. 379 analemma; small interior/rim labels at the resolution floor]

points of which the western is nearer to the semicircle of the meridian above the horizon than the eastern, because the declining circle makes an acute angle with the meridian toward the western [and southern] parts. But with the zenith between the equator and the northern parallel, that northern parallel will be cut in two eastern points, and the opposite southern one in two western points.

Again, when the great circle inclined to the meridian does not pass through the zenith: if it is inclined on the northern side and its upper face looks toward the west, and the arc of the meridian between the inclined circle and the horizon is smaller than the arc of the meridian on the northern side between [the northern parallel and the horizon] — so that the inclined plane cuts the meridian between the horizon and the northern parallel — then both that northern parallel and the opposite southern one will be cut in two points, of which the eastern is less distant from the semicircle of the meridian above the horizon than the western, because the inclined circle constitutes an acute angle with the meridian [toward the east]. But if the arc of the meridian between the inclined circle [and the horizon], on the northern side, [lies] between the proposed northern parallel and the horizon in such a way [that it falls] between the equator and the northern parallel, that northern parallel will be cut in two [western points], and the opposite southern one in two eastern points. The contrary will happen if the [upper] face [turns toward the east].

Exactly the same must be said of a circle inclined on the southern side. For if its upper face looks toward the west, and the arc of the meridian on the southern side between it and the horizon is smaller than the arc of the meridian [between the southern parallel and the horizon], both that southern parallel and the opposite northern one will be divided in two points, of which [the eastern] is less distant from the semicircle of the meridian above the horizon than the western, because the inclined circle makes [an acute angle] with the meridian toward the eastern and northern parts. But if [the arc of the meridian] between the inclined circle and the horizon is larger than the arc of the meridian on the southern side

between the [southern] parallel [and the horizon], so that the inclined plane cuts the meridian between the horizon and the southern parallel, then that southern parallel will be cut in two western points, and the [northern] parallel [in two eastern points]. The contrary of these will happen if the upper face of the inclined circle turns toward the east.

[Sense preserved throughout; bracketed spans mark words recovered by context where the print runs into the gutter or the cropped edge of the leaf.]

That which was said above — when the plane was inclined on the northern side — must also be said [here]: it cut the meridian between the arctic pole and the northern parallel, or between [the horizon and] the northern parallel, or between the equator and the northern parallel. All of which can easily be gathered and understood from a material sphere.

Diagram. A set of five closely-related spherical diagrams (two upper rows plus a lower pair), each showing a sphere with the horizon, meridian, equator, a declination-parallel and a great circle inclined to the meridian, illustrating the successive cases of the case-analysis in the text (which face turns east/west; where the zenith and the intersection points fall). Common labels across the figures: A at the top (pole/zenith end of the meridian), C at the bottom, B and D on the horizon, E at the center, F/G/H flanking a parallel, and R, S, K, L, M, N, P, T, I, O marking the intersection points of the inclined great circle with equator and parallels.

- Upper-left sphere: A (top), F, H, G (upper arc), B, R, T, K (left), E (center), D (right), M, O, I (lower), N, C (bottom)
- Upper-middle sphere: A (top), F, R, H, G, S; K, P, T, E, D, L, B; N, H, I, O, C
- Upper-right sphere: A (top), R, H, G; T, K, E, P; I, H, M, N; O, C, D, L
- Lower-left sphere: A (top), F, S, G; Q, L, B, V, E, T, K, D, P; N, E, O, M; C (bottom)
- Lower-middle sphere: A (top), R, H, G, F; T, I, K, P, E, D; H, M, O; C (bottom)

[Five overlapping figures with many small, partly-overlapping point-labels; numerous labels not individually resolvable]

[Margin: "At which hour before and after noon the inclined circle intersects the Sun's parallels, and hence how many hours are found above each face of that circle, and at what hour the Sun begins or ceases to illuminate each — by what route this is inquired through sines."]

And so, by this reasoning, we shall investigate the smaller arcs of the parallels between the inclined circle [and the semicircle of the meridian] above the horizon, which we suppose to be E K, H M, H R. From the arctic pole of the world O, through the points M, R, let there be drawn the great circles of declination O M, O R, cutting the equator at P and T. And since, in the spherical triangle E I K — whose angle E is right, and whose angle I (the inclination of the inclined circle to the meridian) is known by proposition 27 of Book I, together with the arc of the meridian E I between the plane and the equator —

[Margin: "How large the arc of the meridian is between the inclined plane and the equator above the horizon — how it is understood."]

For since, by the corollary of proposition 28 of Book I, the arc of the meridian between the inclined plane and the arctic pole is known, and since between the arctic pole and the equator a quadrant of the meridian is intercepted, the arc of the meridian between the inclined plane and the equator will also be known. For if the plane is inclined on the northern side, yet below the pole, the arc of the meridian between the plane and the equator above the horizon will be composed of a quadrant and the arc of the meridian between the arctic pole and the inclined plane. But if the plane is inclined on the northern side, above the pole — that is, in such a way that the arc of the meridian between the horizon and the inclined plane is greater than the elevation of the pole above the horizon — [and such that the arc of the meridian between the horizon and the inclined plane is greater than the altitude of the equator] — then the arc of the meridian between the plane and the equator is left, if the arc of the meridian between the plane and the arctic pole is taken away from the quadrant. And finally, if the plane is inclined on the southern side, but below the equator — that is, so that the arc of the meridian between the plane and the horizon is smaller than the altitude of the equator — the arc of the meridian between the plane and the equator will be had, if a quadrant is subtracted from the arc of the meridian between the plane and the arctic pole. [This may be done] by proposition 18 of Book IV of Johannes Regiomontanus, *De triangulis*; or by proposition 14 of Book I of Geber [Jābir ibn Aflah]; or by proposition 42 of our own *Spherical Triangles* —

[The scholium continues beyond this page.]

[The scholium of Problem 1 of Book V continues from the previous page. The sentence begun there completes here with a spherical-triangle proportion.]

[Margin: The angle which the inclined plane makes with the equator.]

[of our Spherical Triangles], it holds that: as the sine of angle EIK — the inclination of the plane to the meridian — is to the whole sine [radius], so the sine of the complement of angle EKI, which the plane makes with the equator, is to the sine of the complement of the arc of the meridian EI intercepted between the plane and the equator. By inversion, then, it will be: as the whole sine is to the sine of the angle of inclination of the plane to the meridian, EIK, so the sine of the complement of the arc of the meridian EI, between the plane and the equator, is to the sine of the complement of angle EKI, which the plane makes with the equator. Therefore, if we arrange it so that as the whole sine is to the sine of the angle of inclination of the plane to the meridian, so the sine of the complement of the arc of the meridian EI, between the plane and the equator, is to a fourth term, we shall find the sine of the complement of angle EKI; and hence the angle EKI itself, which the plane makes with the equator, will be known.

Again, since in the same right-angled spherical triangle EIK — by proposition 16 of Book IV of Johannes Regiomontanus [Regiomontanus], *On Triangles*, or by proposition 13 of Book I of Geber [Jābir ibn Aflaḥ], or by proposition 41 of our own *Spherical Triangles* — it holds that: as the sine of angle EKI, which the plane makes with the equator, is to the sine of the arc of the meridian EI between the plane and the equator, so the sine of angle EIK, the inclination of the plane to the meridian, is to the sine of the arc of the equator EK, the Sun's distance from the meridian. If we arrange it so that as the sine of the found angle [EKI], which the plane makes with the equator, is to the sine of the arc of the meridian [EI] between the plane and the equator, so the sine of the inclination of the plane to the meridian is to a fourth term, we shall find the sine of the smaller distance of the Sun from the meridian — the distance at which the Sun, being on the equator, begins to illuminate one face of the inclined plane and ceases to illuminate the other.

[Margin: The smaller distance of the Sun from the meridian on the equator, when the Sun lies on the inclined circle.]

Diagram. The first of five worn woodcut sphere-diagrams (this one at the top left of the page) illustrating the cases of the inclined plane cutting the meridian. The sphere shows the meridian as a vertical great circle (A at the top, C at the bottom), a roughly horizontal great circle across the middle, and a set of oblique circles — the equator, the horizon, the inclined plane, the declination-circles, and the day-parallel — intersecting near the centre E. Readable letter-labels: A (top of meridian), C (bottom of meridian), E (centre), B (left), D (right), and around the

sphere F, G, H, I, K, M, O, P, R, T. Several labels are abraded and their exact placement cannot be verified at this resolution. [— many labels [?].]

Diagram. The second sphere-diagram (top centre), of the same construction. Readable letter-labels: A (top), C (bottom), E (centre), B, D, L, and around the rim F, G, H, I, K, M, N, O, P, R, T, V. Exact roles of the peripheral labels are not verifiable. [— many labels [?].]

Diagram. The third sphere-diagram (top right), of the same construction. Readable letter-labels: A (top), C (bottom), E (centre), and around the sphere D, F, G, H, I, K, L, M, N, O, P, Q, R, S, T. [— many labels [?].]

Diagram. The fourth sphere-diagram (lower left, drawn larger), of the same construction, with the meridian A (top) ... C (bottom) and centre E. Readable letter-labels: A, C, E, B, D, and around the sphere F, G, H, I, K, L, M, N, O, P, Q, S, T, V. [— many labels [?].]

Diagram. The fifth sphere-diagram (lower right), of the same construction. Readable letter-labels: A (top), C (bottom), E (centre), B, D, and around the sphere F, G, H, I, K, L, M, O, P, R, S, T, V. [— many labels [?].]

Next, since in the right-angled spherical triangle KMP — by proposition 16 of Book IV of Regiomontanus, *On Triangles*, or by proposition 13 of Book I of Geber, or by proposition 41 of our *Spherical Triangles* — it holds that: as the sine of angle PKM, which the inclined plane makes with the equator (and which we have already determined), is to the sine of the arc MP, the declination of the parallel, so the whole sine is to the sine of the arc KM of the inclined plane intercepted between the equator and the parallel. If we arrange it so that as the sine of the found angle, which the inclined plane makes with the equator, is to the sine of the declination of the parallel, so the whole sine is to a fourth term, we shall find the sine of that arc of the inclined plane which lies between the equator and the parallel.

[Margin: The arc of the inclined plane between the equator and the parallel.]

Again, since in the same triangle — by proposition 19 of Book IV of Regiomontanus, *On Triangles*, or by proposition 13 of Book I of Geber, or by proposition 43 of our *Spherical Triangles* — it holds that: as the sine of the complement of the arc KM, just found, is to the sine of the complement of the arc MP, the declination of the parallel, so the sine of the complement of the arc KP is to the whole sine. By inversion it will be: as the sine of the complement of the arc MP, the declination of the parallel, is to the sine of the complement of the arc KM,

just found, so the whole sine is to the sine of the complement of the arc kP. If, therefore, we arrange it so that as the sine of the complement of the declination of the parallel is to the sine of the complement of the arc of the inclined plane intercepted between the equator and the parallel (just found), so the whole sine is to a fourth term, we shall find the sine of the complement of that arc of the equator KP which lies between the plane and the declination-circle; and hence the arc KP itself will be known — an arc equal to the three others KT, LQ, LV.

[Margin: The arc of the equator between the inclined plane and the declination-circle of the parallel drawn through the Sun, when the Sun lies on the inclined plane.]

For since the two angles PKM, TKR at the vertex K, and likewise the two angles QLN, VLS at the vertex L, are equal by proposition 6 of our *Spherical Triangles*; and since the angle EKI is equal to the angle ELI by proposition 13 of the same *Spherical Triangles* — the two angles at the vertex K will be equal to the two angles at the vertex L. Since, then, the angles at P, T, Q, V are right, the two angles MPK, PKM of triangle KPM will be equal to the two angles RTK, TKR of triangle KRT, and likewise the two angles NQL, QLN of triangle LNQ [equal] to the two angles SVL, VLS of triangle LSV. Moreover, the arcs MP, RT, NQ, SV — opposite the equal angles at K and L — are equal, because they measure the declinations of opposite parallels, which are equal. Therefore, by proposition 22 of our *Spherical Triangles*, the remaining arcs too will be equal, namely the arcs PK, TK, QL, VL.

From this arc of the equator between the inclined plane and the declination-circle of the parallel drawn through the Sun (when the Sun is on the inclined plane) — such as PK, or TK, or QL, or VL, which we have just found — we shall investigate the smaller distance of the Sun from the meridian, that is, the arc HM and the arc HR.

[Margin: By what method the smaller distance of the Sun from the meridian is investigated when the Sun lies on the inclined plane, which cuts the meridian between the arctic pole and the horizon.]

Whenever the plane, raised on the northern side above the horizon, cuts the meridian between the arctic pole and the horizon, as in the first figure, the arc of the equator PK just found — which lies between the inclined plane and the declination-circle — must, when the Sun is northern, be added to the arc of the equator EK situated between the plane and the meridian; but when the Sun is southern, the arc Tk, which we showed equal to the arc PK, must be subtracted

from the same arc of the equator EK. For thus, from that addition, there will arise the arc EP, which by proposition...

[proposition] 10 of Book II of Theodosius [Theodosius of Bithynia], [applied] to the arc HM (which measures, in the northern parallel, the Sun's distance from the meridian), is similar. And by subtraction there will be left the arc ET, which by the same proposition 10 of Book II of Theodosius is similar to the arc HR (the Sun's distance from the meridian in the opposite southern parallel).

But when the inclined plane cuts the meridian between the arctic pole and the northern parallel, as in the second figure, the arc PK, found from the arc [previously] found, must be subtracted, so that the arc EP is left; and thus [EP], similar to HM, becomes known, measuring in the northern parallel the Sun's distance from the meridian. But the arc TK, which is equal to the arc PK, must be added to the same arc EK, so that the arc ET arises — known, and similar to the arc HR — measuring the Sun's distance from the meridian in the opposite southern parallel.

Finally, when the plane cuts the meridian between the equator and the northern parallel, as in the third figure, if the arc of the equator EK, intercepted between the plane and the meridian, is subtracted from the arc PK of the same equator set between the plane and the declination-circle, there will remain the arc EP, which is similar to the arc HM (the Sun's distance from the meridian in the northern parallel). But if to the same arc of the equator EK the arc TK is added, which was shown equal to the arc PK, the arc ET will be produced, which is similar to the arc HR (the Sun's distance from the meridian in the opposite southern parallel).

[Margin: When the plane inclined on the northern side cuts the meridian between the arctic pole and the northern parallel.]

But if the plane is raised on the southern side above the horizon, and cuts the meridian between the horizon and the southern parallel, as in the fourth figure, we shall investigate the Sun's distance from the meridian in the same way as in the first figure, where the plane, inclined on the northern side, cuts the meridian between the horizon and the arctic pole. But if the plane cuts the meridian between the equator and the southern parallel, as in the fifth figure, the arc of the equator EK, set between the plane and the meridian, must be subtracted from the arc TK, which lies between the plane and the declination-circle, so that the arc ET is left, similar to the arc HR (the Sun's distance from the meridian in the southern parallel). And to the same arc EK the arc PK must be added, so that the arc EP is produced, similar to the arc HM (the Sun's distance from the meridian in the

opposite northern parallel). Finally, if the inclined plane, on the southern side, cuts the meridian between the equator and the northern parallel, or between the zenith of the place and the northern parallel, the Sun's distance from the meridian must be sought as in the third figure — where the plane inclined on the northern side cuts the meridian between the equator and the northern parallel — or as in the second figure, where the plane inclined on the northern side cuts the meridian between the arctic pole and the northern parallel.

[Margin: When the plane inclined on the northern side cuts the meridian between the equator and the northern parallel.]

[Margin: When the plane inclined on the southern side is set to the horizon, wherever it may cut the meridian — by what method the smaller distance of the Sun from the meridian is found when the Sun is on that plane.]

Thus far we have investigated the smaller arc of the Sun's distance from the meridian in any parallel from the smaller arc of the equator intercepted between the inclined plane and the meridian, such as EK. But if we subtract the said arc of the equator EK from the semicircle KL, there will remain the greater arc of the equator EL, which is intercepted on the other side between the plane and the meridian. Through this we shall explore, in exactly the same way, the greater distance of the Sun in any parallel — that is, the arc HN or HS — namely by adding the arc QL or VL to the arc EL, or by subtracting it, as has been said.

When the plane cuts the meridian between the equator and the northern parallel, as in the third figure — so that the parallel itself is cut by that plane at two points, one western and one eastern — the arc QL must be subtracted from the arc EL, so that the arc of the equator EQ is left, similar to the arc HN, that is, to the greater distance of the Sun from the meridian in the northern parallel. From this arc HN, if the smaller distance from the meridian HM is subtracted, there will be left, known, the arc MN of the northern parallel; and since, by proposition 19 of Book II of Theodosius, this is equal to the alternate segment of the opposite southern parallel, then if to the arc HR — the Sun's smaller distance from the meridian in the southern parallel — an arc equal to MN is added, the greater distance of the Sun from the meridian in the opposite southern parallel will be obtained.

Finally, when the plane cuts the meridian between the equator and the southern parallel, as in the fifth figure — so that the parallel itself is cut by that plane at two points, one eastern and one western — the arc VL must likewise be subtracted from the arc EL, so that the arc of the equator EV is left, similar to the arc HS, that is, to the greater distance of the Sun from the meridian in the

southern parallel. From this arc HS, if the smaller distance of the Sun from the meridian HR is subtracted, there will be left, known, the arc RS of the southern parallel; and since, by proposition 19 of Book II of Theodosius, this is equal to the alternate segment of the opposite northern parallel, then if to the arc HM — the Sun's smaller distance from the meridian in the northern parallel — an arc equal to RS is added, the greater distance of the Sun from the meridian in the opposite northern parallel will be obtained.

[Margin: When the parallel is cut at two points by the inclined plane, whether on the eastern or the western side — by what method the greater distance of the Sun from the meridian is inquired.]

We shall illustrate the whole matter with a single example. Let a plane be set erect to the horizon but declining from the true vertical by 30 degrees, from the meridian toward the east — the kind of dial-plane we described in proposition 1 of Book III — so that it is inclined to the meridian by 60 degrees. Let it be: as 100000, the whole sine, is to 86602, the sine of the plane's inclination to the meridian, so 74314, the sine of the complement of the arc of the meridian between the plane and the equator, is to a fourth term; and there will be found here approximately the sine 64357, to which corresponds an arc of 40 degrees 4 minutes, whose complement, 49 degrees 56 minutes, gives the angle EKI which the plane makes with the equator.

Again let it be: as 76529, the sine of the found angle EKI, is to 66913, the sine of the arc of the meridian between the equator and the plane, so 86602, the sine of the plane's inclination to the meridian, is to a fourth term; and there will be found here approximately the sine 75720, to which corresponds an arc of 49 degrees 13 minutes. Such is the arc of the equator EK, comprising 3 hours 17 minutes, by which the plane is illuminated by the Sun after noon on the southern side; while on the northern side it begins to be illuminated by the Sun at 3 hours 17 minutes from the meridian.

After this, let it be: as 76529, the sine of the found angle EKI which the plane makes with the equator, is to 39874, the sine of the declination of the parallel of Cancer [♋] or Capricorn [♐], so 100000, the whole sine, is to a fourth term; and there will be found here approximately the sine 52103, to which corresponds an arc of 31 degrees 24 minutes. Such is the arc KM of the inclined plane, intercepted between the equator and the parallel of Cancer.

Again let it be: as 91706, the sine of the complement of the declination of the parallel of Cancer or Capricorn, is to 85355, the sine of the complement of the arc

KM just found (which we said comprises 31 degrees 24 minutes), so 100000, the whole sine, is to a fourth term; and there will be found here approximately the sine 93075, to which corresponds an arc of 68 degrees 33 minutes, whose complement, 21 degrees 27 minutes, gives the arc of the equator KP, which is drawn between the inclined plane and the declination-circle set through the Sun on the inclined plane and the parallel of Cancer — an arc to which the arcs KT, LQ, LV have been shown equal.

And so, since the proposed example answers to the second figure — the southern face of the plane being turned toward the east — if the arc KP, 21 degrees 27 minutes, is subtracted from the arc of the equator EK, 49 degrees 13 minutes, there will remain the arc EP, and hence the arc HM similar to it, of 27 degrees 46 minutes, which comprises 1 hour 51 minutes. Therefore at 1 hour 51 minutes after noon the Sun, being on the parallel of Cancer, ceases to illuminate the southern face of the proposed plane.

But if we subtract the arc of the equator EK from the semicircle kL, there will remain the arc EL, 130 degrees 47 minutes; and if from this the arc LQ, 21 degrees 27 minutes, is again subtracted, there will remain the arc EQ, or its similar HN, 109 degrees 20 minutes, comprising 7 hours 17 minutes. Therefore at 4 hours 43 minutes after midnight the Sun, being on the parallel of Cancer, begins to illuminate the southern face of the proposed plane.

Now if we add the same arc KT, or LV, 21 degrees 27 minutes, to the arc EK, 49 degrees 13 minutes, and to the arc EL, 130 degrees 47 minutes, we shall find the arc HR, 70 degrees 40 minutes — that is, 4 hours 43 minutes — and the arc HS, 152 degrees 14 minutes — that is, 10 hours 9 minutes. Therefore the Sun, being on the parallel of Capricorn, ceases to illuminate the southern face of the plane at...

4 hours 43 minutes after noon, and begins to illuminate it at the first hour [numeral:?] after midnight. These distances from the meridian we have also found above.

But to inquire into the Sun's altitudes it is not altogether necessary to investigate how many hours are contained above the face of the proposed circle; for the computation itself will teach us whether the given hour falls above the offered face or above the opposite one — according as the difference between the sine of the meridian altitude and the sine of the Sun's altitude at the time of observation is smaller, or greater than the sine of the meridian altitude, as we said a little earlier in this proposition.

Diagram. The same five-figure set as is repeated here (top row of three spheres, lower row of two). This first sphere (top left) shows the meridian A (top) ... C (bottom) with centre E, and the oblique great circles (equator, horizon, inclined plane, declination-circles, parallels). Readable letter-labels: A, C, E, B, D, F, G, H, I, K, M, O, P, R, T. [— many labels [?].]

Diagram. Second sphere (top centre), same construction. Readable letter-labels: A, C, E, B, D, L, F, G, H, I, K, M, N, O, P, R, T, V. [— many labels [?].]

Diagram. Third sphere (top right), same construction. Readable letter-labels: A, C, E, D, F, G, H, I, K, L, M, N, O, P, Q, R, S, T. [— many labels [?].]

Diagram. Fourth sphere (lower left, larger), same construction, meridian A ... C with centre E. Readable letter-labels: A, C, E, B, D, F, G, H, I, K, L, M, N, O, P, Q, S, T, V. [— many labels [?].]

Diagram. Fifth sphere (lower right), same construction. Readable letter-labels: A, C, E, B, D, F, G, H, I, K, L, M, O, P, R, S, T, V. [— many labels [?].]

But so that the altitudes of all the hours may be computed more conveniently and easily, the distances from the meridian of the proposed circle above the horizon should be taken for all 24 hours of one parallel, and the altitudes of those same hours computed — of which some will fall above one face of the given circle and some above the opposite face — provided that those which before were reckoned from the meridian are now reckoned from midnight, and vice versa, and those which before were reckoned from sunset are now reckoned from sunrise, and vice versa. For these altitudes will be equal to the altitudes of the same hours of the opposite parallel. Likewise, those which before fell above one face of the given circle will now fall above the opposite face — as we shall presently demonstrate, if first, that the matter may be better understood, we illustrate it with a few examples.

[Margin: It is enough if the Sun's altitudes are computed for the hours of one parallel; for these are equal to the Sun's altitudes for the same hours of the opposite parallel.]

First, then, above the face of the vertical circle properly so called: on the southern side the antarctic pole is elevated 48 degrees, at latitude 42 degrees, and the complement of this altitude is 42 degrees. Therefore the meridian altitude of Cancer will comprise 18 degrees 30 minutes, to which corresponds the sine 31730; while the meridian depression is 65 degrees 30 minutes, to which corresponds the sine 90996. The half of the sum of the sine of the meridian

altitude of Cancer and the sine of the depression will be 61363. The distances which the hours reckoned from sunset have from the meridian above the horizon, in the parallel of Cancer (for the Sun, being at the beginning of Cancer, illuminates the southern face of the vertical circle both before and after noon), are the following — because the hour-circle of 16 hours 28 minutes and the parallel of Cancer cut the meridian above the horizon at one and the same point, so that the 16th hour is distant from the meridian toward the east by 0 hours 28 minutes, that is, 7 degrees 0 minutes; while the 17th hour is distant from it toward the west by 0 hours 32 minutes, that is, 8 degrees 0 minutes.

[Margin: Examples of the Sun's distances from the proper meridian of various great circles.]

The tables follow.

(Continuing the Scholium of Problema 1 of Book V. The Sun stands at the beginning of Cancer, at latitude 42°; the following tables — introduced by the "SEQVVNTVR TABELLÆ" of the previous opening — give, for each hour, the distance of the hour-circle from the meridian, and then the Sun's altitudes. Throughout, the zodiac glyphs are: ☊ = Cancer, ♈ = Aries, ♎ = Libra, ♐ = Capricorn. The paired headers "G." / "M." stand for Gradus (degrees) and Minuta (minutes); each cell is transcribed as printed, in the form "degrees. minutes.")

Table — Hours in Cancer (☊), reckoned from sunset; distances from the meridian (first part).

By the same reasoning, the distances from the meridian that the hours reckoned from sunrise have, in the same parallel of Cancer, are as follows — because the meridian cuts the parallel of Cancer at the hour of 7 hours 32 minutes after

sunrise. Therefore the 7th hour from sunrise is distant from the meridian toward the east by 0 hours 32 minutes, that is, 8 degrees 0 minutes; while the 8th hour from sunrise is distant from it toward the west by 0 hours 28 minutes, that is, 7 degrees 0 minutes.

Meridiano (G. M.)	0	.0	.0	.0	.0	.0	.0	.0	.0	.0	.0	.0

The distances from the meridian that the hours reckoned from noon and from midnight have — the same for all parallels, since the meridian cuts every parallel at the 12th hour of noon — are as follows.

Table — Hours from midnight / from noon; distances from the meridian.

Horæ à med. noc.	11	10	9	8	7	6	5	4	3	2	1
Horæ à merid.	1	2	3	4	5	6	7	8	9	10	11
Distantiæ à	15.	30.	45.	60.	75.	90.	105	120	135	150	165
Meridiano (G. M.)	0	0	0	0	0	0	.0	.0	.0	.0	.0

Next, above the southern face of a vertical circle that declines eastward by 30 degrees from the vertical circle properly so called: at latitude 42 degrees, the antarctic pole is elevated 40 degrees 3 minutes, and the complement of this altitude comprises 49 degrees 57 minutes. Therefore the meridian altitude of Cancer will comprise 26 degrees 27 minutes, to which corresponds the sine 44541; while the meridian depression is 73 degrees 27 minutes, whose sine is 95857. Half the sum of the said sine of the meridian altitude and the sine of the depression will be 70199. The distances which the hours reckoned from sunset, in the parallel of Cancer, have from the proposed meridian of the vertical circle above the horizon — because the Sun, standing at the beginning of Cancer, illuminates the southern face of that same vertical circle both before and after

noon — are as follows, since the proper meridian of that circle recedes from the meridian of the horizon toward the east by 40 degrees 48 minutes. Hence, since in the same parallel of Cancer the 14th hour is distant toward the east from noon by 37 degrees, if this distance is subtracted from 40 degrees 48 minutes, there remain 3 degrees 48 minutes for the distance of the 14th hour, reckoned from sunset, toward the west from the proper meridian of the declining vertical. Likewise, since the 13th hour recedes toward the east from noon by 52 degrees, if from these 40 degrees 48 minutes are taken away, there will remain 11 degrees 12 minutes for the distance of the 13th hour from that proper meridian toward the east.

Table — Hours in Cancer (♋), reckoned from sunset; distances from the proper meridian of the declining vertical (first part).

Likewise, the distances from the same proper meridian that the hours reckoned from sunrise have, in the same parallel of Cancer, are as follows — because the proper meridian of the said declining vertical circle recedes from the meridian of the horizon toward the east by 40 degrees 48 minutes. Hence, since in the parallel of Cancer the 5th hour from sunrise is distant toward the east from noon by 38 degrees, if this distance is subtracted from 40 degrees 48 minutes, there will remain 2 degrees 48 minutes for the distance of the 5th hour from sunrise from the proper meridian of the declining vertical, toward the west. Likewise, since the 4th hour from sunrise is distant toward the east from noon by 53 degrees, if from these 40 degrees 48 minutes are taken away, the remainder will be 12 degrees 12 minutes for the distance of the 4th hour from sunrise from that proper meridian toward the east.

Table — Hours in Cancer (♋), reckoned from sunrise; distances from the proper meridian of the declining vertical (first part).

	8	8	8	8	8	8	8					

But the distances which the hours reckoned from noon and from midnight have from the same meridian of the said vertical circle — the same in all parallels, since in all parallels the said meridian is distant from noon (that is, from the 12th hour) toward the east by 40 degrees 48 minutes, and hence the 9th hour from midnight is distant from that meridian toward the east by 4 degrees 12 minutes, while the 10th hour from midnight recedes from it toward the west by 10 degrees 48 minutes — are contained in the following table.

Table — Hours from midnight, then from noon (A meridie); distances from the proper meridian of the declining vertical (first part).

(The "A meridie" [at noon] column is a header cell only; its distance cell is left blank in the print.)

Now, care must be taken to set down together the distances of those hours contained in the eastern hemisphere and, separately, of those contained in the western, so that in laying out sundials we may more easily grasp which hours incline eastward from the line of the style (which serves as the meridian line) and which tend westward. Thus you see that in all the examples given above, the hours contained in the eastern hemisphere are placed first, and then those in the western. The eastern hemisphere, moreover, is separated from the western by the proper meridian circle of the proposed great circle, above which the Sun's altitudes are set for investigation.

[Margin: An easy way to find the Sun's distances from the proper meridian of the given great circle.]

You see, therefore, that the distances of all the hours from the proper meridian, in either hemisphere, can be found with no trouble, once the distances of the two nearest hours lying on either side of that meridian have first been found. For if 15 degrees are added to either distance, the distance of the next hour will be found; and so, by the continual addition of 15 degrees, the distances of all the hours will be found.

[Margin: The Sun's altitudes above one face of the given great circle, at each hour of one parallel, are equal to the Sun's altitudes above the other face of the same circle at the same hours of the opposite parallel.]

That the altitudes of all 24 hours of any parallel, found above any great circle, are equal to the altitudes of the same 24 hours of the opposite parallel above the same great circle — provided that those which before were counted from noon or from sunrise are now counted from midnight or from sunset, and those which before fell on one face of that great circle now fall on the opposite face, and vice versa — we shall prove as follows. Let some hour-circle, drawn through the poles

of the world, be understood to pass through that point of any parallel — namely ♊ (Capricorn) — where it is cut by the great circle above which the Sun's altitudes are set for investigation, and to pass, in the opposite parallel, namely ♋ (Cancer), through a point which [is set] diametrically opposite the former point through the sphere. For since the arc of the said hour-circle between the tropic point ♊ and the antarctic pole is equal to the arc of the same hour-circle between the tropic point ♋ and the arctic pole — because each arc is the complement of the declination of either tropic — if the common arc, less than a semicircle, between the tropic point ♊ and the arctic [pole] is added, the composite arcs become equal. Since, then, the arc comprehended between the two poles is a semicircle, the other arc between the said two [points] will also be a semicircle. This can be perceived more clearly than daylight from a material sphere, if the said hour-circle is imagined, in any position whatever, to be a colure of the equinoxes — so that where it cuts the tropic ♊ above the horizon, through that point [a great circle is understood to pass]. Thereby it comes about that the same [colure] necessarily passes through the point where that same great circle [cuts it]; for there the hour-circle is cut in two, since that point is [opposite] through a diameter, as we have shown, and by Proposition 11 of Book 1 of Theodosius, [that] all great circles in a sphere mutually [bisect one another]. If, then, the point of the earlier parallel belongs to some hour reckoned from noon, the later [point] of the other [parallel] will belong to [the same hour reckoned] from midnight, and conversely; likewise, if the earlier point looks to the hours reckoned from sunset in the earlier parallel,

it will [in the] later [parallel] look to the hours reckoned from sunrise in the opposite parallel, and conversely — because these points lie in different semicircles of the said hour-circle, as is evident; and that different semicircles belong to different hours (so that one indicates the hour from noon or from sunset, the other the same hour from midnight or from sunrise) we showed in Propositions 9 and 10 of Book 1. Nor does it matter that the said hour-circle is not an hour-circle of [the hours reckoned] from sunrise or from sunset, since it is supposed to pass through the poles; for if through those same two points of the opposite parallels an hour-circle of [the hours] from sunrise or from sunset were understood to be drawn — one that would of course touch the greatest of the ever-apparent parallels — those two points would still lie in different semicircles of this circle. From this it comes about that, by as much as the hours reckoned from noon or from sunset are distant from the earlier point, proceeding against the succession of the signs, by just so much are the hours reckoned from midnight or from sunrise distant from the later point, and conversely — yet in such a way that, if those [former] hours stand above the northern or upper face

of the proposed circle and are in the southern parallel, these [latter] stand above the opposite face, namely the southern or lower, and in the opposite, northern parallel, as is evident from a material sphere. Since, then, those two opposite parallels have equal inclinations to the proposed great circle, the hours reckoned from noon or from sunset will have, above one face of the said great circle, the same altitudes that the opposite hours reckoned from midnight or from sunrise have above the other face. All of which the very computation of the Sun's altitudes will teach more clearly than daylight.

There now follow the tables of the Sun's altitudes above all the great circles from which the dials of Books 2 and 3 are equidistant — computed partly for the hours reckoned from noon and midnight, partly for the hours reckoned from sunrise and sunset, and also for unequal hours, at the northern latitude of 42 degrees, with the Sun traversing the tropic of Cancer (♋), the Equator, and the tropic of Capricorn (♐). Similar tables can be drawn up, by the same rules, for any other great circles whatever, and for any other latitudes, and with the Sun traversing any parallel whatever — for hours whether equal or unequal, whether these be whole hours, halves, quarters, or other fractions of hours — provided their distance from the meridians of the said great circles is correctly taken, as we taught above. Now any hours equally distant on either side from the proper meridian of the proposed great circle have equal altitudes, as happens on the horizon, on the vertical circle, on the meridian, and on the circle of the 6th hour from noon or from midnight, as regards the hours numbered from noon and from midnight, and so on.

Moreover, in tables 3, 4, 10, and 11 we have computed the Sun's altitudes above both faces of the vertical circle properly so called and of the declining vertical, so that you may also learn by example that the hours of Cancer reckoned from noon have, above the southern face, the same altitudes that the hours of Capricorn reckoned from midnight have above the northern face, and vice versa, as we have just demonstrated.

I. The Sun's altitudes above the horizon, computed for the hours reckoned from noon and from midnight, at latitude 42 degrees.

These three pages continue, without a break, the table series of the Scholium to Problema 1 of Book V (begun in the preceding pages under "SEQVVNTVR TABELLÆ"). They consist entirely of the Sun's altitude tables. Each table's Latin row-labels are kept verbatim; the standard phrases are:

- *Horæ [sign], à med.noc.* = "Hours of [sign], reckoned from midnight"
- *Horæ [sign], à meridie.* = "Hours of [sign], reckoned from noon"
- *Horæ [sign], ab occasu.* = "Hours of [sign], reckoned from sunset"
- *Altitudines Solis (G. M.)* = "The Sun's altitudes (degrees. minutes)"

Zodiac sorts: ♈ Aries, ♎ Libra, ☊ Cancer, ♐ Capricorn.

[Continuation of Table II — The Sun's altitudes above the horizon,
computed for the hours reckoned from sunset, at latitude 42 degrees]

Aries and Libra (♈ & ♎): — each column carries two hour-labels (symmetric
about hour 18 = noon).

Altitudines Solis (G. M.)	71. 7	62. 42	52. 0	—	40. 38	29. 10	17. 56	7. 11

Aries and Libra (♈ & ♎):

Horæ ♈, & ♎, à med.no.	4	5	6	7	8	9	†
Altitudines Solis (G. M.)	8. 15	19. 28	30. 1	39. 17	46. 18	49. 46	49. 57

Book Five (continued)

These pages continue the run of hour-and-altitude tables from Problem 1's Scholium in Book Five. All altitudes are given as "G. M." — degrees (gradus) and minutes (minuta). A cross (†) placed in a column, in place of an hour, marks the meridian altitude (see the note below the first table). A blank cell headed "A meridie" separates the hours reckoned from midnight from those reckoned from noon.

Table X (concluded)

Concluding the table begun on the preceding page: the Sun's altitudes above the southern face of a vertical circle declining from the meridian toward the east by 30 degrees, at latitude 42 degrees.

Aries and Libra (♈ & ♎) — afternoon portion (the morning portion stands on the preceding page):

Horæ ♈, & ♎, à med. noc.	10	11	12	A meridie.	1	2	3
Alt. Solis (G. M.)	48. 45	43. 34	35. 25	—	25. 29	14. 35	3. 13

Cancer (♋):

Horæ ♋, à media nocte.	5	6	7	8	9	†	10	11	12	A meridi e.	1
Alt. Solis (G. M.)	2. 48	11. 40	18. 54	23. 57	26. 20	26. 27	25. 39	22. . 3	15. 57	—	8. 2

In this table, and in those that follow, the value placed beneath this sign † is the meridian altitude — that is, the altitude the Sun has above the circle in question when it stands on that circle's own meridian. Since no whole hour falls exactly on that meridian, I have chosen to put the said sign in place of an hour, and to record the meridian altitude beneath it.

[Margin: What the cross-sign signifies in the tables.]

XI. The Sun's altitudes above the northern face of a vertical circle declining from the north toward the west by 30 degrees, computed for the hours reckoned from noon and from midnight, at latitude 42 degrees.

Cancer (♋):

Hor. ♋, à merid.	2	3	4	5	6	7	8	9	†
Alt. Solis (G. M.)	1. 28	11. 50	22. 50	34. 12	45. 40	56. 51	66. 51	73. 4	73. 27

Horæ ♋, à merid.	10	11	12	A med. nocte.	1	2	3	4
Alt. Solis (G. M.)	71. 7	61. 42 [?]	52. 0	—	40. 38	29. 10	17. 56	7. 11

Aries and Libra (♈ & ♎):

Horæ ♈, & ♎, à mer.	4	5	6	7	8	9	†
Alt. Solis (G. M.)	8. 15	19. 28	30. 1	39. 17	46. 18	49. 46	49. 57

Horæ ♈, & ♎, à mer.	10	11	12	A med. nocte.	1	2	3
Alt. Solis (G. M.)	48. 45	43. 34	35. 25	—	25. 29	14. 35	3. 13

Capricorn (♐):

Hor. ♊, à merid.	5	6	7	8	9	†	10	11	12	A me. noct.	1
Alt. Solis (G. M.)	2.	11.	20.	23.	26.	26.	25.	22.	15.	—	8.
	48	40	7	57	20	27	39	3	57		2

You see, then, from tables 3, 4, 10 and 11, that the Sun has the same altitudes on both faces of a vertical circle — whether one properly so called or a declining one — at the same numbered hours, provided that the hours counted from noon in the Cancer parallel on one face are counted, on the other face, in the Capricorn parallel from midnight, and vice versa. The same is to be understood for the other planes that follow. We have, moreover, set out the hours and their altitudes for one face only.

XII. The Sun's altitudes above the southern face of a vertical circle declining from the south toward the east by 30 degrees, computed for the hours reckoned from sunset, at latitude 42 degrees.

Capricorn (♑):

Hor. ♑, ab occasu.	10	11	12	13	14	15	16	†
Alt. Solis (G. M.)	6.	16.	28.	39.	50.	61.	70.	73.
	13	55	7	33	57	45	31	27

(Table XII, Capricorn, continued from the foot of the previous page:)

Hor. ♑, ab occasu.	17	18	19	20	21	22	23	24
Alt. Solis (G. M.)	73.	67.	57.	46.	35.	23.	12.	2.
	17	40	51	44	16	53	51	24

Aries and Libra (♈ & ♎):

Horæ ♈, & ♎, ab occasu.	10	11	12	13	14	15	†
Alt. Solis (G. M.)	8.	19. 28	30.	39. 17	46. 18	49. 46	49. 57
	15		1				

Horæ ♈, & ♎, ab occasu.	16	17	18	19	20	21
Alt. Solis (G. M.)	48. 45	43. 34	35. 25	25. 29	14. 35	3. 13

Cancer (♋):

Horæ ☿, ab occa.	10	11	12	13	†	14	15	16	17	18
Alt. Solis (G. M.)	7.	15.	21.	25.	26.	26.	24.	19.	11.	3.
	42	46	55	36	27	21	5	4	53	3

To help you understand the principle by which the Sun's altitudes above one face of a great circle equal its altitudes above the other face at the same hours — with the hours reckoned from noon or from sunset converted into hours reckoned from midnight or from sunrise, and the northern parallels changed into southern ones, and vice versa — I will make the matter clear with an example or two. Suppose, for instance, that the Sun's altitude is to be found above the northern face of a vertical circle declining from the north toward the west by 30 degrees, at hour 13 from sunrise, in the parallel of Cancer. I look up hour 13 from sunset in the parallel of Capricorn, whose altitude above the southern face of the said vertical circle amounts to 39 degrees 33 minutes. The Sun, therefore, has that same altitude at hour 13 from sunrise in the parallel of Cancer, above the northern face of the vertical circle in question. In the same way, since the Sun at hour 10 from midnight in the parallel of Cancer has, above the southern face of the same vertical circle, an altitude of 25 degrees 39 minutes, the Sun will have the same altitude at hour 10 from noon in the parallel of Capricorn, above the northern face of the same vertical circle — as is evident from tables 10 and 11. Finally, since above the superior face of a great circle declining 30 degrees from the horizon and standing at right angles to the vertical circle properly so called (the one that faces the zenith and the west), the Sun at hour 4 from noon in the parallel of Cancer has an altitude of 67 degrees 24 minutes — as appears from the following table — the Sun will have the same altitude at hour 4 from midnight in the parallel of Capricorn, above the inferior face of the same great circle, and so on. The same is to be understood for all the other tables.

[Margin: How the same altitudes are also fitted to the opposite faces of great circles.]

XIII. The Sun's altitudes above the superior face of a great circle declining 30 degrees from the horizon and standing at right angles to the vertical circle properly so called (the one facing the zenith and the west), computed for the hours reckoned from noon and from midnight, at latitude 42 degrees.

Cancer (☿):

Horæ ☾, à media noc.	8	9	10	11	12	A meridie.	1	2	†

Alt. Solis (G. M.)	20. 0	19. 17	17. 14	14. 0	9. 51	5. 5	0. 0

The Sun, when it is in the parallel of Capricorn, does not illuminate the superior face of this circle but only the inferior one; therefore there are no altitudes of the hours of the Capricorn parallel above the superior face. And the gnomon's shadow, when the Sun is at the first point of Cancer, describes an ellipse.

This opening continues the long series of numbered altitude tables in the Scholium to Problema 1 of Book V (*Liber Quintus*). Each table gives the Sun's altitudes above the upper face of a particular declining-and-inclined great circle, computed for latitude 42°. The tables are printed as bare numbered rubrics with no connecting prose; the altitudes are given in the printed "degrees. minutes" form (e.g. 9. 16 = 9°16'). The dagger † marks the meridian (culmination) column; A meridie divides the midnight-reckoned hours from the noon-reckoned ones.

XVI.

XVI. The Sun's altitudes above the upper face of a great circle declining from the meridian toward the east by 40°, and inclined to the horizon on its northern side by 20°, computed for the hours reckoned from noon and from midnight, for latitude 42°.

Hor. ☿ [Cancer], à med.

Horæ ♐, inæquales	8	9	10	11	12	Hora 1, ♓ & ♒ [Pisces & Aquarius]
Alt. Solis (G. M.)	87. 45	78. 21	68. 17	58. 12	48. 9	17. 25

We have here also added the Sun's altitude for the first unequal hour in the parallel of Pisces [♓] and Aquarius [♒], because from the length of the shadow belonging to this altitude the first unequal hour is to be drawn on the sundial that lies parallel to

this great circle — the circle above which the Sun's altitudes have been computed — as will become clear in its proper place.

The tropic of Capricorn [♋] does not cut this great circle, but lies wholly below it, just as the tropic of Cancer [♋] stands wholly above it. Hence it comes about that, when the Sun is at the first point of Cancer, the gnomon's shadow traces an ellipse on the upper face of the said circle; but when the Sun is at the first point of Capricorn, it does not illuminate that face, but the lower one. Therefore no altitudes of the Sun are given for the hours of the tropic of Capricorn.

XX.

XX. The Sun's altitudes above the upper face of a great circle declining from the north toward the east by 60° , and inclined to the horizon on its southern side by 80° , computed for the hours reckoned from the setting (west), for latitude 42° .

No solar altitudes for the hours of Cancer are set down here, because the whole tropic of Cancer stands above the lower face of this circle, just as the whole tropic of Capricorn stands above its upper face. Hence, when the Sun lies in Cancer it does not illuminate the upper face; but when it lies in Capricorn the shadow of the gnomon traces an ellipse on the upper face.

PROBLEMA 2. PROPOS. 2. [Problem 2, Proposition 2]

Given the Sun's altitude above any plane, to find the ratio of the gnomon to its shadow — both to the right shadow [vmbra recta] and to the versed shadow [vmbra versa]; and conversely, from the ratio of the shadow (whether right or versed) to the gnomon, to derive the Sun's altitude.

Diagram. A circle with two diameters crossing at right angles at the centre E: the vertical diameter AC (A at top, C at bottom) and the horizontal diameter BD (B at left, D at right). From the centre E a ray runs up to the right to the point I on the circumference (the Sun's centre), so that the line IE produced passes through E toward C. From I a perpendicular IK is dropped onto the diameter BD, meeting it at K (between E and D). On the left half, two short verticals descend from the horizontal diameter BD at the points H and L (H to the left, L just to its right) down to a lower horizontal chord; G lies on that lower chord at the foot below H,

and F lies on it below E; M lies between the verticals, on the oblique line running from L down toward G.

- A (top of circle): pole of the proposed plane; top of the vertical diameter AC
- B (left of circle): left end of the horizontal diameter BD
- C (bottom of circle): bottom of the vertical diameter AC
- D (right of circle): right end of the horizontal diameter BD
- E (centre): intersection of the diameters; vertex of the gnomon / centre of the world
- I (upper right, on circle): the Sun's centre
- K (on BD, between E and D): foot of the perpendicular IK dropped from I
- F (lower middle, below E): tip of the right shadow FG
- G (lower left): common endpoint of the two shadow-lines FG and HG
- H (on BD, left of centre): foot of the style EH
- L (on BD, just right of H): end of the style EL (taken equal to the gnomon EF)
- M (below H/L): endpoint of the versed shadow LM

Let a circle ABCD be drawn, together with the diameters AC and BD, which cut one another at right angles at the centre E. Suppose this circle to be drawn through the Sun's centre, placed at I, and through A, the pole of the proposed plane; and let the straight line BD be the common section of this same circle and of the great circle to which the plane is parallel. On these assumptions, AC will be the axis of the proposed plane. Let EF be equal to the gnomon standing perpendicular to the plane — drawn through the straight line FG parallel to the great circle of diameter BD; and let EH be equal to the gnomon standing perpendicular to the plane — drawn through the straight line HG, parallel to the great circle that is drawn through AC and stands perpendicular to the circle ABCD. From I, the Sun's centre, let the ray IE fall, passing through the centre of the world (that is, through the vertex of each gnomon), so that it meets the straight line FG at G and the straight line AG [recte: HG] at G.

Now, by Proposition 11 of Book I, the shadow of the style EF is projected onto the straight line FG, the common section of the plane and of the great circle ABCD in which the Sun lies; while the shadow of the style EH falls onto the straight line HG, the common section of the other plane and of the same great circle ABCD. It follows, from what we demonstrated in Proposition 2 of Book I and in the *Quadratum Geometricum* [Geometrical Square], that FG is the length of the right shadow and HG the length of the versed shadow.

[Margin: By what method the length of the right shadow is to be investigated from the Sun's altitude. — a: (*Elements*) I.29; b: VI.4]

Now drop the perpendicular IK from I onto BD. Since the triangles EIK and GEF are similar — because angle GEF equals angle EIK (the exterior equal to the interior), and the right angle at F equals the right angle at K, and so on — it follows that as IK, the right sine of the Sun's altitude, is to KE, the sine of the complement of that altitude, so EF, the gnomon, is to FG, the right shadow. Therefore, if we set it thus: as the sine of the known solar altitude is to the sine of its complement, so the gnomon — divided into any number of equal parts (we take it to be divided into 12 equal parts) — is to a fourth term, then the length of the right shadow will be found, expressed in the same parts into which the gnomon is divided. For example, when the Sun has an altitude of 30°: if we set 50000 (the sine of the Sun's altitude) to 86602 (the sine of the complement of that altitude) as the gnomon of 12 parts is to a fourth term, the right shadow will be found to be 20 parts 47 minutes, of the kind of which the gnomon is reckoned as twelve.

[Margin: c: (*Elements*) I.15; d: VI.4]

By the same reasoning, since the triangles GEH and IEK are similar — because the vertical angles at E are equal, and the angles at H and K are right, and so on — it follows that as EK, the sine of the complement of the Sun's altitude, is to KI, the sine of that altitude, so EH, the style, is to HG, the versed shadow. So if we set it thus: as the sine of the complement of the known solar altitude is to the sine of the solar altitude, so the gnomon is to a fourth term, then the versed shadow will be found in parts equal to those into which the gnomon is divided. As in the same example: if we set 86602 (the sine of the complement of the Sun's altitude) to 50000 (the sine of that altitude) as 12 is to a fourth term, the versed shadow will be found to be 6 parts 56 minutes, of the kind of which the gnomon contains 12.

[Margin: The way by which the length of the versed shadow is to be explored from the Sun's altitude. — e: (*Elements*) I.47; f: VI.4; g: VI.22]

Again, if the shadow — whether right or versed — is known, then the squares described on the shadow and on the gnomon will be known; and since these are together equal to the square on the straight line EG, the square on EG will also be known. And since, by the similarity of the triangles EGF and EIK, EG is to EF as EI, the whole sine, is to IK, the sine of the Sun's altitude, it will likewise follow that as the square on EG is to the square on the gnomon EF, so the square of the whole sine EI is to the square of the sine of the Sun's altitude IK; and thus, from the

known square of IK, the sine IK itself will be known. Or, more briefly: from the known square on EG, the straight line EG itself will be known. If, then, we set EG (known) to the gnomon EF as the whole sine EI is to a fourth term, the sine IK of the Sun's altitude will be known. In the same way, since — by the similarity of the triangles EGH and EIK — as GH is to EH, so EI is to IK, it will likewise follow that as the known square on EG is to the known square on the versed shadow GH, so the square of the whole sine EI is to the square of the sine of the Sun's altitude IK; and hence, from the square of IK, the sine IK itself will be found. Or, more briefly: from the square on EG, the straight line EG itself will be known. If, then, we set EG (known) to the versed shadow GH as the whole sine EI is to a fourth term, the sine IK of the Sun's altitude will be found. Therefore, from the Sun's altitude known above any plane, we have derived the ratio, and so on. Which was to be done.

[Margin: The manner in which the Sun's altitude is sought from the length of the shadow, whether right or versed. — h: (*Elements*) VI.4; i: VI.22]

SCHOLIUM. [Scholium]

Since, by the similarity of the triangles EFG and EHG, the right shadow FG is to the gnomon EF as the gnomon EH is to the versed shadow HG — and the same holds if the style EL is taken equal to the gnomon EF, so that the versed shadow is LM — it follows that any gnomon whatever is a mean proportional between the right shadow and the versed shadow cast by that same gnomon.

Likewise, if the circle drawn through AC is conceived to be the horizon, FG is the versed shadow of the style EF — entirely the same, that is, as the shadow which was previously the right shadow

of that same style EF with respect to the horizon drawn through BD; and since AI is the Sun's altitude above the horizon drawn through AC, while DI is the complement of the altitude above the earlier horizon, the result is that the right shadow of any solar altitude above the horizon is exactly the same as the versed shadow of the complement of that altitude above the same horizon. This is also clear from what has been demonstrated. For since (as we showed) the gnomon is to the versed shadow as the sine of the complement of the Sun's altitude is to the sine of that altitude — and, taking a solar altitude that is the complement of the altitude DI, so that DI is in turn the complement of that altitude — the straight line IK is the sine of the complement of the altitude, and EK the sine of the altitude itself; then, since IK is to KE as EF is to FG, the straight line FG, which was previously the right shadow, becomes in this case the versed shadow, and so on.

[Margin: The right shadow of any solar altitude above the horizon is the same as the versed shadow of the complement of that same altitude above the horizon. How the lengths of the shadows are to be taken from the following table if the style is divided into more or fewer parts than 12.]

Since this is so, one and the same table will comprehend both the right and the versed shadows, provided that the Sun's altitudes are placed in one part of the table and their complements in the other — as you see has been done in the following table. In it are contained the lengths of the shadows, both right and versed, expressed in parts of which the gnomon is 12, computed for each degree and minute of the Sun's altitude. In the sundials of this book, however, we shall use only the right shadows (as we did in the earlier books too), since the gnomon always stands perpendicular to the planes of those sundials. And what we have said about the horizon must be understood of every plane as well, since every great circle to which the plane of a sundial is parallel is a horizon in some region, as is evident.

But if ever the gnomon is of such a size that it can conveniently be divided into more parts — as into 24 — then each shadow of the following table must be doubled. And if the gnomon is divided into 36 parts, they must be tripled; quadrupled if into 48; and quintupled if into 60 — because in this way the same ratio is always preserved, since the parts stand in the same ratio to their equal multiples. Similarly, if the style is so small that it cannot conveniently be divided into 12 parts, let it be divided into 6, and let the halves of the individual shadows be taken, and so on.

[Margin: a: (*Elements*) V.15]

SEQVITVR TABVLA VMBRARVM. [There follows the table of shadows.]

Table of shadows — Degrees of the Sun's altitude for right shadows [*Gradus altitudinum Solis pro vmbris rectis*].

Column headers as printed: the top band reads **Grad.** over the first degree-column and **G.** over each of the others; beneath run the degree numbers **0–9**; beneath those the sub-heads **Par. Mi.** (for degree 0) and **P. ... M.** (partes / minuta) for degrees 1–9. The leftmost **M.** column is the minute-argument (0–60) read downward with the top degree-labels (0–9) for the **right shadow** [*Minuta altitudinum Solis pro vmbris rectis*]; the rightmost **M.** column (60→0) is read upward with the bottom degree-labels (89–80) for the **versed shadow** [*Minuta altitudinum Solis pro vmbris versis*]. Each shadow-length cell is given as *partes. minuta*, gnomon = 12 partes.

Book V — Table of Shadows (continued)

This opening continues the great Tabula umbrarum (shadow table) of Book V begun on the preceding pages. It tabulates, for each degree of the Sun's altitude, the length of the shadow cast by a gnomon of 12 partes. The three pages here cover the Sun's altitude from 10° through 39°.

Each table is read two ways (dual entry):

- **Right (direct) shadows** [umbrae rectae] — enter with the **top** degree headings (10–19, 20–29, 30–39) and the **left** minute-argument column (0 → 60). The rotated title in the left margin reads "*Minuta altitudinum Solis pro umbris rectis*" (minutes of the Sun's altitude for right shadows).
- **Versed (turned) shadows** [umbrae versae] — enter with the **bottom** degree labels and the **right** minute-argument column (60 → 0). The rotated title in the right margin reads "*Minuta altitudinum Solis pro umbris versis*" (minutes of the Sun's altitude for versed shadows).

Every cell is partes. minuta (P. M.), the gnomon being 12 partes.

running header: GNOMONICES · *Gradus altitudinum Solis pro umbris rectis* (Sun's-altitude degrees for right shadows)

Degrees of altitude 10–19 (top, right shadows) / 79–70 (bottom, versed shadows).

Lower rubric (foot of page): *Gradus altitudinum Solis pro umbris versis* (Sun's-altitude degrees for versed shadows).

LIBER QVINTVS · 401 — *Gradus altitudinum Solis pro umbris rectis*

Degrees of altitude 20–29 (top, right shadows) / 69–60 (bottom, versed shadows).

Lower rubric (foot of page): *Gradus altitudinum Solis pro umbris versis.*

Gnomonics, Book V — *Tabula umbrarum* (continued)

(Continuation of the twelve-part gnomon shadow table. Each page tabulates shadow length in partes and minuta (P. M — twelfths and sixtieths-of-a-twelfth of the gnomon) for whole degrees of solar altitude read across the head, against the minutes of altitude read down. The left-hand minute argument (0–60) and the centred head-rubric "Degrees of the Sun's altitude, for right shadows" serve the umbra recta; the right-hand minute argument (60–0) and the foot-rubric "Degrees of the Sun's altitude, for versed shadows," with the degree labels along the foot, serve the* umbra versa*. The rotated marginal titles read "Minutes of the Sun's altitude, for right shadows" (left) and "...for versed shadows" (right).)**

[Source page 403] — running header "LIBER QVINTVS."

Head-rubric (centred): *Gradus altitudinum Solis pro umbris rectis.* — "Degrees of the Sun's altitude, for right shadows."

Degree columns 40°–49° (umbra recta, read with the left minute-column); the same body serves degrees 49°–40° for the umbra versa (read with the foot labels and the right minute-column).

Foot-rubric: *Gradus altitudinum Solis pro umbris versis.*

Gnomonics, Liber V — *Tabula umbrarum* (concl.) and Problema 3

(Batch covers = printed folios 406–408. The twelve-part table of shadow lengths [*Tabula umbrarum*] of Book V concludes on folios 406–407, whereupon the discursive text resumes with the use of the table and Problema 3.)

Folio 406 — Table of shadow lengths, Sun's altitude 70°–89° (right shadows) / 19°–0° (versed shadows)

Centred sub-rubric: *Gradus altitudinum Solis pro umbris rectis.* — Degrees of the Sun's altitude for **right (direct) shadows** (read from the top, entering the altitude-degree along the top and its minutes down the **left** margin).

Rotated left-margin title: *Minuta altitudinum Solis pro umbris rectis* — Minutes of the Sun's altitude for right shadows. Rotated right-margin title: *Minuta*

altitudinum Solis pro umbris versis — Minutes of the Sun's altitude for versed shadows.

Each cell gives the shadow length in **partes. minuta** (parts and sixtieths) for a gnomon of 12 parts; e.g. 4.22 = 4 parts 22 minutes. M. = minutes of altitude (left argument, right shadows). The final column is the minutes of altitude for **versed** shadows (right argument, read upward with the bottom degree row).

Foot-rubric: *Gradus altitudinum Solis pro umbris versis.*

Folio 408 — Resumption of the text

[Margin: *The use of the preceding table of shadow lengths.*]

Now the use of this table — which is general, and fitted to every clime — is as follows. Given the altitude of the Sun, look up its degrees in the upper part of the table, and the minutes, if there are any, in the left-hand margin. At once, in the cell where they meet, you will find the parts and minutes of the **right (direct) shadow**, reckoned in the units of which the gnomon contains twelve. But if the

degrees are taken in the lower part of the table, and the minutes, if there are any, in the right-hand margin, then in the common cell you will find the parts and minutes of the **versed shadow**. For example, if the length of the right shadow is sought for a Sun's altitude of 64° , we shall find it to contain 5 parts 51 minutes. The same shadow, when the Sun has an altitude of $31^\circ 30'$, will span 19 parts 35 minutes, and so on. Likewise, if the versed shadow is sought for a Sun's altitude of 26° , we shall find it to span 5 parts 51 minutes; whereas, when the Sun has an altitude of $58^\circ 30'$, it will be 19 parts 35 minutes, and so on.

[Margin: *The lengths of the solstitial, equinoctial, and brumal (winter-solstice) shadows — how, by what method, they are found from the preceding table for any latitude of place.*]

From this same table we shall also learn the lengths of the solstitial, equinoctial, and brumal shadows for any latitude of place — a purpose for which many authors have composed special tables. For if the meridian altitude at either solstice is taken, we shall find from it the shadow's length more quickly than can be told. And for the equinoctial shadow, one must look up in the table the complement of the pole's elevation; for so great is the meridian altitude then, and so on. Thus at latitude 42° , the meridian altitude of the first point of φ (Cancer) is $71^\circ 30'$, to which there correspond in the table 4 parts 1 minute, for the length of the right solstitial shadow. Again, the meridian altitude of the first point of γ (Aries) or ζ (Libra) is 48° , to which in the same table there answer 10 parts 48 minutes, for the right equinoctial shadow. Finally, the meridian altitude of the first point of ψ (Capricorn) is $24^\circ 30'$; therefore the right brumal shadow will span 26 parts 20 minutes, and so with the rest.

[Margin: *How, geometrically, the length of the shadow is found from the Sun's altitude.*]

Geometrically, too, the length of the right shadow for any altitude of the Sun is found in this way. In any circle — for instance in the one we drew above in this proposition — draw two straight lines A C and B D cutting one another at right angles in the centre E. On AC take a straight segment EF equal to the gnomon whose shadow-length is being sought, and through F draw FG parallel to BD. Lastly, from point D (or from B) toward A, count off the Sun's altitude up to a point I, which in the worked example comes to about 38° . For a straight line IE drawn from I through the centre E will cut the line FG in G, and F G will be the length of the right shadow for the given Sun's altitude D I, as we demonstrated above. In the same way HG will be the versed shadow, if the segment EH is taken equal to the gnomon and through H a parallel HG to AC is drawn.

PROBLEMA 3. PROPOS. 3.

To investigate the arc of any great circle intercepted between that circle's own Vertical [circle], properly so called, and the Vertical circle which at any given hour is drawn through the centre of the Sun.

[Margin: *By what route the arc of any great circle, intercepted between its own Vertical properly so called and the other Vertical which is drawn through the Sun, is to be sought.*]

Let the third figure of proposition 36, book 1 be repeated, in which ABCD is the proposed great circle — whether it be the Horizon or not; BED is its own proper Meridian, drawn of course through its poles and through the poles of the world; AFC is the Vertical circle of the proposed circle, properly so called, passing namely through the poles of that circle and through the poles of its proper Meridian; ELO is the Vertical drawn through the centre of the Sun, placed at L; and NL is the hour-circle passing through the poles of the world and through the centre of the Sun at the proposed hour. Then AO will be the arc lying between the said two Vertical circles, which we shall find as follows. Since, in the spherical triangle ENL — by proposition 17, book 4 of Johannes Regiomontanus, *On triangles* [Regiomontanus, *De triangulis* IV.17], or by proposition 13, book 1 of Geber [Jābir ibn Aflāḥ, *Gebri*, I.13], or by proposition 41 of our own [treatise] on spherical triangles — it holds that, as the sine of arc EL, the complement of the Sun's altitude above the proposed circle, is to

Diagram 1. The first (largest) of three spherical schematics illustrating the construction of Problema 3. A great circle ABCD is drawn with several interior great-circle arcs. Readable labels and their positions:

- B (top of circle) — top pole of the proper Vertical
- D (bottom of circle) — opposite pole
- A (left of circle) — point of the proper Vertical AFC
- C (right of circle) — opposite point of AFC
- Q (upper-left, interior) — [?] point on an interior arc
- F (upper-centre, on the meridian BED) — pole/intersection
- H (centre, on the meridian, below F)
- E (centre of the sphere)
- P (just below E, on the meridian)
- N (below P, on the meridian) — foot of the hour-circle NL
- L (centre-left, position of the Sun's centre)

- M (upper-left of L, interior)
- K (lower-left of L, interior)
- O (left, on the proper Vertical, between A and L)
- G (lower-left of circle)
- I (lower-right of circle)

Diagram 2. The second, smaller spherical schematic of the same construction (a different position of the Sun). Readable labels:

- A (upper) — point of the proper Vertical
- C (upper-left) — opposite point
- M (interior, near A)
- K (interior, right of M)
- O (interior, below M) — [?]
- L (interior, below O) — Sun's centre
- G (lower) — lower point
- Q (upper, faint) — [?]

(The peripheral cardinal points B/D of this compressed sphere are not separately legible on the scan.)

Diagram 3. The third spherical schematic of the same construction (yet another position of the Sun). Readable labels:

- B (top of circle)
- D (bottom of circle)
- C (right of circle)
- F (upper-centre, on the meridian)
- H (centre, on the meridian, below F)
- E (centre of the sphere)
- N (below E, on the meridian)
- P (below N, on the meridian)
- I (lower-right of circle)
- K (left interior) — [?]
- L (left interior, Sun's centre)

(The far-left point A of this sphere falls at the cropped edge of the scan.)

the sine of angle ENL, the distance of the Sun from the Meridian of the proposed circle, so is the sine of arc NL, the complement of the declination (for when the

Sun is in a southern parallel, as in the fourth circle, the arc N L has the same sine as the remaining arc of the semicircle included between L and the other pole, which is the complement of the declination LM), to the sine of angle NEL. If, then, it be made that as the sine of the complement of the Sun's altitude is to the sine of the Sun's distance from the Meridian of the proposed circle, so is the sine of the complement of the declination to a fourth [sine], the sine of angle N E L will be found — that is, of arc DO, whose complement is AO, the arc sought — which we shall thus investigate from arc DO. If the Sun stands beyond the proper Vertical, toward the hidden pole, as in the first and fourth circles (how this is recognized will be explained shortly in a scholium), we shall subtract from the quadrant AB the arc BO owed to the found sine of angle BEO (for this angle, or arc BO, has the same sine as angle NEL, or arc DO, since those two angles are equal to two right angles, and the said two arcs make up a semicircle), and there will remain the arc sought, AO, known, toward the hidden pole. But if the Sun is found on the near side of the Vertical properly so called, toward the visible pole, as in the second, third, and sixth circles, we shall take away from the quadrant AD the arc DO answering to the found sine of angle NEL, and there will be left the arc sought, AO, toward the visible pole.

[Margin: *The same arc is more easily investigated at the time of the equinoxes.*]

The problem is made **easier**, however, when the Sun is on the Equator, because then the multiplication is by the whole sine [radius]. For if, in the first circle, the parallel GHI be conceived to be the Equator — so that the proper Vertical passes through G and I, and the arc sought is GO — then the arc N L will be a quadrant, to which corresponds the whole sine,

the whole sine [radius] — and not the sine of the complement of the declination, as before. Therefore, if it be made that as the sine of arc EL, the complement of the Sun's altitude, is to the sine of angle ENL, the Sun's distance from the Meridian of the proposed circle, so is the whole sine of the quadrant NL to a fourth [sine], the sine of angle NEL, or BEO, will be found; and its arc BO, subtracted from the quadrant BG, will leave the arc sought, GO, etc.

Diagram. The first of three spherical schematics across the top of the page (a repeat of the six-circle construction of Prop. 1, for a further position of the Sun). Readable labels:

- B (top of circle)
- P (upper-centre, on the meridian below B)
- L (upper-left, interior)

- M (left of centre)
- F (centre)
- E (centre-lower) — [?]
- N (lower-centre, on the meridian)
- D (bottom of circle)

to a fourth, the sine of angle NEL, or BEO, will be found; and its arc BO, subtracted from the quadrant BG, will leave the arc sought, GO, etc.

This arc is nothing when the Sun stands on the Vertical properly so called of the proposed circle; but it is equal to a quadrant when the Sun is placed on the Meridian of the same proposed circle, as is evident.

[Margin: *When the said arc is either nothing or equal to a quadrant.*]

We shall find the same arc on the Meridian of the Horizon by the following method. Let the figure of Prop. 1 of this book be repeated, in which the said arc is EI; there the Equator BED is the Vertical properly so called of the Meridian of the Horizon, and BHI is the Vertical drawn through B, the pole of the Meridian, and through H, the Sun's place. Since in the spherical triangle BHK the angle K is right, it will hold — by Prop. 16, Book 4, of Johannes Regiomontanus [Regiomontanus] *On Triangles*, or by Prop. 41 of our books on spherical triangles — that as the sine of arc BH, the complement of the Sun's altitude above the Meridian of the Horizon, is to the whole sine of the right angle K, so is the sine of arc HK, of the declination, to the sine of angle HBK, or of arc EI, which is sought.

[Margin: *How the same arc is found on the Meridian of the Horizon.*]

If, then, it be made that as the sine of the complement of the Sun's altitude above the Meridian is to the whole sine, so is the sine of the declination to a fourth, there will be found the sine of the arc of the Meridian included between the two Verticals, which is sought.

Finally, we shall find this same arc on the Right Horizon, or on the circle of the 6th hour from noon or midnight, in this way. Since in the spherical triangle EHK the angle K is right, it will hold — by the same Prop. 16, Book 4, of Regiomontanus, or by Prop. 13, Book 1, of Geber [Jābir ibn Aflah], or by Prop. 41 of our work on spherical triangles — that as the sine of arc EH, the complement of the Sun's altitude above the circle of the 6th hour or the Right Horizon, is to the whole sine of the right angle K, so is the sine of arc HK, of the declination, to the sine of angle HEK, or of arc BL. This arc is included between the Vertical properly so called BED — for the Equator, drawn through E, the pole of the said circle, is its primary Vertical — and the Vertical EL, drawn through the Sun's centre H.

Diagram. A large spherical figure (the repeated figure of Prop. 1), symmetric about its vertical meridian. Readable labels:

- A (top of circle)
- C (bottom of circle)
- F (left rim, one upper and one lower)
- G (right rim, one upper and one lower)
- D (right rim, at mid-height)
- O (lower-right rim)
- E (centre)
- K (left interior)
- L (upper-left and lower-left, on the circle)
- H (upper-left interior and lower-left interior)
- I (interior, beside the meridian — one upper, one lower)
- M (interior, on the meridian — one upper below A, one lower)
- N (right-of-centre interior)

Therefore, if it be made that as the sine of the complement of the Sun's altitude above the circle of the 6th hour or the Right Horizon is to the whole sine, so is the sine of the declination to a fourth, there will be found the sine of the arc of the said circle, placed between the two named Verticals.

These arcs, for the sake of the doctrine, we shall call the "latitudes of the shadows" [latitudines umbrarum], because — as we shall teach in Prop. 5 of this book — from them we shall know how great a latitude the gnomon's shadow has in the proposed circle, that is, toward which quarter it is cast at any proposed hour. We have therefore found the arc of any great circle intercepted between the Vertical of its own circle, etc. Which was to be done.

SCHOLIVM.

It is enough, however, if such arcs be investigated for the individual hours on one face of the proposed great circle. For these same arcs are the same, in number, on the other face for the same hours — provided that the hours from sunrise and noon in the parallel of ♋ [Greek/astronomical sign: Cancer, i.e. the Tropic of Cancer] be changed into hours from sunset and midnight in the parallel of ♏ [Capricorn, i.e. the Tropic of Capricorn], and conversely. For, as we showed above in Prop. 1 of this book, such hours — if the said exchange be made — have the same altitudes above each face of the proposed great circle, and are equally distant from the Meridian or the Horizon.

But to know whether the Sun, at a given hour, lies beyond the Vertical circle, or on the Vertical itself, or on the near side of it — namely, when it stands in a parallel that is cut by the Vertical in the hemisphere above the proposed circle (such as the parallel lying between the Equator and the visible pole above the proposed circle, and having a declination smaller than the altitude of the pole above the given circle; for a parallel between the visible pole and the Equator that has a declination greater than the altitude of the pole above the given circle is in no way cut by the Vertical, whereas a parallel between the Equator and the hidden pole either is not cut by the Vertical at all, or is cut only in the hemisphere below the proposed circle, as is evident) — we shall first investigate, from what we have shown partly in Prop. 36, Book 1, and partly in Prop. 1 of this book, how great the Sun's distance from the Meridian of the proposed circle is when it is set on the Vertical circle of the same. For if the Sun, at the given hour, has a distance from the Meridian smaller than that found value, it will lie beyond the Vertical; if equal, it will be found on the Vertical itself; if finally greater, it will be placed on the near side of the Vertical. Or else we shall find, from what we demonstrated in Prop. 36, Book 1, how great an altitude the Sun has on the proper Vertical of the proposed circle. For if at the given hour it has an altitude greater than that found value, the Sun will lie beyond the Vertical; if equal, on the Vertical itself; if finally smaller, it will be placed on the near side of the Vertical.

[Margin: *By which parallels of the Equator [the Sun] is cut by the proper Vertical of each proposed circle, and by what method this is known.*]

Now in all great circles we call that part "on the near side of" [citra] their Vertical circle which, from its Vertical, inclines toward the visible pole — the pole, that is, which is raised above the given circle; and that part "beyond" [ultra] the Vertical which, from its Vertical, recedes toward the other pole, which is hidden. And in sundials the former is always drawn back from the stylus toward the centre of the dial, while the latter [inclines] toward the equinoctial line.

[Margin: *Which part of each great circle is called "on the near side of" the Vertical, and which "beyond" the Vertical.*]

But if it should happen that a parallel between the visible pole and the Equator does not cut the proper Vertical of that great circle (which occurs only when the declination of the parallel is greater than the altitude of the pole above the proposed great circle), then all such arcs of the latitudes of shadows will lie on the near side of the Vertical — that is, toward the visible pole above the given circle, or toward the equinoctial line of the dial, as is evident.

[Margin: *When all the latitudes of shadows lie on the near side of the Vertical circle.*]

By this technique we have computed various little tables, in which the said arcs, or latitudes of shadows, are contained for the individual hours — whether reckoned from noon or midnight, or from sunrise or sunset, or even the unequal hours in the same great circles above which we investigated the Sun's altitudes in Prop. 1. You will find these tables in Prop. 5 of this book, where we shall construct various sundials from them.

PROBLEMA 4. PROPOS. 4.

To find the arc of any given great circle not passing through the poles of the world — the arc included between, on the one hand, the great circle that passes through the poles of the world and through the common sections of the Equator and the given great circle (such as the circle of the 6th hour from noon and midnight — in the Horizon, in the Vertical, and in every other circle inclined indeed to the Horizon but at right angles to the Meridian of the Horizon); and, on the other hand, any other hour-circle drawn at any given hour through the poles of the world and the Sun's centre.

[Margin: *By what technique is computed the arc of any great circle not passing through the poles of the world, placed between the great circle drawn through the poles of the world and the common sections of the Equator and the given circle (like the circle of the 6th hour from noon and midnight in the Horizon), and any other hour-circle drawn through the poles of the world and the Sun.*]

Diagram. A spherical figure for the demonstration of Problema 4. Readable labels:

- G (top of circle)
- C (bottom of circle)
- B (left rim)
- D (right rim)
- I, A, M (upper interior, left to right; A on the meridian)
- O, P (left interior)
- H, E, N (central row, left to right; E at the centre)
- K (lower-left rim)
- L (lower-left interior)
- F (bottom-centre interior, above C)

Let ABCD be the great circle — whether it be the Horizon or not, provided it does not pass through the poles of the world; let AEC be its proper Meridian, passing through F and G, the poles of the world; let BED be the Equator; and let FHG be the hour-circle drawn through the same poles, cutting the Equator in H and the proposed circle in I; and let the arc EH — the Sun's distance from the Meridian — be less than a quadrant, or six hours. The arc to be found is IB, of the proposed circle, lying between B — the common section of it and of the Equator, through which, of course, the hour-circle is drawn, like the circle of the 6th hour from noon and midnight in the Horizon — and the hour-circle FHG.

Since in the spherical triangle AGI the angle A is right, it will hold — by Prop. 18, Book 4, of Regiomontanus *On Triangles*, or by Prop. 14, Book 1, of Geber, or by Prop. 42 of our work on spherical triangles — that as the sine of angle G, the Sun's distance from the proper Meridian of the proposed circle, is to the whole sine, so is the sine of the complement of angle I to the sine of the complement of arc AG, the altitude of the pole above the proposed circle. And by conversion: as the whole sine is to the sine of the Sun's distance from the proper Meridian of the given circle, so is the sine of the complement of the pole's altitude to the sine of the complement of angle I. Moreover, in the triangle BHI, by Prop. 16, Book 4, of Regiomontanus *On Triangles*, or by Prop. 13, Book 1, of Geber, or by Prop. 41 of our work on spherical triangles, it holds that as the sine of angle I is to the sine of arc BH, the complement of the Sun's distance from the proper Meridian of the given circle, so is the whole sine of the right angle H to the sine of arc BI, which is proposed to be found.

Therefore, if it be made that as the whole sine is to the sine of the Sun's distance from the proper Meridian of the given circle, so is the sine of the complement of the pole's altitude above the proposed circle to a fourth, there will be found the sine of a certain arc, whose complement will give the angle I. And if again it be made that as the sine of the found angle I is to the sine of the complement of the Sun's distance from the proper Meridian of the proposed circle, so is the whole sine to a fourth, there will be obtained the sine of that arc of the proposed great circle which is sought.

[Margin: *What the hour-arcs in the proposed circle are called.*]

But if another hour-circle be described, FK, cutting the Equator in K and the proposed circle in L, such that the arc EK — the Sun's distance from the proper Meridian of the given circle — is greater than a quadrant, or six hours, the arc BL will be found in the same way. For it will hold, as before, in the spherical triangle CFL: as the whole sine is to the sine of angle CFL, the Sun's distance from the

proper Meridian of the given circle (for the angles CFL and EFK have the same sine, since they are equal to two right angles), so is the sine of the complement of arc CF, the altitude of the pole above the proposed circle, to the sine of the complement of angle L; and thus the angle L itself will be known. Again, in the triangle BKL it holds that as the sine of angle L is to the sine of arc BK, the complement of the Sun's distance from the Meridian of the proposed circle, so is the whole sine of the right angle K to the sine of arc BL, which is sought.

Furthermore, for the sake of the doctrine and of brevity, we may call arcs of this kind "hour-arcs" [arcus horarios] in the proposed circle, because they indicate — as will become clear from what follows — how far apart, in the proposed plane, the hour-lines (or hour-spaces) ought to lie: that is, the common sections of the proposed plane and of the hour-circles drawn through the poles of the world. We have said in the proposition that these arcs are included between the great circle drawn through the poles of the world by way of the common sections of the Equator and the given circle (like the circle of the 6th hour from noon and midnight in the Horizon) and the other hour-circles drawn through the poles of the world — and not between the common sections of the Equator and the given circle and the other hour-circles, though this latter is nonetheless true; so that we may more easily demonstrate, in the following proposition, how sundials are made from these arcs upon a plane parallel to the proposed great circle.

On the Equator the said arcs are equal to the complements of the Sun's distances from the Meridian circle — such as the arcs BH, DN, etc. Hence it is not necessary to seek out the arcs of the Equator lying between the circle drawn like the 6th-hour circle from noon or midnight in the Horizon and the other hour-circles drawn through the poles of the world. We have therefore found the arc of any great circle not passing through the poles of the world, included between the [aforesaid] great circle, etc. Which was to be done.

SCHOLIVM.

It is evident, moreover, that when the Sun's distance from the proper Meridian of the given circle is less than a quadrant, or six hours, the said arcs extend from the common section of the proposed circle and of that great circle drawn through the poles of the world (like the 6th-hour circle from noon and midnight in the Horizon) toward the hidden pole — as from point B, or D, toward A; but in the sundial they extend beyond the centre of the dial, and not toward the equinoctial line, because then the hour-circle cuts the quadrant of the Equator EB, or ED, and thus also the quadrant of the proposed great circle AB, or AD. But when the Sun's distance from the Meridian is equal to a quadrant — that is, when it comprises

six hours — the said arc is nothing, because the hour-circle then passes through the point B, or D. And when the Sun's distance from the Meridian is nothing, the said arc is a quadrant. Finally, when that same distance is greater than a quadrant, or six hours, the said arcs extend from the common section of the proposed circle and of that great circle drawn through the poles of the world (like the 6th-hour circle from noon and midnight in the Horizon) toward the visible pole — as from point B, or D, toward C — and in the sundial toward the equinoctial line, that is, on the near side of the centre of the dial; because then the hour-circle falls beyond the point B, or D, on the Equator, and consequently cuts the quadrant of the proposed circle CB, or CD.

[Margin: *Toward which part the hour-arcs incline in the proposed circle, and how this is known from the Sun's distance from the proper Meridian.*]

Now if the Meridian AEC be one of the hour-circles, or at least equally removed from two hours set on either side of it, then the arcs of the proposed great circle belonging to two hours equally distant from the Meridian of the proposed circle — the arcs intercepted between that great circle drawn through the poles of the world (like the circle of the 6th hour from noon and midnight) and the hour-circles of those hours drawn through the poles of the world — will be equal, one of them being eastern and the other western. For in the spherical triangles AGI, AGM: if the hour-circles FIG, FMG be posited as equally distant from the Meridian FAG, the angles at G will be equal, because of the equality of the arcs EH, EN; the angles at A are moreover right, and the side AG is common, lying adjacent to the equal angles. Therefore, by Prop. 23, Book 1, of Menelaus (in the version handed down by Francesco Maurolico [Francesco Maurolico]), or by Prop. 20 of our books on spherical triangles, the arcs AI, AM will also be equal; and when these are taken away from the quadrants AB, AD, the remaining arcs IB, MD will be equal.

[Margin: *Which hour-arcs are equal to one another.*]

Again, the arcs of the same proposed great circle answering to two hours — of which the distance of one from the proper Meridian is as much less than a quadrant as the other's is greater — will be equal. For if two hour-circles FK, FO be posited as equally distant from the point B, so that the arcs of the Equator BP, BK are equal, then in the spherical triangles BKL, BPO the angles at the vertex B will be equal, the angles K, P right, and the sides BK, BP equal. Wherefore, as before, the arcs BL, BO will be equal.

From these it follows that it is enough — in the Horizon and in the Vertical circle properly so called (if we speak of hours from noon and midnight) — to investigate such arcs for five hours before or after noon. For the arc of the 6th hour from noon and midnight is nothing; the arc of the 5th hour after noon is equal to the arc of the 7th hour after noon, the arc of the 4th hour to that of the 8th hour, and so on, as we have demonstrated. Indeed, in the other great circles it will likewise be enough if, of those twelve hours from noon or midnight, the arcs be investigated for those hours which are distant from the proper Meridian of the circle by less than six hours — all of which, as is clear from what has been said, lie beyond the centre of the dial, that is, toward the hidden pole. For the hour-lines of these arcs, which cut the equinoctial line in the dial, when produced beyond the centre of the dial will also give the hours that do not cut the equinoctial line and that have a distance from the proper Meridian of the proposed circle greater than six hours. All of which will become clear from the following proposition.

[Margin: *In the Horizon and the Vertical properly so called it is enough to compute the hour-arcs for five hours before or after noon; but in the other great circles, for those 12 hours from noon and midnight that are less than six hours away from their proper Meridians.*]

For the rest: since the altitude of the pole above the Vertical circle properly so called of any region is the complement of the altitude of the pole above the Horizon of the same region — because the arc of the Meridian drawn from the vertex through the pole of the world down to the Horizon (which measures the pole's altitude both above the Vertical and above the Horizon) is a quadrant, as we also taught in Prop. 13, Book 3 — it comes about that the arc of the Horizon for any hour from noon or midnight, computed for one region by this proposition, is the arc of the Vertical for the same hour in another region whose latitude is equal to the complement of the latitude of the former region. For in the latter region the altitude of the pole above the Vertical is the same as its altitude above the Horizon in the former. For, as is established from what has been said, the altitude of the pole above the Vertical of that region whose latitude, together with the latitude of the former region, makes up a quadrant is equal to the complement of the altitude of the pole above the Horizon of the same region — that is, to the altitude of the pole above the Horizon of the former region. Therefore it will be enough to compute the said arcs of the Horizon for all latitudes, for the hours from noon or midnight; for the same arcs will serve for the Vertical circles, if instead of the latitude of the place its complement be taken. Thus, if the said horizontal arcs be computed for all latitudes, the arcs for latitude 42° will indeed

be horizontal in the region whose latitude comprises 42° , whereas the arcs computed for latitude 48° will be the Vertical arcs in that same region of latitude 42° , etc.

[Margin: *The altitude of the pole above the Vertical properly so called of any region is the complement of the altitude of the pole above the Horizon of the same region.*]

But if the complements of the hour-arcs computed by this proposition be taken, one obtains those same hour-arcs that take their beginning from the proper Meridian of the proposed great circle — the arcs which many writers have computed. These too we shall trace out from the proposed figure. After the angle I has been found in the triangle AGI, as we have taught, then — since in the same triangle, by Prop. 16, Book 4, of Regiomontanus *On Triangles*, or by Prop. 13, Book 1, of Geber, or by Prop. 41 of our books on spherical triangles, it holds that as the sine of angle I is to the sine of arc AG, the altitude of the pole above the proposed circle, so is the sine of angle G, the Sun's distance from the proper Meridian, to the sine of arc AI, which is proposed to be found — if it be made that as the whole sine is to the sine of the Sun's distance from the proper Meridian, so is the sine of the complement of the pole's altitude above the proposed circle to a fourth, there will be found, as above, the sine of a certain arc whose complement will give the angle I. And if again it be made that as the sine of the found angle I is to the sine of the pole's altitude above the proposed circle, so is the sine of the Sun's distance from the proper Meridian to a fourth, there will be obtained the sine of that arc of the great circle which is sought.

[Margin: *By what reasoning the hour-arcs of all Horizons are also the hour-arcs of all Verticals properly so called.*]

[Margin: *How the same hour-arcs, taking their beginning from the proper Meridian, are investigated.*]

Furthermore, we shall set out several tables of hour-arcs in the following proposition.

PROBLEMA 5. PROPOS. 5.

To construct various sundials from the tables that we taught how to compute in the preceding propositions.

[Margin: What must be computed for each plane, so that sundials may be constructed on it.]

So that it may be fully and thoroughly understood by what method sundials are made from the tables we taught how to compute in the preceding propositions, we shall lay out sundials on all those planes on which we constructed sundials in Books 2 and 3. In this way every variety and difficulty that might arise will be removed. We shall not, however, describe on every plane all four kinds of hours, as we did in Books 2 and 3, but on some the hours from noon or from midnight together with those from the west only [ab occ. duntaxat]; on some, only the hours from noon and midnight, or from the east, or from the west, or even the unequal hours. For since all hours, of whatever kind, are described in the same way, it will be enough to set out examples of a single kind.

For each plane, therefore, one must compute — by Prop. 3 of this book — the shadow-latitudes for those hours which we wish to place on the sundial, with the Sun at the beginning of ♋ [Cancer], ♈ [Aries] or ♎ [Libra], and ♏ [Capricorn], taking careful note, however, of which arcs of the shadow-latitudes fall on the near side of the plane's own vertical circle and which lie beyond it, and likewise which are eastern and which western with respect to the plane's own Meridian. Then, from the table of shadow-lengths which we computed in Prop. 2 of this book, one must extract the lengths of the direct shadows [longitudines umbrarum rectorum] corresponding to the Sun's altitudes which we found for the same hours in Prop. 1 of this book.

Let it be required, then, to construct a horizontal astronomical sundial from tables containing the said shadow-latitudes and shadow-lengths, for latitude 42°, of the kind that follow.

Shadow-latitudes and shadow-lengths on a horizontal sundial, for the hours from noon and from midnight, at latitude 42°.

In the tropic of ♋ [Cancer] the shadow-latitudes are partly northern and partly southern, as these syllables [Bor. / Austr.] indicate.

	5	6	7	8	9	10	11	12	
Hours ♋ from midnight	Bo r.	Bo r.	Bo r.	Aus tr.	Aus tr.	Aust r.	Aust r.	Aust r.	eastern [orientales]
Hours ♋ from noon	7 Bo r.	6 Bo r.	5 Bo r.	4 Aus tr.	3 Aus tr.	2 Aust r.	1 Aust r.	0 Aust r.	western [occidentales]
Shadow-latitude (G. M. = deg. min.)	27 .1 2	17 .5 4	8 48	0.34	11.5 7	27.9	51.1 9	90.0	

	5	6	7	8	9	10	11	12	
Hours ☉ from midnight	Bo r.	Bo r.	Bo r.	Aus tr.	Aus tr.	Aust r.	Aust r.	Aust r.	eastern [orientales]
Shadow-length (P. M. = parts. min.)	13 2. 17	43 .1 9	24 .1 6	15.4 1	10.3 7	7.13	4.56	4.1	

In the Equator all the hours and shadow-latitudes are southern.

Hours ☿ & ♄ from midnight	6	7	8	9	10	11	12	eastern [orientales]
Hours ☿ & ♄ from noon	6	5	4	3	2	1	0	western [occidentales]
Shadow-latitude (G. M.)	0.0	10. 10	21. 7	33. 47	49. 12	68. 11	90. 0	
Shadow-length (P. M.)	Infin i.	61. 16	29. 59	19. 26	14. 16	11. 39	10. 48	

In the tropic of ♊ [Capricorn] all the hours and shadow-latitudes are southern.

Hours ♊ from midnight	8	9	10	11	12	eastern [orientales]
Hours ♊ from noon	4	3	2	1	0	western [occidentales]
Shadow-latitude (G. M.)	37. 13	48. 24	61 .1	75. 3	90. 0	
Shadow-length (P. M.)	162 .8	54. 30	35 .7	28. 12	26. 20	

In these little tables the eastern hours — and therefore the eastern shadow-latitudes — are easily distinguished from the western. For all the hours from midnight are eastern, and those from noon western, as is noted in these tables. Further, the syllable [Bor.] signifies that the hour to which it is attached, and the shadow-latitude corresponding to it, is northern in the Horizon — that is, falls on the near side of the vertical circle; while the syllable [Austr.] indicates that the hour to which it is assigned, and the shadow-latitude corresponding to it, is southern, that is, falls beyond the vertical circle.

On the plane of the sundial let a circle ABCD of any size be described, with centre E, at which the stylus [gnomon] is to be fixed at right angles; and let two diameters AC and BD be drawn, cutting one another at right angles at the centre. Of these let AC be the meridian line — that is, the common section of the

Meridian and of the sundial's plane — and consequently BD (which is to be drawn occult) the common section of the vertical circle properly so called and of the same sundial's plane. For since both the vertical circle and the Horizon — and therefore also the plane of the sundial parallel to it — make right angles with the Meridian,^a the common section of the vertical circle and of the sundial's plane will be perpendicular to that same Meridian, and hence also^a to the meridian line AC lying in the Meridian, by Def. 3 of Euclid, Book 11. Therefore, since both the Meridian and the vertical circle are drawn through the stylus, the line BD — drawn through E, the place of the stylus, perpendicular to AC — will be the common section of the vertical circle and of the sundial's plane. By this same demonstration it can be shown, in all the sundials that follow, that the line which at the place of the stylus cuts the stylus-line, or the proper meridian line, at right angles is the common section of the sundial's plane and of the vertical circle properly so called of that plane.

[Margin: Description of the horizontal astronomical sundial from the tables.]

[Margin (keyed to the superscript ^a): "a 19. vnde." — cross-reference; the figure "19." and the abbreviation are only partially legible [?]]

Now if the sundial's plane is fixed and parallel to the Horizon, then in it — by what we demonstrated in the scholium to Prop. 23 of Book 1 — one must find the meridian line AC, from whose point E, where the stylus is to be placed, the circle ABCD is to be described, and the occult diameter BD perpendicular to AC is to be drawn as the common section of the vertical circle and of the sundial's plane. Let the meridional or southern parts be set at A, the northern at C, and consequently the eastern at B and the western at D. Choose also any length of stylus EF, and from a straight line GH cut off any number of equal parts you please; at the end of the first part write the number 12, at the end of the second the number 24, and so on, always adding 12. Likewise let the line GH be produced toward G, and let a further line GI be taken, equal to the stylus, divided into 12 equal little parts. For in this way we shall not be forced to divide each single part of the line GH into 12 parts in order to take the shadow-lengths; rather, they can most conveniently be taken from the whole line IH, as we shall soon teach.

After this — since, with the Sun in the Equator, the stylus's shadow at noon, that is, at the 12th hour from midnight, is cast toward the north and comprises 10 parts 48 minutes, as is clear from the preceding tables under the 12th hour of ♊ or ♎ — if this shadow be taken from the line GI by means of the compass and transferred from E toward the northern parts C, as far as the point K, then at the time of the equinoxes the extremity of the shadow will at noon fall at K; and so

through K the equinoctial line must be drawn perpendicular to the meridian line, such as is KL.

[Margin: How the equinoctial line is drawn in the horizontal sundial.]

We shall also draw it in this way. Let the line EF, equal to the stylus, be set up perpendicular to AC, and at F let the angle EFK be made equal to the altitude of the pole (which is easily done if from F, toward D, a circle be described, on which the altitude of the pole is counted off from the line FD toward C, and so on), so that the line FK cuts the meridian line toward the northern parts at K. For through the point K the equinoctial line must be drawn perpendicular to AC, as we demonstrated in the scholium to Prop. 1 of Book 2. But if at F another angle EFM be made, equal to the complement of the pole's altitude, so that the line FM cuts the meridian line at M, then M will be the centre of the sundial, in which all the hour-lines from noon and midnight meet, as we demonstrated in the same scholium to Prop. 1 of Book 2.

[Margin: By what method the centre of the horizontal sundial is found.]

We shall also find this centre by the following method. In the table of shadow-lengths of Prop. 2 of this book, take the altitude of the pole, 42° , whose shadow is 13 parts 20 minutes. For if this shadow be taken from the line IH by the compass — placing one foot of the compass on the number 12, and the other on 1 part 20 minutes of the line GI, so that the whole line contained between the feet of the compass comprises 13 parts 20 minutes — and transferred from E along the meridian line toward the southern parts A as far as M, then M will be the centre of the sundial. For if the Sun were placed at the arctic pole, the shadow of the stylus — and therefore the Sun's ray, that is, the axis of the world — would fall at the point M, since it would then have an altitude of 42° above the Horizon. Hence, as we taught in the corollary to Prop. 21 of Book 1, the point M will be the centre of the sundial.

Now (to come to the drawing of the hours) let the line of the 6th hour from noon be described. Under the 6th hour of the tropic of $\mathfrak{E}$, which is western and northern, I find the arc of shadow-latitude $17^\circ 54'$. This number, therefore, from D,

Diagram. A large horizontal-sundial construction figure occupying the lower two-thirds of the page. [The identical woodcut is reprinted on the following page so the text on both leaves can refer to it; it is described once here.] Above the circle runs a horizontal graduated scale line, marked **H** at its left end and **I** (with a fine comb-graduation) at its right, carrying the numbers (left→right) **144, 132,**

120, 108, 96, 84, 72, 60, 48, 36, 24, 12, then **G**, then **I** — the scale IGH of shadow-parts (I = 0, G = 12 = one stylus-length, H = 144). Below it is the main circle **ABCD** (the horizon-plate), with a vertical diameter (the meridian line AC) and a horizontal diameter.

Readable labels (position; content):

- A (top of circle): **A**, with **MER.** [meridies — south] beside it
- C (bottom of circle): **C**, with **BOR.** [borealis — north]
- L (left end of horizontal diameter): **L**
- B (left, above L): **B**, with **ORI** [oriens — east] set vertically beside it
- R (left, above B): **R**
- M (centre region): **M** — the sundial's centre, with dashed lines converging on it from the left
- E (just right of M, centre): **E** — the stylus-foot; a small **12** stands near M/E
- n (far left, on a dashed line): **n**
- f (left, script, on the dashed line): **f**
- T (upper-left, on the circle): **T**
- X (upper-left, on the circle): **X**
- 4 (left of centre): **4**
- O (left of centre, near an "r"): **O**
- u (lower-left): **u**
- P (lower-left, on a radiating line): **P**
- d (lower centre-left): **d**
- 23 (lower-left) with an adjacent glyph resembling **h/h** [?], and a second **P** beside it
- Bottom row of hour-numbers (left→right): **22, 21, 20, 19, 18, 17, 16**
- Right side, radiating hour-lines top→bottom: **10, 11** (with **m** beside it), **12, 13, 14, 15**
- Upper-interior small labels: **6, 8** and (script) **f, 6, q, Q**, with script **C, C** [these small interior sorts are only partly legible]
- Central cluster (left of centre): **E, S, 8, Z, Z, K, V**, and **4F** (a "4" beside **F**)
- Centre-right, descending the meridian: **D, N, Q, α** [alpha], and lower **Y**

The figure shows the two tropic day-arcs and the equinoctial line crossing the plate, with the hour-lines (numbered 6 through 23) radiating from the centre M and the shadow-tip construction points (K, L, N, O, P, Q, R, S, T, V, X, Y) laid out as the text describes. The interior of the figure is exceedingly dense; many of the

small numerals and script letters listed above cannot be resolved with full confidence. **

414

[Margin: The use of that quadrant constructed at the beginning of Book 1.]

toward the western point, at C, I lay off the northern parts as far as N (which I accomplish by means of that quadrant we constructed at the beginning of Book 1; for by it all arcs are easily transferred into any circle, so that its wonderful usefulness may appear especially in this matter). And from N, through E, I draw the occult line NEO, which will be the common section of the sundial's plane and of the vertical circle passing through the Sun at the 6th hour from noon. For since the vertical circles cut the Horizon — and the circle ABCD parallel to it — into similar parts, by Prop. 10 of Book 2 of Theodosius; and since the arc DN is similar to the one intercepted in the Horizon between the primary vertical and that vertical which is drawn through the Sun at the 6th hour from noon; and since the primary vertical passes through D — then another vertical will pass through N, and therefore the line NEO will be the common section of that vertical and of the sundial's plane. Therefore, by Prop. 11 of Book 1, the shadow of the stylus will fall on the line EO, inasmuch as it falls on the eastern and southern side, which is opposite to the western and northern side on which the Sun then is. And in this way, from the arcs of the shadow-latitudes, the shadow-latitude is found —

[Margin: By what technique the latitude of the shadow is sought from the arcs of the shadow-latitudes.]

that is, the direction in which the shadow is cast is known, if the said arcs are correctly reckoned from the point D or B, toward C or A, according as they are western or eastern, and northern or southern.

Again, under the same 6th hour of the tropic of $\mathfrak{S}$, I find the shadow-length 43 parts 19 minutes. This, then, taken from the line IH by the compass (placing one foot of the compass on the number 36, and the other on 7 parts 19 minutes of the line GI, so that the whole line lying between the feet of the compass comprises 43 parts 19 minutes), I transfer from E onto the occult line EO, as far as the point O. For at this point the extremity of the shadow will fall at the 6th hour from noon, with the Sun at the beginning of $\mathfrak{S}$. And since, as we showed in Prop. 1 of Book 2, the line of the 6th hour from noon is parallel to the equinoctial line and perpendicular to the meridian line, if through O a line be drawn perpendicular to AC — or equidistant from the equinoctial line — the line of the 6th hour from noon will be described.

But if to the arc DN an equal arc BP be taken, toward C, and from P, through E, the occult line PEQ be drawn, and from EQ a line EQ be cut off equal to EO, then the extremity of the shadow will fall at the point Q at the 6th hour from midnight, with the Sun in the tropic of ♌ . For the arc is the same for this hour as for the former, and the shadow-length the same; but the arc of the 6th hour from midnight is eastern, just as the arc of the 6th hour from noon is western, as appears from the table.

Let the line of the 9th hour from midnight now be described. Since its shadow-latitude in the table, with the Sun at the beginning of ♌ , is southern and eastern, and comprises $11^{\circ} 57'$, I lay it off from B, the eastern point, toward the south as far as R, and I draw the occult line RES; and from ES I cut off the shadow ES of 10 parts 37 minutes, which I find in the table under the 9th hour from midnight, with the Sun in the tropic of ♌ . For in this way the point S will be found, at which, with the Sun in the tropic of ♌ , the extremity of the shadow will fall at the 9th hour from midnight; and therefore through S the line of the 9th hour from midnight must be drawn.

Next, since with the Sun at the beginning of ♌ or ♍ the shadow-latitude of the same hour is eastern and southern, and comprises $33^{\circ} 47'$, I lay it off from B toward A, as far as the point T. For if the occult line TEV be drawn, cutting the equinoctial line at V, then at the time of the equinox the extremity of the shadow will fall at the point V at the 9th hour from midnight; and so through V the line of the 9th hour from midnight must be drawn. This point V we shall also detect by means of the shadow-length, in the following way. Under the 9th hour from midnight, with the Sun at the beginning of ♌ or ♍ , let the shadow-length 19 parts 26 minutes be taken from the table. For if this, taken by the compass, be laid on the line IH, and from E an occult arc of a circle be described, it will cut the equinoctial line at the point V. And thus we shall find the point of each hour on the equinoctial line either from the shadow-latitude alone or from the shadow-length alone.

Furthermore, with the Sun at the beginning of ♌ , I lay off from B toward A, as far as X, the shadow-latitude of the same hour — eastern and southern — found in the table as $48^{\circ} 24'$; and I draw the occult line XEY. For if from EY the shadow-length 54 parts 30 minutes, due to the same hour, be cut off, as is plain from the table, the point Y will be found, at which, with the Sun at the beginning of ♌ , the extremity of the shadow will fall at the 9th hour from midnight; and therefore through V the line of the 9th hour from midnight must be drawn. So if from S to Y a straight line be drawn — which will pass entirely through V, if no error has

been made — the line of the 9th hour from midnight will be described. In this way all the hour-lines will be drawn, if for each three points are found: one in the tropic of $\mathfrak{S}$, another on the equinoctial line, and a third in the tropic of $\mathfrak{V}$, as has been done for the 9th hour from midnight. But if perchance in one of the tropics a point of some hour

Diagram. The same horizontal-sundial construction figure as on the previous leaf, reprinted here (see the full description under fig-p425-1: scale H...G...I with 144–12, circle ABCD with A/MER at top, C/BOR at bottom, L at left, B/ORI east, centre M and stylus-foot E, hour-lines 6–23 radiating, and shadow-tip points K, L, N, O, P, Q, R, S, T, V, X, Y). The dense interior small numerals and script letters are again only partly legible. **

cannot be found, then the hour-line will have to be drawn through two points, one of which has been found in one tropic and the other on the equinoctial line. Thus you see that the 7th hour from midnight has been drawn through the point Z, found in the tropic of $\mathfrak{S}$, and through the point a on the equinoctial line. But if it should sometimes happen that a given hour has its point in one tropic only, its line must be drawn through that point once found and through M, the centre of the dial; or else through that point of the equinoctial line which belongs to the opposite hour. For example, if the 7th hour from noon is to be drawn, its point will be found in $\mathfrak{S}$ alone — though in our example it is in fact not found, because it lies farther than it should from E, the place of the style. Through that point, then, and through the point a of the equinoctial line, which corresponds to the 7th hour from noon, the line of the 7th hour from noon must be drawn.

Now since, as is clear from the tables set out above, two hours always have the same arc and the same shadow-length, they will be described by one and the same operation, provided the arc taken from the table is reckoned from B and from D, toward A or toward C. For if, equal to the arc B X by which we found the point Y in the tropic of $\mathfrak{V}$ for the 9th hour from midnight, we take the arc D b, and from b through E draw the occult straight line b Ed, and make the shadow Ed equal to the shadow EY, the point d will be found, in the tropic of $\mathfrak{V}$, for the 3rd hour from noon — since the 3rd hour from noon and the 9th hour from midnight are equally distant from the meridian, and so on. By this art the whole astronomical dial has been described. And if the points found in the tropics are suitably joined by curved lines, the arcs of $\mathfrak{S}$ and $\mathfrak{V}$ will be described. And if for the other signs the Sun's altitudes for the same hours are found, and from these the shadow-lengths — which are transferred from E, the place of the style, by means of the compass onto the hour-lines, marking points on them — the arcs of

the other signs will likewise be described. Or, if the shadow-latitudes for the hours of the other signs are found, then wherever their occult lines drawn through E cut the hour-lines, through those points the same arcs of the signs are to be delineated. And all the lines of the hours from noon and from midnight, if no error has been made in the drawing, will pass through M, the centre of the dial, when they are produced.

By exactly the same art all other dials whatever will be made, provided the shadow-latitudes and shadow-longitudes are correctly taken for each of the hours to be drawn. For the Italian horizontal dial the following tables have been computed, containing the shadow-latitudes and shadow-longitudes for the hours from sunset, for latitude 42°.

Shadow-latitudes and shadow-longitudes in the horizontal dial, for the hours from sunset, at latitude 42°.

In the tropic of ϖ the shadow-latitudes are partly northern and partly southern, as these syllables [Bor. Austr.] indicate.

Table — In the tropic of ϖ (hours 9–16; eastern group, "Orientales"). "G. M." = degrees and minutes (shadow-latitude); "P. M." = parts and minutes (shadow-length); Bor. = northern, Austr. = southern.

Hours of ϖ , from sunset	9	10	11	1	2	13	14	15	16	(Easter n)
direction	Bor.	Bo r.	Bo r.	B or	Aus tr.	Aus tr.	Aus tr.	Aus tr.	Aus tr.	
				.						
Shadow-latitudes (G. M.)	31.45	22. 11	13. 5	3. 4 9	6.24	19.2 1	38.2 7	70.2 0		
Shadow-longitudes (P. M.)	1031. 45	64. 14	30. 56	1 9. 3	12.4 3	8.39	5.51	4.14		

Table — In the tropic of ϖ (hours 17–24; western group, "Occidentales").

Hours of ϖ , from sunset	17	18	19	20	21	22	23	24	(Wester n)
direction	Aus tr.	Aus tr.	Aus tr.	Aus tr.	Bo r.	Bo r.	Bo r.	Bor.	

Hours of ☿, from sunset	17	18	19	20	21	22	23	24	(Weste rn)
Shadow-latitudes (G. M.)	67.4 3	36.5 3	18.2 1	5.45	4.3 2	13. 40	22. 48	32.27	
Shadow-longitudes (P. M.)	4.17	6.1	8.53	13.3	19. 36	32. 8	68. 46	Infin i.	

On the Equator all the hours, and the shadow-latitudes, are southern.

Table — On the Equator (signs ♈ and ♎). Upper hour-row = eastern ("orientales"); lower hour-row = western ("occidentales").

Hours of ♈ & ♎, from sunset (E)	12	13	14	15	16	17	18
(from sunset, W)	24	23	22	21	20	19	18
Shadow-latitudes (G. M.)	0.0	10.1 0	21.7	33.4 7	49.1 2	68.1 1	90.0
Shadow-longitudes (P. M.)	Infini.	61.1 6	29.5 9	19.2 6	14.1 6	11.3 9	10.4 8

In the tropic of ♋ all the hours and shadow-latitudes are southern.

Table — In the tropic of ♋ (hours 16–24). "orien."/"or." = eastern; "occ." = western; all shadow-latitudes southern.

Hours of ♋, from sunset	16	17	18	19	20	21	22	23	24
direction	orie n.	or.	or.	or.	occ	occ.	occ	occ.	occ.
Shadow-latitudes (G. M.)	42.1 6	54. 6	67. 25	81. 58	82. 58	68. 21	54. 56	43. 1	32.27
Shadow-longitudes (P. M.)	82.5 6	42. 44	31. 3	26. 51	26. 43	30. 36	41. 32	77. 40	Infini.

Now, just as by these syllables [Bor. Austr.] we distinguish the northern shadow-latitudes from the southern, so by these syllables [or. oc.] we mark off the eastern from the western.

[Margin: When a point is found in one tropic only, and on the equinoctial line — or in one tropic only — how the hour-line is to be drawn.]

[Margin: How the arcs of the signs are described in the dial from the tables.]

And so, if the line of the 23rd hour from sunset is to be described, we shall reckon off its shadow-latitude, $22^{\circ}48'$, which in the tropic of $\mathfrak{S}$ it has as western and northern, in the preceding figure from D toward C, as far as e; and we shall draw the occult line e Ef, from which, if we cut off the shadow 68 parts 46 minutes — namely the straight line Ef — we shall obtain f, the point of the 23rd hour in the tropic of $\mathfrak{S}$. Then we shall compute the shadow-latitude of the same 23rd hour, $43^{\circ}1'$, which in the tropic of $\mathfrak{V}$ it has as western and southern, from D toward A, as far as g; and we shall draw the occult straight line g Eh, from which, if we cut off the shadow 77 parts 40 minutes — namely the straight line Eh — the point h will be found, the point of the 23rd hour in the tropic of $\mathfrak{V}$. Therefore the straight line f h, once joined, will give the 23rd hour from sunset, which will pass entirely through the point L on the equinoctial line, through which the line of the 5th hour from noon has been drawn.

For the shadow-latitudes are the same in the hours reckoned from sunset or from sunrise — and in the unequal hours — as in the hours reckoned from noon or from midnight. Hence, once the points on the equinoctial line have been found for one class of hours, there is no need to investigate them again for the others. We shall draw the lines of the other hours from sunset in just the same way, provided you remember that those hours which have no points in the tropic of $\mathfrak{V}$ — such as the 15th, 14th, and 13th — must be drawn through their points found in the tropic of $\mathfrak{S}$ and on the equinoctial line. Thus you see that the line of the 13th hour from sunset has been carried through the point found in the tropic of $\mathfrak{S}$ and through a, the point of the equinoctial line, through which of course the line of the 7th hour from midnight has been drawn. And you will easily understand, from the table of Proposition 19 of Book 1, which hours from noon or midnight on the equinoctial line correspond to which hours from sunrise or sunset. The line of the 12th hour from sunset must be drawn through the point found in the tropic of $\mathfrak{S}$, parallel to the equinoctial line, as we demonstrated in Proposition 1 of Book 2. But the remaining hours before the 12th, which do not cut the equinoctial line, must be drawn through points found in the tropic of $\mathfrak{S}$ by means of the corresponding hours on the equinoctial line, as is established from the table of Proposition 19 of Book 1: thus the line of the 11th hour from sunset [is drawn] through the 23rd hour from sunset (or 5th from noon) on the equinoctial line, and the line of the 10th hour from sunset through the 22nd from sunset (or 4th from noon), and so on. Or else, for these same hours, other points must be sought in the parallel of $\mathfrak{I}$ or $\mathfrak{Q}$, by means of their shadow-latitudes and shadow-longitudes found in the said parallel.

But if the tropics have been drawn, we shall describe the Italian dial more easily, either by the shadow-longitudes alone or by the shadow-latitudes alone. For if, by means of the compass, the shadow-longitudes are taken from the straight line IH, and from E the occult arcs are described cutting the tropics; or if the occult lines of the shadow-latitudes are drawn cutting the tropics — then in either tropic the points of the hours from sunset will be obtained. If, then, the corresponding points are connected by straight lines passing through the hours from noon and midnight on the equinoctial line, the Italian dial will be described.

The shadow-longitudes can also be investigated geometrically from the Sun's altitudes, as we set forth at the end of the scholium to Proposition 2 of this book. For let there be a circle, or rather (which is sufficient) a semicircle ABC,

Diagram. A large semicircle ABC standing on a horizontal base-line, used to derive shadow-lengths geometrically from the Sun's altitude. The diameter BC is horizontal through the centre D, and the semidiameter AD rises perpendicularly to the apex A. A second horizontal line IG runs below and parallel to BC, passing through E (the foot of the style; DE, produced downward from D, is the gnomon). Rays are drawn from D (and from the diameter-ends B and C) through altitude-points on the arc down to the base-line, where the shadow-tips are marked; nearly-equal shadows are set on opposite sides of E (eastern hours to the right, western to the left) to avoid confusion.

- A (top, apex of the arc): terminus of the perpendicular semidiameter AD
- Q (upper left, on the arc)
- O (upper right, on the arc)
- M (left, on the arc, below Q)
- F (left, on the arc, below M)
- K (right, on the arc, below O)
- H (right, on the arc, below K)
- B (left end of the horizontal diameter BC)
- C (right end of the horizontal diameter BC)
- D (centre of the semicircle)
- E (on the base-line IG, foot of the style; DE = gnomon)
- I (left end of the base-line)
- L (on the base-line, left of E): shadow-tip
- P (on the base-line, left of E): shadow-tip E P
- R (on the base-line, right of E): shadow-tip E R
- N (on the base-line, right of E): shadow-tip E N

- G (right end of the base-line): shadow-tip E G

whose centre is D, and in which the diameter BC is cut at right angles by the semidiameter A D. Let there be taken in A D, produced, a straight line DE equal to the gnomon of the dial, and through E let IG be drawn parallel to the diameter BC. If then, for example, the arc BF is taken equal to the Sun's altitude at the 16th hour from sunset in the tropic of ♊ — that is, $8^{\circ}14'$ — and the straight line FDG is drawn cutting the straight line I G in G, then E G will be the length of the shadow cast by the style D E, as is clear from what we showed at the beginning of Proposition 2 and at the end of the scholium of the same proposition in this book. By the same art E I will be found, the shadow-length for the 23rd hour in the tropic of ♊, from CH, the arc of the Sun's altitude for the same hour. Likewise from C K, the arc of the Sun's altitude at the 21st hour in the tropic of ♊, the shadow-length E L for the same 21st hour from sunset will be found. So too B M, the arc of the Sun's altitude at the 18th hour from sunset in the tropic of ♊, will give EN, the shadow-length for the same hour; and C O, the arc of the Sun's altitude for the same hour in the tropic of ♋, will yield the shadow-length E P. Finally, from B Q, the arc of the Sun's altitude at the 15th hour from sunset in the tropic of ♋, we shall arrive at the shadow-length ER, and so on. It will be worthwhile to investigate the shadow-lengths for the eastern hours on one side of the style — namely the right — and those for the western hours [on the other side], as has been done in the figure. For unless this is done, shadows that are nearly equal will often be confused with one another — such as the two shadows E P and E R, or EL and EN, which are almost equal to each other.

Instead of the shadow-latitudes we can very conveniently use the hour-arcs which we taught how to compute in Proposition 4 of this book, in those dials where the centre can conveniently be marked. This can be done in the following way. From M, the centre of the dial, let a circle i p l m n of any size be described, in which the diameter i m is drawn perpendicular to the meridian line A C — which diameter will be the common section of the plane of the dial and of the circle of the 6th hour from noon or midnight, as we demonstrated in Proposition 1 of Book 2. Now let there be found, by Proposition 4 of this book, the hour-arc — for example, for the 23rd hour from sunset in the tropic of ♋ — enclosed between the circle of the 6th hour from noon or midnight and another great circle drawn through the poles of the world and through the 23rd hour from sunset in the tropic of ♋; this arc contains $11^{\circ}52'$, and it is

western and northern, because the Sun's distance from the meridian exceeds a quadrant. Now let this arc be reckoned from the point m toward the northern

parts, as far as l , and let the occult straight line $l M f$ be drawn. For if, by means of the compass, the shadow-length for the 23rd hour from sunset in the tropic of $\mathfrak{S}$ is taken and, from E (the place of the style), transferred toward f , the straight line $M f$ will be cut at f , the point of the 23rd hour from sunset in the tropic of $\mathfrak{S}$.

For since the circle of the 6th hour from noon or midnight, and that great circle drawn through the poles of the world and the 23rd hour from sunset in the tropic of $\mathfrak{S}$, are both drawn through the axis of the world, and meet the horizon — to which the horizontal dial is parallel — at the centre of the world, that is at F , the vertex of the style set perpendicular to the plane of the dial, it comes about that with the horizon they make common sections, [namely] straight lines, which at the centre of the world form an angle subtended by the arc of the horizon that lies between the circle of the 6th hour from noon or midnight and that other great circle. And since these two circles meet the axis of the world, ^a and make with it common sections that are parallel, ^b the like lines in the plane of the dial will comprehend an angle equal to the one which those former lines form in the horizon. Therefore, since the angle $m M l$ [is equal to] the one those lines form in the horizon — the angle in the plane of the dial being equal to the angle subtended by the arc of the horizon between the circle of the 6th hour from noon or midnight and the other great circle — the angle $m M l$ is equal to it, because the arc $m l$ is similar to the arc of the horizon enclosed between the circle of the 6th hour from noon or midnight and that other great circle, since it comprehends just as many degrees and minutes. Let $M m$, then, be the common section of the plane of the dial and of the circle of the 6th hour from noon or midnight; the straight line $M l$ will be the common section of the plane of the dial and of the other great circle through the poles of the world and the 23rd hour from sunset in the tropic of $\mathfrak{S}$. And accordingly, with the Sun placed in this circle — namely at the point where it cuts the tropic of $\mathfrak{S}$ — the shadow of the style will be projected, by Proposition 11 of Book 1, onto the straight line $l M f$. Since, therefore, the interval $E f$ has been taken equal to the length of the shadow, the shadow of the style at the 23rd hour from sunset in the tropic of $\mathfrak{S}$ will fall on the point f .

The matter will perhaps be carried out more conveniently if the hour-arc is reckoned in the opposite part of the circle $i p l m n$ — namely, the arc $m l$, which is western and northern, [reckoned] in the eastern and southern part, such as is $i n$. For it will then be sufficient if the straight line $M n$ is drawn, onto which, from E , the shadow-length $E f$ is to be transferred. The same is to be understood of the shadow-latitude arcs. For if, for example, in place of the arc $D N$ — the shadow-latitude of the 6th hour from noon in the tropic of $\mathfrak{S}$, which is western and northern — the opposite arc $B t$, eastern and southern, is taken, then only the

straight line $E t$ need be drawn, from which the shadow-length EO must be cut off, and so on. Again, let the hour-arc of the same 23rd hour from sunset in the tropic of φ be sought — namely $49^{\circ}26'$; this, since it is western and southern, is reckoned in the opposite part, from i toward the northern parts, as far as p , and the occult straight line $M p$ is drawn. For if, into this line, from E , the shadow-length corresponding to the 23rd hour from sunset in the tropic of φ is transferred, as far as the point h , then h will be the point of the 23rd hour in the tropic of φ . Finally, we shall find the hour-arc of the same 23rd hour from sunset, with the Sun placed on the Equator: $21^{\circ}49'$; and this, since it is western and southern, if we reckon it in the opposite part from the point i , as far as u , and draw the straight line $M u$, the equinoctial line will be cut at L , the point of the 23rd hour from sunset. When, therefore, the straight line $f L h$ is drawn, it will give the 23rd hour from sunset, and so on for the rest.

There is, however, a point here worth considering: any occult straight line drawn from M through the extreme point of any hour-line whatever in the tropic of φ , if it is produced beyond the centre M , passes through the extreme point of the line of another hour in the same tropic which is twelve hours distant from the first. Thus you see that the straight line $f M$, which is drawn through f , the extreme point of the 23rd hour from sunset in the tropic of φ , when produced beyond M , passes through q , the extreme point of the 11th hour from sunset in the same tropic. Likewise the straight line $r M f$ is drawn through the extreme points of the 22nd and 10th hours from sunset, and so on. Hence, if two hours from sunrise or sunset that are twelve hours apart fall in one and the same tropic, it will be enough to investigate the hour-arc of just one of them. The reason for this is that the great circle through the poles of the world, drawn through any hour from sunset in a tropic, also passes in the same tropic through the opposite hour — which of course is twelve hours distant from it — since it bisects the tropic, by Proposition 15 of Book 1 of Theodosius. From this it follows that the common section of that circle and the plane of the dial, drawn through M , passes in the plane of the dial through those two opposite hours.

Now this description of a dial by means of hour-arcs is carried out most expeditiously for the hours from noon and midnight, because, since all such hours pass through the centre M , it is not necessary to seek three arcs for each hour, as was done for the 23rd hour from sunset, but it will be enough if single arcs are sought — such as the following, for the several hours from noon and midnight of the horizontal dial, at latitude 42° .

Hour-arcs in the horizontal dial, for the hours from noon and midnight, at latitude 42°.

Table — Upper hour-row = hours from midnight ("Orientales", eastern); middle hour-row = hours from noon ("Occidentales", western); "G. M." = degrees and minutes of the hour-arc; all southern ("Australes").

Hours from midnight	6	7	8	9	10	11	12
Hours from noon	6	5	4	3	2	1	0
Hour-arcs (G. M.)	0.0	21.49	40.48	56.13	68.53	79.50	90.0

From these arcs, if they are reckoned from the points i and m toward the northern (or opposite) parts — since the arcs themselves are southern — and from M, the centre of the dial, straight lines are drawn through the ends of the reckonings, and if these lines are then cut off according to the intervals of the shadow-longitudes which the Sun has when it is in the tropics, the astronomical dial will be described. You have an example in the 7th hour from midnight and the 5th hour from noon, each of which has a southern hour-arc of 21°49'. If this is reckoned from the points i and m toward the opposite (that is, northern) parts, as far as * [?] and u, and the straight lines M * [?] and M u are drawn, onto which the intervals of the shadow-length of these same hours in the tropic of ☊ are transferred, the lines of the 7th hour from midnight and the 5th hour from noon will be described. And the same is to be done for the remaining hours. But the lines are first to be drawn as occult from the centre M, until the shadow-longitudes have been marked on them, because the parts of them outside the tropics are superfluous.

For the vertical southern dial — astronomical, and likewise Italian — the following tables have been computed, containing the shadow-latitudes and shadow-longitudes for the hours from noon and midnight as well as from sunset, and also the hour-arcs for the hours from noon and midnight. But since the horizon, with respect to the vertical circle taken as a horizon, is a ver-

[Margin: ^a 16. und[e] [?]; ^b 10. und[e] [?] — two keyed marginal notes, verbatim glyphs uncertain.]

[Margin: How, in place of the hour-arcs and shadow-latitude arcs, the opposite arcs may be taken in the description of dials.]

[Margin: It is enough, for two hours from sunrise or sunset one of which is twelve hours distant from the other, that a single hour-arc be investigated.]

[Margin: The description of the hours from noon and midnight by means of hour-arcs is most expeditious.]

is a vertical circle, we have called "inferior" those shadow-latitudes that lie below the horizon — that is, on the near side of the vertical of this vertical circle itself, toward the visible pole (which, of course, is elevated above the vertical circle, as is the antarctic pole); and "superior" those that lie above the horizon — that is, beyond the vertical of the vertical — toward the hidden pole (that is, toward the arctic pole), or toward the center of the dial. This is because the former are to be reckoned below the horizontal line, and the latter above it, in laying out the hours. Moreover, the shadow-latitudes of those hours which lie below the horizon — that is, on the near side of the vertical of the vertical — are those which have smaller altitudes above the vertical circle (taken as a horizon) than the Sun has in the horizon, when it is set upon that same vertical (as its own vertical) above the same vertical taken as a horizon, as we wrote in the scholium of proposition 3 of this book.

Shadow-latitudes and shadow-longitudes in the vertical southern dial, for the hours from noon and midnight, at latitude 42°.

In the tropic of Capricorn ♄, the shadow-latitudes are partly inferior and partly superior, as these labels [Infer. Super.] indicate.

Hours ♄ from midnight	5	6	7	8	9	10	11	12	(eastern)

From these tables, then, we shall lay out a vertical southern dial as follows. On the plane of the dial let a circle ABCD of any size be described, with center E, where the stylus is to be fixed at right angles. Draw two diameters, AC and BD, cutting each other at right angles at the center E. Let AC be the meridian line,

since it is the common section of the meridian and the plane of the dial; and accordingly let the other line, BD, be — as we showed in the horizontal dial — the common section of the vertical properly so called (namely, of the horizon) and of that same plane of the dial. That is, it is the horizontal line, which serves as the vertical line of this vertical dial, and from which the shadow-latitudes are to be reckoned. Now if the plane of the dial is fixed, parallel to the vertical circle and facing due south, then by means of a plumb-line the straight line AC, perpendicular to the horizon, is to be drawn on it as the meridian line; and from its point E, where the stylus is to be placed, the circle ABCD is to be described, and the diameter BD is to be drawn perpendicular to AC,

[Margin: Description of the vertical southern dial from the tables.]

Diagram. A large construction figure for the vertical southern dial. The identical woodcut is reprinted on the following page (folio 420, — see fig-p420-1), so the reader has it before them on both sides of the page-turn. Structure: a full circle labelled **ABCD** — **A** at the top, **C** at the bottom, **B** at the left, **D** at the right — with center **E**. The vertical diameter is **A–C** (the meridian line); the horizontal diameter is **B–D**, which runs along the horizontal line across which the word **HORIZON** is lettered (as "HORI...ZON"). Along the upper arc the two quadrant labels **OCC.** (Occasus, west; upper-left) and **ORI.** (Oriens, east; upper-right) are engraved following the curve. Above the whole figure runs a graduated straight scale from **I** (left) to **H** (right), marked with a fine-tick zone near the start at **G** and then numbered **12, 24, 36, 48, 60, 72, 84, 96, 108, 120, 132, 144, 156** — the gnomon-length / shadow-length scale (line IH). On the horizontal line: **F** lies just left of the center **E**, **M** stands to the right of center (the center of the vertical dial), then **P**, then the point **i** at the right end; a small **6** marks a point on this line. Near **E** cluster the small shadow-scale digits **8, 9, 10, 11, 12** and the short radiating marks **2, 3, 4, 5**. Below **E** is the convergence point **K**. From **K/E** a dense sheaf of hour-lines radiates to the lower arc, labelled with the hour-numbers **14, 15, 16, 17, 18, 19, 20, 21, 22, 23, 24**. External to the circle at upper-left is the ray-endpoint **V** (with a short cross-bar), and at upper-right the ray-endpoint **Y** (with an adjacent **7** and cross-bar). Lower-left of the figure: **L** on a line, and the bold point **Q** beside the "14" line. Lower-center: **N** (a second **N** also appears on the upper-left arc near **OCC.**) and **X** to its right. Bottom edge: **R** (left of center), **T** (center), and the ray-endpoints **B** (bottom-left) — hour-lines produced beyond the circle. A lowercase **m** sits at the far left of the horizontal (dashed) line. The text names further construction points **O, S, Z** on these lines and the auxiliary circle **iXZm**; the glyphs at those positions on the woodcut are small and partly overrun by ruled lines.

- I (top-left, scale start): endpoint of shadow-scale line IH
- G (top, after the fine-tick zone): scale origin of the divided part
- H (top-right, scale end): endpoint of shadow-scale line IH
- A (top of circle): superior point / meridian top
- C (bottom of circle): inferior point / meridian foot
- B (left of circle, on horizontal): western point; also used as ray-endpoint below
- D (right of circle, on horizontal): eastern point
- E (center): stylus foot
- F (horizontal line, left of E): gnomon point EF
- M (horizontal line, right of E): center of the vertical dial
- P (horizontal line, right): construction point
- i (right end of horizontal line): construction point of circle iXZm
- m (far left of horizontal, lowercase): construction point of circle iXZm
- K (below E): foot where FK meets the meridian below the stylus
- L (lower-left): point on the equinoctial line
- Q (lower-left, by "14"): shadow-latitude point (DQ / BQ)
- N (lower-center; also upper-left arc): shadow-latitude point on line EN
- X (lower-center-right): hour-point on circle iXZm
- R (bottom, left of center): hour-line endpoint
- T (bottom-center): hour-line endpoint
- V (upper-left, external): hour-arc endpoint (arc mV)
- Y (upper-right, external): hour-arc endpoint (arc iY)
- OCC. (upper-left arc): Occasus (west)
- ORI. (upper-right arc): Oriens (east)
- HORIZON (across horizontal line): the horizontal line
- 2, 3, 4, 5 (radiating near E): hour marks
- 6 (on horizontal line): hour-6 point
- 7 (by Y): hour-7 mark
- 8, 9, 10, 11, 12 (small, near E): shadow-scale divisions
- 14–24 (around lower arc): hour-line numbers
- O [?] (on line EN, per text): shadow-point of hour 13 from sunset — glyph not clearly resolved on the woodcut
- S [?] (per text, points S near the arc): glyph not clearly resolved
- Z [?] (lower-left / circle iXZm, per text): glyph not clearly resolved

to serve as the common section of the vertical properly so called — which does not differ from the horizon — and of the plane of the dial, that is, as the horizontal line. Or else, in the first place, on the plane of the dial the straight line BD, parallel to the horizon, is to be drawn by means of the plumb-line as the horizontal line; and from its point E, in place of the stylus, the circle ABCD is to be described, and the diameter AC, perpendicular to BD, is to be drawn as the meridian line. Let the superior parts be set toward A, the inferior toward C, and accordingly the eastern toward D and the western toward B. Choose also any length of gnomon EF you please, from which as many equal parts as you like are to be cut off on the straight line GH; and to it add further GI, equal to that same stylus and divided into 12 equal parts, so that from this line the shadow-lengths can be taken, as we described for the horizontal dial.

[Margin: How the equinoctial line is described in the vertical dial.]

And so, since — when the Sun is on the Equator — the shadow of the stylus at the 12th hour, noon, is cast below the horizontal line (just as at all the other hours it stands out above the horizon), and since this shadow, as is clear from the table of hours from noon and midnight, contains 13 parts 20 minutes: if we transfer this shadow with the compass from the line IH, taken onto the meridian line, downward from E as far as K, we shall draw through K the equinoctial line KL, perpendicular to AC. We shall also draw it by the following method. On the horizontal line BD, with EF taken equal to the stylus, if

Diagram. The identical vertical-southern-dial construction woodcut described above under fig-p419-1, reprinted here so that it faces the continuing text across the page-turn. Same labels: circle ABCD (A top, C bottom, B left, D right), center E, dial-center M, horizontal line HORIZON with points F, P, i, m and small 6; shadow-scale line I–H (12...156); convergence K below E; radiating hour-lines numbered 14–24; external hour-arc endpoints V (with 7-mark) and Y; lower points L, Q, N, X, R, T. See fig-p419-1 for the full label list; the same small glyphs O, S, Z remain uncertain.

[Margin: By what device the center of the vertical dial is found.]

if at F an angle EFK is constructed equal to the altitude of the pole above the vertical circle — that is, to the complement of the altitude of the pole above the horizon — so that the straight line FK cuts the meridian line below the stylus at K, then the equinoctial line will have to be drawn through K. And if at F another angle EFM is constructed, equal to the complement of the altitude of the pole above the vertical circle (that is, equal to the altitude of the pole above the

horizon), so that the straight line FM cuts the meridian line at M, then M will be the center of the dial. We shall find this same center in another way by this art. In the table of shadow-longitudes of proposition 2 of this book, take the altitude of the pole above the vertical circle — namely the complement of the altitude of the pole above the horizon — 48 degrees, whose shadow is 10 parts 48 minutes. For if this shadow is transferred with the compass from E along the meridian line upward as far as M, then M will be the center of the dial. This will be demonstrated as in the horizontal dial. The hours will be drawn just as in the horizontal dial, provided the shadow-latitudes are reckoned from B or D, upward or downward, as the tables indicate, and so on.

For example: for the 13th hour from sunset in the tropic of Capricorn ♑, count off its shadow-latitude of 21 degrees 43 minutes — the inferior and eastern one — from D, the eastern point, downward as far as N; or, on the opposite side (as we said for the horizontal dial), from B, the western point, upward as far as N. For if, on the hidden line EN, the shadow-longitude of that same hour, 55 parts 35 minutes, is cut off on the opposite side, the point O will be found — the point of the 13th hour from sunset in the tropic of Capricorn. In the same way, from DP — the eastern and superior shadow-latitude of the same 13th hour from sunset, in the Equator, 11 degrees 16 minutes — or from the opposite latitude BP, or from the shadow-longitude of that same hour, 68 parts 17 minutes, the point L was found on the equinoctial line, for the 13th hour from sunset. Likewise, from DQ — the eastern and superior shadow-latitude of the 9th hour from midnight in the tropic of Cancer ♋, 49 degrees 6 minutes — or from the opposite latitude BQ, together with the shadow-longitude of that same hour, 86 parts 29 minutes, the point R was found, for the 9th hour from midnight in the tropic of Cancer. And in the same tropic, from the same latitude BS — western and superior — of the 3rd hour from noon, or from the opposite DS with the same longitude, the point T was found, for the 3rd hour from noon. And if the same is done for the remaining hours, the vertical southern dial will be complete. By the same method, from the hour-arc mV — western and superior, 19 degrees 50 minutes — of the 5th hour from noon, or from the opposite iX, on the circle iXZm described from M, the point X was found, through which the 5th hour from noon is drawn. And from the same hour-arc iY — eastern and superior — of the 7th hour from midnight, or from the opposite mZ, the point Z was found on the same circle, through which the 7th hour from midnight is to be drawn. These two hour-lines, produced beyond the center M, will give the 5th hour from midnight and the 7th hour from noon, and so on.

[Margin: By what art, from a dial already constructed, one derives the dial to be placed on the opposite face of the plane — namely the northern from the southern, etc.]

But the portion above the horizontal line will yield the vertical northern dial, to be placed on the opposite face of the plane if it is inverted, as we prescribed at propositions 13 and 14 of book 2. For the hours from sunset, however, those from sunrise must first be drawn on the southern dial, since on the northern dial they are changed into hours from sunset, as we taught in the scholium of proposition 23 of book 2. And by the same method, from the dials that follow, there will be cut off from the horizontal line those dials that are to be placed on the opposite faces of the planes.

For the construction of both meridian dials, the following little tables of shadow-latitudes and shadow-longitudes have been composed, both for the hours from noon and midnight and for those from sunset. Now the circle of the 6th hour from noon and midnight passes through the poles of the world and through the poles of the meridian — namely through the common sections of the Equator and the horizon — and so is, as it were, the meridian of the meridian itself. Therefore the Equator, since it is at right angles both to the meridian and to the circle of the 6th hour from noon and midnight, will stand with respect to the meridian just as the vertical properly so called does. For in the same way the vertical of the horizon is at right angles [to it], and is drawn through both the poles of the horizon and the meridian of the horizon. And this is to be observed for every circle properly called the vertical of any given great circle: namely, that it passes and...

passes through the poles of that great circle itself, and through the poles of the meridian proper to that same great circle. Therefore, in the Meridian dial the shadow-latitudes [latitudines umbrarum] must be reckoned from the equinoctial line — that is, from the common section of the plane of the dial and the vertical properly so called of the Meridian itself. When the Sun runs through the northern signs, they are reckoned toward the northern parts of the dial; but when it stays in the southern signs, toward the southern. Again, since a quadrant of each parallel lies between the Meridian and the circle of the 6th hour from noon and midnight, the shadow-latitudes belonging to those hours which are less than six hours from the meridian must be computed from the upper part of the equinoctial line, while the latitudes of the hours whose distance from the meridian exceeds a quadrant must be computed from the lower part. Hence it comes about that in the tables certain hours of each tropic, and their latitudes,

are called inferior, and others superior. Finally, the latitudes of the forenoon (or eastern) hours must be computed in the eastern dial, and those of the afternoon (or western) hours in the western dial.

Shadow-latitudes and shadow-longitudes in each Meridian dial, for the hours from noon and midnight, for any latitude whatever.

In the tropic of Cancer ☿ all shadow-latitudes are Northern, and in the tropic of Capricorn ♄, Southern. Also, in each tropic the shadow-latitudes are partly Inferior and partly Superior, as these syllables [Infer. Super.] indicate.

In the tropic of Capricorn ʒ all shadow-latitudes are Southern, and all placed here are Superior. The Eastern are distinguished from the Western by these syllables [or. occ.].

Hours ʒ, from sunset	16 (or.)	17 (or.)	18 (or.)	19 (or.)	20 (occ.)	21 (occ.)	22 (occ.)	23 (occ.)	24 (occ.)
Shadow-latitudes (G. M.)	35.5 1	28.5 3	25.1 7	23.4 2	23.39	25.8	28.34	35.14	48.0
Shadow- longitudes (P. M.)	11.9	17.3 3	31.1 7	93.1 5	106.4 3	32.48	18.8	11.29	7.38

In these tables we could give all the hours from noon and midnight, so that they might all be drawn in each Meridian dial — although those that fall above the horizontal line are superfluous. We did the same for the hours from sunset when the Sun runs through the Equator. And if one should wish, the same could be done for those same hours from sunset when the Sun is in the tropics; but we have not done this, and have noted only those hours that fall below the horizontal line, since the style's shadow marks only these while the Sun stands above the Horizon.

[Margin: Construction of the Meridian dial from the tables.]

Therefore, to construct the Meridian dial: in the plane of the dial draw the straight line AB for the horizontal line — which, on a stable and firm plane, must be drawn parallel to the Horizon by means of a plumb-line. On this line choose the style's location C, and from it describe a circle of any size, DEF. Then, in the eastern dial from point B — which lies to the north and, when we turn toward the dial, is placed on our right — and in the western dial from point A — likewise northern, set on our left when we turn our face to the dial — count downward the complement of the pole's altitude as far as F; and draw the straight line FCD, which the straight line EC cuts at right angles at the center C. By what we demonstrated in proposition 25 of book 2, DF will be the equinoctial line, and EC the line of the 6th hour from noon or midnight. After this, having taken the length of the style, cut off for it any number of equal parts from the line GH, as was done in the preceding constructions. And so, if for the 11th hour from midnight the shadow-latitude is taken...

Diagram. A large construction figure for the two Meridian dials, occupying the lower two-thirds of the page. Above the two circles runs a horizontal graduated scale (the line of equal parts GH): at its left terminus the letter I, then G, then the graduations 12, 24, 36, 48, 60, 72, 84, 96, 108, and at the right terminus H.

Beneath it are two large equal circles set side by side and overlapping in a central vesica.

- The **left circle** carries the heading **OCCIDENTALE** ("Western [dial]").
- The **right circle** carries the heading **ORIENTALE** ("Eastern [dial]").
- A single horizontal line runs through both circles, labelled **HORI = ZON** (HORIZON — "HORI=" over the left circle, "ZON" over the right); its left terminus is **A**, its right terminus **B**.
- **BORE.** (*Borealis*, north) is lettered along the upper rim of each circle; **AVST.** (*Australis*, south) along the lower rims, twice near the central vesica.
- Point **E** stands at the top on the vertical of the left/upper region; the style-locus **C** lies at the center on the horizon line.
- **D** appears twice (one for each dial, near the upper center); **F** and **M** appear near the lower part of each dial (F above M).
- The rims carry repeated endpoint-letters **N, K, L** in clusters (e.g. "N K" / "K N" at the tops, "K L N" at the bottoms).
- Numerous small Italian-hour numerals (**1** through **24**) and interior point-letters (including **R, V, X, O, P, T** near the central vesica) are printed as fine hour-marks on the radiating hour-lines.

[?] The dense field of small hour numerals (1–24) and interior point-letters cannot be individually resolved with confidence at this resolution; more than two labels are uncertain. Marked as a

the shadow-latitude of 24 degrees 14 minutes — which is superior and, in the tropic of Cancer ☊, northern — and it is counted in the eastern dial from D toward the northern parts (or, on the opposite side, from point F) as far as K; and if along the hidden line CK, on the opposite side, the shadow-longitude of that same hour, 49 parts 6 minutes, is carried over from C as far as L, the point L will be found, for the 11th hour from midnight in the tropic of Cancer. In the same way we shall find the point L in the tropic of Capricorn ☋, for the same hour, if the same shadow-latitude is counted from D toward the south (or, on the opposite side, from point F) as far as K, and the same shadow-longitude is cut off along the hidden line CK. And if on the equinoctial line the segment CM is taken, equal to the shadow-longitude of that same hour in the Equator — which amounts to 44 parts 47 minutes — the line LML will give the 11th hour from midnight in the eastern dial. By the same reasoning we shall draw, in the western dial, the 1st hour from noon from the same shadow-latitude and shadow-longitude, as is clear in the figure. And if the same is done for the remaining hours from midnight and

from noon, both Meridian dials will be complete. We shall, however, accomplish this more briefly as follows.

Let the shadow-longitudes for the individual hours in the Equator be transferred onto the equinoctial line, marking points on it. For through these points, straight lines raised perpendicular to the equinoctial line will give the hours from noon and midnight. If these perpendiculars are cut off from C according to the shadow-longitudes that the hours have in the tropics — or else by the hidden lines of the shadow-latitudes — the points of the tropics will be obtained. Moreover, by one and the same operation, eight points in the tropics will be found from a single shadow-latitude. Thus you see that from the shadow-latitude of 32 degrees 12 minutes — which in each tropic the 9th and 3rd hours from midnight, and the 3rd and 9th from noon, possess — computed on both sides from the points D and F, in each dial, as far as N, the eight points of those same hours are found: O, P, Q, R, S, T, V, X. And so for the rest, provided one carefully observes in the tables which hours' latitudes are Northern or Southern, and which are Superior or Inferior, and likewise which are to be transferred to the eastern dial and which to the western. In the same way, by a single operation, four points will be found on the equinoctial line from one shadow-longitude. Thus you see that from the shadow-longitude of 12 parts 0 minutes — which in the Equator the 9th and 3rd hours from midnight, and the 3rd and 9th from noon, and likewise the 15th, 9th, 21st, and 3rd from sunset, possess — four points Y, Z, a, b are found on the equinoctial line for the said hours.

[Margin: How, by one operation, eight points are found in the tropics for the hours from noon and midnight, and four also on the equinoctial line for the hours from sunset.]

Again, if for the 9th hour from sunset in the tropic of Cancer ☿ — which is eastern — the shadow-latitude of 49 degrees 16 minutes is taken (which is inferior and northern), and it is computed from point F northward as far as d in the eastern dial, and the hidden line dC is drawn, there will be found on it, by means of the shadow-longitude, the point of the 9th hour from sunset in the tropic of Cancer; and this point, joined by a straight line to the point Z of the 3rd hour from midnight, gives the hour from sunset. For the 9th hour from sunset, on the equinoctial line, passes through the 3rd hour from midnight; on the equinoctial line it will give the 9th hour from sunset, as is established from the table of proposition 19 of book 1. By like reasoning, if for the 21st hour from sunset in the tropic of Capricorn ♎ — which is western — the shadow-latitude of 25 degrees 8 minutes is taken (which is superior and southern), and it is counted

in the western dial from D toward the south as far as e, we shall find, by means of the shadow-longitude, on the hidden line eC, the point f of the 21st hour from sunset in the tropic of Capricorn; and so we shall find the points of the remaining hours. If, then, the corresponding points found both in the tropics and on the equinoctial line are joined by straight lines, the Italian dial will have been drawn. Only the lines of the 18th hour from sunset and the 6th from sunrise must be drawn parallel to the equinoctial line, through the points found in the tropic of Cancer in each dial, as we demonstrated in proposition 34 of book 2. And it is easily gathered from the table of proposition 19 of book 1 through which hours from noon or midnight, on the equinoctial line, the hours from sunset must be drawn.

[Margin: In the Meridian dial there is no use for the hour-arcs.]

Here, however, there is no use for the hour-arcs, since the Meridian — to which the dial is parallel — passes through the poles of the world.

For the superior polar dial, which is parallel to the circle of the 6th hour from noon and midnight, the following tables are to be used, computed for the hours from noon and midnight and from sunset. These we shall draw on the superior dial alone, since the inferior one derives from it, as we said above concerning the Vertical dial — provided that, for the hours from sunset on the superior dial, one first draws those hours from sunrise which, on the inferior dial, must be changed into hours from sunset, as we set forth in the scholium of proposition 23 of book 2. For this reason we have written in these tables only those hours that fall on the superior dial — that is, those whose distance from the meridian is less than a quadrant, or six hours. And since the Meridian of the Horizon is also the Meridian of the circle of the 6th hour from noon and midnight, the Equator, standing at right angles both to the Meridian and to the circle of the 6th hour from noon and midnight, will be as it were the vertical of that same circle. Therefore, in the polar dial the shadow-latitudes must be reckoned from the equinoctial line — that is, from the vertical line of the dial itself — toward the upper (or northern) parts when the Sun occupies the first degree of Cancer ☊, and toward the lower (or southern) parts when the Sun is at the beginning of Capricorn ☋.

Shadow-latitudes and shadow-longitudes in the superior polar dial, for the hours from noon and midnight, for any latitude whatever.

In the tropic of Cancer ☊ all shadow-latitudes are Northern or Superior; in the tropic of Capricorn ☋, Southern or Inferior.

	6	7	8	9	10	11	12	
Hours $\mathfrak{S}$ & $\mathfrak{V}$, from midnight	6	7	8	9	10	11	12	Eastern
Hours $\mathfrak{S}$ & $\mathfrak{V}$, from noon	6	5	4	3	2	1	0	Western
Shadow-latitudes (G. M.)	23.30	24.14	26.40	32.12	41.11	59.14	90.00	
Shadow-longitudes (P. M.)	Infinite	49.65	23.15	14.5	9.11	6.17	5.13	

On the equator there are no shadow-latitudes, since there, by proposition 11 of book 1, the style's shadow falls perpetually on the equinoctial line. Their longitudes, however, are as follows.

Hours $\mathfrak{V}$ & $\mathfrak{A}$, from midnight	6	7	8	9	10	11	12	orientales
Hours $\mathfrak{V}$ & $\mathfrak{A}$, from noon	6	5	4	3	2	1	0	occidentales
Shadow-longitudes (P. M.)	Infinite	44.47	20.47	12.0	6.56	3.13	0.	

Shadow-latitudes and shadow-longitudes in the superior polar dial, for the hours from sunset, for latitude 42 degrees.

In the tropic of Cancer $\mathfrak{S}$ all shadow-latitudes are northern, or superior.

Hours $\mathfrak{S}$, from sunset	11	12	13	14	15	16	Orientales
Shadow-latitudes (G. M.)	23.42	25.17	28.53	35.51	49.16	74.19	
Shadow-longitudes (P. M.)	93.15	31.16	17.33	11.9	7.26	5.28	
Hours $\mathfrak{S}$, from sunset	17	18	19	20	21	22	Occidentales
Shadow-latitudes (G. M.)	72.16	48.3	35.14	28.30	25.8	23.39	
Shadow-longitudes (P. M.)	5.32	7.37	11.29	18.8	32.48	106.43	

On the equator there are no shadow-latitudes, because there the gnomon's shadow is perpetually cast onto the equinoctial line, as was shown in proposition 11 of book 1. Their longitudes, however, are these.

							1	
Hours Υ & $\underline{\alpha}$, from sunset	12	13	14	15	16	17	8	orientales

[Margin: The construction of the polar dial from the tables.]

So then, in the plane of the sundial let the straight line AB be drawn to serve as the equinoctial line. Since the plane is fixed and firm, and equidistant from the circle of the 6th hour from noon and midnight, this line must be drawn parallel to the horizon by means of a plumb-line. On this line take the point C as the place of the style, and about it describe a circle DEF of any size you like. In it draw the diameter DC, cutting the straight line AB at right angles; this will be the meridian line, as we demonstrated in proposition 37 of book 2. Then, taking a gnomon of any length, mark off along it as many equal parts as you please from the straight line GH, as was explained above.

And so, if the shadow-latitudes are reckoned from point F or from point E — according as they are eastern or western — toward the north or the south, according as they are northern or southern, the polar dial will be laid out, just like the meridian dial, as may be seen in the accompanying figure. In it, from the fourfold shadow-latitude FK of 24 degrees 14 minutes — which belongs to the 7th hour from midnight and the 5th from noon, reckoned both from the eastern point

F and from the western point E, toward the north and the south — and from its shadow-longitude of 49 parts 6 minutes, the fourfold point L has been found; and by one and the same operation, for the 7th hour from midnight and the 5th from noon, in the tropic of Cancer ☿ and of Capricorn ♑. And from the shadow-longitude of those same hours on the equator — namely 44 parts 47 minutes — the points A and B have been found, for the same hours on the equinoctial line, and so on. Again, from the shadow-latitude EM — western and northern — of 72 degrees 16 minutes, or its opposite FM, which belongs to the 17th hour from sunset in the tropic of Cancer ☿, and from its shadow-longitude of 5 parts 32 minutes, the point N has been found, for the 17th hour from sunset in the tropic of Cancer ☿. Likewise, from the shadow-latitude

FO — eastern and southern — of 35 degrees 14 minutes, or its opposite EO, which corresponds to the same 17th hour from sunset in the tropic of Capricorn ♑, and from its shadow-longitude of 11 parts 29 minutes, the point P has been found, for the 17th hour from sunset in the tropic of Capricorn ♑. Finally, from the western shadow-longitude of 3 parts 13 minutes of that same 17th hour on the equator — for since this hour is eastern on the equator, its shadow falls on the western side of the dial, that is, on the opposite side — the point a has been found, for the same 17th hour from sunset on the equinoctial line, and so on. The lines of the 12th and 24th hours from sunset, and of the 6th from sunrise, must be drawn through the points found in the tropics, parallel to the equinoctial line, as was shown in proposition 46 of book 2. Moreover, the line of the 24th hour from sunset, when extended, will give the horizontal line, since it is the common section of the plane of the dial and the circle of the 24th hour from sunset — that is, of the horizon. We shall draw it in the following way as well.

[Margin: How the horizontal line, and the line of the 12th hour from sunrise or sunset, are to be drawn.]

From the table of shadow-longitudes in proposition 2 of this book, take the shadow-longitude corresponding to the altitude of the pole above the horizon — in our example, the one corresponding to 42 degrees, which comes to 13 parts 20 minutes. With the compasses transfer it from C along the meridian line toward the north, as far as the point Q. For through this point the horizontal line must be drawn — the line of the 24th hour — parallel to the equinoctial line, or perpendicular to CD. For the arc of the meridian that lies on the southern side, between the horizon and the circle of the 6th hour from noon and midnight (to which the dial is parallel), measures the altitude of the pole above the horizon; that is, in our example, it spans 42 degrees. If the Sun were placed at that point of

the horizon on the southern side where it is cut by the meridian, it would have, above the circle of the 6th hour from noon and midnight, an altitude of 42 degrees — precisely the altitude of the pole above the horizon. Therefore the shadow cast by the style would fall on the point Q, toward the northern parts, which lie opposite the Sun, since the shadow CQ corresponds to 42 degrees, that is, to the altitude of the pole. And since the line of the 12th hour from sunrise or sunset is just as far from the equinoctial line on the other side as the horizontal line is distant, if a length CR is taken equal to CQ, the line of the 12th hour from sunrise or sunset must be drawn through R, parallel to the equinoctial line, or perpendicular to DC.

Diagram. A large construction figure for the polar sundial. Along the top runs a straight graduated scale-line GH — the gnomon-parts scale — with a bracketed origin-mark at the far left labeled **I**, then **G**, and graduation numbers **12, 24, 36, 48, 60, 72, 84, 96**, terminating at **H** on the right. Below it stands the large horizon circle DEF, with the four cardinal labels set around its rim: **BOR** (Boreas, north) at the top, **AVST** (Auster, south) at the bottom, **ORI** (Oriens, east, lettered vertically) on the right near F, and a matching vertical direction-label on the left near E which I read as the western label but cannot resolve with confidence [Occ.? — glyphs worn].

- Vertical diameter (meridian line): **D** at top, through the center down to **R** at the bottom center; **M** appears near D at the top and again near AVST at the bottom (the meridian endpoints).
- Horizontal diameter (equinoctial line AB): **A** on the left, **B** on the right; **E** left of center, **F** right of center; **C** the center (place of the style) and **Q** on the meridian near center.
- Hour-lines radiate obliquely and carry the hour numbers **7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18, 19, 20, 21, 22, 23, 24**.
- Point-clusters where hour-lines meet the circle are labeled with repeated letters (the text speaks of a "fourfold point L"): **L**, **O**, and **K** occur several times on both the left and right flanks; **P** near the center; **S** on the lower right. Several of these small peripheral letters do not resolve cleanly on the scan and are flagged [?]; the figure should be re-examined.

[Margin: In the polar dial the hour-arcs have no use.]

Here too the hour-arcs have no place, just as they have none in the meridian dial, because the circle of the 6th hour from noon and midnight — to which the dial is parallel — passes through the poles of the world, exactly as the meridian does.

[Margin: Why the equinoctial dial is not constructed by means of the tables.]

Furthermore, we have composed no tables for the construction of the equinoctial dial, because the equinoctial dial is built far more easily by the method we set out in book 2 than by any tables. Tables for building a dial of this kind would seem to be drawn up pointlessly and to no purpose, especially since all the shadow-latitudes and hour-arcs are equal to one another at every hour, the Sun's altitude is likewise the same at every hour of each parallel, and consequently the shadow-longitude too is always the same, as is clear from what has been said above.

For the south-facing vertical dial that declines 30 degrees from the meridian toward the east, the following little tables have been drawn up, for the hours from noon (or midnight) and from sunset. In them this sign † marks the hour that falls on the proper meridian of the declining dial, as we explained in the tables of the Sun's altitudes in proposition 1 of this book. In these tables we call "superior" those shadow-latitudes that lie beyond the dial's own vertical — that is, toward the center of the dial — and "inferior" those that lie on the near side of that same vertical, that is, toward the equinoctial line. The hour-arcs, in turn, are called "superior" when they lie beyond the center of the dial.

Hour-arcs in the south-facing vertical dial, which declines 30 degrees from the meridian toward the east, for the hours from noon and midnight, for latitude 42 degrees.

Gnomonics — Book V (continued)

We have calculated, for the hours from noon and from midnight, the hour-arcs of only those twelve hours (from which, together with the shadow-lengths, we shall here construct the astronomical dial) that are less than six hours distant from their proper meridian — which, as we advised in the scholium of the preceding proposition, had to be done, since from these the whole dial will be described, as will become clear. And we noted the shadow-lengths of those hours that fall on the southern face of the dial. We did the same for the shadow-latitudes and shadow-lengths for the hours from sunset. This too we shall observe in what follows.

[Margin: Construction of the vertical declining dial from the tables.]

Now in the plane of the dial let a straight line AB be drawn to serve as the horizontal line, so placed in the fixed and firm plane that it is parallel to the horizon; and on it let the place of the style be set at the point C. From C let a circle DEFG of any size be described, and in it, from the center, let a hidden perpendicular CH be dropped to the line AB — a line that can be dropped straight to the horizon on the fixed plane by means of a plumb-line. Then, by Proposition 30 of Book 1, let there be computed the arc of the great circle to which the declining dial is equidistant [parallel], the arc intercepted between the meridian of the horizon and the proper meridian, drawn through the poles of the world and through the poles of that same great circle. We found this arc to comprise 29 degrees 3 minutes.

Diagram. A construction figure for the vertical dial declining 30° from south toward east, at latitude 42° . Across the top runs a graduated scale-bar (a scale of gnomon-parts) with its ends marked **I** (left) and **H** (right); its graduations are labelled **G**, then **12, 24, 36, 48, 60, 72**. Below it stands the large dial circle. The horizontal diameter carries the split legend **HORI·ZON** (Horizon), with **ORT**. (Ortus / east) marked near its center-right and endpoint letters toward the left (**A**) and center-right (**B**). Readable perimeter and radial labels:

- **b** (top of circle)
- **N** (upper left, on the circle)
- **D, Y** (upper right; **D** on the circle, **Y** adjacent)
- **E** (mid-left) with hour-number **4** nearby
- **M** (interior, right of center — the convergence point / center of the dial and apex of the shadow triangle)
- Interior letters near center-left: **L, A, U, O**
- Radial hour-numbers reading down the right and around the lower rim: **2, 3, 23, 22, 21, 20, 19, 18, 17, 16, 15, 14, 13**, and **11** (set as "II") on the left
- Lower and lower-left points: **F** (on the circle), **Q, Z, G** (right, near the 22 line), **P** (lower right), **V, a, H** (a second H, lower center), **R, S, T, K, C**
- Crowded central cluster of small letters/digits (**d, i, s, f, C**, and the digits **5, 6, 7, 8, 9, 10, 11**) marking the graduated shadow-triangle — these interior sorts are too small and overprinted to resolve individually. [Several interior labels [?]]

This arc we shall reckon in the circle DEFG from the point H — toward the west (which, for us facing the dial, lies to the left, that is, toward A) if the plane of the

dial declines from south toward east; but toward the right (that is, toward the east, or point B) if the plane of the dial turns aside from south toward west. In our example, since we suppose the dial to decline from south toward east by 30 degrees, we counted the said arc as far as F.

[Margin: The line of the style, or the proper meridian, in the declining dial.]

For the straight line FCD, when drawn, will be the common section of the plane of the dial and of its own meridian — that is, the line of the style, standing as the proper meridian line, which separates the eastern part of the dial from the western, as we demonstrated in Proposition 1 of Book 3; since the line CH is parallel to the meridian line of the dial, which of course marks the 12th hour, and since this too is perpendicular to the horizontal line AB, and so on.

[Margin: The equinoctial line in the declining dial.]

Let the straight line EG cut this at right angles in the center; it will be the common section of the plane of the dial and of the vertical properly so called of that same plane of the dial, and from it the shadow-latitudes are to be reckoned. On the line EG, having taken a style CI of any length, let there be cut off from the line HI as many equal parts as you please, of which GI is subdivided into 12 equal parts, as was done above. After this, by Proposition 29 of Book 1, let there be computed the elevation of the pole above the great circle to which the dial is equidistant, which we find to be 40 degrees 3 minutes; and its complement therefore 49 degrees 57 minutes.

[Margin: The center of the declining dial.]

If, then, from the table of shadow-lengths of Proposition 2 of this book, one takes the shadow-length 10 parts 5 minutes, corresponding to the complement of the said elevation of the pole — that is, agreeing with the altitude of the Sun when placed in the Equator and on the proper meridian of the dial — and this, by means of the compass, is taken from the line HI and carried down along the line CF as far as K, then the straight line KL, drawn through K to DF, will be perpendicular: it is the equinoctial line, necessarily cutting the horizontal line, provided no error has been made at the point L, which terminates the shadow of the 6th hour from noon or midnight, or of the 12th hour from sunrise or sunset, when the Sun is in the Equator. That shadow, as is established from the preceding table of the hours of Aries ♈ and Libra ♎ under the 12th hour from sunset, is 20 parts 46 minutes.

If again the shadow-length 14 parts 17 minutes, corresponding to the elevation of the pole above the great circle to which the dial is equidistant, is carried from C upward along the line CD as far as M, then M will be the center of the dial. This, however, we shall find together with K, the point of the equinoctial line, if with the style CI we make the angle CIK — the angle of the elevation of the pole above the great circle to which the dial is equidistant — and another angle CIM, of the complement of the elevation of the pole. Through M, the center of the dial, let a perpendicular be drawn to DF...

a perpendicular NO, which will stand as the line of the 6th hour from noon and from midnight if the dial were horizontal, and from which the hour-arcs are to be counted in the circle NPO described from M.

The hours we shall describe as follows. From N and O let the hour-arcs be computed in the circle NPO, in the opposite parts — namely all below the line NO, since they are all upper [superiores]. Likewise the eastern ones from N, and the western from O. For if, from M, straight lines drawn through the endpoints of those arcs are cut off by means of the compass according to the shadow-lengths that belong to the hours from noon and from midnight in the tropics, the astronomical dial will be delineated. It can nevertheless also be described by means of the shadow-latitudes, if these are reckoned from the line EG. For example:

Diagram. The same declining-dial construction figure as on the facing page is reprinted here — an identical woodcut, with the same top scale-bar (ends **I** and **H**; graduations **G**, 12, 24, 36, 48, 60, 72), the same **HORI·ZON** diameter with **ORT**. and endpoint letters **A/B**, and the same perimeter and interior labelling (**b**, **N**, **D**, **Y**, **E**, **M**, **L**, **A**, **U**, **O**, **C**, the hour-numbers 2, 3, 13–23 and 11 as "II", and the lower points **F**, **Q**, **Z**, **G**, **P**, **V**, **a**, **H**, **R**, **S**, **T**, **K**). As on the previous page, the crowded central cluster (**d**, **i**, **s**, **f**, digits 5–11) is too fine to resolve label-by-label.

[Reprinted figure; several interior labels [?]]

Since the arc of the 12th hour from midnight, 60 degrees 57 minutes, is western and upper, we shall count it from O, the eastern point, downward as far as P; and the straight line MP, when drawn, will be the line of the 12th hour, or of midnight — that is, the meridian line — which, if there is no error in anything, will be perpendicular to the horizontal line AB, and will not differ from the thread of a plumb-line freely dropped from M on the fixed plane. So too, since the arc of the 8th hour from midnight is eastern and upper, if it is counted from the point N, the western point, downward as far as Q, the straight line MQ will give the line of the 8th hour from midnight; on it, at R, we shall cut off according to the shadow-

length 27 parts 1 minute, which belongs to that same 8th hour from midnight in the parallel of Cancer ☊, so that we obtain R, the point of the tropic of Cancer ☊. And so with the rest.

Again, from the shadow-latitudes that were computed for the hours from sunset (reckoned from the line EG), and from their lengths, we shall compose the Italian dial, as in the preceding cases. Thus you see that, by the shadow-latitude GX of the 15th hour from sunset in the tropic of Cancer ☊ — an upper and eastern latitude, comprising 27 degrees 40 minutes — and by the length of that same shadow, 6 parts 27 minutes, the point S is found, for the 15th hour from sunset in the tropic of Cancer ☊. In like manner, from GY, the eastern and upper shadow-latitude — or its opposite EZ — of 83 parts 29 minutes [P.83.M.29], which suits that same 15th hour from sunset in the Equator, or indeed from the shadow-length 10 parts 9 minutes of that same hour in the Equator, the point T is found on the equinoctial line for the 15th hour from sunset; through which the line will pass entirely, if no fault has been committed — the same as the 9th hour from midnight on the equinoctial line. Lastly, from Eb, the western shadow-latitude of 71 degrees 7 minutes — or its opposite Ga — and from the length of that same shadow, 26 parts 51 minutes, the point V is found, the point of the 15th hour from sunset in the tropic of Cancer ☊; and thus the line STV of the 15th hour from sunset is drawn.

The same reasoning holds for the remaining hours. Only this must be noted: that the 23rd hour from sunset is drawn through the point found in the tropic of Capricorn ☋, and through the 5th hour from midnight — or the 11th from sunset — on the equinoctial line, as is prescribed in the table of Proposition 19 of Book 1; likewise through that point where the 6th hour from midnight and the 13th hour from sunset intersect one another, namely through the point d. So too the 22nd hour is drawn through the point found in the tropic of Capricorn ☋, and through the point e, where the 14th hour from sunset intersects the 6th hour from midnight — because the 4th hour from midnight, through which it ought to be drawn, cuts the equinoctial line too far off. But the 21st hour is drawn through the point found in the tropic of Capricorn ☋, and through the point f, where the 15th hour from sunset divides the 6th hour from midnight, and so on. All these points of the 6th hour from midnight are derived from the table of Proposition 20 of Book 1, whose title is "The line of the 6th hour from noon or from midnight." Nevertheless, for the same hours, other points can be found in the parallel of Aries ♈ or Libra ♎, if the shadow-latitudes and lengths are found.

For the construction of the upper dial declining 30 degrees from the horizon and facing west, the tables that follow — computed for the hours from sunrise — are to be used. For as an example of all such dials we shall construct only the Babylonian dial. In these tables, the northern [Boreales] shadow-latitudes are those that lie on the near side of the dial's proper vertical, that is, toward the equinoctial line; while the southern [Australes] are those that lie beyond that same vertical, toward the center of the dial, as in the horizontal dial.

Shadow-latitudes and shadow-lengths in the upper dial declining 30 degrees from the horizon on the eastern side — but set at a right angle to the vertical properly so called — for the hours from sunrise, at latitude 42 degrees.

In the tropic of Cancer ☿, the shadow-latitudes are partly northern and partly southern, as these syllables [Bor. / Austr.] indicate.

Table — In the tropic of Cancer ☿ (hours from sunrise), eastern [orientales]:

Hours ☿, from sunrise	3 Bor	4 Bor	5 Bor	6 Bor	7 Austr	8 Austr	9 Austr	10 Austr.	†
Shadow-latitudes (G. M.)	18. 2	19. 57	12. 23	4.4 4	3.54	15.39	36.42	86.18	9 0. 0
Shadow-lengths (P. M.)	438 .45	53. 11	26. 24	16. 12	10.31	6.43	3.56	2.32	2. 3 2

Table — In the tropic of Cancer ☿ (hours from sunrise), western [occidentales]:

Hours ☿, from sunrise	11 Austr.	12 Austr.	13 Austr.	14 Bor.	15 Bor.
Shadow-latitudes (G. M.)	40.18	16.56	5.13	3.53	11.32
Shadow-lengths (P. M.)	3.42	6.21	10.2	15.25	24.51

In the Equator all the shadow-latitudes are southern.

Table — In the Equator ♃ & ♄ (hours from sunrise), eastern [orientales]:

Hours ♃ & ♄, from sunrise	3	4	5	6	7	8	†
Shadow-latitudes (G. M.)	4.10	13.1	23.4	36.4	54.0	76.3	90.

Hours γ & α , from sunrise	3	4	5	6	7	8	†
		8	3	4		9	0
Shadow-lengths (P. M.)	117.28	37.9	21.1	14.1	10.3	8.46	8.3
			3	6	3		2

Table — In the Equator γ & α (hours from sunrise), western [occidentales]:

Hours γ & α , from sunrise	9	10	12	11	13	14
Shadow-latitudes (G. M.)	77.46	54.54	37.24	24.13	13.43	4.35
Shadow-lengths (P. M.)	8.44	10.26	14.3	20.47	36.0	107.33

In the tropic of Capricorn γ , all the shadow-latitudes are southern, but the western are distinguished from the eastern by these syllables [or. / occ.].

Table — In the tropic of Capricorn γ (hours from sunrise):

Hours γ , from sunrise	3	4	5	6		7	8	9	10	11
	or.	or.	or.	or.	†	occ.	occ.	occ.	occ.	occ.
Shadow-latitudes (G. M.)	36.	47.	59.	74.	90.	89.4	74.1	59.3	47.6	36.3
	45	21	52	22	0	9		4		2

	16	18	8	16	54	4	0	9	6	0

[Margin: Description of the dial declining from the horizon, from the tables.]

Let, then, a straight line AB be drawn in the plane of the dial, in any position, but so placed in the fixed and firm plane that it is parallel to the horizon, by means of a plumb-line; and thereupon the meridian line too is to be drawn in the dial. For in this dial the horizontal line and the meridian line are equidistant [parallel], as we demonstrated in Proposition 14 of Book 3. On the line AB, having assumed the place of the style C, let a circle AFDG of any size be described from C; in it let there be counted, from B — the northern point — the arc of the great circle to which the dial is equidistant, intercepted between the meridian of the horizon and the proper meridian of that same great circle, which by Proposition 30 of Book 1 we find to comprise 24 degrees 14 minutes.

toward F indeed, that is toward the eastern parts, if the dial faces west (that is, declines from the horizon on the eastern side); but toward G, that is toward the western parts, if the dial faces east (that is, declines from the horizon on the western side). In our example, since we suppose the dial to decline from the

horizon on the eastern side by 30 degrees, so that it faces west, we counted the said arc as far as D.

[Margin: The line of the style, or the proper meridian, in the dial declining from the horizon.]

For the straight line DCE, when drawn, will be the common section of the plane of the dial and of its own meridian — that is, the line of the style, standing as the proper meridian line, which separates the eastern parts of the dial from the western, as we showed in Proposition 13 of Book 3, since the line AB is set to be equidistant [parallel] to the meridian line to be drawn. The line FG, cutting this at right angles in the center C, will be the common section of the plane of the dial and of the vertical properly so called of that same plane of the dial, from which will be computed the...

will be the shadow-latitudes. On this line FG, having taken the style CH of any length whatever, let there be cut off from the line HI as many equal parts as you please, of which GI is subdivided into 12 equal small parts, as was also done above. Then let the altitude of the pole above the great circle to which the dial is parallel be found by Proposition 29 of Book 1 — which we determined to be 35 degrees 25 minutes, so that its complement is 54 degrees 35 minutes. If from the table of shadow-lengths (Proposition 2 of Book 1) one takes the shadow-length of 8 parts 32 minutes, corresponding to the complement of the said pole-altitude — that is, agreeing with the altitude of the Sun when set in the Equator and on the proper meridian of the dial — and if, with the help of the compass, this length taken from the line HI is transferred downward along the line CD as far as I, then the line IK, drawn through I perpendicular to DE, will be the equinoctial line [aequinoctialis]. If no error has been made, this line necessarily cuts, at the point K, the line CK (which is drawn perpendicular to AB, and which, as was shown in Proposition 16 of Book 3, is the common section of the plane of the dial and of the vertical properly so called of the horizon itself). The point K marks the end of the shadow of the 6th hour from noon, or of the 12th hour from sunrise or sunset, when the Sun is in the Equator — the shadow which in the preceding table measures 20 parts 47 minutes.

[Margin: How the equinoctial line is to be drawn.]

Again, if the shadow-length of 16 parts 53 minutes, corresponding to the altitude of the pole above the great circle to which the dial is parallel, is transferred from C upward along the line CE as far as L, then L will be the center of the dial. This

point, however, together with I, the point of the equinoctial line, we shall find as in what preceded, if with the style CH...

Diagram. A crowded construction figure for the dial declining from the horizon (declination 30° on the eastern side, facing west), showing the disc of the dial with its hour-lines, the equinoctial line, and the horizon/meridian framework. A horizontal shadow-length ruler runs across the top; a great circle occupies the body of the figure, with radiating hour-lines and shadow-construction lines. Because the figure is densely lettered and several small peripheral labels do not resolve cleanly, it is flagged as a

- Top shadow-length ruler (left to right): M · I · G · 12 · 24 · 36 · 48 · 60 · 72 · H (fine tick-marks between M, I, G)
- AVST (upper center): AVSTER — south
- HORI... ZON (left rim, vertical, split): HORIZON — the horizon circle
- ORI (left, vertical): ORIENS — east (eastern side)
- OCCI (right, vertical): OCCIDENS — west (western side)
- BORE (bottom center): BOREA — north
- L (upper center): center of the dial
- K (center hub): terminus of the 6th-hour shadow / where hour-12 line meets the equinoctial
- C, a, H, z, Y, I, O (central construction points)
- F, Q (mid-left): style-point F and shadow-latitude point Q
- R (mid-lower): shadow point for hour 4 from sunrise
- N, R (right): point where a construction line meets the circle
- P, D (lower center, on circle)
- S, T (lower right, on the arc)
- e, e (labels on the western/occidens arc) [?]
- Hour-line numbers on the left margin (radiating): 15, 14, 13, 12, 11, 10, and, nearer the hub, 9, 7, 6
- A, E, V (upper); V, 4, x, B (bottom)

[Several small rim and hour-line labels flagged [?]]

let us set up the angle CHI, [equal to] the altitude of the pole above the great circle to which the dial is parallel, and another angle CHL, [equal to] the complement of the same pole-altitude. And if MN is drawn through M perpendicular to DE, this will serve as the line of the 6th hour from noon and midnight, as if the dial itself were horizontal; and it is from this that the hour-arcs would be counted in the

circle MPN, described from L, had they been computed. The meridian line must be drawn from L, parallel to AB itself, or perpendicular to CK, such as is LO. Likewise the horizontal line is drawn through the point K, where the equinoctial line and the line CK (drawn perpendicular to AB) intersect one another — which point, as we said, is the terminus and end of the shadow of the 6th hour from noon, or of the 12th hour from sunrise or sunset, when the Sun is in the Equator. This point K, moreover, will also be found in the following way. On the line AB, taking the segment Ca with a style equal at a, let the angle CaK be made [equal to] the complement of the declination from the horizon. For the line aK will cut the line CK at the point K, where the 12th hour from sunrise cuts the equinoctial line.

[Margin: Center of the dial.]

[Margin: Meridian line.]

[Margin: Horizontal line.]

Now, if the shadow-latitudes are duly computed in the circle AFDG — the eastern ones from the point F, the western from the point G, toward the north B or toward the south A, as the tables indicate — this dial will be laid out just like the preceding ones. Thus you see that from the eastern and northern shadow-latitude FQ (or its opposite GQ) of 19 degrees 57 minutes, which belongs to the 4th hour from sunrise in the tropic of Cancer [♋], and from the shadow-length of that same hour, 53 parts 11 minutes, the point R was found for the 4th hour from sunrise in the tropic of Cancer. Likewise, from FS, the eastern and southern shadow-latitude of 13 degrees 18 minutes (or its opposite GS) of the same 4th hour from sunrise in the Equator — or indeed from the shadow-length of 37 parts 9 minutes, which agrees with the same hour in the Equator — the point T was found for the said hour on the equinoctial line. Finally, from FV, the eastern and southern shadow-latitude of 47 degrees 21 minutes (or its opposite GV), which corresponds to the same 4th hour from sunrise in the tropic of Capricorn [♐], and from the shadow of the same hour, 38 parts 18 minutes, the point X was found for the 4th hour from sunrise in the tropic of Capricorn; and so on.

The 6th hour from sunrise will necessarily pass through the point O, where the meridian line cuts the equinoctial line. The 14th hour from sunrise, because it cuts the equinoctial line too far off, is drawn through the point found in the tropic of Cancer and through the point Y, where the line of the 10th hour from sunrise cuts the meridian line. And the 15th hour from sunrise is drawn through the point found in the tropic of Cancer and through the point Z, where the 9th hour from sunrise, when produced, meets the meridian line — as is clear from the

table of Proposition 20 of Book 1, whose title is "The line of the 12th hour from noon or midnight." Nevertheless, for these same hours the shadow-latitudes and shadow-lengths can also be investigated in the parallel of Gemini [Υ] or of Leo [ϱ], and from these still other points found on the dial.

For an upper dial inclined to the horizon by 68 degrees on the southern side, and set at right angles to the meridian, we shall use the following tables, computed for the hours from noon and midnight. For it will be enough to give the example in the hours from noon and midnight. In these tables we call "superior" those shadow-latitudes that lie on the near side of the vertical circle of the dial — that is, toward the pole that is seen above the dial — and "inferior" those that lie beyond the said vertical, namely toward the center of the dial, or toward the hidden pole.

The shadow-latitudes and shadow-lengths on an upper dial inclined to the horizon by 68 degrees on the southern side, and at right angles to the meridian, for the hours from noon and midnight, at latitude 42 degrees.

In the tropic of Cancer [☿] the shadow-latitudes are partly superior and partly inferior, as is indicated by the syllables [Super. Infer.].

Hours in Cancer, from midnight	0	1	2	3	4	5	6	(easter n)
Hours in Cancer, from noon	12	11	10	9	8	7	6	(wester n)
	Infe r.	Infe r.	Infe r.	Infe r.	Infe r.	Infe r.	Sup er.	
Shadow-latitudes (G. M.)	90. 0	71.1 0	53. 4	36. 6	20.2 0	5.37	8.28	
Shadow-lengths (P. M.)	12.3 9	13. 1	14.1 0	16. 9	19. 7	23.2 6	29.4 2	

[illegible]

Hours in Cancer, from midnight	7	8	9	10	11	12	(eastern)
Shadow-latitudes (G. M.)	22. 1	36. 2	48.59	62.33	76.14	90. 0	
Shadow-lengths (P. M.)	38.53	53.46	77.31	115.4	166.4	196.1	
				8	5	3	

In the Equator all shadow-latitudes are Inferior.

Hours in Aries [♈] & Libra [♎], from midnight	0	1	2	3	4	5	6	(eastern)
Hours in Aries & Libra, from noon	12	11	10	9	8	7	6	(wester n)
Shadow-latitudes (G. M.)	90. 0	74. 5	58. 26	43. 13	28. 29	14. 8	0. 0	
Shadow-lengths (P. M.)	32. 58	34. 18	38. 41	48. 8	69. 7	134. 54	Infini.	

All the hours of the tropic of Capricorn [♋] fall on the lower face of the dial, since the tropic of Capricorn does not cut the plane of the dial but stands wholly above the lower face — just as the tropic of Cancer stood wholly above the upper face. Hence it comes about that we have computed no shadow-latitudes for the hours of the tropic of Capricorn. The shadow of the gnomon, when the Sun is at the beginning of Cancer, describes on the upper dial an ellipse, which, however, for lack of space has not been drawn complete in the example.

We shall lay out the dial as follows.

[Margin: Layout of the dial inclined to the horizon, from the tables.]

In the plane of the dial let the straight line AB be drawn as the common section of the plane of the dial and of the vertical of that great circle to which the dial is parallel — a line to be drawn invisibly, and, in a firm and stable plane, set parallel to the horizon by means of a plumb-line. On it, having assumed the place of the style C, let a circle ADB of any size be described from C; in it, through the center C, let DE be drawn perpendicular to AB. This will be the common section of the meridian of the plane of the dial (or of the horizon — for the meridian of the horizon and of the plane of the dial is one and the same) and of the plane of the dial itself, namely the meridian line, as is established by Proposition 25 of Book 3.

[Margin: Meridian line.]

Then let as many equal parts as you please be cut off from the line HI, and so on, as was likewise done above. Then let the altitude of the pole above the great circle to which the dial is parallel be found — as we taught in the same Proposition 25 of Book 3 — which in the given example comprises 70 degrees, so that its complement is 20 degrees. Let the shadow of 32 parts 58 minutes be reckoned, corresponding to the complement of the pole-altitude found, that is, the shadow due to the altitude of the Sun set in the Equator and on the meridian, [measured] along the meridian line from C upward as far as E, if the center of the dial falls below the place of the style C (as happens in our example), but downward if the center of the dial falls above the place of the style. (It will easily be perceived, from what we delivered in Proposition 25 of Book 3, whether the center of the dial falls below or above the style.) For the line EG, drawn through E perpendicular to the meridian line, will be the equinoctial line.

[Margin: Equinoctial line.]

But if from C, in the opposite direction along the meridian line, the shadow-length of 4 parts 22 minutes — which agrees with the pole-altitude found — is measured off as far as H, then H will be the center of the dial. And if a line IK is drawn through H perpendicular to the meridian line, this will be the line of the 6th hour from noon and midnight, as in the horizontal dial, from which the hour-arcs would have to be reckoned in the circle described from H, had they been found for the individual hours. These same two points E and H will also be found if with the style there is made the angle...

[Margin: Center of the dial.]

the angle CFE, [equal to] the altitude of the pole found, and the angle CFH, [equal to] the complement of the same pole-altitude, as was said above. We shall draw the horizontal line thus. From C, upward along the meridian line, we shall reckon the shadow of 4 parts 51 minutes, which agrees with the inclination of the plane of the dial to the horizon — namely 68 degrees in our example — as far as the point M. We shall also find this same point if at F there is set up the angle CFM, [equal to] the complement of the inclination, so that the line FM cuts the meridian line at M. For the line drawn through M perpendicular to the meridian line will be the horizontal line, as is clear from what was demonstrated in Proposition 26 of Book 3.

[Margin: Horizontal line.]

Diagram. A construction figure for the dial declining from the meridian toward the east by 40° and inclined to the horizon on the northern side by 20° , showing

the (incompletely drawn) circle ADB with the horizon line, the meridian line, the equinoctial line, and hour-lines converging on the center of the dial H. A horizontal shadow-length ruler runs across the top; the double-arc rim carries the hour-numbers. Because the figure is densely lettered and several small peripheral labels do not resolve cleanly, it is flagged as a

- Top shadow-length ruler (left to right): I · G · 12 · 24 · 36 · 48 · 60 · 72 · 84 · 9[6?] · 108 · H (fine tick-marks after I; the mark between 84 and 108 reads ambiguously — the ruler runs in steps of 12, so the value is 96, but the printed digit is unclear)
- Row of hour-numbers along the top line (reaching the ruler): 8, 9, 10, 11, E (12), 1, 2, 3, 4
- Lower inner cluster of hour-numbers near the hub: 8, 9, 10, 11, 12, 1, 2, 3, 4
- HORI... ZON (left/right, split across the figure): HORIZON — the horizon line
- ORI (left, vertical): ORIENS — east; also the "OSS"/"ONS" continuation is worn [?]
- Central construction points: M, C, F, H (the meridian/style cluster; H = center of the dial)
- Left side points and hour markers: P, A, N, O, S (repeated on the two rim-arcs), 7, 4, X, and the point "Y 3" (lower left) with its short gnomon-mark
- Right side points and hour markers: R, B, K, 6, Q, L, T, and the point "9 V" (lower right) with its short gnomon-mark; E, 1, 2, 3, 4, O on the upper-right rim; Z (right)
- D (bottom, on the inner arc)

[Several small rim and hour-line labels flagged [?]]

If now the shadow-latitudes are counted from the line AB in the circle ADB, we shall lay out the several hours from their shadow-lengths, as before. For thus you see that from the western and inferior shadow-latitude BL of 28 degrees 29 minutes, which belongs to the 8th hour from noon in the Equator — or from the shadow-length of that same shadow, 69 parts 7 minutes — the point G was found on the equinoctial line for the 8th hour from noon. And from the same eastern and inferior shadow-latitude AN, which also belongs to the 4th hour from midnight — or from the same shadow-length of the same shadow — the point O was found on the equinoctial line for the 4th hour from midnight. Likewise, from AP, the eastern and superior shadow-latitude of 22 degrees 1 minute, which belongs to the 7th hour from midnight in the tropic of Cancer [☿], and from the shadow-length of the same shadow, 38 parts 53 minutes, the point Q was found for the 7th hour from midnight in the tropic of Cancer. And from the same

western and superior shadow-latitude BR, and from the same shadow-length, the point S was found for the 5th hour from noon in the tropic of Cancer. And so with the rest.

Only this must be noted: the superior shadow-latitudes, which above the line AB in the circle ADB (which, for lack of room, has not been drawn complete) cannot conveniently be counted, must be reckoned below the same line, but on the opposite side. Thus, since the shadow-latitude belonging to the 9th hour from midnight in the tropic of Cancer is eastern and superior, comprising 48 degrees 59 minutes, and cannot be counted above the line AB, we shall reckon it below the line AB, from the western point B as far as T. For if from the hidden line CT the segment CV is cut off — the shadow-length of 77 parts 31 minutes corresponding to that same hour — the point V will be obtained for the 9th hour from midnight in the tropic of Cancer. By the same reasoning the point Y was found for the 3rd hour from noon in the tropic of Cancer, from the same eastern and inferior shadow-latitude — although the shadow-latitude of this hour in the table is western and superior.

The individual hours from noon and midnight are for the most part drawn through four points each — as the 9th hour from noon and midnight through the points Z, a, H, V — or at least through three, as the 7th hour from noon and midnight through the points e, H, Q, and the 11th hour from noon through the points d, b, H, and so on. For all the hours from noon and midnight are drawn through H, the center of the dial.

For an upper dial declining from the meridian toward the east by 40 degrees and inclined to the horizon on the northern side by 20 degrees, the following tables have been computed for the hours from noon and midnight, of which alone we here give the example. In these tables we call "superior" those shadow-latitudes that lie on the near side of the proper vertical of the dial, toward the equinoctial line; and "inferior" those that lie beyond the same vertical, toward the center of the dial.

Shadow-latitudes and shadow-lengths on an upper dial declining from the meridian toward the east by 40 degrees, and inclined to the horizon on the northern side by 20 degrees, for the hours from noon and from midnight, at latitude 42 degrees.

In the tropic of Cancer [☿ — *tropico Cancrī*] the shadow-latitudes are partly superior and partly inferior, as the syllables [Super. Infer.] indicate.

Hours in Cancer [☿], from midnight — eastern (orientales):

Hour	5	6	7	8	9	10	11	†
(kind)	Supē r.	Supē r.	Supē r.	Supē r.	Supē r.	Infer .	Infer .	
Shadow-latitude (G. M.)	21.42	16.25	11.39	7.12	2.32	5.48	71.34	90 .0
Shadow-length (P. M.)	73.33	29.39	17.3	10.38	6.24	3.7	0.30	0. 28

Hours in Cancer [♋], from midnight — western (occidentales):

Hour	12	A meridie	1	2	3	4	5
(kind)	Infer .		Supē r.	Supē r.	Supē r.	Supē r.	Supē r.
Shadow-latitude (G. M.)	7.28		2.6	2.37	11.10	15.51	21.5
Shadow-length (P. M.)	2.47		6.0	10.5	16.9	27.37	63.43

In the Equator all shadow-latitudes are inferior.

Hours in the Equator [♈ / ♎ — *Aries / Libra*], from midnight — eastern (orientales):

Hour	6	7	8	9	10	11	†
Shadow-latitude (G. M.)	6.16	13.36	22.51	36.1	56.50	88.5	90.0
Shadow-length (P. M.)	53.6	24.33	14.53	9.50	6.54	5.47	5.47

Hours in the Equator, from midnight — western (occidentales):

Hour	12	A meridie	1	2	3	4	5
Shadow-latitude (G. M.)	59.4		37.5	24.4	14.3	7.0	0.20
	9		2		2		
Shadow-length (P. M.)	6.41		9.25	14.1	23.3	47.1	917.2
				0		8	1

In the tropic of Capricorn [♐ — *tropico Capricorni*] all shadow-latitudes are inferior.

Hours in Capricorn [♐], from midnight — eastern (orientales):

Hour	6	7	8	9	10	11	†
Shadow-latitude (G. M.)	27.11	34.3	44.3	56.9	71.2	88.5	90.0
		8			2	9	
Shadow-length (P. M.)	412.29	50.5	27.1	18.5	15.7	13.5	13.5
		0	6	3		5	5

Hours in Capricorn [$\frac{1}{2}$], from midnight — western (occidentales):

Hour	12	A meridie	1	2	3	4
Shadow-latitude (G. M.)	72.45		57.41	45.15	35.34	27.56
Shadow-length (P. M.)	14.52		18.17	25.57	46.24	229.0

[Margin: Layout of a dial declining from the meridian toward the east by 40 degrees and inclined to the horizon by 20 degrees, from the tables.]

On the plane of the dial draw the straight line AB — laid, however, on a stable and firm plane parallel to the horizon. Taking C as the assumed position of the style, describe about C the circle ADBE of any size you please; and through its center C erect the diameter DE perpendicular to AB. This will be the common section of the dial's plane and of the great circle that measures the plane's inclination to the horizon, as is evident. Now, by Proposition 31 of Book 1, find the arc of the great circle to which the dial is parallel — the arc intercepted between the great circle that measures the plane's inclination and the dial's own meridian — which in our example we find to be 32 degrees 7 minutes; and we shall count it off on the circle

ADBE, from D as far as F, toward the left — that is, toward the western parts A — when the dial declines from the meridian toward the east and is inclined to the horizon on the northern side, as ours is; but toward the right, if the plane, inclined on the same side, is deflected from the meridian toward the west. Then draw the straight line FCG, which will be the common section of the dial's plane and of its own meridian — that is, the style-line.

[Margin: The style-line.]

For if the dial's plane is set in its proper position and declines from the meridian toward the east, the point E falls into the western-and-northern quadrant of the upper hemisphere. So suppose the great circle that measures the inclination, drawn at right angles to the dial's plane through the straight line DE, to be turned in the mind about the style set up at C — always remaining perpendicular to the dial's plane — until it is carried through the arctic pole of the world (which, when

we face the dial, lies to the right of the point E), and is then joined to the dial's own meridian: it will necessarily make in the dial a section, falling below the style between the points A and D, of the kind that FCG is, as is plain. Since, then, DF is an arc similar to the one intercepted between the proper meridian and the great circle drawn through DE that measures the inclination to the horizon, the line FG will be the common section of the proper meridian and of the dial's plane — that is, the style-line.

But if the dial's plane inclines from the meridian toward the west, the point E falls into the eastern-and-northern quadrant of the upper hemisphere, so that the arctic pole lies, when we face the dial, to the left of the point E — that is, toward A. Therefore, if that great circle at right angles to the dial, drawn through DE, is moved toward A until it passes through the pole, the section it makes with the dial's plane will fall below the style, between the points B and D, and so on.

Now if through C a perpendicular HI is drawn to FG, this will be the common section of the dial's plane and of the vertical proper to the dial itself, from which all the shadow-latitudes are to be reckoned. Once the line HI has been prepared and divided into any number of parts equal to the style, as in the preceding cases, and once — by Proposition 29 of Book 1 — the elevation of the pole above the great circle to which the dial is parallel has been found (which in our example amounts to 25 degrees 43 minutes, so that its complement is 64 degrees 17 minutes): then if from C, the style's position, a shadow-length of 5 parts 47 minutes — corresponding to the complement of the pole-elevation found — is counted off upward along the line FG (upward, because the dial's center falls below the style, as happens in planes inclined on the northern side toward the horizon, when the arc of the meridian between the plane and the horizon is less than the pole's elevation above the horizon, as in our example, in which that arc contains 15 degrees 35 minutes, to be found by Proposition 28 of Book 1) as far as L: then LM, drawn perpendicular to FG, will be the equinoctial line.

[Margin: The equinoctial line.]

This shadow must be reckoned downward when the arc of the proper meridian between the horizon and the plane of the dial is greater than the elevation of the pole above the horizon, because the dial's center then falls above the style, as will appear in the following dial, in which the said arc contains 68 degrees 50 minutes. But if from C, on the opposite part along the line FG — that is, downward here — the shadow-length of 24 parts 55 minutes, corresponding to the pole-elevation found of 25 degrees 43 minutes, is reckoned, the point N, the dial's center, will be obtained. These two points L and N will likewise be found, as

was said above for other dials, if at the point K where the equinoctial line meets the style's vertex — perpendicular to the line FG — an angle CKL equal to the pole-elevation found, 25 degrees 43 minutes, is constructed; and, for the dial's center, an angle CKN equal to the complement of that same elevation, 64 degrees 17 minutes. Then from the straight line QR, drawn through the dial's center perpendicular to FG, the hour-arcs — if they have been computed for the several hours — are to be counted off, on the circle described from N.

[Margin: The dial's center.]

The HOURS will be laid out from the tables set out above, as in the earlier cases, if from the points H and I the eastern and western shadow-latitudes are reckoned, carefully observing which are superior and which inferior, and so on, as appears in the accompanying figure. And all the hours from noon and from midnight pass through N, the dial's center;

Diagram. A large sundial-construction figure for the dial declining from the meridian toward the east by 40° and inclined to the horizon on the north by 20° (latitude 42°). An outer great circle (the plane of the dial / horizon circle) contains a second, inner circle (the hour circle described from the dial's center). A horizon line runs across the upper part of the figure, lettered across the top **HORI ... ZON** (the word *Horizon* split by the diagram), and terminates at the right at G, where a graduated vertical scale-bar stands. The chief lettered points and lines, as read from the scan:

- HORI ... ZON (top): the horizon line, split lettering.
- E (top): upper end of the vertical diameter DE.
- D (bottom): lower end of the vertical diameter DE.
- C (center): the style position, center of the circle ADBE.
- A (left): left end of the base line AB.
- B (right, near hour "3"): right end of the base line AB.
- F (lower left, on the circle): with G defines the style-line FCG / FG.
- G (right, terminus of the horizon/style line): foot of the vertical scale-bar.
- M (upper center, on the horizon line): intersection used for the horizontal line.
- P (below E, on the vertical): point on DE.
- H (center-left): with I defines the vertical-proper line HI.
- I (right / lower right): other end of HI; also lettered at the top of the scale-bar.
- K (left of center): the style's vertex.

- N (lower left, interior): the dial's center, through which the hour-lines pass.
- O (near center): equinoctial-line point.
- S (near center, and again lower left): [?] two occurrences.
- Q, R (line QR through N, perpendicular to FG): the hour-reckoning line.
- Hour numerals ranged around the rim: 6, 7, 8, 10, 11, 12, 1, 2, 3, 4 (the "9" is [?], obscured by line-crossings).
- Small letters near the top: a, b, [?], [?] (two of the four minuscule labels are not resolvable).
- A vertical graduated scale-bar at the right edge, headed I (top) and G, with tick-labels 12, 24, 36, 48, [?], [?] and H at the foot (the two lower tick-labels are [?] — they read like "96" and "108" but do not sit in an even arithmetic run with the upper ticks, so they are left uncertain).

so that, if the dial's center were so far from the style that it could not conveniently be marked on the dial, then for those hours which have only a single point in one of the tropics — but none in the other tropic or on the equinoctial line, and other points in a neighboring parallel (as, for instance, in our example, in the parallel of Gemini [Π — *Geminorum*] or of Leo [ϱ — *Leonis*]) — the horizontal line must be drawn through the point M, where the line of the 6th hour from noon or from midnight cuts the equinoctial line, perpendicular to the straight line DE.

[Margin: The horizontal line.]

Or, taking on the straight line AB the length of the style CO, if the angle COP of the complement of the inclination is made upward, the straight line DE will be cut at the point P, through which the horizontal line is to be drawn perpendicular to DE; and this, if there has been no error, will necessarily pass through the point M of the 6th hour on the equinoctial line. Or, indeed, if the shadow of 32 parts 58 minutes, corresponding to the plane's inclination to the horizon, is transferred from C upward along the straight line DE, the point P will be found, through which the horizontal line is to be drawn perpendicular to DE.

The line of the 12th hour, which is the meridian line, we shall likewise draw by this method.

[Margin: The meridian line.]

The hour-arc of the 12th hour from midnight — which here we find to contain 83 degrees 44 minutes, and to be western and inferior (for since the 12th hour of noon is at a smaller distance from the dial's proper meridian than that of 6 hours, being distant by only 14 degrees 10 minutes — precisely the inclination of the

proper meridian to the meridian of the horizon — the hour-arc of the 12th hour from midnight will be inferior, that is, will lie beyond the dial's center, as we said in the scholium of the preceding proposition; and again, because the dial's plane declines from the meridian toward the east, the style's shadow is projected at noon toward the east, so the hour-arc will then be western, that its shadow may fall on the contrary, eastern part, as the case requires) — is to be reckoned on the opposite part of the circle Q[?] described from N: namely, from the point of the straight line QR, eastward and upward, as far as b. For the line Nb will be the meridian line.

FOR an upper dial declining from the meridian toward the west by 20 degrees and inclined to the horizon on the northern side by 70 degrees, the tables that follow have been drawn up for the unequal hours, of which alone we shall give the example. In these tables those shadow-latitudes are called inferior which lie on the near side of the dial's own vertical — that is, toward the equinoctial line; and superior, those which lie beyond the same vertical, toward the dial's center.

Shadow-latitudes and shadow-lengths on an upper dial declining from the meridian toward the west by 20 degrees, and inclined to the horizon on the northern side by 70 degrees, for the unequal hours, at latitude 42 degrees.

In the tropic of Capricorn [♑], the shadow-latitudes are partly inferior and partly superior, as these syllables [Infer. Super.] declare.

Unequal hours in Capricorn [♑] — eastern (orientales):

Hour	12	1	2	3	4	5	6	7	†
(kind)	Infe r.	Infe r.	Infe r.	Infe r.	Infe r.	Infe r.	Sup er.	Sup er.	
Shadow-latitude (G. M.)	20.4 1	10.5 2	13.2 1	10.4	6.50	3.33	0.30	9.38	90 .0
Shadow-length (P. M.)	58.2 2	31.0	20.2	13.5 4	9.48	6.42	4.9	1.54	0. 23

Unequal hours in Capricorn [♑] — western (occidentales):

Hour	8	9	10	11	12
(kind)	Super.	Super.	Super.	Infer.	Infer.
Shadow-latitude (G. M.)	53.17	6.39	0.1	4.10	7.42
Shadow-length (P. M.)	0.28	2.28	4.47	7.26	10.45

Appended single value — Hour 1, in the parallel of Aries [♈] & Aquarius [♐], inferior and eastern:

	G.	M.
Shadow-latitude	14.	36.
Shadow-length (P. / M.)	38.	15.

Here we have appended the shadow-latitude, and its length, which the Sun produces at the 1st unequal hour in the parallel of Aries [♈] and Aquarius [♐], since from it must be drawn the 1st unequal hour on the dial, as we shall explain. The length of this shadow, moreover, is given by the Sun's altitude, which we recorded in Table 17 of the Sun's altitudes.

In the Equator all shadow-latitudes are superior, but the eastern are distinguished from the western by these syllables [or. occ.].

Unequal hours in the Equator [♈ / ♎] — eastern (or.) and western (occ.):

Hour	2	3	4	5	6	7	†	8	9	10	11	12
(kind)	or.	or.	or.	or.	or.	or.		oc c.	oc c.	oc c.	oc c.	oc c.
Shadow-latitude (G. M.)	3.5 6	10. 50	19. 11	30. 34	48. 16	76. 29	9 0	69. 23	43. 38	27. 42	17. 17	9.1 5
Shadow-length (P. M.)	82. 45	30. 9	17. 17	11. 9	7.3 6	5.5 0	5. 4	6.4 3	8.1 12	12. 12	19. 16	35. 17

(Continuing within Book V. The following table completes the set of shadow-tables for the upper dial declining from the meridian toward the west by 20 degrees and inclined to the horizon on the northern side by 70 degrees, whose Capricorn, Aries–Aquarius, and Equator tables were given just before.)

In the tropic of Cancer [♋], all the shadow-latitudes are superior, but the eastern are distinguished from the western by these syllables [or. occ.].

Unequal hours in Cancer [♋] — eastern (or.) and western (occ.):

		4	5	6	7		8	9	10	11
Unequal hours ♋	3 or.	or.	or.	or.	or.	†	occ.	occ.	occ.	occ.
Shadow-latitude (G.	26.30	35.	48.	65.	87.	90.	70.	51.	38.1	28.1

		4	5	6	7		8	9	10	11
Unequal hours $\mathfrak{S}$	3 or.	or.	or.	or.	or.	†	occ.	occ.	occ.	occ.
M.)		51	30	48	31	0	11	48	5	8
Shadow-length (P.	1115.1	44.	22.	15.	13.	13.	15.	20.	36.3	176.
M.)	[?]	7	42	49	43	42	3	35	6	48

[Margin: Description of a dial declining from the meridian toward the west by 20 degrees, and inclined to the horizon by 70 degrees, from the tables.]

[Margin: The style-line.]

[Margin: The equinoctial line. The center of the dial.]

Therefore, on the plane of the dial draw the straight line AB, which is to lie in a stable and firm plane parallel to the horizon. From the assumed position C of the style on it, describe a circle ADBE of any size, in which the diameter DE cuts the straight line AB at right angles; this diameter will be the common section of the dial's plane and of the great circle that measures the inclination of the plane to the horizon. Then, having found — by Proposition 31 of Book 1 — the arc of the great circle to which the dial is parallel, intercepted between the great circle that measures the inclination of the plane and the dial's own meridian (which in the dial proposed we find to be 16 degrees 22 minutes), we shall reckon it from D toward the east — that is, toward point B — as we said in the preceding dial, since this dial declines from the meridian toward the west up to F. For the straight line FCG will be the style-line, that is, the common section of the dial's plane and of the dial's own meridian.

From the straight line KL, which cuts FG at right angles, the shadow-latitudes are to be counted, since it is the common section of the dial's plane and of the dial's own vertical. Next divide the straight line HI into as many parts equal to the style as you like, as in the earlier cases; and having found the altitude of the pole above the great circle to which the dial is parallel — which in the given dial is 25 degrees 18 minutes, and therefore its complement is 64 degrees 42 minutes — if from C, the position of the style, the shadow-length 5 paces 40 minutes corresponding to the altitude of the pole so found is counted downward along the straight line CF (as we said in the preceding dial), up to H, then the straight line HI drawn perpendicular to FG will be the equinoctial line. But if, in the proposed example, the shadow-length 25 paces 23 minutes corresponding to the altitude of the pole so found is reckoned upward along the line FG, point M, the center of the dial, will be found, so that the straight line NO cutting FG at M at right angles serves as the line of the 6th hour from noon and from midnight, from which the

hour-arcs computed for the several hours are to be counted. These same two points H and M will also be found by means of the angle of the pole's altitude, CPH, and of its complement, CPM, as above, if CP on the straight line KL is taken equal to the style.

Diagram. A construction figure for the upper dial declining from the meridian toward the west by 20 degrees and inclined to the horizon by 70 degrees. Across the top runs a graduated scale-bar (a straight line from I at the left to H at the right), marked off in units 12, 24, 36, 48, 60, 72, 84, 96. Beneath it stands the horizon circle ADBE, labelled across its middle **HORI = ZON**. The diameter DE runs vertically (E at top, a dashed vertical line dropping from E; D at the bottom); the horizontal AB runs through the circle. West is marked **OCC** (occidens) at the lower left of the rim and east **ORT** (oriens) at the right. The style-line and the various hour-lines radiate from the central region through the numbered hour-points.

Readable labels:

- Scale-bar: I (left end), then graduations 12, 24, 36, 48, 60, 72, 84, 96, and H (right end)
- G — upper left, on the circle
- E — top of the circle (foot of the dashed vertical)
- O — upper right, outside the circle
- M — upper-middle (center of the dial)
- N — far left, on the horizontal line
- V — left, near the hour-12 mark
- 12 — left (hour 12)
- A — center, on the horizontal line
- Z, P — center
- HORI = ZON — horizon label across the middle
- L — right, beside the vertical legend ORT
- R, B — right of center (R above, B below)
- 12 — right (hour 12)
- 11 — right, lower
- 6, 7, 8, 9, 10 — hour-lines radiating toward the lower center
- K — lower left, beside the vertical legend OCC
- I — lower left
- 2, 3 — hour-lines at the lower left

- S [ʃ], T [t], U [u], Q [k] — small labels clustered at the center (individual letters not fully resolved)
- D, F — at the bottom of the circle

The hour-lines are drawn here as in the earlier cases: if the shadow-latitudes are counted from points K and L — the superior ones toward point G, the inferior ones toward F, the eastern likewise from point L, and the western from point K, and so on — as is seen in the accompanying figure. But for the 1st unequal hour, which has no point in the tropic of Cancer [♋] nor on the equinoctial line, but only the point Q in the tropic of Capricorn [♐], we investigated it in the parallel of Aries [♈] and Aquarius [♒]: from the eastern and inferior shadow-latitude LR of that hour (or its opposite KS), and likewise from the length of the same shadow, 38 paces 15 minutes, we found point T, so that the straight line QT, cast through points Q and T, marks the 1st unequal hour. The horizontal line, however, is the very line of the 12th unequal hour, since at that hour the Sun rises and sets — that is, is on the horizon. For that morning hour, when the Sun rises in the tropic of Capricorn [♐], we find point V; and for the evening hour, when the Sun sets in the same tropic...

we find point X; and also point I on the equinoctial line. This horizontal line — that is, the line of the 12th unequal hour, drawn through the three points V, X, I so found — will necessarily cut the straight line DE at right angles, if no error has been made anywhere. On an astronomical, Italian, or Babylonian dial the same line will pass through that point where the 6th hour from noon or from midnight, or the 12th hour from sunrise or sunset, cuts the equinoctial line: and this will always be point I. Furthermore, if the shadow-length 4 paces 22 minutes corresponding to the inclination of the plane to the horizon is carried from C upward along the straight line DE up to Z, then through Z the horizontal line is to be drawn perpendicular to DE. And if on the straight line AB you take CY equal to the style, and set up the angle CYZ of the complement of the inclination, you will likewise find on the straight line DE the point Z, through which the horizontal line is to be drawn perpendicular to DE and through the points V, X, I, and so on.

The line of the 6th unequal hour will also be the meridian line, so that when produced it necessarily passes through M, the center of the dial. We shall draw this meridian line as well if we reckon the hour-arc of the 12th hour from midnight — which we find to be 80 degrees 45 minutes, and eastern and superior. (For since the 12th hour of noon has a smaller distance from the dial's own meridian than that of the 6th hour, being distant only by as much as the inclination of the proper meridian to the meridian of the horizon, namely 20

degrees 52 minutes, the hour-arc will be superior — that is, it will recede beyond the center of the dial, as we wrote in the scholium of the preceding proposition. And again, since the dial's plane declines from the meridian toward the west, the shadow of the style will be cast at noon toward the west; and so the hour-arc of the 12th hour from midnight will be eastern, so that its shadow may fall on the opposite, western side, as the case requires.) We reckon it, then, on the opposite part of the circle NaO described about M — namely from the western point N downward as far as b. For the straight line Mb will be the meridian line.

For the upper dial declining from the meridian toward the east by 45 degrees, and inclined to the horizon on the northern side by 51 degrees 51 minutes, the following tables have been drawn up for the hours from noon and midnight; of this alone we shall give the example. Now since the Equator is the proper vertical of this dial, just as it is of the polar dial, the shadow-latitudes are to be computed from the equinoctial line — upward for the hours of the tropic of Cancer [☿], but toward the lower parts for the hours of the tropic of Capricorn [♊], as we said in the polar dial; for this dial too, like that one, lacks a center, since the greatest circle to which it is parallel is drawn through the poles of the world.

The shadow-latitudes and shadow-lengths on the upper dial declining from the meridian toward the east by 45 degrees, and inclined to the horizon on the northern side by 51 degrees 51 minutes, for the hours from noon and midnight, at latitude 42 degrees.

In the tropic of Cancer [☿] all the shadow-latitudes are superior; but in the tropic of Capricorn [♊], inferior.

Hours of Cancer [☿] and Capricorn [♊], from midnight — eastern (orientales):

Hour	4	5	6	7	8	9	†
Shadow-latitude (G. M.)	23.33	24.40	27.37	33.25	44.32	65.54	90.0
Shadow-length (P. M.)	198.7	38.51	20.14	12.36	8.18	5.50	5.13

Hours of Cancer [☿] and Capricorn [♊], from midnight — western (occidentales):

Hour	10	11	12	A meridie	1	2	3
Shadow-latitude (G. M.)	81.2	53.2	38.2	—	30.2	25.5	23.5

Hour	10	11	12	A meridie	1	2	3
	4	8				1	4
Shadow-length (P. M.)	5.17	6.52	10.1	—	15.4	27.5	66.9
			1		9		

In the Equator there are no shadow-latitudes, since then — by Proposition 11 of Book 1 — the shadow of the style falls perpetually on the equinoctial line. Their lengths, however, are these:

Hours of Aries [Υ] and Libra [ϱ], from midnight — eastern (orientales):

Hour	4	5	6	7	8	9	†
Shadow-length (P. M.)	181.29	35.17	17.56	10.31	5.55	2.23	0. 0

Hours of Aries [Υ] and Libra [ϱ], from midnight — western (occidentales):

Hour	10	11	12	A meridie	1	2	3
Shadow-length (P. M.)	0.48	4. 5	8. 2	—	13.42	24.22	60.31

[Margin: Description of a dial declining from the meridian toward the east by 45 degrees, and inclined to the horizon by 51 degrees 51 minutes, from the tables.]

[Margin: The style-line. The equinoctial line.]

And so, on the plane of the dial draw the straight line AB, which is to lie in a stable and firm plane parallel to the horizon. From C, the assumed position of the style, describe a circle ADBE of any size, in which the diameter DE cuts the straight line AB at right angles; this will be the common section of the dial's plane and of the great circle measuring the inclination to the horizon. Then, having found — by Proposition 31 of Book 1 — the arc of the great circle to which the dial is parallel, intercepted between the great circle that measures the inclination and the dial's own meridian (which in the proposed example we find to be 31 degrees 42 minutes), we shall count it from D toward A, that is, toward the western parts, up to F — just as we said in the dial declining from the meridian toward the east by 40 degrees and inclined to the horizon by 20 degrees, since this dial too declines from the meridian toward the east, like that one. For the straight line FCG, when drawn, will be the style-line, that is, the common section of the dial and of its own meridian. And the straight line KL, cutting this at right

angles, will be the equinoctial line — that is, the common section of the dial's plane and of the Equator — from which the shadow-latitudes are to be computed.

Diagram. A construction figure for the upper dial declining from the meridian toward the east by 45 degrees and inclined to the horizon by 51 degrees 51 minutes. Across the top runs a graduated scale-bar (from I at the left to H at the right), marked off in units 12, 24, 36, 48 (printed here as "46"), 60, 72, 84, 96. Below it stands the horizon circle ADBE, labelled across its middle **HORI = ZON**, with the diameter DE vertical (E at top, foot of a dashed vertical; D at the bottom) and the horizontal AB through it. West **OCC** (occidens) is marked at the upper left of the rim and east **ORT** (oriens) at the lower right. The style-line FCG and the hour-lines radiate from the center.

Readable labels:

- Scale-bar: I (left end), then graduations 12, 24, 36, 48 ["46" as printed — see below], 60, 72, 84, 96, and H (right end)
- E — top of the circle (foot of the dashed vertical)
- G — upper right, on the circle
- OCC — upper left (occidens), with X beside it
- H — left, on the horizontal line
- I — center-left
- A — lower left, on the horizontal line
- M — center
- B — right (hour region)
- ORT — lower right (oriens), with L beside it
- L — lower right
- K — lower center
- 6, 7, 8, 9, 10, 12, 1, 2, 3 — hour-lines radiating from the center
- S [?] — small label near the center
- D — bottom of the circle
- F — lower left

The hours will be described from the shadow-latitudes computed from points K and L, together with their lengths, as on the meridian and polar dials; and the hours from noon and from midnight will be perpendicular to the equinoctial line and parallel to one another, as in those dials. The horizontal line is to be drawn through point H, where the 6th hour from noon or from midnight cuts the equinoctial line, parallel to AB itself, or perpendicular to DE. But if along the

straight line DE we count upward the shadow 9 paces 26 minutes, which corresponds to the inclination of the plane to the horizon, up to I, the horizontal line is to be drawn through I, and so on. Or, if on the straight line AB you take CM equal to the style and make the angle CMI of the complement of the inclination, the straight line DE will again be cut at the point I, through which the horizontal line is drawn, and so on.

For the upper dial declining from the north toward the west by 20 degrees, and inclined to the horizon on the southern side by 30 degrees, take the following tables computed for the hours from noon and from midnight. In them the inferior shadow-latitudes are those which lie on the near side of the dial's own vertical, toward the equinoctial line; the superior, those which are found beyond the same vertical, toward the center of the dial.

THE TABLES FOLLOW.

Gnomonices, Liber Quintus (continued)

Shadow-latitudes and shadow-lengths, in the upper dial declining from north toward west by 20 degrees and inclined to the horizon on its southern side by 30 degrees, for the hours from noon and from midnight, at latitude 42 degrees.

In the tropic of Cancer (♋) the shadow-latitudes are partly inferior and partly superior, as the tables themselves show.

(In each table the shadow-latitude is given in degrees and minutes [G. M. = gradus, minuta]; the shadow-length in paces and minutes [P. M. = passus, minuta]. The "†" is a column-marker printed in the source.)

Table 1 — Hours of Cancer, from midnight; eastern & inferior (hours 2–8).

	2	3	4	5	6	7	8
Shadow-latitude	87° 42'	73° 59'	60° 22'	46° 56'	33° 38'	20° 22'	6° 54'
Shadow-length	396p 38'	262p 36'	143p 25'	84p 40'	55p 2'	38p 39'	28p 45'

Table 1 (continued) — Hours of Cancer, from midnight → noon; eastern & superior (hours 9–12, A meridie, 1, †).

	9	10	11	12	A meridi e	1	†
Shadow- latitude	7° 4'	21° 49'	37° 46'	55° 7'	—	73° 48'	90° 0'
Shadow- length	22p 23'	18p 4'	15p 8'	13p 13'	—	12p 9'	11p 53'

Table 2 — Hours of Cancer, from noon; western & superior (hours 2–7).

	2	3	4	5	6	7
Shadow- latitude	86° 46'	67° 27'	49° 10'	32° 18'	16° 46'	2° 23'
Shadow- length	11p 54'	12p 25'	13p 45'	16p 0'	19p 20'	24p 14'

Table 2 (continued) — Hours of Cancer, from noon → midnight; western & inferior (hours 8–12, A med. nocte, 1, †).

	8	9	10	11	12	A med. nocte	1	†
Shadow- latitude	11° 26'	24° 47'	38° 3'	51° 23'	64° 53'	—	78° 33'	90° 0'
Shadow- length	31p 34'	43p 8'	62p 54'	99p 54'	175p 17'	—	314p 49'	400p 29'

In the Equator all shadow-latitudes are superior, as the tables indicate.

Table 3 — Hours of Aries (♈) and Libra (♎), from midnight; eastern & superior (hours 8–12, A meridie, 1, †).

	8	9	10	11	12	A merid ie	1	†
Shadow- latitude	2° 24'	16° 19'	30° 36'	45° 23'	60° 44'	—	76° 34'	90° 0'
Shadow- length	737p 0'	106p 59'	58p 59'	42p 10'	34p 26'	—	30p 53'	30p 2'

Table 4 — Hours of Aries and Libra, from noon; western & superior (hours 2–7).

	2	3	4	5	6	7
Shadow-latitude	87° 19'	71° 15'	55° 33'	40° 24'	25° 48'	11° 38'
Shadow-length	30p 3'	31p 42'	36p 26'	46p 21'	69p 0'	149p 10'

On this dial all the hours of the tropic of Capricorn (♑) fall on the lower face of the dial, because the whole tropic of Cancer stands above the upper face and the tropic of Capricorn below it. For this reason you see no shadow-latitudes for the hours of the tropic of Capricorn entered in the tables. From this it follows that, when the Sun is at the beginning of Cancer, the gnomon's shadow traces an ellipse on the upper dial — one that we have not, however, drawn complete, owing to the narrowness of the space.

So draw the straight line AB in the plane of the dial, set parallel to the horizon on a firm and stable plane; and from C, taken as the position of the style, describe a circle ADB of any size you please, in which the straight line DCE, cutting AB at right angles at the center, is the common section of the plane of the dial and of the great circle that measures the inclination of the plane to the horizon. Then, having found (by Prop. 31 of Book 1) the arc of the great circle to which the dial is parallel — the arc intercepted between the great circle that measures the inclination and the dial's own meridian, which in the present case we find to be 43° 20' — we shall count it off from D toward A, that is, toward the eastern parts of the dial, as far as F. This is because the given dial declines from north toward west, and its center falls above the equinoctial line. (Whether the center falls above or below the equinoctial line will be known from what we set out in Prop. 37 of Book 3.

[Margin: Construction of the dial declining from north toward west by 20 degrees and inclined to the horizon by 30 degrees, from the tables.]

For when the arc of the meridian between the horizon and the plane inclined on its southern side is less than the complement of the pole's altitude — as happens in our example, since that arc, investigated by Prop. 28 of Book 1, comes to 28° 29' — the center of the dial falls above the equinoctial line; but when that same arc equals or exceeds the complement of the pole's altitude, it falls below, as we said in that proposition, in the second construction of a dial that is at once declining and inclined.)

[Margin: The style-line.]

For the straight line FC will be the style-line — that is, the common section of the plane of the dial and of its own proper meridian. For if the dial is set in its proper position — declining, that is, from north toward west — the point E will fall in the southern and eastern quadrant of the upper hemisphere, and the point D in the northern and western quadrant of the lower hemisphere, so that, when we face the dial, the north pole lies to the left of the point D. Hence, if the great circle that measures the inclination — drawn through the line DE and the style — is imagined to turn about the style set at C until it passes through the north pole (that is, until it coincides with the dial's own meridian), it will make with the dial a section falling below the style, between the points A and D, such as DCE, and so on. The contrary will happen if the plane deflects from north toward east and the center of the dial is above the style. Therefore the shadow-latitudes are to be reckoned from the straight line GH — which cuts FC at right angles at C — as from the common section of the plane of the dial and of its own proper vertical circle.

Now, with the line HI prepared and divided into parts equal to the gnomon, as above, and with the pole's altitude above the plane of the dial found (by Prop. 29 of Book 1) — which in our example we find to be $68^{\circ} 13'$, its complement being $21^{\circ} 47'$:

[Margin: The equinoctial line. The center of the dial.]

if from C, the position of the style, one counts downward along the style-line (since the center of the dial, as we said, falls above the style, and the equinoctial line below) a shadow of 30 paces 2 minutes — the amount required by the complement of the pole's altitude found — as far as I, then the straight line IK drawn through I perpendicular to FC will be the equinoctial line. And if from C upward, as far as L, one counts a shadow of 4 paces 48 minutes, answering to the pole's altitude found, then L will be the center of the dial; so that from the line ML to FL — the perpendicular in the circle MN described from L — the hour-arcs are to be numbered, if they are computed hour by hour. The two points I and L will also be found from the angle CPI (of the pole's altitude found) and the angle CPL (of the complement of that altitude), if on the line GH one marks off CP equal to the style.

In laying out the hours there is no difficulty, provided the shadow-latitudes are correctly computed from the points G and H, and so on, as is plain in the accompanying figure. In it, because the circle ADB could not be drawn complete,

we numbered the superior and eastern shadow-latitudes downward from the point H (the western point), and the western ones from the point G (the eastern point).

[Margin: The horizontal line.]

For instance, for the shadow-latitude of the 10th hour from midnight in the tropic of Cancer — which is eastern and superior, and comes to $21^{\circ} 49'$ — we took the western and inferior HQ; and from the shadow-length of 18 paces 4 minutes we found the point R for the tenth hour from midnight in the tropic of Cancer, and so on. The horizontal line is drawn from the point k, where the 6th hour from noon or from midnight cuts the equinoctial line, parallel to AB itself, or perpendicular to DE; it passes exactly through the point E, which on the line DE marks off CE, the shadow-length of 20 paces 47 minutes, answering to the inclination of the plane to the horizon. That point will also be found if on the line AB one takes CS equal to the style and makes the angle CSE the complement of the inclination.

[Margin: The meridian line.]

The 12th hour, moreover, from noon or from midnight will give the meridian line, which must pass through the point O — the point that on the circle MN terminates the hour-arc MO of $64^{\circ} 12'$, belonging to the 12th hour from noon or from midnight. In our dial this meridian line lies farther west than the style-line FC, because the plane of the dial declines toward the west; for this is why at noon the style's shadow is cast toward the western parts of the dial.

Diagram. The construction figure for the upper dial declining from north toward west by 20 degrees and inclined to the horizon by 30 degrees. Along the top runs a graduated scale-bar, from I at the left through G and the graduations 12, 24, 36, 48, 60, 72, 84 to H at the right end. Below it stands the horizon circle centered at C, with the vertical diameter DE (E above, on the dashed vertical dropped from the scale; D at the bottom) and the horizontal diameter AB (A at the left, B at the right). The horizontal line is labelled **HORIZON** across its middle, split as **K HORI** (K at its left end) ... **ZON** (right). The style-line **FCG** and the hour-lines radiate from the center; L is the dial's center just above C, with S beside it. The circle MN and points R, Q, O locate the hour-points and the meridian point.

Readable labels:

- Scale-bar: I (left end), G, graduations 12, 24, 36, 48, 60, 72, 84, H (right end)
- K — left end of the horizon line; HORIZON — label across the horizontal
- E — on the vertical DE, upper-middle (foot of the dashed vertical)

- ORT — near upper center (oriens), on a dashed line, with a G beside it
- P — upper left, on the rim
- A — left, on the horizontal line
- B — right, on the horizontal line
- C — center
- L — just above C (center of the dial); S — beside C
- M — lower right; D — bottom of the circle
- N, F — lower left
- R — lower center; Q — lower center
- Hour-numerals radiating from the center: 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12
- O [?] — a small label lower-left; a second "CC"/"occ" [?] mark near the H/M region does not fully resolve

For the upper dial declining from north toward east by 60 degrees, and inclined to the horizon on its southern side by 80 degrees, the following tables have been constructed for the hours from sunset. In them the superior shadow-latitudes are those lying on the near side of the dial's own vertical, toward the equinoctial line; the inferior are those found beyond that same vertical, toward the center of the dial.

Shadow-latitudes and shadow-lengths, in the upper dial declining from north toward east by 60 degrees and inclined to the horizon on its southern side by 80 degrees, for the hours from sunset, at latitude 42 degrees.

In the tropic of Cancer (♋) the shadow-latitudes are partly superior and partly inferior, as these abbreviations [Super. = superior, Infer. = inferior] declare.

Table 5 — Hours of Cancer, from sunset; western group (hours 3–9, †).

	3	4	5	6	7	8	9	†
Region	Super.	Super.	Super.	Super	Super	Infer.	Infer.	—
Shadow-latitude	24° 19'	18° 11'	12° 40'	7° 17'	1° 30'	6° 39'	30° 4'	90° 0'
Shadow-length	155p 58'	39p 52'	21p 11'	13p 3'	8p 9'	4p 35'	1p 44'	0p 55'

Table 5 (continued) — Hours of Cancer, from sunset; eastern group (hours 10–16).

	10	11	12	13	14	15	16
Region	Infer.	Infer.	Super.	Super.	Super.	Super.	Super.
Shadow-latitude	31° 54'	7° 5'	1° 33'	7° 6'	12° 28'	17° 59'	24° 4'
Shadow-length	1p 39'	4p 29'	8p 0'	12p 50'	12p 47'	38p 46'	141p 56'

In the Equator all shadow-latitudes are inferior; the western are distinguished from the eastern by these abbreviations [or. = eastern, occ. = western].

Table 6 — Hours of Aries (♈) and Libra (♎), from sunset (hours 6–17).

	6	7	8	9	10	11	12	13	14	15	16	17
Region	occ	occ.	occ.	occ	occ.	occ.	or.	or.	or.	or.	or.	or.
Shadow-latitude	6° 46'	14° 39'	24° 27'	38° 6'	58° 51'	88° 22'	61° 29'	39° 51'	25° 37'	15° 31'	7° 31'	0° 15'
Shadow-length	53p 54'	25p 4'	15p 19'	10p 16'	7p 24'	6p 20'	7p 13'	9p 54'	14p 39'	23p 39'	48p 29'	1006 p 38'

In the tropic of Capricorn (♐) all shadow-latitudes are inferior; the western are separated from the eastern by these abbreviations [or. = eastern, occ. = western].

Table 7 — Hours of Capricorn, from sunset (hours 8–17, †).

	8	9	10	11	12	†	13	14	15	16	17
Region	occ.	occ.	occ.	occ.	occ.	—	or.	or.	or.	or.	or.
Shadow-latitude	30° 43'	39° 19'	50° 5'	63° 36'	79° 47'	90° 0'	82° 43'	66° 10'	52° 10'	40° 58'	32° 10'
Shadow-length	111 p 4'	39p 8'	24p 4'	17p 56'	15p 23'	15p 0'	15p 11'	17p 19'	22p 40'	35p 19'	84p 30'

So let the straight line AB be drawn in the plane of the dial, parallel to the horizon on a stable plane; and in it, at C taken as the position of the style, let a circle ADBE of any size be described, and let the straight line DE cut the line AB at right angles at the center. This DE will be the common section of the plane of the dial and of

the great circle that measures the inclination of the plane to the horizon. Then, having found (by Prop. 31 of Book 1) the arc of the great circle to which the dial is equidistant — the arc set between the great circle that measures the inclination and the dial's own meridian, which in the present example we find to be $47^{\circ} 0'$ — we shall count it off from D, *not* toward the west B, as we said in the preceding dial (even though this dial declines from north toward east), because the center of the dial falls below the style: for the arc of the meridian between the horizon and the plane of the dial is greater than the complement of the pole's altitude, amounting indeed to $72^{\circ} 57'$. Rather we count it from D toward the east A, as far as F. (And if instead the dial declines from north toward west, one whose center lies below the equinoctial line or below the style, it is counted from D toward the west B.)

[Margin: The style-line.]

For the straight line FCG drawn will be the style-line, that is, the common section of the plane of the dial and of its own proper meridian. For when the dial is set in its proper position — so that the point E falls in the western and southern quadrant of the upper hemisphere, when the dial declines from north toward east — since the center of the dial falls below the style, the axis of the world will be inclined to the plane of the dial entirely between the points B and E; just as, when the center falls above the style, the dial is inclined to its plane, since the axis of the world must necessarily run through the top of the style. This can be evident to anyone who examines a little more attentively the position of the dial, of its center, and of the axis of the world.

Therefore, if the great circle that measures the inclination through the line DE is imagined to be turned about the style set upright to the dial, until it passes through the poles of the world and so through the axis of the world, it will assume exactly such a position that the plane of the dial cuts it between the points B and E, and hence between A and D, because of the inclination of the axis between those same points, as has been said. The contrary of this will happen on a plane declining from north toward west, if the center of the dial falls below the style, or below the equinoctial line...

[Margin: Construction of the dial declining from north toward east by 60 degrees and inclined to the horizon by 80 degrees, from the tables.]

the equinoctial line. From the straight line HI, which cuts the line FG at right angles at the center, the shadow-latitudes are to be reckoned. [Margin: The equinoctial line. The center of the dial.] Once the line HI has been prepared and

divided into parts equal to the gnomon, as was said above, and once the altitude of the pole above the plane of the dial has been found (by Prop. 29 of Book 1) — which in the present example we find to be $27^{\circ} 50'$, so that its complement is $62^{\circ} 10'$ — then, if from C (the position of the style) we count upward along the style-line a shadow of 6 parts 20 minutes, corresponding to the complement of the pole's altitude just found, as far as K (for the center of the dial, as we said, falls below the style, while the equinoctial line falls above it), the straight line KL drawn perpendicular to FG will give the equinoctial line. And if we count a shadow of 22 parts 44 minutes downward, we shall arrive at M, the center of the dial; so that the hour-arcs are to be counted from the line MN — which cuts FG at right angles — provided they have been computed for the individual hours in the circle NO described about M. But the two points K and M can also be found another way: on the line HI, take CP equal to the style, and construct the angle CPK equal to the pole's altitude just found, and the angle CPM equal to the complement of that same altitude.

Diagram. An uncaptioned sundial-construction figure for the dial declining from north toward the east by 60° and inclined to the horizon by 80° (the dial whose construction was begun on the preceding pages). The horizon runs across as a bold horizontal line lettered **HORI = ZON**, with **A** at its left end and **B** at its right end. A large circle is centered near the middle of the figure. Along the top edge runs a straight graduated scale-line (the line HI divided into gnomon-equal parts) bearing the points **L, I, G** at the left and running with tick-marks and hour-numerals to **H** at the far right. The dial's hour-lines radiate through the figure and are numbered around the rim: **4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16**. The words **ORI** (oriens, east) appear written vertically in the upper-right quadrant and **occ** (occidens, west) in the lower-right quadrant.

- **HORI=ZON** (bold central horizontal): the horizon line, endpoints **A** (left) and **B** (right)
- **L, I, G** (top left, on the graduated scale-line): style/gnomon division line HI, running to **H** (top right)
- **N** (left of center, on the circle): terminus of the line MN
- **S** (upper left): meridian-line terminus
- **P** (upper right of center): style/pole point
- **O** (right of center, on the circle): the circle NO about M
- **C** (center): position of the style
- **M** (below center-left): center of the dial
- **K, R, Q, T** (crowded about the center): equinoctial and hour-line points

- F (lower left): style-line terminus
- D (bottom): lower terminus of the vertical
- I (bottom): lower point of the construction

It is now easy to describe the hours from the tables set out, if the shadow-latitudes are computed from the points H and I, carefully observing which are eastern and which western, and which upper and which lower, as may be seen in the accompanying figure. [Margin: The horizontal line.] The horizontal line is drawn through the point R — where the 12th hour from sunrise or sunset (or the 6th hour from noon or midnight) intersects the equinoctial line — parallel to the line AB, or perpendicular to DE. This line will necessarily pass through the point a, which on the line DE marks off a shadow of 2 parts 7 minutes, corresponding to the plane's inclination to the horizon. We shall find the same point a if, on AB, we take CQ equal to the style and construct the angle CQa equal to the complement of the inclination to the horizon.

The meridian line too, if one wishes to draw it on the dial, must be drawn through M, the center of the dial, and through the point L, where the 6th hour from sunrise or sunset divides the equinoctial line. But if the point L cannot be had, because of cramped space, one must seek the hour-arc of the 12th hour from noon or midnight, whose distance from the dial's own meridian is the same as the inclination of that meridian to the meridian of the horizon. We find this to contain $28^{\circ} 31'$. And since the plane of the dial cuts the eastern quadrant of the equator above the horizon — the arc between the plane and the horizon being greater than the complement of the pole's altitude — and consequently cuts the western quadrant below the horizon, the Sun, when it stands on the equator and on the meridian above the horizon, will not illuminate the upper face of the plane; rather it will illuminate it when it lies below the horizon on the equator and meridian, were it not blocked by the earth. For this reason the shadow of the style then falls toward the eastern parts on the equinoctial line, that is, toward L. We shall therefore reckon the said arc from N as far as the point S, through which the meridian line is to be drawn.

We have also traced those hours from sunset which lie below the horizon but still above the plane of the dial — namely 8, 7, 6, 5, 4, and so on — so that their position may be considered. Thus we drew the 5th hour, which has no point on the tropic of Capricorn or on the equinoctial line, through the point found on the tropic of Cancer and through the point e, where the 7th hour from sunset cuts the line of the 6th hour from noon or midnight — the line drawn through the center M and through the point R — as is clear from the table of the line of the 6th hour

from noon or midnight (Prop. 20 of Book 1). Likewise you see that the 4th hour from sunset has been drawn through the point found on the tropic of Cancer and through the point f on the line of the 6th hour from noon or midnight — through which the 8th hour from sunset passes, as is plain from the same table — or else through the point T on the equinoctial line, through which the 16th hour from sunset is drawn, as is clearly gathered from the table of Prop. 19 of Book 1.

Finally, for an upper dial declining from north toward the east by 30° , and inclined to the horizon on the southern side by $52^\circ 3'$, we have drawn up the following tables for the hours from noon and from midnight. In them the upper and lower shadow-latitudes are to be taken as we said for the preceding dial.

The latitudes and longitudes of the shadows in an upper dial declining from north toward the east by 30° , inclined to the horizon on the southern side by $52^\circ 3'$, for the hours from noon and midnight, at latitude 42° .

In the tropic of Cancer, the shadow-latitudes are partly upper and partly lower, as appears in the tables.

Table I — In the tropic of Cancer (hours from noon). (Latitudes in G[radus]·M[inuta] = degrees·minutes; Longitudes in P[artes]·M[inuta] = gnomon-parts·minutes.)

	6	7	8	9	10	11	12
Hours of Cancer, from noon	6	7	8	9	10	11	12
(complement)	6	5	4	3	2	1	0
Latitudes of the shadows (G·M)	90·0	76·16	62·40	49·16	36·4	22·58	9·43
Longitudes of the shadows (P·M)	2429·6	699·12	224·1	107·33	63·31	42·19	30·28

Right-hand rubrics: top numeral row — *Western and upper*; second numeral row — *Eastern and upper*.

Table II — In the tropic of Cancer (hours from midnight).

	6	7	8	8	10	11	12
Hours of Cancer, from midnight	6	7	8	8	10	11	12
(complement)	6	5	4	3	2	1	0

	6	7	8	8	10	11	12
Latitudes of the shadows (G·M)	90·0	70·8	51·19	34·5	18·23	3·58	9·43
Longitudes of the shadows (P·M)	11·18	11·43	12·58	15·6	18·21	23·10	30·28

Right-hand rubrics: top numeral row — *Eastern and lower*; second numeral row — *Western and lower, except the last; This last one is upper*.

In the equator, all shadow-latitudes are lower.

Table III — In the equator (Aries and Libra), hours from midnight.

	6	7	8	9	10	11	12
Hours of Aries and Libra, from midnight	6	7	8	9	10	11	12
(complement)	6	5	4	3	2	1	0
Latitudes of the shadows (G·M)	90·0	73·45	57·52	42·35	27·57	13·50	0·0
Longitudes of the shadows (P·M)	27·59	29·8	33·2	41·21	59·42	117·8	Infini.

Right-hand rubrics: top numeral row — *eastern*; second numeral row — *western*. The final longitude is **Infini.** (infinite).

On this dial all the hours of the tropic of Capricorn fall above the lower face of the plane in question, because the plane does not cut that tropic but hides it entirely beneath itself — just as the tropic of Cancer lies entirely above the plane. Hence no mention is made of the hours of the tropic of Capricorn in these tables.

Moreover, when the Sun is at the beginning of Cancer, the gnomon's shadow describes an ellipse, though on the dial, because of the cramped space, it does not appear in full.

Diagram. An uncaptioned sundial-construction figure for the dial declining from north toward the east by 30° and inclined to the horizon on the southern side by 52° 3' (the dial of the tables above). The horizon runs across as a bold horizontal line lettered **HORI = ZON**, with **A** at its left end and **B** at its right end. Down the left margin runs the graduated style-line (the line HI divided into gnomon-equal parts), lettered from the top **I, T** (with the numeral **10**), then **G**, then the tick-numerals **12, 24, 36, 48, 60**, down to **H** at the foot. A large circle is centered at **C**

(the position of the style). The hour-lines radiate through the circle and are numbered **12, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12** around the rim. **ORT** (oriens, east) is written vertically in the upper part, with **occ** (occidens, west) marked lower down toward the foot.

- HORI=ZON (bold central horizontal): the horizon line, endpoints A (left) and B (right)
- I, T, G, and the scale 10 · 12 · 24 · 36 · 48 · 60 · H (left margin): the divided style-line HI
- M, H, E (top): upper construction points
- ORT (upper, vertical): oriens (east) marker
- C (center): position of the style
- P, S, Q (about the center): equinoctial / horizontal-line points
- K (on the horizon, right of center): style-line meets the equinoctial line
- O (lower center): hour-line point
- F (left): style-line terminus
- D, I, N (foot of the figure): lower construction points; occ (occidens) marked nearby

So let the straight line AB be drawn in the plane of the dial, lying in a stable plane parallel to the horizon; and taking C on it as the position of the style, describe about C any circle ADBE, in which let the line DE cut AB at right angles at the center, as the common section of the plane of the dial and of the great circle that measures the inclination to the horizon. [Margin: Construction of the dial declining from north toward the east by 30° and inclined to the horizon by 52° 3', from the tables.] Then, having found (by Prop. 31 of Book 1) the arc of the great circle to which the dial is equidistant — the arc between the great circle that measures the inclination and the dial's own meridian, which in the dial before us we find to be 70° 28' — we shall count it off from D toward A, on the eastern side, as we said for the preceding dial. (For on this dial too the center falls below the style and the equinoctial line above it, since the arc of the meridian between the plane and the horizon is equal to the complement of the pole's altitude above the horizon, namely 48° 0'.) We count it off as far as F.

[Margin: The style-line.] For the straight line FCG will be the style-line, that is, the common section of the plane of the dial and of its own meridian. And from the line HI — which cuts FG at right angles at C, as the common section of the plane of the dial and of its own vertical circle — the shadow-latitudes are to be counted, as has often been done already. [Margin: The equinoctial line. The center of the

dial.] Then the line HI is divided into parts equal to the style; and once the altitude of the pole above the plane of the dial has been found (by Prop. 29 of Book 1) — which in our example we find to contain $66^{\circ} 47'$, so that its complement is $23^{\circ} 13'$ — if from C (the position of the style) we count upward along the style-line a shadow of 27 parts 59 minutes, which belongs to the complement of the pole's altitude just found, we shall find the point K, through which the equinoctial line is to be drawn perpendicular to FG. And if downward we take the shadow CL of 5 parts 9 minutes, corresponding to the pole's altitude just found, the point L will be found — the center of the dial. Through it, if we draw MN perpendicular to FG, the hour-arcs are to be reckoned from the points M and N in the circle described about L, provided they have been computed for the individual hours. These two points K and L can also be found if on HI one takes CO equal to the gnomon, and makes the angle COK equal to the pole's altitude just found, and the angle COL equal to the complement of that same altitude.

If now the shadow-latitudes are computed from the points H and I, carefully observing which are eastern and which western, and which upper and which lower, the dial will be constructed as in the preceding cases. [Margin: The horizontal line.] The horizontal line must be drawn through the point K — where the style-line, which on the given plane marks the 6th hour from noon or midnight, cuts the equinoctial line — parallel to AB, or perpendicular to DE, passing entirely through the point P, which on the line CE marks off a shadow of 9 parts 22 minutes, corresponding to the plane's inclination to the horizon. This point P will likewise be found if on the line AB one takes CQ equal to the style and constructs the angle CQP equal to the complement of the inclination, and so on. [Margin: The meridian line.] The meridian line on this dial is perpendicular to FG, so that it does not differ from the line MN, because the hour-arc of the 12th hour from noon or midnight contains $0^{\circ} 0'$ in the given example.

Diagram. The same sundial-construction figure as on the facing page (the dial declining from north toward the east by 30° and inclined by $52^{\circ} 3'$) is reprinted here, so that it stands alongside the construction text that runs across the opening. The layout and lettering match fig-p455-1: horizon **HORI** = **ZON** with **A** (left) and **B** (right); the graduated style-line **I · T · 10 · G · 12 · 24 · 36 · 48 · 60 · H** down the left margin; center **C**; the upper points **M, H, E** with **ORT** (oriens) vertical; hour-lines numbered **12, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12** around the rim; **K** on the horizon right of center; **P, S, Q** about the center; **O** lower center; **F** at left; **D, I, N** and **occ** at the foot.

From all this I think it easy to grasp how dials are made from tables, since we have given examples for every dial we described in Books 2 and 3, with the exception of the equinoctial dial, for the reason stated above. [Margin: The excellence of describing dials from tables.] Of the placing of all these dials we have said nothing at all: they are to be set up as we prescribed in Books 2 and 3. And this method of describing dials, drawn from tables, is the most reliable and the easiest, provided the tables are correctly computed, as we have taught in this book. For in it there is no need to draw as many perpendicular or parallel lines as in the other methods; it is enough to draw the lines of the shadow-latitudes as hidden construction lines, so that from them the shadow-longitudes may be cut off. These are to be obtained either from the shadow-table of Prop. 2 of this book, or found geometrically from the Sun's altitudes, as we set out in this proposition when we constructed the horizontal dial, and so forth. For in this way the points of the tropics — and of other parallels too, if one wishes — will be found. Add to this that by the very same method one may paint a dial of any size on a wall, for any given length of style, so that there is no need to draw it first on paper and afterward enlarge it onto the wall.

I had indeed intended to compute various tables here for various latitudes; but since the book was growing to an enormous size, I judged it better to demonstrate the method by which anyone can construct such tables on his own, and to illustrate the matter by a few examples that lay out every variety and difficulty. This I believe I have done abundantly in this book. There is this further point: no tables could suffice for all elevations of the pole, and all declinations and inclinations of planes, unless one were willing to construct tables for each single minute of elevation, declination, and inclination — which would be an almost infinite labor. At some other time, perhaps, when leisure allows, [I shall bring] a number of tables to light...

we shall bring a number of tables to light — especially for horizontal dials, and for verticals, meridians, and dials declining from the vertical which are laid out on walls at right angles to the horizon, since these are the kinds more commonly in use.

Nor should it be passed over in silence here that on any astronomical dial whatever — one laid out by means of the hour-arcs computed by the preceding proposition of this book — we can draw the parallels, or the arcs of the signs, exactly as in the earlier books: that is, by means of the figure in which the rays of the signs are contained, or else by the Analemma, provided careful account is kept of that triangle which is contained in every dial of this proposition where a

center has been marked. The base of this triangle is the portion of the style-line lying between the center of the dial and the equinoctial line; its two sides meet at the tip of the style. Of these sides, the one that falls from the tip of the style onto the equinoctial line is the common section of the Equator and of the Meridian proper to that dial (namely if the said triangle is understood to be revolved about the style-line until it stands perpendicular to the plane of the dial); the other, enclosed between the tip of the style and the center of the dial, represents the axis of the world, as is clear from what we demonstrated in Books 2 and 3.

[Margin: By what method the arcs of the signs can be drawn on an astronomical dial constructed by means of hour-arcs.]

For example: suppose a dial declining from the meridian toward the east by 40° , and inclined to the horizon by 20° (which is indeed the first of the six last dials of this proposition), has been laid out by hour-arcs. Then, on the axis of that figure in which the rays of the signs are contained, one must take a straight line equal to the axis KN in the triangle KLN of the said dial; and on the radius of the Equator, which at its outer point K is perpendicular to that axis, one must cut off a straight line equal to the line KL of the same triangle. Next, on the style-line of the dial, one must take a straight line LS — whether directed upward or downward — equal to that same KL. Finally, the intervals between S and the hour-points on the equinoctial line are to be transferred onto the radius of the Equator with the help of compasses, and so on.

As for the drawing of the signs from the Analemma: an Analemma must be constructed, with account taken of the angle KNL, the elevation of the pole, and so forth. We have therefore composed various dials from the tables which we taught how to compute in the preceding propositions. Which was what had to be done.

END OF THE FIFTH BOOK.

GNOMONICS. BOOK SIX.

By the author **CHRISTOPH CLAVIUS** *of Bamberg, of the Society of Jesus.*

Ptolemy published a most penetrating little book on the Analemma, in which he investigates certain arcs of circles both geometrically and by numbers, and by which — in almost the same way we used in the last book — dials of every kind may be described. This Federico Commandino [Federicus Commandinus] carried out successfully in his little book on the description of dials, which he attached to that work on the Analemma. But since very many people, while they esteem and

admire both Ptolemy's Analemma and the description of dials drawn from it by Federico Commandino — on account of the sharpness of the genius and the subtlety of the demonstrations — nonetheless at the same time gravely charge both authors with a certain studied obscurity, so that they wholly despair of gaining any fruit from their writings: I judged it altogether necessary to set out in this book, more clearly and (so far as may be) more briefly, that method of describing dials which Federico Commandino, as I said, drew from Ptolemy's Analemma — a method most delightful and most subtle — so that it may be understood and grasped by anyone who is not entirely ignorant of geometry. I shall not, however, follow Ptolemy's words, but his meaning and the substance of the matter itself, especially in finding the arcs and circumferences by numbers, where I have devised computations much shorter than Ptolemy's, as anyone will readily judge who compares what I here offer with Ptolemy's writings.

An explanation of the circles and circumferences which Ptolemy chiefly considers in the Analemma.

CHAPTER I.

[Margin: Which circles Ptolemy chiefly considers in the Analemma.]

Ptolemy seems to have taken account chiefly of three dials — the horizontal, the vertical, and the meridian. (We, however, by the same method, on the pattern of the horizontal dial, shall describe all the other dials we treated in the earlier books.) For that reason he considers in the Analemma chiefly only three great circles, which in any position of the sphere mutually intersect one another at right angles — namely the Horizon, the Meridian, and the circle properly called the Vertical — from which the said three dials are equidistant, as is clear from the earlier books. For each of these three circles is drawn through the poles of the remaining two, as is evident. Their common sections make right angles with one another at the center of the world, because any two of these circles are perpendicular to the third, as we said; [Margin: (a) prop. 19.] and therefore their common section too is perpendicular to that same third circle, and so on.

[Margin: What the meridian line, the equinoctial line, and the gnomon are, according to Ptolemy.]

Now the common section of the Horizon and the Meridian is called by Ptolemy the meridian line; the common section of the Horizon and the Vertical is called the equinoctial line, because it is also the common section of the Horizon and the equinoctial circle; and finally the common section of the Meridian and the

Vertical is called the gnomon. All these appear in the figure below, in which the circle ABCD is the Meridian; AFCG the Horizon, at right angles to the Meridian; BFDG the Vertical properly so called, at right angles to both the named circles; the straight line AC the meridian line, namely the common section of the Horizon and the Meridian; the straight line FG the equinoctial line, that is, the common section of the Horizon and the Vertical; and finally the straight line DB the gnomon, that is, the common section of the Meridian and the Vertical.

[Margin: How the three said circles are understood by Ptolemy to move.]

To each of these three circles Ptolemy next assigns a certain motion. For they must all pass through the center of the Sun, in whatever place or point of the heaven the Sun happens to be, so that each takes on as many positions in a day as there are places through which the Sun passes. Now the Horizon moves about the equinoctial diameter and its section, toward that which is above the earth and below the earth — as he himself says, that is, toward the zenith of the head and its opposite point; these two points are the poles of the fixed Horizon, and are equally distant from it. And so the greatest circle which is conceived as drawn through the center of the Sun (wherever it may be) and through the poles of the Meridian — that is, the common sections of the Horizon with the Equator or the Vertical — is called by Ptolemy in this place the movable Horizon.

[Margin: The movable horizon.]

Parallel to this movable Horizon is the dial declining from the Horizon which we constructed in Prop. 13 of Book 3. The Meridian, finally, moves about the meridian line, toward the rising and the setting — as he himself puts it — that is, toward the point of the equinoctial rising and setting; these two points are the poles of the fixed Meridian, and are equally distant from it. And so the greatest circle drawn through the center of the Sun, wherever it exists, and through the poles of the Horizon — that is, the common sections of the Meridian and the Vertical — is understood by Ptolemy in this place to be the movable Vertical.

Diagram. An armillary-type sphere shown at the top of the page, illustrating the three fixed and the three movable great circles Ptolemy considers in the Analemma. Rays of the Sun (a hatched fan) issue from the upper-left, marking the Sun's position at point H. The lettered points around and within the sphere are:

- D (top of the sphere): zenith of the head; upper end of the gnomon DB.
- B (bottom of the sphere): the point opposite the zenith; lower end of the gnomon DB.
- A (lower left): the southernmost point; end of the meridian line AC.

- C (right): the northernmost point; other end of the meridian line AC.
- F (lower center-left): one end of the equinoctial diameter FG (equinoctial rising).
- G (center, near E): other end of the equinoctial diameter FG (equinoctial setting).
- E (center of the sphere): the center of the world, through which all three movable circles' common sections (HEQ, LEM, KEO, NEP) pass.
- H (left, at the Sun): the center of the Sun, where the three movable circles intersect above the earth.
- Q (lower center): the point opposite H, where the three movable circles intersect below the earth.
- L (upper left): point on the movable Horizon (Hectemorion) FHLGQM.
- K (mid-left): point on the movable Meridian (Hour-circle) AHKCQON.
- M (lower right): point on the movable Horizon (Hectemorion) FHLGQM.
- N (lower left, near A): point on the movable Vertical (Descensive) DHNBQP.
- O (lower center, near Q) [?]: point on the movable Meridian (Hour-circle) AHKCQON.
- P (center-right): point on the movable Vertical (Descensive) DHNBQP.

The fixed circles are the Meridian ABCD, the Horizon AFCG, and the Vertical BFDG; the movable circles are the Hectemorion FHLGQM, the Hour-circle AHKCQON, and the Descensive DHNBQP.

And in order to distinguish these movable circles from the fixed ones, he gives them their own proper names. For the movable Horizon he calls ἑκτημόριον [Greek: hektēmōrion, "sixth-part" — the hectemorion], because — as Olympiodorus writes in his commentaries on the third book of Aristotle's *Meteorology* — it takes on six distinct positions in a day, on account of the six unequal hours which the ancients counted each day from sunrise to noon and from noon to sunset.

[Margin: The movable Meridian.]

The movable Meridian is called the Hour-circle [circulus Horarius], because it accompanies each single hour-space from rising all the way to setting.

[Margin: The movable Vertical. The hectemorion circle.]

The movable Vertical, finally, is called καταβατικός [Greek: katabatikos, "descending" — the descensive circle], that is, the Descensive, because it shows

the descent of the Sun from its highest part to its lowest, since on it the Sun's altitude above the Horizon is always reckoned.

[Margin: The hour-circle. The descensive circle.]

As in the figure above: if the Sun be placed at the point H, the movable Horizon, or Hectemorion, will be FHLGQM, drawn through the center of the Sun; and it turns about the equinoctial diameter FG, toward the zenith of the head D, above the earth, and toward its opposite B, below the earth. The movable Meridian, or Hour-circle, will be AHKCQON, passing through the same center of the Sun, and moving about the meridian line AC toward the equinoctial rising F and setting G. The movable Vertical — that is, the Descensive circle — will be DHNBQP, likewise passing through the center of the Sun, and revolving about the gnomon DB toward the southernmost point A and the northernmost point C. Above the earth, then, all three movable circles intersect one another at H, the center of the Sun; below the earth, at the opposite point Q. Their common section is the straight line HEQ; the section of the Hectemorion and the Meridian is the straight line LEM; the section of the Hour-circle and the Vertical is the straight line KEO; and finally the section of the Descensive and the Horizon is the straight line NEP.

Now, since the purpose of this book is to teach by what method dials are described — dials equidistant from the Horizon, the Vertical circle, and the Meridian — by means of the arcs or certain circumferences of the said circles, we must, together with Ptolemy, carefully consider in those six circles (of which three are fixed and three movable, as we said) six circumferences for each hour, one in each circle: three indeed in the three fixed circles, and as many in the movable ones. All of these take their name from the circles of which they are parts, so that the one taken in the Horizon is called the horizontal circumference; the one in the Descensive, the descensive; the one in the Vertical, the vertical; the one in the Hour-circle, the horary; the one in the Meridian, the meridian; and finally the one in the Hectemorion, the hectemorial.

[Margin: Six circumferences are to be considered in the said six circles.]

[Margin: The horizontal circumference. The descensive. The vertical. The horary. The meridian. The hectemorial.]

The horizontal circumference is contained in the Horizon between the Vertical circle and the Descensive — such as the circumference of the Horizon FN. The descensive is comprehended in the Descensive circle between the center of the Sun and the zenith of the head — such as the circumference of the Descensive circle DH. The vertical is enclosed in the Vertical circle between the Meridian and

the Hour-circle — such as the circumference of the Vertical circle DK. The horary is intercepted in the Hour-circle between the center of the Sun and one of the poles of the Vertical circle — such as the circumference of the Hour-circle AH. The meridian is contained in the Meridian circle between the Horizon and the Hectemorion — such as the circumference of the Meridian AL. And finally the hectemorial lies in the Hectemorion circle between the center of the Sun and the point of the equinoctial rising or setting — such as the circumference of the Hectemorion FH.

[Margin: None of the said circumferences ought to exceed a quadrant.]

But since the said circumferences are sometimes quadrants, and sometimes greater or smaller than a quadrant, whenever they exceed a quadrant we must take those which together with them make up a semicircle — not because this is altogether necessary, but because dials are more conveniently described this way. Thus, for example, if the Sun is past the meridian, we must not take that horizontal circumference which lies between the Vertical circle on the east side and the Descensive on the west, since it exceeds a quadrant, but rather the one that lies between the Vertical on the west side and the Descensive, since this is smaller than a quadrant; and so it must be judged for the rest.

[Margin: From where the said six circumferences take their beginning.]

Hence, since all the said circumferences take their beginning from those three common sections of the three fixed circles — the horizontal and the hectemorial from the equinoctial section FG, which is the axis of the Meridian, since it is drawn through its poles; the vertical and the descensive from the gnomon DB, which is the axis of the Horizon, passing through its poles; and finally the meridian and the horary from the meridian line AB [?] [recte AC: the meridian line is defined as AC, both here and on p. 448], which is the axis of the Vertical, since it passes through its poles — it follows that in the forenoon both the horizontal circumference and the hectemorial take their beginning from the equinoctial diameter on the east side, namely from the equinoctial rising; but in the afternoon from the west side, that is, from the equinoctial setting. By the same reasoning it comes about that both the vertical circumference and the descensive have their beginning at the gnomon, from the zenith of the head, wherever the Sun may be above the Horizon, because... ..because one of them is always smaller than a quadrant, while the other — the one begun from the point opposite the zenith — is larger than a quadrant. Finally, it is clear that when the Sun is in that part of the southern hemisphere which slopes from the Vertical circle toward the antarctic pole, both the meridian circumference and the horary

take their beginning from the meridian line on the south side; whereas when the Sun is in that part of the northern hemisphere which extends from the Vertical circle toward the arctic pole, they begin from the same line on the north side. And if at any time some circumference happens to equal a quadrant, it makes no difference from which end of the section the beginning is taken.

[Margin: The functions of the said six circumferences.]

From these six circumferences, then, is determined the position of the solar ray in the planes parallel to the Horizon, the Vertical, and the Meridian — the position it has at any given hour. For the horizontal circumference indicates the latitude of the shadow in the plane parallel to the Horizon; that is, it shows how far the shadow deviates from the common section of the Vertical circle and that plane — a section which runs from east to west. For since the horizontal circumference is FN, taking its beginning from the equinoctial diameter FG, in such a way that the Descensive circle DHN is drawn through the center of the Sun H and makes the section NEP on the Horizon, the shadow of the style — whose tip is set at E, the center of the world, as we showed at Book I, prop. 2 — will fall (by Book I, prop. 11) onto the common section of the Descensive circle DHN and of the plane of the dial that is parallel to the Horizon.

[Margin: (a) Euclid XI.16 ("16. vnde.")] [Margin: (b) Euclid XI.10 ("10. vnde.")]

(a) Now since the Descensive circle and the Vertical circle properly so called make, with the plane of the horizontal dial, common sections parallel to the straight lines NEP and FEG, (b) these sections will contain in the plane of the dial an angle equal to the angle NEF. And therefore, from the circle described in that same plane from the position of the style — where that angle is formed — they will cut off an arc similar to the horizontal circumference FN, by what we demonstrated in the scholium to prop. 33 of Euclid Book VI. Rightly, therefore, the horizontal circumference FN — or rather the arc similar to it in the plane of the dial — is said to indicate the latitude of the shadow, since it shows how far the straight line onto which the shadow falls must lie from the common section of the Vertical circle and the plane of the dial. The complement of the descensive circumference DH — namely the circumference HN — shows the Sun's altitude above the Horizon at that moment. Therefore, as we demonstrated in the preceding book at props. 2 and 5, by means of it we shall find the length of the shadow geometrically.

[Margin: The horizontal and the descensive circumferences are required for constructing the horizontal dial.]

Thus the position of the Sun's ray — that is, the tip of the shadow — will now be determined. And these two circumferences, the horizontal and the descensive, are required, and suffice, for constructing the horizontal dial, as we shall say later. Again, the Vertical circumference DK, taking its beginning from the gnomon DB, shows the latitude of the shadow on a Vertical dial. For the shadow of the style whose tip is at E will fall (by Book I, prop. 11) onto the common section of the hour-circle AKCO and of the plane of the dial that is parallel to the Vertical.

[Margin: (c) Euclid XI.16 ("16. vnde.")] [Margin: (d) Euclid XI.10 ("10. vnde.")]

[Margin: The Vertical and the horary circumferences are required for constructing the Vertical dial.]

(c) Since the Hour-circle and the Meridian make, with the plane of the Vertical dial, common sections parallel to the straight lines KEO and DEB, (d) these sections will contain in the plane of the dial an angle equal to the angle KED; and accordingly they will cut off, from the circle described in that same plane from the position of the style where that angle is formed, an arc similar to the Vertical circumference DK, by what we wrote in the scholium to prop. 33 of Euclid Book VI. The Vertical circumference DK, then — or rather the arc similar to it in the plane of the dial — indicates the latitude of the shadow, since it shows how far the straight line onto which the shadow falls must lie from the common section of the Meridian and the plane of the dial. The complement of the horary circumference AH — that is, the circumference HK — makes plain the Sun's altitude above the Vertical at that moment. Therefore from it, as we showed at props. 2 and 5 of the previous book, we shall find the length of the shadow geometrically; and so the position of the solar ray — that is, the tip of the shadow — will now be determined. And thus, from the Vertical circumference and the horary, the Vertical dial will be produced, as will be said in its place.

[Margin: (e) Euclid XI.19 ("19. vnde." — printed 19; the parallel clauses (a) and (c) cite XI.16)] [Margin: (f) Euclid XI.10 ("10. vnde.")] [Margin: The meridian and the hectemorial circumferences are required for the construction of the Meridian dial.]

Lastly, the meridian circumference AL, begun from the meridian line AC, shows the latitude of the shadow on a Meridian dial. For in the same way the shadow of the style will fall onto the common section of the Hectemorial circle FLGM and of the plane of the dial that is parallel to the Meridian. (e) And since the Hectemorial circle and the Horizon make, with the plane of the dial, common sections parallel to the straight lines LEO and AEC, (f) these sections will contain in the plane of the dial, at the position of the style, an angle equal to the angle

LEA; and therefore, by what we demonstrated in the scholium to prop. 33 of Euclid Book VI, they will cut off, from the circle described in that same plane from the position of the style, an arc similar to the meridian circumference AL. This being so, with full right the meridian circumference — or rather the arc similar to it in the plane of the dial — is said to indicate the latitude of the shadow, since it shows how far the straight line onto which the shadow falls must lie from the common section of the Horizon and the plane of the dial. And the complement of the hectemorial circumference FH — namely the arc HL — measures the Sun's altitude above the Meridian circle at that time; through it, by what was handed down at props. 2 and 5 of the previous book, we shall find the length of the shadow geometrically. Hence the position of the solar ray — namely the tip of the shadow — will be determined. And these two circumferences, the meridian and the hectemorial, are to be used for constructing the Meridian dial, as we shall explain below. And so the whole art of laying out dials from Ptolemy's *Analemma* [Ptolemaeus, *Analemma*] consists in finding the said circumferences for each individual hour — which we shall now proceed to teach how to determine.

Diagram. An armillary-sphere woodcut illustrating the six circles of the *Analemma* construction of Chapter I, with the Sun's rays entering as a hatched fan from the upper left. The sphere is drawn as an assembly of banded great circles (Meridian, Horizon, Vertical, Hectemorion, Hour-circle, Descensive) intersecting at a common center. Legible labels (positions approximate):

- D (top of sphere)
- L (upper region, left of K)
- K (upper region)
- A (left)
- B (bottom of sphere)
- G (center-right)
- P (right, beside G)
- C (right side)
- Q (lower band, curved)
- M (lower right)
- E (center, where the circles and the incoming rays converge)

The text of this chapter also names interior points F, N, O and H, which lie among the crossing bands and could not be individually resolved on the scan.

The finding of the hectemorial, horary, descensive, meridian, Vertical, and horizontal circumferences (of which we spoke in the preceding chapter), from the Analemma, with the Sun in the Equator, for any latitude whatsoever.

CAPVT II.

Let the Meridian of the Analemma be ABCD, in which two diameters AC and BD cut one another at right angles: let AC be the common section of the Vertical circle and the Meridian, and BD the common section of the same Meridian and the Horizon. Let the axis of the world also be HI, such that the arc DH comprises 42 degrees — the altitude of the pole at Rome, for which we construct all the dials in this work. Let the diameter of the Equator be FG, cutting the axis at right angles at the center E.

If, then, about the diameter FG a semicircle of the Equator is imagined described perpendicular to the Meridian and inclining toward the east (the Meridian being placed in its proper position), it will be exactly equal to the semicircle FHG, since both semicircles have the same diameter FG. Therefore the latter can rightly be taken here for the former, so that FHG performs the office of the eastern semicircle of the Equator — the one, namely, that the Meridian separates from the remaining western semicircle. And FH will be the eastern quadrant of the Equator above the earth, while HG will be the eastern quadrant below the earth, so that the straight line EH is the common section of the Horizon and the eastern semicircle of the Equator.

This will be easily grasped if the semicircle of the Equator FHG is imagined turned about the diameter FG until it stands perpendicular on the plane of the Meridian; and likewise the semicircle of the Horizon set upon the diameter BD, perpendicular to the same plane of the Meridian. (a) For then the common section of these semicircles will be perpendicular to that same plane of the Meridian, and hence, by Euclid, Book XI, definition 3, also perpendicular to the straight line FG.

[Margin: (a) Euclid XI.19 ("19. vndec.")]

For this reason the straight line EH, perpendicular to FG, will be the common section of the Equator and the Horizon. For no other straight line in the plane of the semicircle of the Equator FHG can be perpendicular to FG at E except EH — which, however, is required for the common section of the Horizon and the

Equator, as we have said. And so, since the quadrant of the Equator FH runs from the rising point — placed at H, where the Horizon intersects the Equator — all the way to the south, placed at F, where the Equator [printed "Æqnator"; recte: *Æquator*] cuts the Meridian, that same quadrant can not inaptly play the role of the other quadrant, which begins at the south F and ends at the setting, so that H is also the point of setting. For the western quadrant of the Equator has exactly the same position on the sphere as the eastern; and in this way the quadrant FH will represent for us the whole semicircle of the Equator above the earth.

Let the Sun, then, be placed at one or the other equinox, at the point K of the equinoctial circle — whether that point marks off some hour from noon or from midnight, or from the east or west, or at least some fraction of an hour — in such a way that HK is the arc of the Equator lying between the center of the Sun and the Horizon, while the arc of the Equator FK lies between the Meridian and the center of the Sun, on either the eastern or the western side; and let it be required to find geometrically, from the Analemma, how great the six circumferences set out are at that time.

From K, the point of the given hour where the Sun is placed, let the straight line KL be drawn perpendicular to FG, the diameter of the Equator; and through L let two perpendiculars NLM and OLP be raised to BE and AE. These are greater than the line kL.

[Margin: (b) Euclid I.47 ("47 primi")] [Margin: (c) Euclid I.19 ("19 primi")]

(For draw the straight lines EK, EM, EP. Since their squares are equal to one another, (b) and the square on EK equals the two squares on EL and LK together, the square on EM the two squares on EN and NM, and the square on EP the two squares on EO and OP, the two squares on EL and LK will be equal both to the two squares on EN and NM and to the two on EO and OP. Since, then, (c) the square on both EN and EO is less than the square on EL — that is, in the right triangles ELN and ELO the line EL [is the greater] [?] [the print of this parenthetical clause is compressed and partly garbled] — the remaining square, that on NM, and likewise that on OP, will each be greater than the remaining square on LK; and for this reason each of the lines NM and OP will be greater than the line LK.)

From NM and OP let there be cut off two [segments] NQ and OR equal to KL; and through the points Q and R, from the center E, let two straight lines EQS and ERT be drawn, cutting the circumference of the Meridian at S and T. When this has been duly carried out, all the said six circumferences for the proposed time will

have been found — namely when the Sun stands at the point K of the Equator. For, as we shall demonstrate in the following chapter, HK will be the hectemorial circumference; BM the horary; AP the descensive; BF the meridian; AT the Vertical; and AS the horizontal. The use of the other lines of this figure — such as the lines FY, SV, TX, FZ, KN, KO — will appear in chapter 7 of this book.

Diagram. The planar Analemma construction of Chapter II: a full circle (the Meridian ABCD) filled with chords and radii from the center. The horizontal diameter runs left-to-right through the center, and numerous straight lines connect the perimeter points to the interior construction points. Legible labels (positions approximate):

- A (top of circle)
- M, S (upper arc, just left of A)
- K (upper arc, right of A)
- F (upper left)
- H (right)
- P, R (left)
- B (left end of the horizontal diameter)
- Y, V, N (left half of the horizontal diameter, moving inward toward the center)
- E (center)
- D (right end of the horizontal diameter)
- I (lower left)
- G (lower right)
- C (bottom)
- interior construction points L, O, X (near the center)

The text additionally names the points Q, R, T, Z (the intersections EQS, ERT and the auxiliary lines FZ etc.); these small interior labels among the dense chords could not all be individually resolved on the scan.

SCHOLIVM.

From what has been said, the method is clear by which, with the Sun in the Equator, any one of the said circumferences can be investigated separately, when needed, without regard to the others.

[Margin: How, with the Sun in the Equator, any of the circumferences may be found, without regard to the others.]

For up to now all six have been sought at once, though we do not always need them, but only one or another. For, as we said in the preceding chapter, only the horizontal and descensive circumferences are necessary for constructing the horizontal dial; for the Vertical dial we need the Vertical and horary circumferences; and finally for the Meridian dial the meridian and hectemorial circumferences must be found. Therefore, to investigate any one of them, from K — the point of the hour where the Sun is set — a perpendicular KL must be drawn to the diameter of the Equator FG. Then, if...

[Margin: Horizontal.] if the horizontal circumference is to be found, a perpendicular MN must be drawn through the point L to the diameter of the Horizon BD; and if from it a line NQ is cut off equal to KL, and from the center E through Q a line EQ is drawn cutting the circumference of the Meridian at S, then AS will be the horizontal circumference, taking its beginning in the Analemma from the diameter of the Vertical circle — that is, from the gnomon AE.

[Margin: Descensive.] But if the descensive circumference is to be found, a perpendicular OP must be drawn through the point L to the diameter of the Vertical circle AC, cutting the circumference of the Meridian at P. For AP will be the descensive circumference, begun in the Analemma from the diameter of the Vertical circle AC.

[Margin: Vertical.] And if the Vertical circumference is wanted, a perpendicular OP must be drawn through the point L to the diameter of the Vertical circle AC. For if from it a line OR is subtracted equal to KL, and from the center E through R a line ER is drawn cutting the circumference of the Meridian at T, then AT will be the Vertical circumference, beginning in the Analemma from the Vertical diameter AC.

[Margin: Horary.] If, however, the horary circumference is sought, a perpendicular MN must be drawn through L to the diameter of the Horizon BD, cutting the circumference of the Meridian at M. For BM will be the [horary] circumference, setting its beginning on the diameter of the Horizon BD.

[Margin: Meridian.] So that the meridian circumference may be had [?] [printed verb uncertain — reads "habeatur"/"horaria"], take the arc BF, between the Horizon and the Equator — that is, the complement of the altitude of the pole above the Horizon.

[Margin: Hectemorial.] Finally, for the hectemorial circumference the arc HK is to be taken, between the point of rising (or setting) and the Sun's place — that is, the complement of the Sun's distance from midday.

DEMONSTRATION OF WHAT WAS SAID in the preceding chapter concerning the finding of the aforesaid six circumferences.

CAPVT III.

[Margin: Demonstration of the finding of the said six circumferences, with the Sun in the Equator.]

Let there be conceived, about the diameter of the Equator FG in the figure of the preceding chapter, the semicircle of the Equator FKHG, turned into its proper position — that is, until it stands perpendicular to the Meridian ABCD, and passes through K, the Sun's place. About the gnomon AC let the Vertical semicircle AXVHC be conceived, perpendicular to the same Meridian. And about the same gnomon AC let the Descensive semicircle AKYZC be conceived, described through the center of the Sun k. Likewise, about the diameter of the Horizon BD let its semicircle BYaHD be imagined described, perpendicular to the Meridian; and about the same diameter let the Hour semicircle BKXbD be drawn through the center of the Sun K.

The semicircle of the Hectemorion, moreover, is exactly the same as that of the Equator FKHG turned to its proper position, because both the Equator and the Hectemorion pass through the center of the Sun k, and both have the same diameter — namely the common section of the Equator and the Horizon, whose half is EH. Next, the straight line MN being produced as far as d, let there be conceived, from B, the pole of the Vertical circle, and with radius BM, a semicircle MKaZd described on the surface of the sphere, which by Theodosius [Theodosius, *Sphaerica*], Book II, prop. 2, will be parallel to the Vertical circle. (a) And since the common sections which the Vertical circle and this semicircle make with the Meridian are parallel —

[Margin: (a) Euclid XI.16 ("16. vnde.") [Margin: (b) Euclid I.28 ("28. primi")]

(b) now the straight lines AC and Md are parallel to one another, because of the right angles AEN and MNE, and AC is the common section of the Vertical and the Meridian — therefore Md will be the common section of the semicircle MKaZd and the Meridian. But since the semicircle of the Equator FKHG and the semicircle MKaZd are perpendicular to the Meridian (for since the Meridian is drawn through the poles of the semicircle MKaZd, it will be perpendicular to it, by Theodosius, Book I, prop. 15, and hence conversely that semicircle too will be perpendicular to the Meridian; and the Equator is set perpendicular to the Meridian in its proper position), (c) their common section too will be

perpendicular to it, and hence, by Euclid, Book XI, definition 3, also perpendicular to the straight line FG.

[Margin: (c) Euclid XI.19 ("19. vndec.")] [Margin: (d) Euclid XI.16 ("16. vnde.")]
[Margin: (e) Euclid I.28 ("28. primi")] [Margin: (f) Euclid XI.19 ("19. vnde.")]

Since, then, the line KL, by Euclid, Book XI, definition 4, is perpendicular to the plane of the Meridian — inasmuch as it lies in the plane of the Equator, which is perpendicular to the Meridian, and is perpendicular to FG, the common section of the Equator and the Meridian — the line KL will be the common section of the Equator and the semicircle MKaZd, since the planes of these circles cut one another at the point L; and therefore the semicircle MKaZd will pass through K, the Sun's place. And the straight line aN will be the common section of that same semicircle and the Horizon.

Again, the straight line PO being produced as far as e, let there be conceived on the surface of the sphere, from A, the pole of the Horizon, and with radius AP, a semicircle PKVbe described, which by Theodosius, Book II, prop. 2, will be parallel to the Horizon; (d) and hence the sections which the Horizon and this semicircle make with the Meridian will be parallel to one another. (e) Since, then, the straight lines BD and Pe are parallel to one another, because of the right angles BEO and POE, and BD is the common section of the Horizon and the Meridian, Pe will be the common section of the semicircle PKVbe and the Meridian. But since both the Equator and this semicircle are perpendicular to the Meridian (for the Equator in its proper position is set perpendicular to the Meridian, while the Meridian, drawn through the poles of the said semicircle [printed "semirculi"; recte: semicirculi] PkVbe, is perpendicular to that semicircle, by Theodosius, Book I, prop. 15, and hence conversely the semicircle too will be perpendicular to the Meridian), (f) their common section too will be perpendicular to the Meridian; and consequently, by Euclid, Book XI, definition 3, also perpendicular to the straight line FG. Therefore, since the line kL, by Euclid, Book XI, definition 4, is perpendicular to the plane of the Meridian, as we showed a little before, the line KL will be the common section of the Equator and the semi-[circle...]

Diagram. The demonstration figure of Chapter III: a sphere shown as a circle crowded with great-circle and semicircle arcs (Equator, Vertical, Descensive, Horizon, Hour, and the parallel semicircles MKaZd and PKVbe) together with radii and chords from the center. Legible labels (positions approximate; the figure mixes capital and lowercase letters):

- A (top)
- K, M (upper arc)
- F (upper left)
- H (right)
- b (lowercase, right)
- P, R (left)
- E (center)
- B (left)
- Y (lower left)
- G (lower right)
- C (bottom)
- interior points X, W, I, O, L, N (near center)
- lowercase d, f and point Z (lower interior arcs)

Because this figure carries many small interior and lowercase labels among overlapping arcs, several could not be resolved with certainty on the scan.

(Continuation of the demonstration of Chapter III — the equality of the six meridian arcs to the corresponding circumferences.)

and of the semicircle PkVbe. Since the planes of these circles cut one another at L, the semicircle PKVbe will therefore pass through K, the place of the Sun. And the straight line VO will be the common section of this same semicircle and the Vertical.

Moreover, let the common section of the Descensive circle [circulus descensiuus] and the semicircle MKaZd be the straight line KZ; and let the common section of that same Descensive circle and the Horizon be the straight line YE, which must pass through the point f, where the straight lines aN and KZ cut one another. For each of the lines aN and YE lies in the plane of the Horizon — since aN is the common section of the Horizon and the semicircle MKaZd, and YE is the common section of that same Horizon and the Descensive circle; and the point Y lies between B and a, because the semicircle MkaZd cuts the Descensive circle both above and below the Horizon (as can easily be understood if the said semicircle and the Descensive circle are conceived in their proper positions). Hence the straight lines aN and YE will cut one another in the plane of the Horizon at some point, which let be f; and this will necessarily lie on the straight line KZ. For since the point f, where aN and YE intersect, lies both in the common section of the Descensive circle and the Horizon (namely on YE) and in the common section of the semicircle MKaZd and that same Horizon (namely on aN), it will necessarily

lie both in the plane of the Descensive circle and in the plane of the said semicircle. It will therefore lie on their common section — that is, on the straight line KZ.

Let the straight line Kb likewise be the common section of the Horary circle [circulus horarius] and the semicircle PKVbe; and let the common section of that same Horary circle and the Vertical be the straight line XE, which must pass through the point I, where the straight lines VO and Kb intersect. For each of VO and XE lies in the plane of the Vertical — since VO is the common section of the Vertical and the semicircle PKVbe, while XE is the common section of the Vertical and the Horary circle; and the point X lies between A and V, because the semicircle PkVbe cuts the Horary circle both on this side of and beyond the Vertical (as is evident if the said semicircle and the Horary circle are understood in their proper positions). Hence VO and XE will cut one another in the plane of the Vertical at some point, which let be I; and this will certainly lie on the straight line Kb. For since the point I, where VO and XE intersect, lies both in the common section of the Horary circle and the Vertical (namely on XE) and in the common section of the semicircle PKVbe and that same Vertical (namely on VO), it will necessarily lie both in the plane of the Horary circle and in the plane of the said semicircle. It will therefore lie on their common section — that is, on the straight line Kb.

Likewise, let the common section of the Equator (or hectemorion [hectemorius; Greek *hektēmōrion*, "sixth-part" — the great circle of the hours]), the Descensive circle, and the Horary circle — all drawn through the Sun's center K and the center of the world E — be the straight line kE. Finally, let the common section of the Horizon, the Vertical, and the Equator (or hectemorion) — all of which cut one another at the equinoctial rising or setting and are drawn through the center of the world — be the straight line EH.

Now that all these things have been rightly grasped and demonstrated, it must be shown: that the arc HK on the Meridian is equal to the hectemorial circumference Hk on the hectemorion (that is, on the Equator in its proper position); that the arc BM on the Meridian is equal to the horary circumference BK on the Horary circle; and that the arc AP on the Meridian is equal to the descensive circumference AK on the Descensive circle. Likewise, that the arc BF is equal to the meridian circumference between the Horizon and the hectemorion; that the arc AT on the Meridian is equal to the vertical circumference AX on the Vertical, between the Meridian and the Horary circle; and finally that the arc AS on the Meridian is equal to the horizontal circumference HY on the Horizon, between the Vertical

and the Descensive circle. This we shall demonstrate in nearly the same way as Federico Commandino [Federico Commandino].

[Margin: Demonstration of the hectemorial circumference.]

Draw the straight line Ek in the plane of the Meridian. The two sides EK and KL of the triangle EKL in the plane of the Meridian are equal to the two sides EK and KL in the plane of the hectemorion. For each EK is drawn from the center E to the surface of the sphere, and so the one is equal to the other; while the straight line kL in the Meridian will coincide with the straight line kL, the common section of the hectemorion and the semicircle MkaZd, if the meridian semicircle FHG is turned about the straight line FG until it stands perpendicular to the plane of the Meridian — since each is then perpendicular to the plane of the Meridian: the one, KL, which lies in the plane of the Meridian, by Euclid, *Elements* XI, definition 4 [Margin: (a) *Elements* XI.19]; the other, because it is the common section of two planes perpendicular to the Meridian (for from this it follows that it is perpendicular to that same Meridian). Since, then, each kL is bounded on the surface of the sphere, the one will be equal to the other — and the base EL is common — so the angles K of those triangles will be equal [Margin: (b) *Elements* I.8]. But that angle K in the plane of the Meridian is equal to the alternate angle KEH in the same plane [Margin: (c) *Elements* I.29], because the straight lines KL and HE are parallel, owing to the right angles kLE and HEL [Margin: (d) *Elements* I.28]; while this angle K in the hectemorion, for the same reason, is equal to the angle KEH in the same hectemorion [Margin: (e) *Elements* XI.16] — for the straight lines kL and EH are parallel, since they are the sections made by the hectemorion in parallel planes, namely in the Horizon and in the semicircle PKVbe. Therefore the angle KEH in the Meridian will be equal to the angle KEH in the hectemorion, and hence the arc HK in the Meridian is equal to the arc HK in the hectemorion [Margin: (f) *Elements* III.26]. Which was to be shown.

This can also be inferred more briefly as follows. Since at the time of the equinox the hectemorion does not differ from the Equator, the arc Hk (if the Meridian be taken for the Equator), lying between the Horizon and the Sun's center, will be the hectemorial circumference.

[Margin: Demonstration of the horary circumference.]

Next: since the Meridian and the Horary circle are drawn through B and D, the poles of the Vertical circle and of the semicircle MKaZd (which is equidistant from the Vertical), the arc AM of the Meridian and the arc XK of the Horary circle, being enclosed between parallel circles, will be equal to one another, by

Theodosius, Book II, prop. 10. Since, then, AB and XC are quadrants — because B, the pole of the Vertical, is a quadrant distant from the Vertical itself, by the corollary to Theodosius, Book I, prop. 16 — the remaining arc BM on the Meridian will also be equal to the remaining horary circumference BK on the Horary circle. This too we shall demonstrate more briefly thus: since B is the pole of the semicircle MKaZd, the chords BM and BK will be equal, by the definition of a pole; therefore the arcs BM and BK will also be equal [Margin: (g) *Elements* III.28]. Which is what was proposed.

[Margin: Demonstration of the descensive circumference.]

By like reasoning: since the Meridian and the Descensive circle are drawn through A and C, the poles of the Horizon and of the semicircle PKVbe (which is equidistant from the Horizon), the arc PB of the Meridian and the arc YK of the Descensive circle, being enclosed between parallel circles, will be equal to one another, by Theodosius, Book II, prop. 10. Since, then, BA and YA are quadrants, by the corollary to Theodosius, Book I, prop. 16, the remaining arc AP on the Meridian will also be equal to the remaining descensive circumference AK on the Descensive circle. We shall conclude this more easily thus: since A is the pole of the semicircle PKVbe, the chords AP and AK will be equal, by the definition of a pole; therefore the arcs AP and AK will also be equal [Margin: (h) *Elements* III.28]. Which is what was proposed.

[Margin: Demonstration of the meridian circumference.]

That BF is a meridian circumference is now evident, since it lies between the meridian line BD (that is, the Horizon) and the hectemorion FHG.

[Margin: Demonstration of the Vertical circumference.]

Again, since the Horary circle BKXbD cuts two parallel circles — namely the Horizon and the semicircle PKVbe — the sections it makes in them, that is, the straight lines BD and Kb, will be parallel to one another [Margin: (i) *Elements* XI.16]. And on account of the right angles BEO and POE, the straight line Pe is also parallel to BD [Margin: (l) *Elements* XI.9]. Therefore the straight lines Kb and Pe will likewise be parallel to one another [Margin: (m) *Elements* XI.16]. Likewise, since the semicircle PKVbe, cutting the parallel circles — namely the Vertical and the semicircle MKaZd — makes the common sections VO and KL parallel, KLOI will be a parallelogram [Margin: (n) *Elements* I.34]; and therefore the straight line OI

will be equal to the straight line LK — that is, to OR, since OR was taken equal to KL. Since, then, the two sides IO and OE of the triangle IOE are equal to the two sides RO and OE of the triangle ROE, and the angles IOE and ROE contained by them are right — (for since both the Vertical and the semicircle PKVbe are perpendicular to the Meridian [Margin: (a) *Elements* XI.19], their common section VO will also be perpendicular to that same Meridian, and hence also to the straight line AC, by Euclid, *Elements* XI, definition 3; therefore the angle IOE is right, while the angle ROE is right by construction) — the angle REO will be equal to the angle IEO [Margin: (b) *Elements* I.4]. And therefore the arc AT on the Meridian, subtending the angle TEA at the center, will be equal to the vertical circumference AX, which subtends the angle XEA at the center [Margin: (c) *Elements* III.26].

[Margin: Demonstration of the horizontal circumference.]

Finally, since the Descensive circle AKYZC cuts two parallel circles — namely the Vertical and the semicircle MKaZd — the sections it makes in them, that is, the straight lines AC and KZ, will be parallel to one another [Margin: (d) *Elements* XI.16]. And on account of the right angles AEN and MNE, the straight line Md is also parallel to AC [Margin: (e) *Elements* I.28]. Therefore the straight lines KZ and Md will also be parallel to one another [Margin: (f) *Elements* XI.9]. Likewise, since the semicircle MKaZd, cutting the parallel circles — namely the Horizon and the semicircle PKVbe — makes the common sections aN and KL parallel, KLNf will be a parallelogram [Margin: (g) *Elements* XI.16]; and consequently the straight line fN is equal to KL — that is, to NQ, which was taken equal to kL. Since, then, the two sides fN and NE of the triangle fNE are equal to the two sides QN and NE, and contain right angles — (for since both the Horizon and the semicircle MKaZd are perpendicular to the Meridian [Margin: (h) *Elements* I.34], their common section aN will also be perpendicular to that same Meridian, and on that account also to the straight line BD; therefore the angle fNE is right, while the angle QNE is right by construction) [Margin: (i) *Elements* XI.19] — the angle fEN will be equal to the angle QEN [Margin: (k) *Elements* I.4]. Therefore the arcs BY and BS, which are subtended by these angles, will also be equal to one another [Margin: (l) *Elements* III.16]. Since, then, BH and BA are quadrants — because B, the pole of the Vertical, is a quadrant distant from the Vertical, by the corollary to Theodosius, Book I, prop. 16 — the remaining arc AS on the Meridian will also be equal to the remaining horizontal circumference HY on the Horizon. All of which were the things to be demonstrated.

The finding of the hectemorial, horary, descensive, meridian, vertical, and horizontal circumference, from the Analemma, the Sun being in any parallel outside the equinoctial circle, for any latitude.

CAPUT IIII.

Let ABCD be the Meridian of the Analemma, in which the two diameters AC and BD cut one another at right angles. Of these, let AC be the common section of the Vertical circle and the Meridian, and BD the common section of this same Meridian and the Horizon. Let HI also be the axis of the world, and FG the diameter of the Equator, cutting the axis at right angles. Finally, let ab be the diameter of any parallel, whether northern or southern, about which is described the semicircle aKb of that parallel; and from d, where the diameter of the parallel cuts the diameter of the Horizon, let de be drawn perpendicular to ab, the diameter of the parallel — this will be the common section of the Horizon and the parallel. For since both the Horizon and the parallel are perpendicular to the Meridian [Margin: (m) *Elements* XI.19], their common section too will be perpendicular to that same Meridian, and hence, by Euclid, *Elements* XI, definition 3, also perpendicular to the straight line ab at the point d, where the Horizon and the parallel cut one another in the Meridian. Since, then, from d only one perpendicular can be drawn to ab in the plane of the parallel, the perpendicular de will be the common section of the Horizon and the parallel — so that ae is the segment of the parallel above the earth, and eb the segment of the same below the earth. Of these, the former (ae) represents to us the portion of the parallel from the rising e to noon a, and the portion from noon a to the setting e; while the latter (eb) represents the portion from the setting e to midnight b, and the portion from midnight b to the rising e — because the portion before noon is similar and equal to the portion after noon, and likewise the portion before midnight to the portion after midnight. And in this way the segment ae will represent to us the whole diurnal arc of the parallel above the Horizon, and the segment eb the whole nocturnal arc below the Horizon.

[Margin: In these six figures of this chapter, let the straight line YE be produced as far as Z, as was done in figures 1 and 6. Likewise in figure 2 let the straight line KE be drawn, as in the others.]

Diagram. The first analemma figure for Chapter IIII: a full circle (the Meridian of the Analemma ABCD) crowded with straight lines — the Vertical diameter AC, the

Horizon diameter BD, the world-axis HI, the Equator diameter FG, the parallel diameter ab and its semicircle aKb — together with numerous chords, perpendiculars, and construction lines radiating from the center E. Legible labels (positions approximate; the figure mixes capitals and small italics among heavily overlapping lines):

- A (top), with a small italic *g* to its right
- f, M, S, F (upper-left cluster, near the top arc)
- a (upper left, small italic)
- Y, T, P, B (left side)
- R, L, N (left of center); X, O, E (center)
- m (below center, small italic)
- K (lower left)
- e, f, I, a (lower-left arc, small italics)
- P (bottom left)
- g (bottom center, small italic); C (bottom)
- b (lower right); H, D, e (right side); Q (lower right)

The figure carries many small italic labels among densely overlapping construction lines; several could not be resolved with certainty on the scan.

Let it then be supposed that the Sun in its parallel occupies the point *k*, which marks the end of some whole hour or fraction of an hour — whether that hour is equal (reckoned from the rising, or the setting, or from noon or midnight) or unequal — so that *eK* is the arc of the parallel intercepted between the Sun's center and the Horizon, whether on the eastern or the western side; while the arc *ak* of the parallel lies between the Meridian and the Sun's center, whether before or after noon. And let it be required to find geometrically, from the Analemma, how great at that time are the six circumferences set forth.

[Margin: The finding of the said six circumferences from the Analemma, the Sun being outside the Equator.]

From *K*, the point of the given hour where the Sun is placed, let the straight line *KL* be drawn perpendicular to *ab*, the diameter of the proposed parallel; and through *L* let two perpendiculars *NLM* and *OLP* be raised to *BE* and *AE*. Of these, since they are greater than the straight line *KL* — for if the semicircle of the parallel is conceived as turned back into its proper position, so as to be perpendicular to the Meridian, then *KL*, by Euclid, *Elements* XI, definition 4,

will be perpendicular to that same Meridian, and hence, by Euclid, *Elements* XI, definition 3, perpendicular to all the lines drawn through L in it. Therefore, when the straight line ELY has been drawn, the angle kLE will be right. Since, then, the angles MNE and POE are also right, if three radii of the sphere EK, EM, EP are drawn — whose squares are equal — then both the two squares of MN and NE, and the two squares of PO and OE, will be equal to the two squares of KL and LE [Margin: (a) *Elements* I.47]. Wherefore, since both the square on NE and the square on OE are less than the square on LE — because both NE and OE, in the right triangles NEL and OEL, are less than LE [Margin: (b) *Elements* I.[?]] (margin numeral illegible) — the remaining square of MN, and the remaining square of PO, will each be greater than the remaining square of KL; and therefore each of the straight lines MN and PO will be greater than KL.

Only when the perpendicular KL falls on the point n, where the diameter of the parallel divides the diameter of the Vertical — as happens in figure 3 — is the straight line kL equal to the straight line PO [Margin: (c) *Elements* I.47]. For then the two squares on KL and LE are equal to the two squares on PO and OE; and if the common square on LE is taken away, the remaining square on KL will equal the remaining square on PO — and consequently KL and PO will be equal. Nevertheless, even then the straight line MN will exceed KL, since MN is then a radius of the sphere, while KL is less than a radius. Let two lines NQ and OR be cut off equal to KL; and through the points Q and R let straight lines EQS and ERT be drawn from the center E, cutting the circumference of the Meridian at S and T. Finally, at the straight line EY let two perpendiculars Eg and Lf be raised at E and L. When these things have been duly carried out, all the said six circumferences for the proposed time will have been found — namely when the Sun is at the point K of the parallel aeb. For, as we shall show in the next chapter, gf will be the hectemorial circumference; BM the horary; AP the descensive; BY the meridian; AT the vertical; and AS the horizontal.

Diagram. The upper of three analemma figures on this page (figure 2, in which KE is drawn). A full circle with the Vertical, Horizon, axis, Equator, and parallel diameters, and a dense web of chords and perpendiculars converging on the center E. Legible labels (positions approximate; capitals and small italics intermixed):

- a, S, M, A (upper-left arc); K (top)
- f, f, H, e (upper right to right side)
- F, P (left side); l, X, o (left of center)
- Q, m (center); k, v, N, E (center)

- p, q (below center, small italics)
- a, C (bottom); G (lower right), with a small italic *g*
- q (center-right); D (right); a, b (lower right)

Several small labels among overlapping lines could not be resolved with certainty. [Dense analemma schematic]

But the three movable circumferences — the hectemorial, horary, and descensive — can be found more easily, without so many perpendicular lines, in the following way.

[Margin: Another method of finding the hectemorial, horary, and descensive circumference.]

Having drawn KL from K, the Sun's place, perpendicular to ab, the diameter of the parallel, let the straight line ELY be drawn from E through L, and to it let the perpendicular Eg be raised at E. For if, with L as center and LK as radius, the point f is taken on the Meridian by means of the compasses, gf will be the hectemorial circumference. But if, with the point d — where the diameter of the parallel cuts the diameter of the Horizon — as center and dK as radius, the point M is taken on the Meridian, BM will be the horary circumference. And if, finally, with the point n — where the diameter of the parallel cuts the diameter of the Vertical — as center and nK as radius, the point P is taken on the Meridian by means of the compasses, AP will be the descensive circumference.

Diagram. The middle of three analemma figures on this page (figure 3, in which the perpendicular KL falls on n). A full circle with the usual diameters and a converging web of construction lines. Legible labels (positions approximate):

- o, A, Y, S, M (top arc); K (upper right, on the circle)
- F (left); l, X, L, n, o (left of center)
- Q, R (upper center); H, P, T, R (upper right)
- e (right); m (center); k, f, E, V (center)
- d (center right); B (right)
- q, p (below center); I (lower left); G (bottom); a small italic *g* and *b* (lower right)

Several small labels among overlapping lines could not be resolved with certainty. [Dense analemma schematic]

The reason for this is that the straight line fL, when drawn, is perpendicular to the straight line ELY; the straight line MLN, when drawn, is perpendicular to BD;

and the straight line PLO to AC — as we shall demonstrate presently. Since, then, the three said circumferences were first found by means of these perpendiculars Lf, MLN, PLO (as we shall show in the next chapter), the same will also be found by the points f, M, P taken on the Meridian, as we have said.

Diagram. The lower of three analemma figures on this page. A full circle densely filled with a star-like web of chords and radii from the center E. Legible labels (positions approximate):

- a, A, M, S, Y (top arc); K (upper right, on the circle)
- F (left); Q, n, x, o (left of center)
- H, T, P, R (right of center); e (right)
- m (center); E, V, N, U, S (center); a (center); f, B (center right)
- q, p (below center); b (lower right); G, C, α (bottom)

Several small labels among overlapping lines could not be resolved with certainty. [Dense analemma schematic]

We shall prove that the straight line fL is perpendicular to ELY in the following way. Draw the straight line Ef. Since the two sides KL, LE of triangle KLE are equal to the two sides fL, LE of triangle fLE — because the distance Lf was taken equal to the distance LK — and the base kE is equal to the base fE (since each is a radius of the sphere), [Margin: (a) *Elements* I.8] the angle kLE will be equal to the angle fLE. Therefore, since kLE is a right angle, as we showed just above, fLE too will be a right angle, and so fL will be perpendicular to ELY.

Conversely, we shall also prove that if from L a perpendicular Lf is drawn to ELY, it is equal to the straight line LK. For since the squares on Ek and Ef are equal, [Margin: (b) *Elements* I.47] the two squares on EL and LK will be equal to the two squares on EL and Lf. So, taking away the common square on EL, the remaining squares on LK and Lf will be equal, and therefore the straight lines LK and Lf will be equal too.

We shall also confirm this as follows. Extend the straight line YE as far as Z. Now since KL, being perpendicular to ab, the diameter of the parallel, is the mean proportional between the segments aL and Lb (by the scholium to *Elements* VI.13), [Margin: (c) *Elements* VI.17] the square on KL will be equal to the rectangle contained by aL and Lb. In the same way, fL, drawn perpendicular to YZ, will be the mean proportional between the segments YL and LZ, so that the square on fL is equal to the rectangle under YL and LZ. [Margin: (d) *Elements* III.35] Therefore, since the rectangles under aL, Lb and under YL, LZ are equal, the squares on KL

and fL will be equal as well, and consequently the straight lines KL and fL are equal.

Now that the straight lines MLN and PLO are perpendicular to the straight lines BD and AC we shall easily establish, provided we first show the following: if through L the straight lines MLN and PLO are drawn perpendicular to BD and AC , and the straight lines dM , dK and nP , nK are joined, then dM is equal to dK , and nP is equal to nK . We shall demonstrate this — and indeed much more briefly than Federico Commandino [Federico Commandino]. Extend the straight line MN as far as α . [Margin: (e) *Elements* III.3] Since the straight line $M\alpha$ is bisected at N and cut unequally at L , [Margin: (f) *Elements* II.5] the square on MN will be equal to the rectangle under ML , $L\alpha$ together with the square on LN . Adding, then, the common square on Nd , the squares on MN and Nd will be equal to the rectangle under ML , $L\alpha$ together with the squares on LN and Nd . [Margin: (g) *Elements* I.47] But the squares on MN and Nd equal the square on dM , and the squares on LN and Nd equal the square on dL . Therefore the square on dM will be equal to the rectangle under ML , $L\alpha$ together with the square on dL . [Margin: (h) *Elements* III.35] But the rectangle under ML , $L\alpha$ is equal to the rectangle under aL , Lb . So the square on dM will also be equal to the rectangle under aL , Lb together with the square on dL . [Margin: (i) *Elements* VI.17] But the square on KL is equal to the rectangle under aL , Lb , since KL is the mean proportional between aL and Lb (by the scholium to *Elements* VI.13). Therefore the square on dM will also be equal to the squares on KL and Ld . [Margin: (k) *Elements* I.47] Since, then, the square on dK is likewise equal to those same squares on KL and Ld , the squares on dM and dK will be equal to each other, and consequently the straight lines dM and dK are equal.

Again, extend the straight line PO as far as t . [Margin: (l) *Elements* III.3] Since Pt is bisected at O and cut unequally at L , [Margin: (m) *Elements* II.5] the square on PO will be equal to the rectangle under PL , Lt together with the square on LO . Adding, then, the common square on On , the squares on PO and On will be equal to the rectangle under PL , Lt together with the squares on LO and On . [Margin: (n) *Elements* I.47] But the squares on PO and On equal the square on nP , and the squares on LO and On equal the square on nL . Therefore the square on nP will be equal to the rectangle under PL , Lt together with the square on nL . [Margin: (o) *Elements* III.35] But the rectangle under PL , Lt is equal to the rectangle under aL , Lb . So the square on nP will also be equal to the rectangle under aL , Lb together with the square on nL . [Margin: (p) *Elements* VI.17] But the square on KL is equal to the rectangle under aL , Lb , since KL is the mean proportional between aL and Lb (by the scholium to *Elements* VI.13). Therefore the square on nP will also be

equal to the squares on KL and Ln. [Margin: (q) *Elements* I.47] Since, then, the square on nK is likewise equal to those same squares on KL and Ln, the squares on nP and nK will be equal to each other, and consequently the straight lines nP and nK are equal. Which was to be demonstrated.

Since this is so, it is clear that, if with the compasses the distance dM is taken equal to the distance dK, the straight line MLN is perpendicular to BD — that is, the perpendicular raised through L to BD falls on the point M. For if it fell elsewhere — say at S — then the straight line dS, drawn as in what we have just demonstrated, would be equal to the straight line dK,

Diagram. The upper of two full-circle analemma figures on this page. It reprints one of the dense analemma constructions of the preceding chapter (cf. the figures on printed p. 455), a circle filled with the usual pair of perpendicular diameters and a converging web of chords and radii from the centre E. Legible labels (positions approximate): on the top arc, a, A, M, S; K (upper right, on the circle); F with a script *g* (upper left); f; on the left, D, and along the horizontal diameter f, I; along the vertical, X, O, E; near the centre, N, V, d; upper right, Y[?]/H and e/l[?]; right of centre, T, P, R and a long-s [?]; lower centre, q, p; I (lower left); G (bottom); α and C (bottom); a script *g* and *b* (lower right). Several labels within the overlapping line-web could not be resolved with certainty. [Dense analemma schematic]

Diagram. The lower of two full-circle analemma figures on this page, likewise a reprint of a dense analemma construction of the preceding chapter. A full circle with a star-like web of chords and radii from the centre E. Legible labels (positions approximate): on the top arc, A, f, M, S; a script *g* (upper left); K (right, on the circle); F (left); n, μ [?]; on the left, t, v and a bracket-like f/[?]; centre, E, L; right, R; h, N, d; q, ρ /p[?]; b (right); I (lower left); G, S, α (bottom); a script *g* and f (lower right). Several labels within the overlapping line-web could not be resolved with certainty. [Dense analemma schematic]

equal to dK — that is, equal to dM, which was taken equal to that same dK — which is absurd; [Margin: (a) *Elements* III.7] for dM is greater than dS. So that perpendicular will not fall on S; and in the same way it will fall on no point other than M, and thus the straight line MLN is perpendicular to BD. In just the same way we shall show that PLO is perpendicular to AC, if the distance nP is taken equal to the distance nK. All of which was to be demonstrated. As for the other lines in these figures that have not been mentioned here — such as the lines alh, SV, Yf, TX, bpg, and, in the fifth figure, the line Hr, and, in the sixth, the lines kN and KO — they will be put to use in chapter 7 of this book.

SCHOLIUM.

From what has been said it is clear by what method, with the Sun on any parallel whatever, any one of the said circumferences can be found when needed, without regard to the others. [Margin: By what method, with the Sun on any parallel, any one of the circumferences may be found without regard to the others.] For to find any of them, from K — the hour-point where the Sun is placed — one must draw KL perpendicular to ab, the diameter of the parallel.

Then, if the horizontal circumference is sought, one must draw MN through L perpendicular to BD, the diameter of the horizon; or (what comes to the same thing) taking d — where the diameter of the parallel cuts the diameter of the horizon — as centre and dK as radius, one takes the point M on the meridian with the compasses, and through M and L draws the straight line MN, which, as we demonstrated, is perpendicular to BD. [Margin: Horizontal.] For if from MN one cuts off NQ equal to KL, and from the centre E through Q draws a straight line cutting the circumference of the meridian at S, then AS will be the horizontal circumference, taking its start in the analemma from the diameter of the vertical, that is, the gnomon AC.

If, however, the descensive circumference is to be found, one must draw PO through L perpendicular to AC, the diameter of the vertical, cutting the circumference of the meridian at P; or (what is the same) taking n — where the diameter of the parallel cuts the diameter of the vertical — as centre and nK as radius, one takes the point P on the meridian with the compasses. [Margin: Descensive.] For AP will be the descensive circumference, whose beginning in the analemma is taken from the gnomon, that is, the diameter of the vertical.

If the vertical circumference is wanted, one must draw PO through L perpendicular to AC, the diameter of the vertical; or (what is the same) from the point n, where the parallel's diameter divides the diameter of the horizon [so printed; the descensive passage just above has n as the point where the parallel's diameter cuts the diameter of the *vertical* — the two passages disagree], one takes, as centre and with radius nK, the point P on the meridian with the compasses, and through P and L draws the straight line PO, which, as we demonstrated, is perpendicular to AC. [Margin: Vertical.] For if from OP one cuts off OR equal to KL, and from the centre E through R draws a straight line cutting the circumference of the meridian at T, then AT will be the vertical circumference, taking its start in the analemma from the gnomon, that is, the diameter of the vertical, AC.

But if it is proposed to find the horary circumference, one must draw MN through L perpendicular to BD, the diameter of the horizon, cutting the circumference of the meridian at M; or (what is the same) with the compasses, taking d — where the diameter of the parallel cuts the diameter of the horizon — as centre and dK as radius, one takes the point M on the meridian. [Margin: Horary.] For BM will be the horary circumference, having its beginning from the diameter of the horizon BD in the analemma.

To obtain the meridian circumference, one must draw from the centre E through L a straight line cutting the circumference of the meridian at Y. For BY will be the meridian circumference. [Margin: Meridian.]

Finally, for the hectemorial circumference [hectemoria — the "sixth-part" circle], one must draw from the centre E through L the straight line EY, and to it, from E and from L, raise the two perpendiculars Eg, Lf, cutting the circumference of the meridian at g and f; or (what is the same), having drawn the perpendicular Eg to EY, one takes, from L as centre and with radius LK, the point f on the meridian with the compasses. For gf will be the hectemorial circumference. [Margin: Hectemorial.]

Furthermore, for a northern parallel we have made five figures, so that every variation that can occur might be set out. [Margin: Why five figures were made for a northern parallel, but only one for a southern.] For in the second figure of this chapter the Sun lies beyond the vertical circle, and therefore the perpendicular KL falls beyond AC, the diameter of the vertical circle, toward the south. In the third, the Sun is placed on the vertical circle, so that the perpendicular KL falls on the point n, where the diameter of the vertical is cut by the diameter of the parallel. Then in the fourth, the Sun is set on the near side of the vertical circle, yet so that its distance from the meridian is less than a quadrant, or six hours; from which it comes about that the perpendicular KL falls on the near side of the diameter of the vertical, but above m, the centre of the parallel. Again, in the fifth the Sun is six hours distant from the meridian, and so the perpendicular KL falls on m, the centre of the parallel. Finally, in the sixth the Sun has a distance from the meridian greater than six hours, and so the perpendicular falls below m, the centre of the parallel. In all these figures, however, the method of finding the said circumferences is always the same, as is evident. For a southern parallel we have described only one figure, namely the first, because there the Sun, while above the horizon, always lies beyond the vertical, and has a distance from the meridian less than six hours, as is evident.

DEMONSTRATION OF THE THINGS SAID IN THE PRECEDING CHAPTER concerning the finding of the aforesaid six circumferences.

CHAPTER V.

In any figure of the preceding chapter (in which, however, the axis of the world and the diameter of the equator are not drawn, lest the multitude of lines cause confusion), let there be conceived, about ab , the diameter of the parallel, the semicircle aeb of the parallel, turned into its proper position so that it stands upright to the meridian and passes through K , the centre of the Sun. And since, by *Elements* XI, definition 4, KL in that position stands upright to the plane of the meridian, extend the straight line YE as far as Z , and through the straight lines YZ and KL let a plane be drawn, making on the surface of the sphere, by Theodosius I.1, the semicircle $YKHZ$, [Margin: Demonstration of the finding of the six said circumferences, with the Sun placed on any parallel.] which will be upright to the plane of the meridian, and so will represent the hectemorion [Hectemorion], since it too is drawn through the centre of the Sun and stands upright to the meridian (by Theodosius I.15), inasmuch as it passes through the poles of the meridian, as was said above. [Margin: (b) *Elements* XI.18] Let the rest be constructed in the figure as in the figure of chapter 3.

Now since the straight line Lf is equal to the straight line LK — either by construction, or from what was demonstrated in the preceding chapter (for we said that, with radius LK , the point f is to be taken from L as centre on the meridian, for finding the hectemorial circumference; and likewise, if from L a perpendicular Lf is drawn to ELY , we demonstrated that Lf is equal to LK) — the two sides Ef , fL of triangle EfL in the plane of the meridian will be equal to the two sides EK , KL of triangle EKL in the plane of the hectemorion. [Margin: Demonstration of the hectemorial circumference.] And they have the base EL in common as well. [Margin: (c) *Elements* I.8] Therefore the angle EfL will be equal to the angle EKL . But the alternate angle fEg is equal to the angle EfL , [Margin: (d) *Elements* I.29] because, since the angles fLE and gEL are right angles, [Margin: (e) *Elements* I.28] the straight lines fL and gE are parallel. Likewise, by the same reasoning, the alternate angle KEH is equal to the angle EKL , [Margin: (f) *Elements* XI.16] because the straight lines KL and HE are parallel, being the sections made by the plane of the hectemorion in parallel planes — namely in the horizon and the semicircle $PKVml$. Therefore the angles fEg and KEH will be equal to each other as well; [Margin: (a) *Elements* III.26] and consequently the arc

gf on the meridian will be equal to the hectemorial circumference HK on the hectemorion. [Margin: Demonstration of the horary circumference.]

Next, that the arc BM on the meridian is equal to the horary circumference BK on the horary circle will be shown, as above in chapter 3. For again, by Theodosius II.10, the arcs AM and XK, between the parallel circles AXVHC and MkqGh, through whose poles they pass, will be equal; and consequently the remainders BM and BK, from the quadrants BA and BX, will be equal too. Or at any rate, by the definition of a pole, the chords BM and BK will be equal. [Margin: (b) *Elements* III.28] Therefore the arcs BM and BK will be equal as well.

[Margin: Demonstration of the descensive circumference.] By like reasoning we shall demonstrate, as above in chapter 3, that the arc AP on the meridian is equal to the descensive circumference AK on the descensive circle. For again, by Theodosius II.10, the arcs BP and FK, between the parallel circles BqHeD and PKVinl, will be equal; and therefore the remainders AP and AK, from the quadrants AB and AF, will be equal too. Or at any rate, by the definition of a pole, the chords AP and Ak will be equal. [Margin: (c) *Elements* III.28] Hence the arcs AP and Ak will be equal as well.

[Margin: Demonstration of the meridian circumference.] That the arc BY is the meridian circumference is evident, since it is the portion of the meridian intercepted between the horizon (that is, the meridian line BD) and the hectemorion YKHZ.

Now we shall show, as above in chapter 3, that the straight lines XE and VO cut each other at the point I, which lies on the straight line Km, the common section of the horary semicircle BKXmD and the semicircle PKVml. [Margin: Demonstration of the vertical circumference.] Likewise, that KLOI is a parallelogram, [Margin: (d) *Elements* I.34] and therefore that the straight line IO is equal to kL — that is, to OR, which was taken equal to KL itself; [Margin: (e) *Elements* I.4] and that, in triangle REO, the angle REO is equal to the angle IEO of triangle IEO, because the two sides OR, OE of the former are equal to the two sides OI, OE of the latter, and they contain equal angles, namely right angles. [Margin: (f) *Elements* III.26] From which it follows that the arc AT on the meridian is equal to the vertical circumference AX on the vertical circle.

Finally, by the same reasoning we shall conclude, as above in chapter 3, that the straight lines FE and qN cut each other at the point p, which lies on the straight line KG, the common section of the descensive semicircle AKFGC and the semicircle MKqGh. [Margin: Demonstration of the horizontal circumference.]

Likewise, that KLNp is a parallelogram, [Margin: (g) *Elements* I.34] and therefore that the straight line pN is equal to KL — that is, to NQ, which was taken equal to KL itself; [Margin: (h) *Elements* I.4] and that, in triangle QEN, the angle QEN is equal to the angle pEN of triangle pEN, because the two sides QN, NE of the former are equal to the two sides Np, NE of the latter, and they contain equal angles, being right angles. [Margin: (i) *Elements* III.26] Hence the arc BS on the meridian will be equal to the arc BF on the horizon; and consequently the remaining arc AS on the meridian, from the quadrant AB, will be equal to the remaining horizontal circumference HF, from the quadrant HB. All of which was to be demonstrated.

Diagram. A large oblique (perspective) drawing of the sphere used for Chapter V, showing the analemma circles in three dimensions — the meridian, horizon, vertical, the parallel of the Sun, the hectemorion, and the horary and descensive semicircles — as a solid sphere ringed by a dense set of great circles and chords converging on the centre E. Legible labels (positions approximate): K (at the top); A, f (upper right); S, M, X and v (v)[?] (upper centre); on the upper left, a cluster reading K, Q and Γ[?]; L (centre, marked with a dot); o (right of L); F with P (and a second P) on the left; m (right); e/ε[?] (right); n (below the centre); d (right of centre); N and E (centre); B (left); H (lower centre); F and q (lower left); G (bottom); h (bottom centre); C with Z[?] (lower right); b (right, mid-low). The figure is crowded with overlapping circle-arcs and several small labels could not be resolved with certainty. [Dense perspective sphere]

THE DIVISION OF THE ANALEMMA INTO HOURS, for which the aforesaid circumferences are to be found, so that from them a horizontal, a vertical, and a meridian sundial may be constructed.

CHAPTER VI.

There are four kinds of hours, as we said at the beginning of Book 1. Some take their start from midday or midnight, and are called astronomical, or common; from these an astronomical sundial is constructed. Others have their beginning from sunset, and others from sunrise; the former are called Italian, the latter Babylonian. From the former an Italian sundial is composed, from the latter a Babylonian one. All these hours are equal, and they divide each parallel of the Sun into 24 equal parts — the start being made, in the first kind, from midday or midnight; in the second, from sunset, that is, from that point of the parallel where

it is cut by the horizon on the western side; and in the third kind, from sunrise, namely from that point of the parallel where it is cut by the horizon on the eastern side. Lastly, other hours are unequal, and are called ancient; these cut each parallel of the Sun — the equator alone excepted — into unequal parts, yet on this condition, that they divide each diurnal arc, and likewise each nocturnal arc, into 12 equal parts. From these the ancient sundial is described, as was explained more fully above, especially at the beginning of this our *Gnomonics*.

Now since on any plane all these hours can be described by means of the circumferences we treated above, we must set out by what method the analemma is to be divided for each kind of hour, so that for the individual hours we may find the said circumferences, with the Sun on any parallel whatever — in this chapter, indeed, insofar as from them the horizontal, vertical, and meridian sundials are constructed, of which chiefly, as we said above, Ptolemy [Ptolemy] took account. The other sundials we shall treat in chapter 10 of this book, where we shall also divide the analemma for every kind of hour.

Let, then, the meridian of the analemma be ABCD, whose centre is E; the diameter of the horizon, BD; the diameter of the vertical, AC; the axis

The axis of the world is HI; the diameter of the equator, FG; the diameter of the parallel of Cancer, MN; the diameter of the parallel of Taurus and Virgo, KL; the diameter of the parallel of Capricorn, a b; and the diameter of the parallel of Sagittarius and Aquarius, ST. Around the diameters MN, KL, and a b let semicircles be described; and from the points P, O, and d, where these same diameters are cut by the diameter of the horizon, let the perpendiculars PR, OQ, and d e be drawn to the diameters themselves. As we showed above, these will be the common sections of the parallels and the horizon, so that MR is the portion of the parallel of Cancer above the earth, and RN the portion below the earth; likewise KQ the portion of Taurus and Virgo above the earth, and QL the portion below the earth; and finally b e the portion of Capricorn above the earth, and e a the portion beneath the earth.

Why we have omitted the diameter of the parallel of Gemini and Leo, and likewise the diameter of the parallel of Scorpio and Pisces, the reason is ready to hand: namely, that the three diameters MN, kL, and ST can stand in for all of them. For MN will also serve as the diameter of the parallel of Capricorn, if the analemma is inverted so that I becomes the arctic pole and H the antarctic, C the zenith and A its opposite; in that case NR will be the portion of Capricorn above the earth, and RM the portion beneath it. By the same reasoning KL will also represent the diameter of the parallel of Scorpio and Pisces, so that LQ is the

portion of Scorpio and Pisces above the earth, and QK the portion beneath it. Finally, ST will likewise express the diameter of the parallel of Gemini and Leo; and the portion of the semicircle described about ST (which, however, we did not draw, so as to avoid confusion) that corresponds to the segment TV of the diameter will be the portion of Gemini and Leo above the earth, while the portion answering to the segment VS will lie below the earth. The reason for all this is that the parallels of opposite signs have equal declinations. Since this is so, the diameter a b of the parallel of Capricorn, together with its semicircle, would be superfluous — unless we wished to use it as the diameter of the parallel of Cancer, should the analemma be inverted, as we have said — so that we may set out the divisions of all the hours in the proposed analemma.

[Margin: Division of the analemma into hours reckoned from midday and midnight. (Diuisio Analemmatis in horas à mer. & med. noc.)]

Therefore, for the hours reckoned from midday and midnight, the several semicircles of the parallels are to be divided into 12 equal parts, beginning at those points where their diameters cut the circumference of the meridian. This you see done in MRN, the semicircle of Cancer and Capricorn, where the outer numbers pertain to the hours from midnight, and the inner ones to the hours from midday. The other semicircles we have not divided in this way, because we shall cut them for other kinds of hour; it is enough to have given the example on the tropic of Cancer and Capricorn, from which anyone will readily understand by what method the other parallels are to be divided into hours from midday and midnight. For the rest, the hours of the portion MR fit the diurnal arc of Cancer or the nocturnal arc of Capricorn, and the hours of the portion NR fit the nocturnal arc of Cancer [☿; glyph worn, pinned by context] or the diurnal arc of Capricorn.

[Margin: Division of the analemma into hours reckoned from sunrise and sunset. (Diuisio Analemmatis in horas ab ortu & occasu Solis.)]

Now for the hours reckoned from sunrise and sunset — so that they may more easily be laid down in the analemma — the parallels are to be described separately, together with their diameters and with the common sections of these same diameters and the horizon, and each is to be divided into 24 equal parts, the start being made from the said common sections. For example, about a b, the diameter of Capricorn (which now also plays the part of the diameter of Cancer), a circle a e b is to be described separately, from the center m, where the axis cuts the said diameter, and through the point d, so as to correspond to the point d in the analemma. On either side, up to a b, a perpendicular e d e is to be erected, which, as we have demonstrated, is the common section of the parallel of Cancer

and the horizon; so that e a e is the portion of Cancer above the horizon, that is, the diurnal arc of Cancer, and e b e the portion of Cancer below the horizon, that is, the nocturnal arc of Cancer. Likewise e b e is the portion of Capricorn above the horizon, that is, the diurnal arc of Capricorn, and e a e the portion of Capricorn below the horizon, that is, the nocturnal arc of Capricorn.

Next, the said circle is to be divided into 24 equal parts, the start being made from the point e — from whichever you please, as in our example from the one placed to the right. In this way the parallel of Cancer, or of Capricorn, will be divided into 24 equal hours reckoned from sunrise or from sunset. For on the tropic of Cancer the inner numbers will give the hours from sunrise, while the outer numbers will indicate the hours from sunset; but on the tropic of Capricorn the reverse is to be understood, since there the outer numbers pertain to the hours from sunrise and the inner ones to the hours from sunset. From all this it is plain by what method, from the analemma — if about the diameters of the parallels the parallels themselves

Diagram. A large analemma drawn as the meridian circle projected in the plane, filled with the parallels of declination and their chords, and ringed by the zodiac signs (outer band) and a doubled scale of hour-numbers. The vertical diameter is AC (A at the top, the zenith; C at the bottom); the horizontal diameter is the horizon BD (B at the left, D at the right); the center is E. The equator diameter FG and the world-axis HI cross near the center (H toward the upper right on the rim, I toward the lower right). Legible capital labels (positions approximate): A (top), B (left), C (bottom), D (right), E (center), F and G (equator diameter), H (upper right), I (lower right), K and M (upper left, on the Taurus/Virgo parallel), L (lower right), N and O (near the center, right of E), P and Q (right of center), R (right rim), S and T (lower center). Legible lowercase labels: e (just below A), f (right of center), q (below E), m, n, d, b, h. Around the rim, the zodiac glyphs run in sequence (Aquarius, Capricorn, Sagittarius and neighbours at the upper left; Taurus, Gemini toward the right; Leo, Libra, Scorpio, Sagittarius, Pisces toward the lower rim), with two concentric rings of numbers (hours and degrees) marking the divisions. The figure is extremely crowded with overlapping arcs and small rim numerals; many individual rim glyphs and numbers could not be resolved with certainty. [Dense analemma]

Diagram. A plain circle divided into 24 equal parts, used to divide the parallel into hours reckoned from sunrise and sunset. The point a is at the top and b at the bottom (the vertical diameter a–b); the center is m (marked with a dot on the vertical line). The horizontal diameter is the horizon, drawn through the point d

and meeting the circle at e on the right (at the division marked 24) and at a corresponding point on the left. Two concentric rings of hour-numbers run around the rim in opposite senses (an inner ring and an outer ring, each 1–24), so that the same divisions serve for hours reckoned from sunrise and from sunset. Individual rim numerals are legible in places but are not transcribed cell-by-cell here (they would have to be inferred rather than read); the labelled structural points are a, b, d, e, and the center m.

[Margin: How the quantity of day and night may be known from the analemma. (Quantitas diei & noctis ex Analemmate, quo pacto cognoscatur.)]

the parallels are described and divided into hours, the quantity of day and night of each parallel may be known. For the hours found within the arc e a e make up the diurnal arc of Cancer, or the nocturnal arc of Capricorn; while the hours contained within the arc e b e make up the nocturnal arc of Cancer, or the diurnal arc of Capricorn. This too we taught in Book 1. And if, by help of the compasses, the divisions of the parallel of Cancer and Capricorn, a e b, are transferred into the semicircle of Cancer and Capricorn in the analemma, as appears in the figure — and the same is done for all the other parallels (dividing them, that is, into hours about their own diameters as described, the start being made from the common sections of these parallels and the horizon, and so on, just as has here been done for the parallel of Cancer and Capricorn) — then the analemma will be divided into hours reckoned from sunrise and sunset. In the analemma, however, only the numbers of the hours reckoned from sunset have been written in; for the complements of these numbers up to 24 will give the hours from sunrise. Thus the 23rd hour from sunset will give the 1st hour from sunrise, the 22nd will give the 2nd, and so on for the rest.

The meridian circle, described about FG, the diameter of the equator, is to be divided, like the equator, into 24 equal parts, the start being made from the diameter FG, or from the axis HI. For the point F will be the 12th astronomical hour; the first division-point next to it toward H, the 1st hour from midday and the 11th from midnight; the next point will give the 2nd hour from midday and the 10th from midnight; and so on in succession. In the same way the point H will be the 24th hour, and the 12th from sunset; the first division-point next to it toward F will give the 23rd hour and the 13th from sunset; the next point will belong to the 22nd hour and the 14th from sunset; and so forth. Finally, the same point H will look to the 24th hour, and the 12th from sunrise; the first division-point next to it toward F, to the 1st hour and the 11th from sunrise; the next, to the 2nd hour and the 10th from sunrise; and so of the rest. So that both the 18th

hour from sunset and the 6th from sunrise fall on F, the point of midday; while the 6th hour from sunset and the 18th from sunrise fall on G, the point of midnight.

[Margin: Division of the analemma into unequal hours. (*Diuisio Analemmatis in horas inæquales.*)]

Finally, for the unequal — or ancient — hours, the several portions of the parallels lying between their common sections with the horizon and the meridian circle are to be divided into six equal parts each. For that point where any parallel cuts the meridian will be the 6th unequal hour; the first division-point next to it, toward the common section of the parallel and the horizon, will give the 5th and the 7th hour; the next point the 4th and the 8th, and so on. In this way the semicircle of Taurus and Virgo has been divided in the analemma — which semicircle also represents that of Scorpio [♏] and Pisces. But the numbers of the unequal hours have been written against the points of the diameter kL of the said parallel, upon which fall the perpendiculars dropped from the division-points of the parallel to the diameter. For if they had been set against the points of the semicircle KQL, they would be confused with the numbers of the hours from midday and midnight of the semicircle MRN. By the same reasoning the other parallels will be divided into unequal hours, whenever the matter requires it. Furthermore, we have divided the three semicircles of the three parallels, namely MRN, into astronomical hours (that is, from midday and midnight); then a e b into Babylonian and Italian hours (that is, from sunrise and sunset); and lastly KQL into unequal hours — so that in a single analemma the divisions of all the kinds of hours are contained. The divisions of the meridian, which represents the equator, are suited to all the hours. For the point H will be the 12th unequal hour, while the first division toward F will exhibit the 1st and the 11th unequal hour, and so on, so that the point F gives the 6th unequal hour. And by what means these same divisions fit the equal hours as well, whether these be reckoned from midday and midnight or from sunrise and sunset, we set out a little earlier.

[Margin: How the diameters of the parallels are cut into hours. (*Quomodo diametri parallelorum in horas assecuntur.*)]

Now when the semicircles of the parallels have been divided in this way into hours, whether equal or unequal — according as an equal-hour sundial (say astronomical, or Italian, or Babylonian) or an unequal-hour sundial is to be constructed — hidden perpendicular lines must be drawn from each of the hours of every semicircle to its own diameter, and the points where they cut the diameter must be carefully marked; and, if you like, the same hour-numbers are

to be set against the division-points, as you see done on the diameter KL, which carries the numbers of the unequal hours. On the other diameters we did not write the hour-numbers, so as to avoid confusion; and for the same reason we did not write the numbers of the unequal hours against the parallel KQL. For in this way the analemma will be so prepared that, without great labor, the aforesaid circumferences may be found in it by the earlier rules, as we shall soon tell.

Such perpendiculars will be drawn easily if whole circles are described about the diameters of the parallels, as has been done about the diameter a b; yet the semicircle falling within the analemma may be drawn faintly, so that no confusion arises among the lines. For if, for each of the arcs of the outer semicircle a e b between the point a (or b) and the hour-points, equal arcs are taken on the remaining, inner semicircle, then the straight lines joining the corresponding points will be perpendicular to the diameter. For example, if to the arc between a and the point of the 11th hour from sunset an equal arc a f is taken on the remaining semicircle, then the straight line joining the point of the 11th hour from sunset with the point f will be perpendicular to the diameter a b, cutting that same diameter at the point g — which must be noted. And so of the rest. Indeed, if whole circles are described, there will be no need to describe the parallels separately, since the division can be set up in the analemma itself, if d e, the common section of the horizon and the parallel, is extended up to the point e on the other semicircle, as is plain. The points of the semicircle a f b must then be transferred into the semicircle a e b, so that all the hours are contained in the outer semicircle.

[Margin: Enough for [drawing] the sundials. (Satis est ad horologia.)]

For the most part it is even enough, if the semicircle of Cancer and Capricorn is cut into hours, for any sundial whatever to be described. For just as in the preceding book, from the latitudes and longitudes of the shadows, with the Sun positioned at the beginning of Cancer and of Capricorn, we described sundials, so here too, from the circumferences required for any given sundial — if they are found for the hours of Cancer and Capricorn — we shall lay out any sundial whatever. There is this exception: that sometimes it is necessary to investigate one or another circumference for the drawing of certain hours, when the Sun is on a nearby parallel, as on the parallel of Gemini and Leo, or of Sagittarius [♐; glyph worn] and Aquarius, as we said in the sundials of the preceding book.

[Margin: How it is to be described, if the semicircle of Cancer and Capricorn is divided into hours. (describenda, si semicirculus cancri, & capricorni in horas distribuatur.)]

With these things thus prepared, we shall find any circumference without difficulty, by the rules we handed down in chapters 2 and 4 and their scholia. Suppose, for example, that the horizontal and descensive circumference is to be found for the 23rd hour from sunset, on the parallel of Cancer and Capricorn. Through the point on the diameter ab of the parallel of Cancer and Capricorn that corresponds to the 23rd hour from sunset in the portion ae of Cancer, let a hidden perpendicular hl be drawn to BD , the diameter of the horizon; from it cut off a straight line hn equal to the interval between the 23rd hour and the point corresponding to it on the diameter ab ; and from the center E draw through n a straight line cutting the circumference of the meridian at p . Then Cp will be the horizontal circumference. Likewise, through the same point of the diameter ab , draw a perpendicular qr to AC , the diameter of the vertical; and Cr will be the descensive circumference.

[Margin: In what way the aforesaid circumference may be found, for any hour whatever, in the analemma thus far divided. (Quo pacto circumferentia supradicta in Analemmate hactenus diuiso inuestigentur pro qualibet hora.)]

By the same method, from the hidden perpendiculars st and $\beta\alpha$ [labels as printed; worn], and from an interval $s\lambda$ [?] equal to the interval between the 23rd hour and the point corresponding to it on the diameter ab — with the point taken in the portion be of Capricorn from sunset — the horizontal circumference Au and the descensive circumference $A\alpha$ will be found, for the 23rd hour of the tropic of Capricorn. In just this way we shall find the horizontal and descensive circumferences of the other hours — indeed also the vertical, the horary, the meridian, and the hectemorion circumferences — not only on the tropic of Cancer and of Capricorn, but also on the equator and the other parallels, as is clear from what was demonstrated in chapters 3 and 5 of this book.

THE FINDING OF THE HECTEMORION CIRCUMFERENCE,
THE HORARY, the descensive, the meridian, the vertical, and
the horizontal, by the doctrine of sines, whether the Sun be
on the equator or on any other parallel whatever, for any
latitude.

*(hectemorion [hectemoria; Greek ἑκτημόριον, "sixth-part," the sixth-division
circumference])*

CHAPTER VII.

Ptolemy [Ptolemy] investigates the six circumferences named above by numbers as well, so that those who are less practiced in drawing without error the many perpendicular lines required for finding the said circumferences correctly may find them more easily, and with greater pleasure, by numbers — since in this method there is no need to draw so many perpendicular lines, nor to divide the parallels into hours and into their parts (which is no easy matter); it is enough to know the distance from the meridian of any given hour, or of the point at which the Sun is placed, as will become clear from what we shall demonstrate in this chapter. For we, following in Ptolemy's footsteps, shall try to investigate these same circumferences by numbers in this chapter — a thing we shall accomplish, in my judgment, far more easily and briefly than Ptolemy, since we do not need so many multiplications and divisions as he employs.

First, we shall carry out the whole matter by rectilinear triangles; then the same by spherical triangles: and this indeed first with the Sun outside the equator, on any parallel whatever, and then with the same Sun set on the equator. Before all else, therefore, in all six of the figures of chapter 4 (of which we have here adduced the first as an example for the southern parallels, and the sixth alone for the northern parallels), in which we demonstrated that the hectemorion circumference is fg, the horary BM, the descensive AP, the meridian BY, the vertical AT, and the horizontal AS: let there be drawn from the points a, S, Y to BD, the diameter of the horizon, the perpendiculars a h, S V, Y f, of which a h cuts the straight line P t at l; likewise from the points T, b to AC, the diameter of the vertical, the perpendiculars T X, b q, of which the latter cuts the straight line M N produced at the point p. Finally, let the straight lines KN, KO be joined — which, however, so as to avoid confusion, we have drawn in the sixth figure alone, the one we have here set down; in the others they are merely to be conceived in the mind.

[Margin: The finding of the aforesaid circumferences by sines, from rectilinear triangles, when the Sun is on any parallel outside the equator. (Inuentio supradictarum circumferentiarum per sinus, ex triangulis rectilineis, Sole in quouis parallelo extra Aequatorem existente.)]

Therefore, since it holds that as a m — insofar as it is the whole sine of the proposed parallel — is to KL — insofar as it is the right sine of the Sun's distance from the meridian on the same parallel — so is a m — insofar as it is a part of the whole sine in the greatest circle, say in the meridian — to KL — insofar as it is a part of the same whole sine in the greatest circle, that is, to Lf, which is equal to KL itself (as is clear from chapter 4), and is the right sine of the arc Yf, which, subtracted from the quadrant Yg, leaves the hectemorion circumference fg: [therefore] if it is contrived that, as the whole sine is to the sine of the Sun's distance from the meridian, so the sine of the complement of the declination of the given parallel is to another, there will be found the sine of the complement of the hectemorion circumference; and thus this complement will be known, together with the hectemorion circumference itself.

[Margin: Hectemorion. (Hectemoria.)]

Next, since b n is the versed sine of the semidiurnal arc of that place in which the vertical circle of the given region is the horizon (I call the "given region" that region for which the circumferences are being investigated), that is, the place in which the elevation of the pole

Diagram. The sixth of the figures of chapter 4, drawn for the northern parallels: a large circle (the meridian) filled with a dense web of chords and perpendiculars. The vertical diameter is AC (A at the top, C at the bottom); the horizontal diameter is the horizon BD (B at the left, D at the right); the center is E, with O just above it and X above O on the vertical. H stands on the upper-right rim. Legible capital labels (positions approximate): A (top), B (left), C (bottom), D (right), E (center), H (upper right), K (left), M and N (near the center-left), O (center), P (lower left), S, T, Y (left cluster), X (upper center, below A); a capital at the right rim reads Q or G [?]. Legible lowercase labels: a (left), b (bottom center), e (right rim), f (two occurrences — upper left and lower left), g (bottom center, near q), m and n (lower center), q (bottom center), l, p, t (interior). Named in the text as construction lines: the hectemorion circumference fg, the horary BM, the descensive AP, the meridian BY, the vertical AT, the horizontal AS, with perpendiculars a h, S V, Y f, T X, b q and the joins KN, KO. The figure is very crowded with overlapping straight lines and small labels; several could not be resolved with certainty. [Dense construction figure]

(Continuation of Book VI, Cap. VII — finding the six circumferences by the doctrine of sines.)

[the elevation of the pole] above the horizon — that is, above the northern face of the vertical circle of the given region — is the complement of the elevation of that same pole above the horizon of the given region. In the same way, $a d$ is the versed sine of the semidiurnal arc $a e$, in the given region; likewise $b L$ is the versed sine of the Sun's distance from the meridian in that place, when the meridian there falls at b , or the versed sine of the Sun's distance from midnight in the given region; and $b q$ is the right sine of the meridian altitude of that same place, that is, the sine of the complement of the meridian depression in the given region. Finally, $b p$ is the difference between $b q$ — the sine of the said meridian altitude, or of the complement of the meridian depression — and $b q$ [recte: $p q$], the sine of the arc AM , the complement of the horary circumference $B M$.

[Margin: [a] 4. sexti. (Euclid, *Elements* VI.4.)]

Alternatively, [a] the line compounded of $b q$ — the sine of the said meridian altitude, or of the complement of the meridian depression — and $p q$, the sine of the arc AM , the complement of the horary circumference BM , as in the first and second figures of chapter 4, in which the Sun is placed beyond the vertical.

[Margin: Horaria (the horary [circumference]).]

Now in the triangles $n b q$ and $L b p$, as $n b$ is to $b q$, so is $b L$ to $b p$. Suppose it is contrived that, as the versed sine of the semidiurnal arc of that place — the place in which the elevation of the arctic pole above the horizon is the complement of the elevation of that same pole above the horizon of the given region (which semidiurnal arc will be found by proposition 34 of book 1) — is to the right sine of the meridian altitude of that same place, or of the complement of the meridian depression in the given region (which will be found as we taught in the scholium to proposition 35 of book 1), so is the versed sine of the Sun's distance from the meridian in that same place — that is, the versed sine of the Sun's distance from midnight in the given region (and this versed sine $b L$ will be obtainable here, if from the whole diameter $a b$, that is, from the whole sine doubled, the versed sine $a L$ of the Sun's distance from the meridian in the given region is subtracted; or else, if from $a K$, the Sun's distance from the meridian in the given region, taken from the semicircle $a K b$, is removed, there will remain $b K$, the Sun's distance from the meridian in that place where the vertical of the given region is the horizon, or the Sun's distance from midnight in the given region; and therefore the versed sine of this distance cannot lie hidden) — so is it to another [term].

There will be found the difference between the sine of the meridian altitude of that same place (or of the complement of the meridian depression in the given region) and the sine of the complement of the horary circumference; or else the line compounded of the sine of the meridian altitude of that same place (or of the complement of the meridian depression in the given region) and the sine of the complement of the horary circumference — namely when the Sun is placed beyond the vertical circle.

Therefore, from this compounded line (that is, when the Sun is beyond the vertical of the given region, as happens in the southern parallels, and as in the second figure of chapter 4) let there be subtracted the right sine of the meridian altitude of that said place, or the sine of the complement of the meridian depression in the given region; or else, if the difference has been found (that is, when the Sun lies in the northern parallels on the near side of the vertical of the given region, as appears in figures 4, 5, and 6 of chapter 4), let there be removed from the right sine of the meridian altitude of that same place, or from the sine of the complement of the meridian depression in the given region, [the appropriate term]: the remainder will be the sine of the complement of the horary circumference. This complement, then, together with the horary circumference itself, will not go unknown.

[Margin: [b] 4. sexti. (Euclid, *Elements* VI.4.)]

[Margin: Alia inuentio horaria, & breuior. (Another, and shorter, finding of the horary [circumference].)]

Diagram. A large circle (the meridian) crossed by a dense web of chords and perpendiculars, drawn for the case in which the Sun lies beyond the vertical circle; center E. It is a reprint of one of the chapter-4 figures used for finding the horary circumference. Readable capital labels (positions approximate): A (top), F (upper left), M with a following ς -like sort and Q beneath it (upper right), K (upper right rim), E (center), N (center right), D (left rim), I (lower left), G and S (bottom), T, P, R (right-center cluster). Readable lowercase / minuscule labels: a and f (top), n (upper interior), t, v, h (left), l, m (interior), d, s (lower center), q and p (lower interior), b (lower right), e, f, g (lower-right rim), z (left rim), α (bottom). The figure is extremely crowded with overlapping straight lines and small sorts; several labels could not be resolved with certainty. [Dense construction figure]

The right column continues:

EANDEM — The same horary circumference we shall find, even if we do not suppose the vertical to be the horizon, in this way. Let the Sun's distance from the

meridian be investigated by proposition 36 of book 1, for the case when the Sun is on the vertical circle (which indeed happens below the horizon in the southern parallels, but above the horizon in the northern ones). Let the versed sine $a n$ of this distance be subtracted from the diameter $a b$, that is, from the whole sine doubled, so that the line $n b$ is left marked off. For suppose it is contrived that, as this line $n b$ (once found) is to $b q$, the sine of the complement of the meridian depression (which we shall find from the scholium to proposition 35 of book 1), so is $L b$, the versed sine of the Sun's distance from midnight, to another [term]: [b] then there will be found $b p$, the difference between $b q$ — the sine of the complement of the meridian depression — and $p q$ — the sine of the complement of the horary circumference — or else the line compounded of $b q$, the sine of the complement of the meridian depression, and $p q$, the sine of the complement of the horary circumference, namely when it is beyond the vertical circle, and so on. Or else let it be found by proposition 1...

of book 5: the altitude of the Sun above the vertical circle. For its complement will give the horary circumference, as is plain.

[Margin: [c] 4. sexti. (Euclid, *Elements* VI.4.)]

[Margin: Descensiuua (the descensive [circumference]).]

RVRVS — Again, since in the triangles $a h d$ and $a l L$ [c] it holds that, as $a d$ — the versed sine of the semidiurnal arc $a e$ — is to $a h$, the right sine of the meridian altitude, so is $a L$, the versed sine of the Sun's distance from the meridian, to $a l$, the difference between $a h$ (the sine of the meridian altitude) and $l h$ (the sine of the arc BP , the complement of the descensive circumference AP): suppose it is contrived that, as the versed sine of the semidiurnal arc is to the sine of the meridian altitude, so is the versed sine of the Sun's distance from the meridian to another [term]. There will be found a number which, subtracted from the sine of the meridian altitude, leaves the sine of the complement of the descensive circumference. This complement, then, together with the descensive circumference, will be known. Or else let the altitude of the Sun above the horizon be found by the last method delivered in proposition 36 of book 1, before the spherical triangles; for its complement will exhibit the descensive circumference, as is evident.

[Margin: [d] 4. sexti. (Euclid, *Elements* VI.4.)]

PRÆTEREA — Moreover, since in the triangles ELN and EYS it holds [d] that, as EL — the sine of the hectemorion circumference, that is, the sine of the complement of the Sun's altitude above the meridian — is to LN , the sine of the

complement of the descensive circumference, that is, the sine of the Sun's altitude above the horizon, so is EY, the whole sine, to Y f [Yf], the sine of the meridian circumference B Y: suppose it is contrived...

that, as the sine of the hectemorian circumference already found — that is, as the sine of the complement of the Sun's altitude above the meridian — is to the sine of the complement of the descensive circumference, that is, to the sine of the Sun's altitude above the horizon, so is the whole sine to another [term]. There will be found the sine of the meridian circumference; and thus the meridian circumference itself will become known.

[Margin: Meridiana (the meridian [circumference]).]

AD hæc — Furthermore, since in the triangle k L N the sides KL, LN are equal to the sides RO, OE in the triangle ROE (for in chapter 4 the line OR was taken equal to the line KL; [a] and the line LN is equal to O E in the parallelogram NO), and since they contain equal angles, namely right angles — for by definition 4 of book 11 of Euclid, KL is at right angles to the plane of the meridian, if the semicircle a K b is set up at right angles to that same plane of the meridian, because it is perpendicular to a b, the common section of the said semicircle and the meridian; therefore by definition 3 of book 11 of Euclid it will also be perpendicular to the line M N — [b] the bases KN and RE will be equal. But k N is equal to N M, the sine of the horary circumference BM, because both N K and N M are the semidiameter of the circle drawn in the sphere equidistant from the vertical itself, and drawn through the lines M α and KL (namely through the Sun set at the point k), whose diameter is M α, as is clear if the semicircle a K b is set up at right angles to the meridian. Therefore E R will also be equal to N M, the sine of the horary circumference. Again, since it holds that, as a m (insofar as it is the whole sine of the proposed parallel) is to k L (insofar as it is the right sine of the Sun's distance from the meridian in that same parallel), so is a m (insofar as it is a part of the whole sine in the greatest circle, as in the meridian, that is, insofar as it is the sine of the complement of the declination of the proposed parallel) to K L (insofar as it is a part of the same whole sine in the greatest circle, that is, to RO, which in chapter 4 was taken equal to KL): if it is contrived that, as the whole sine is to the sine of the Sun's distance from the meridian, so is the sine of the complement of the declination of the given parallel to another [term], then the line R O will come out known, in the parts of the whole sine in the greatest circle. [c] And since in the triangles E R O and E T X it holds that, as E R — the sine of the horary circumference, that is, the sine of the complement of the Sun's altitude above the vertical circle (for we showed a little earlier that the line E R is equal to the line N

M) — is to R O, just found in the parts of the whole sine in the greatest circle, so is E T, the whole sine, to TX, the sine of the vertical circumference A T: suppose it is contrived that, as the sine of the horary circumference — that is, the sine of the complement of the Sun's altitude above the vertical circle — is to the sine of the Sun's distance from the meridian (known in the parts of the whole sine in the greatest circle, for R O was taken equal to K L), so is the whole sine to another [term]. There will be found the sine of the vertical circumference; and therefore the vertical circumference itself will be known.

[Margin: [a] 34. primi. (Euclid, *Elements* I.34.)] [Margin: [b] 4. primi. (Euclid, *Elements* I.4.)] [Margin: [c] 4. sexti. (Euclid, *Elements* VI.4.)] [Margin: Verticalis (the vertical [circumference]).]

DENIQUE — Finally, since in the triangle k L O the sides k L, LO are equal to the sides QN, NE of the triangle QNE (for the line QN was taken equal to KL in chapter 4, [d] and the line N E is equal to LO in the parallelogram NO), and since they contain equal angles, namely right angles — for the angle K L O is a right angle by definition 3 of book 11 of Euclid, because k L is perpendicular to the plane of the meridian by definition 4 of book 11 of Euclid, if the semicircle a K b is set up at right angles to the meridian — [e] the bases KO, QE will be equal. But KO is equal to O P, the sine of the descensive circumference AP, because both KO and OP are the semidiameter of the circle drawn in the sphere equidistant from the horizon, and drawn through the lines P t, KL, as is clear if the semicircle from k b is set up at right angles to the meridian. Therefore Q E too will be equal to O P, the sine of the descensive circumference. [f] Again, since in the triangles EQN and ESV it holds that, as E Q — the sine of the descensive circumference, that is, the sine of the complement of the Sun's altitude above the horizon (for we have just shown that the line EQ is equal to the line OP) — is to QN, equal to KL, the sine of the Sun's distance from the meridian, insofar as it is known in the parts of the whole sine in the greatest circle (and it will be known in these parts, as we demonstrated for the vertical circumference a little earlier), so is ES, the whole sine, to SV, the sine of the complement of the horizontal circumference AS: suppose it is contrived that, as the sine of the descensive circumference — that is, the sine of the complement of the Sun's altitude above the horizon — is to the sine of the Sun's distance from the meridian, known in the parts of the whole sine in the greatest circle, so is the whole sine to another [term]. There will be found the sine of the complement of the horizontal circumference. Whereby this complement, together with the horizontal circumference, will become known.

[Margin: [d] 34. primi. (Euclid, *Elements* I.34.)] [Margin: [e] 4. primi. (Euclid, *Elements* I.4.)] [Margin: [f] 4. sexti. (Euclid, *Elements* VI.4.)] [Margin: Horizontalis (the horizontal [circumference]).]

CÆTERVM — But when the Sun is distant six hours from the meridian, that is, through a quadrant of its parallel — in other words, when it is on the circle of the 6th hour from the meridian, or from midnight — the aforesaid six circumferences can be found much more easily, by this reasoning. Since then the perpendicular KL falls on m, the center of the parallel (as is manifest from the fifth figure of chapter 4, which we have here repeated), the line EY does not differ from the axis EH, since both these lines are drawn through m, from E; and consequently neither do Eg and Lf, perpendicular to EY, differ from the perpendiculars drawn from the semidiameters E G and m b to the axis E H. Therefore the declination of the parallel, namely the arc G b, will then be the hectemorion circumference g f.

[Margin: Quando Sol sex horis abest à meridie, facilius nominata circumferentiæ inueniuntur. (When the Sun is six hours from the meridian, the named circumferences are found more easily.)]

[g] **DEINDE** — Next, since in the triangles E H r and E m O it holds that, as E H — the whole sine — is to H r, the sine of the complement of the pole's altitude, so is E m, the sine of the declination of the proposed parallel, to m O, the sine of the arc AM, the complement of the horary circumference BM: suppose it is contrived that, as the whole sine is to the sine of the complement of the pole's altitude, so is the sine of the declination to another [term]. There will be found the sine of the complement of the horary circumference; and thus this complement, together with the horary circumference itself, will be known.

[Margin: [g] 4. sexti. (Euclid, *Elements* VI.4.)] [Margin: Hectemoria (the hectemorion [circumference]).] [Margin: Horaria (the horary [circumference]).]

[h] **RVRSVS** — Again, since in the triangles E H f [EHf] and E m N it holds that, as EH — the whole sine — is to H f, the sine of the pole's altitude, so is E m, the sine of the declination of the proposed parallel, to m N, the sine of the arc B R, the complement of the descensive circumference AP: suppose it is contrived that, as the whole sine is to the sine of the pole's altitude, so is the sine of the declination to another [term]. There will be found the sine of the complement of the descensive circumference. Wherefore this complement, together with the descensive circumference, will come out known.

[Margin: [h] 4. sexti. (Euclid, *Elements* VI.4.)] [Margin: Descensiuua (the descensive [circumference]).]

MERIDIANA — The meridian circumference, moreover, is then the same as the altitude of the pole H B, because the line E Y does not diverge from the axis EH.

[Margin: Meridiana (the meridian [circumference]).]

AD hæc — Furthermore, [i] since in the triangles ERO and ETX it holds that, as ER — the sine of the horary circumference (for it was shown above, in the vertical circumference, that the line E R is equal to N M, the sine of the horary circumference) — is to R O, which was taken equal to KL, that is, to a m, the sine of the complement of the declination, so is E T, the whole sine, to T X, the sine of the vertical circumference A T: suppose it is contrived that, as the sine of the horary circumference — that is, the sine of the complement of the Sun's altitude above the vertical circle — is to the sine of the complement of the declination, so is the whole sine to another [term]. There will be found the sine of the vertical circumference; and therefore the vertical circumference itself will become known.

[Margin: [i] 4. sexti. (Euclid, *Elements* VI.4.)] [Margin: Verticalis (the vertical [circumference]).]

POSTREMO — Lastly, [k] since in the triangles EQN and ESV it holds that, as EQ — the sine of the descensive circumference (for above, in the horizontal circumference, we demonstrated that the line EQ is equal to O P, the sine of the descensive circumference)...

[Margin: [k] 4. sexti. (Euclid, *Elements* VI.4.)]

Diagram, upper figure. A large circle crossed by many chords and perpendiculars, for the case in which the Sun is on the vertical circle (a reprint of the third figure of chapter 4); center E, with the horizontal diameter D–(right) and the vertical diameter A–C. Readable labels: A (top), a and f (top), M with a following ç-like sort (upper right), F (upper left), D (left rim), K (upper-right rim), V and H (right), E (center) with n, X, o, m clustered about it, N and v (center right), d (right), h (center-left), I (or l, center), q and p (lower interior), I (lower-left rim), G with g (lower right), α (bottom), C (bottom, ç-form). The figure is very crowded and several minuscule sorts could not be resolved with certainty. [Dense construction figure]

Diagram, lower figure. A second large circle with a dense web of chords, for the six circumferences hectemorion / descensive / vertical / horary / meridian (a

reprint of a chapter-4 figure); center V E, horizontal diameter D–B, vertical diameter A–C. Readable labels: A with Y (top), S and M (upper center), F (upper left), f and f (two, left rim), l (center), X and L (center), n and o (center), E with V (center), H (right, with an f/P t/R cluster below), K (upper-right rim), B (right), b (lower right), m (interior right), q and p (lower center), D (left rim) with d/δ beneath, h (center-left), I (lower-left rim), α (bottom), C (bottom), G (lower right). Extremely crowded; several sorts uncertain. [Dense construction figure]

The right column continues:

(equal) to QN — equal to k L, that is, to a m, the sine of the complement of the declination — so is E S, the whole sine, to S V, the sine of the complement of the horizontal circumference AS: suppose it is contrived that, as the sine of the descensive circumference (that is, the sine of the complement of the Sun's altitude above the horizon) is to the sine of the complement of the declination, so is the whole sine to another [term]. There will be found the sine of the complement of the horizontal circumference; and by that this complement, together with the horizontal circumference, will be known.

[Margin: Horizontalis (the horizontal [circumference]).]

ÆÆDEM — These same circumferences will be found still more easily, when the Sun is on the vertical circle. For then the perpendicular k L falls on the point n, where the diameter of the parallel intersects the diameter of the vertical, as appears in the third figure of chapter 4 (which we have here repeated); and on that account the lines EQS, EY, MN do not differ from the line AE. Likewise the line OP is equal to k L, as we demonstrated in chapter 4, and therefore the line ERT falls on the point P. Likewise Lf and Eg, perpendicular to E Y, will not diverge from the lines O P and E B, perpendicular to A E.

ITAQVE — And so, since it holds that, as a m (insofar as it is the whole sine in the given parallel) is to K L (insofar as it is the right sine of the Sun's distance from the meridian in that same parallel), so is a m (insofar as it is the sine of the complement of the declination of the given parallel, namely a part of the whole sine in the greatest circle, as in the meridian) to K L (insofar as it is a part of the whole sine in that same greatest circle, that is, to O P, or L f, equal to K L, insofar as it is the sine of the complement of the hectemorion circumference f g, and the right sine of the descensive circumference A P, and of the vertical A T): suppose it is contrived that, as the whole sine is to the sine of the Sun's distance from the meridian, so is the sine of the complement of the declination to another [term]. There will be found the sine O P, of the arc AP, whose complement f g will give

the hectemorion circumference, while the arc AP itself will be the descensive circumference, and the vertical.

HORARIA — But the horary circumference, and the meridian, will be a quadrant of the meridian BM, because (as we said) the lines NM, EY do not differ from the line AE.

HORIZONTALIS — Finally the horizontal circumference AS is then nothing. For the points A and S do not differ, since the Sun is placed on the vertical circle, and therefore the vertical circle drawn through the center of the Sun is the same as the vertical properly so called.

[Margin: Quando Sol in Verticali circulo existit, facillime dictæ circumferentiæ reperiuntur. (When the Sun is on the vertical circle, the said circumferences are found most easily.)]

SED — But now let us inquire into these same six circumferences by rectilinear triangles, when the Sun is on the equator. Let the figure of chapter 2 be repeated, in which are drawn FY, SV, perpendicular to BD, the diameter of the horizon, and FZ, TX, perpendicular to AC, the diameter of the vertical; and let the lines k N, KO be joined. Now, from what was demonstrated in chapter 3, the hectemorion circumference is HK, the horary B M, the descensive AP, the meridian B F, the vertical AT, and the horizontal AS: all of which we shall find from the sines by this reasoning.

[Margin: Inuentio earundem sex circumferentiarum per sinus, ex triangulis rectilineis, dum Sol in Æquatore existit. (The finding of the same six circumferences by sines, from rectilinear triangles, when the Sun is on the equator.)]

PRO hectemoria — For the hectemorion, let the complement of the Sun's distance from the meridian be taken, assigning 15 degrees to each hour, and so on. For HK is the complement of the Sun's distance from the meridian, namely of the arc F K itself.

[Margin: Hectemoria (the hectemorion [circumference]).]

[a] **QVONIAM** — And since in the triangles EFZ and ELO it holds that, as EF — the whole sine — is to F Z, the sine of the pole's altitude, so is E L, the sine of the complement of the Sun's distance from the meridian, to L O, the sine of the arc A M, the complement of the horary circumference BM: suppose it is contrived that, as the whole sine is to the sine of the pole's altitude, so is the sine of the complement of the Sun's distance from the meridian to another [term]. There

would be produced the sine of the complement of the horary circumference. This complement, then, together with the horary circumference, will not lie hidden.

[Margin: [a] 4. sexti. (Euclid, *Elements* VI.4.)] [Margin: Horaria (the horary [circumference]).]

[b] **DEINDE** — Next, since in the triangles EFY and ELN it holds that, as EF — the whole sine — is to FY, the sine of the complement of the pole's altitude, so is E L, the sine of the complement of the Sun's distance from the meridian, to L N, the sine of the arc B P, the complement of the descensive circumference AP: suppose it is contrived that, as the whole sine is to the sine of the complement of the pole's altitude, so is the sine of the complement of the Sun's distance from the meridian to another [term]. There will be found the sine of the complement of the descensive circumference. Whereby this complement, together with the descensive circumference, will become known.

[Margin: [b] 4. sexti. (Euclid, *Elements* VI.4.)] [Margin: Descensiuia (the descensive [circumference]).]

PRO circumferentia meridiana — For the meridian circumference, on the other hand, the complement of the pole's altitude must be taken, as is evident from the figure, namely the arc BF.

[Margin: Meridiana (the meridian [circumference]).]

Again, since in triangle KLN the sides KL, LN are equal to the sides RO, OE of triangle ROE (for OR was taken in chapter 2 equal to KL; ^a and OE is equal to LN because of the parallelogram NO), and since they contain equal angles — namely right angles (for the angle KLN is a right angle, by definition 3 of book 11 of Euclid, because, if the semicircle FKG is set up at right angles to the meridian, the line KL is perpendicular, by definition 4 of book 11 of Euclid, to that same meridian, since it stands at FG, the common section of the said semicircle and the meridian) ^b — the bases kN, ER will be equal. But KN is equal to MN itself, the sine of the horary circumference BM, since both KN and MN are the semidiameter of the circle parallel to the vertical, and are drawn through the lines KL, MN in the sphere, as is evident if the semicircle FKG is placed at right angles to the meridian. Therefore ER too will be equal to MN, the sine of the horary circumference. ^c And since in triangles ERO, ETX it holds that, as ER — the sine of the horary circumference — is to RO (that is, to its equal KL, the sine of the Sun's distance from the meridian), so is ET, the whole sine, to TX, the sine of the vertical circumference AT: then, if it is contrived that, as the sine of the horary circumference (that is, the sine of the complement of the Sun's altitude above the

vertical circle) is to the sine of the Sun's distance from the meridian, so is the whole sine to another [term], the sine of the vertical circumference will be found; and so the vertical circumference itself will not be unknown.

[Margin: [a] 34. primi. (Euclid, *Elements* I.34.)] [Margin: [b] 4. primi. (Euclid, *Elements* I.4.)] [Margin: [c] 4. sexti. (Euclid, *Elements* VI.4.)] [Margin: Verticalis (the vertical [circumference]).]

Finally, since the sides KL, LO of triangle KLO are equal to the sides QN, NE of triangle QNE (for the line QN was taken equal to KL in chapter 2; ^d and NE is equal to LO because of the parallelogram NO), and since they contain equal angles — namely right angles (for KLO is a right angle, by definition 3 of book 11 of Euclid, because KL is at right angles to the meridian, by definition 4 of book 11 of Euclid, as was also said above) ^e — the bases KO, EQ will be equal to one another. Now KO is equal to OP itself, the sine of the descensive circumference AP, since both KO and OP are the semidiameter of the circle parallel to the horizon, and are drawn through the lines kL, OP in the sphere, as is evident if the semicircle FKG is placed at right angles to the meridian. Therefore EQ too will be equal to OP, the sine of the descensive circumference. And since in triangles EQN, ESV it holds that, as EQ — the sine of the descensive circumference, that is, the sine of the complement of the Sun's altitude above the horizon — is to QN (that is, to its equal KL, the sine of the Sun's distance from the meridian), so is ES, the whole sine, to SV, the sine of the complement of the horizontal circumference AS: then, if it is contrived that, as the sine of the descensive circumference above the horizon is to the sine of the Sun's distance from the meridian, so is the whole sine to another [term], the sine of the complement of the horizontal circumference will be found. This complement, then, together with the horizontal circumference, will be known.

[Margin: [d] 34. primi. (Euclid, *Elements* I.34.)] [Margin: [e] 4. primi. (Euclid, *Elements* I.4.)] [Margin: Horizontalis (the horizontal [circumference]).]

Diagram. The figure "of chapter 2, repeated": a great circle (the meridian) with a vertical diameter from A (top) to C (bottom) and a horizontal diameter from B (left) to D (right), meeting at the centre E. The circle is divided into sectors by radii, and the upper part is crossed by many chords forming the rectilinear triangles used in the proof (the semicircle FKG at right angles to the meridian; the perpendiculars FY, SV, FZ, TX; the joined lines kN, KO, etc.). Labels read on the circumference (clockwise from top): A, K, H, D (right end of the horizontal diameter), Q, C (bottom), I, B (left end of the horizontal diameter), P, F; with M and S set close together near the top left of A. Interior points read: R (near P), Z

(upper centre), X and O (centre), L (below X), and along the horizontal diameter, left of centre, Y, V, N; E at the centre.

- A (top): apex of the vertical diameter
- C (bottom): foot of the vertical diameter
- B (left), D (right): ends of the horizontal diameter
- E (centre): intersection of the diameters
- F, P (upper left), K, H (upper right): points on the circumference
- M, S (near top): points of the small upper arc
- I (lower left), Q (lower right): points on the circumference
- R, Z, X, O, L, Y, V, N (interior): endpoints of the chords/perpendiculars
- T [?] (interior; named in the text at TX, glyph not separately resolved)
- G [?] (of the semicircle FKG; glyph not separately resolved on the arc)

By spherical triangles, then, we shall investigate these same six circumferences when the Sun is outside the equator, in any parallel whatever. Let the horizon be ABCD; the meridian BED; the equator AFC; the vertical AEC; the Sun's parallel LM, whether southern or northern. Let the Sun be placed first at the point G, beyond the vertical circle — as happens at every hour of the southern parallel above the horizon, but, in the case of the northern parallel, only at those hours which have a smaller distance from the meridian than the Sun has when it is on the vertical, provided the Sun's parallel does in fact intersect the vertical. This distance of the Sun from the meridian, when the Sun is on the vertical, will be found from what was demonstrated in proposition 36 of book 1. Through E, the zenith, let the descensive circle EGH be drawn through G, the Sun's place; through A, the pole of the meridian, through the same point G, the hectemorion AGI; and from the poles B, D of the vertical circle, through the same point G, the horary circle BGKD. Then AG will be the hectemorion circumference; BG the horary; EG the descensive; BI the meridian; EK the vertical; and AH the horizontal — all of which we shall compute in this way, having first drawn, from the pole of the world O (whether southern or northern), through G, the great circle OGP, which measures the declination of the given parallel and cuts off from the equator the arc FP, which measures the Sun's distance from the meridian, since, by proposition 10 of book 2 of Theodosius, it is similar to the arc of the parallel between the meridian and the point G, that is, to the circle OGP.

[Margin: The finding of the same six circumferences by spherical triangles, when the Sun is in any parallel outside the equator, provided it is in a northern parallel beyond the vertical, on the southern side. (Inuentio earundem sex

circumferentiarum per triangula sphærica, Sole existente in quovis parallelo extra Æquatorem, dummodo sit in parallelo boreali ultra Verticalem ex parte australi.))

Diagram. A pair of armillary-sphere figures showing the general (off-equator) configuration just defined: the horizon ABCD, the meridian BED, the equator AFC, the vertical circle AEC, the Sun's parallel LM, and the circles drawn through the Sun's place G — the hectemorion AGI, the horary BGKD, the descensive EGH, and the great circle OGP. The left sphere is shown complete; the right sphere begins at the page's right edge and continues in the reprint on the following pages. Labels read on the left sphere: B and C (top), H (upper left), I, G, K, P, F (centre cluster), L, A (left), E (centre-bottom), M (right), D (bottom). Labels read on the (partial) right sphere: B (top), H, P, F, G, I, K, E, C, M, A, L, O, D.

Since, then, in the spherical triangle AGP the angle P is a right angle — by proposition 19 of book 4 of Regiomontanus's *On Triangles*, or by proposition 15 of book 1 of Geber [Jābir ibn Aflaḥ], or by proposition 43 of our own *Spherical Triangles* — it holds that, as the sine of the complement of the arc AP (that is, the sine of the arc FP, the Sun's distance from the meridian) is to the whole sine, so is the sine of the complement of the hectemorion circumference AG to the sine of the complement of the declination-arc GP.

And conversely, as the whole sine is to the sine of the Sun's distance from the meridian, so is the sine of the complement of the declination to the sine of the complement of the hectemorion circumference. Therefore, if it is contrived that, as the whole sine is to the sine of the Sun's distance from the meridian, so is the sine of the complement of the declination to another [term], the sine of the complement of the hectemorion circumference will be found; and so that complement, together with the hectemorion circumference, will not be unknown.

[Margin: Hectemoria (the hectemorion [circumference]).]

Diagram. The same pair of armillary spheres reprinted here beside the continuing text (horizon ABCD, meridian BED, equator AFC, vertical AEC, parallel LM, and the circles through G: hectemorion AGI, horary BGKD, descensive EGH, great circle OGP). Labels read on the left sphere: B/C (top), H (upper left), I, G, K, P, F (centre cluster), L, A (left), E (centre), M (right), D (bottom). Labels read on the right sphere: B (top), H, P, F, G, I, K, E, M, C (right), A, L, O, D.

Next, since in triangle OGI the angle I is a right angle — by proposition 19 of book 4 of Regiomontanus's *On Triangles*, or by proposition 15 of book 1 of Geber, or by proposition 43 of our own *Spherical Triangles* — it holds that, as the sine of the

complement of the arc OG (that is, the sine of the declination-arc GP) is to the sine of the complement of the arc GI (that is, to the sine of the hectemorion circumference AG), so is the sine of the complement of the arc OI (that is, the sine of the arc FI, between the equator and the hectemorion) to the whole sine. And conversely, as the sine of the hectemorion circumference is to the sine of the declination, so is the whole sine to the arc of the meridian between the equator and the hectemorion. If, then, it is contrived that, as the sine of the hectemorion circumference is to the sine of the declination, so is the whole sine to another [term], there will result the sine of the arc of the meridian FI, between the equator and the hectemorion. In northern parallels this arc, added to the arc BF (the altitude of the equator, that is, to the complement of the pole's altitude) — but in southern parallels subtracted from the same arc BF (the altitude of the equator, that is, from the complement of the pole's altitude) — will give the meridian circumference BI. And so, in order to find the meridian circumference by spherical triangles, the hectemorion must first be investigated.

[Margin: Meridiana (the meridian [circumference]).]

Again, since in triangle EGI the angle I is a right angle, it will hold — by proposition 19 of book 4 of Regiomontanus's *On Triangles*, or by proposition 15 of book 3 of Geber, or by proposition 43 of our own *Spherical Triangles* — that, as the sine of the complement of the arc GI (that is, the sine of the hectemorion circumference AG) is to the whole sine, so is the sine of the complement of the descensive [arc] EG to the sine of the complement of the arc EI (that is, to the sine of the meridian circumference BI). And conversely, as the whole sine is to the sine of the hectemorion circumference, so is the sine of the meridian circumference to the sine of the complement of the descensive circumference. Therefore, if it is contrived that, as the whole sine is to the sine of the hectemorion circumference, so is the sine of the meridian circumference to another [term], there will be produced the sine of the complement of the descensive circumference; and so this complement, together with the descensive circumference, will be known. But, in order that the descensive circumference be made known through spherical triangles, the hectemorion and the meridian must first be investigated. Hence the same descensive circumference will more easily be investigated by rectilinear triangles, through the Sun's altitude found by the last method, which we explained in proposition 36 of book 1, before [treating of] spherical triangles. For the complement of the Sun's altitude will give the descensive circumference.

[Margin: Descensiuua (the descensive [circumference]).]

Furthermore, since in triangle EGO — by proposition 17 of book 4 of Regiomontanus's *On Triangles*, or by proposition 13 of book 1 of Geber, or by proposition 41 of our own *Spherical Triangles* — it holds that, as the sine of the descensive circumference EG is to the sine of the angle O (that is, to the sine of the Sun's distance from the meridian), so is the sine of the arc OG, the complement of the declination, to the sine of the angle DEH (or BEH, since these two angles have the same sine), that is, to the sine of the arc BH, the complement of the horizontal circumference AH: then, if it is contrived that, as the sine of the descensive circumference is to the sine of the Sun's distance from the meridian, so is the sine of the complement of the declination to another [term], the sine of the complement of the horizontal circumference will be found; and so this complement, together with the horizontal circumference, will be known. The descensive circumference, then, must be investigated first, before the horizontal is sought by spherical triangles.

[Margin: Horizontalis (the horizontal [circumference]).]

Besides this, since in triangle AGK the angle K is a right angle — by proposition 16 of book 4 of Regiomontanus, or by proposition 13 of book 1 of Geber, or by proposition 41 of our own *Spherical Triangles* — it holds that, as the sine of the hectemorion circumference AG is to the whole sine of the right angle K, so is the sine of the arc GK (that is, the sine of the complement of the horary circumference BG) to the sine of the angle A, that is, to the sine of the arc EI, the complement of the meridian circumference BI. And conversely, as the whole sine is to the sine of the hectemorion circumference, so is the sine of the complement of the meridian circumference to the sine of the complement of the horary circumference. Hence, if it is contrived that, as the whole sine is to the sine of the hectemorion circumference, so is the sine of the complement of the meridian circumference to another [term], the sine of the complement of the horary circumference will be found; and so this complement, together with the hectemorion circumference, will become known.

We shall also investigate it in this way. Since in triangle BGH the angle H is a right angle — by proposition 19 of book 4 of Regiomontanus's *On Triangles*, or by proposition 15 of book 1 of Geber, or by proposition 43 of our own *Spherical Triangles* — it holds that, as the sine of the complement of the arc BH (that is, the sine of the horizontal circumference AH) is to the whole sine, so is the sine of the complement of the horary circumference BG to the sine of the complement of the arc GH (that is, to the sine of the descensive circumference EG). And conversely, as the whole sine is to the sine of the horizontal circumference, so is the sine of

the descensive circumference to the sine of the complement of the horary circumference. Hence, if it is contrived that, as the whole sine is to the sine of the horizontal circumference, so is the sine of the descensive circumference to another [term], the sine of the complement of the horary circumference will be found; and so this complement, together with the horary circumference, will be known. And so, in order that the horary circumference be elicited from spherical triangles, one must first investigate the hectemorion and meridian circumferences, or the horizontal and descensive. Hence we shall more easily track down the same horary circumference by rectilinear triangles, as we set out above — especially through the Sun's altitude above the vertical circle, found by proposition 1 of book 5.

[Margin: Horaria (the horary [circumference]).]

Finally, since in triangle BGI the angle I is a right angle — by proposition 16 of book 4 of Regiomontanus's *On Triangles*, or by proposition 13 of book 1 of Geber, or by proposition 41 of our own *Spherical Triangles* — it holds that, as the sine of the horary circumference BG is to the whole sine of the right angle I, so is the sine of the arc GI (the complement of the hectemorion circumference AG) to the sine of the angle B, that is, to the sine of the vertical circumference EK. Hence, if it is contrived that, as the sine of the horary circumference is to the whole sine,

so is the sine of the complement of the hectemorion circumference to another [term], there will result the sine of the vertical circumference; and so the vertical circumference itself will be known.

We shall obtain it by this device as well. Since in triangle GEK the angle K is a right angle — by proposition 19 of book 4 of Regiomontanus's *On Triangles*, or by proposition 43 of our own *Spherical Triangles* — it holds that, as the sine of the complement of the arc GK (that is, the sine of the horary circumference BG) is to the whole sine, so is the sine of the complement of the descensive circumference EG to the sine of the complement of the vertical circumference EK. Therefore, if it is contrived that, as the sine of the horary circumference is to the sine of the complement of the descensive circumference, so is [that same] to another [term], there will be produced the sine of the complement of the vertical circumference; and so this complement, together with the vertical circumference, will be known. And so, in order that the vertical circumference be found by spherical triangles, one must first seek — besides the horary circumference — the hectemorion or the descensive circumference.

[Margin: Verticalis (the vertical [circumference]).]

Now let the Sun be set again in a northern parallel, at the very point G where it cuts the vertical. On this supposition, the hectemorion will not differ from the vertical, since both circles are drawn through the Sun and through the pole of the meridian; and the point k, where previously the horary circle would cut the vertical, will be the same as G, and the point I, at which the hectemorion met the meridian, the same as E.

[Margin: The finding of the same circumferences when the Sun is on the vertical. (Inuentio earundem circumferentiarum, cum Sol in Verticali existit.)]

Diagram. A single armillary-sphere figure (upper right of the page) showing the case in which the Sun is on the vertical: horizon ABCD, meridian BED, equator AFC, vertical AEC, Sun's parallel LM, with the circles converging at the Sun's place G. Labels read: B (top), F, A, P (left cluster), G, L (left), I, E (centre), O (below E), C (right), M (right), D (bottom).

The hectemorion circumference AG, then, will be found as before, as is clear from triangle AGP, which is the same here as above, and so on.

[Margin: Hectemoria (the hectemorion [circumference]).]

The meridian circumference, on the other hand, is then a quadrant of the circle, BI or DI.

[Margin: Meridiana (the meridian [circumference]).]

The descensive circumference is EG, the complement of the hectemorion circumference. And so, to find the descensive circumference, the hectemorion must first be found, as is evident.

[Margin: Descensiuua (the descensive [circumference]).]

The horizontal circumference is then nothing, since the vertical [circle] drawn through the Sun does not differ from the primary vertical.

[Margin: Horizontalis (the horizontal [circumference]).]

The horary circumference is then likewise a quadrant of the circle, BG or DG.

[Margin: Horaria (the horary [circumference]).]

The vertical circumference, finally, is then the same as the descensive, that is, the complement of the hectemorion.

[Margin: Verticalis (the vertical [circumference]).]

But let the Sun now be placed on the near side of the vertical, toward the north, at the point G, provided it is less or more than six hours distant from the meridian. On this supposition, the hectemorion will fall in the northern quadrant of the meridian, DE.

[Margin: The finding of the same circumferences when the Sun is on the near side of the vertical, provided it is less or more than six hours distant from the meridian. (Inuentio earundem circumferentiarum, Sole existente citra Verticalem, dummodo minus, aut plus absit à meridie quam sex horis.)] [Margin: Hectemoria (the hectemorion [circumference]).]

Diagram. A pair of armillary-sphere figures at the foot of the page — the "earlier figure" and the "later figure" of the following argument (the case where the Sun is on the near side of the vertical, less or more than six hours from the meridian). Each shows the horizon ABCD, meridian BED, equator AFC, vertical AEC, parallel LM, and the circles through G, including the declination circle OGP. Labels read on the left sphere (partial): B, E, I, O, C, M, D. Labels read on the right sphere: B (top), F, A, K, P, H (left cluster), L, G, E, O, I (centre), C (right), M (right), D (bottom).

The hectemorion circumference AG, then, will be found as before, when the Sun was placed beyond the vertical toward the south; as is manifest from triangle AGP, which is the same here as above, and so on.

[Margin: Hectemoria (the hectemorion [circumference]).]

But since in triangle OGI the angle I is a right angle — by proposition 19 of book 4 of Regiomontanus's *On Triangles*, or by proposition 15 of book 1 of Geber, or by proposition 43 of our own *Spherical Triangles* — it holds that, as the sine of the complement of the arc OG (that is, the sine of the declination-arc GP) is to the sine of the complement of the arc IG (that is, to the sine of the hectemorion circumference AG), so is the sine of the complement of the arc OI to the whole sine. And conversely, as the sine of the hectemorion circumference is to the sine of the declination, so is the whole sine to the sine of the complement of the arc OI. Therefore, if it is contrived that, as the sine of the hectemorion circumference is to the sine of the declination, so is the whole sine to another [term], the sine of the complement of the arc OI will be found; and so this complement, together with the arc OI, will be known. From this arc OI, which lies between the pole and the hectemorion, we shall thus determine the meridian circumference DI.

When the Sun's distance from the meridian is less than six hours, as in the earlier figure, the arc OI, once found, must be added to the pole's altitude OD, so that the meridian circumference DI may be obtained. For, since the Sun's distance from

the meridian is less than six hours, the declination circle OGP, which measures the Sun's distance from the meridian, will fall in the quadrant of the equator AF, above the horizon, since the point A is six hours distant from the meridian; and accordingly the hectemorion, cutting the said circle at G, will fall in the portion of the meridian OE, between the pole and the vertical. But when the Sun's distance from the meridian is greater than six hours, as in the later figure, the arc OI, once found, must be subtracted from the pole's altitude OD, so that the meridian circumference DI may be obtained. For, since the Sun's distance from the meridian is greater than six hours, the declination circle OGP, which measures the Sun's distance from the meridian, will cut the equator below the horizon, beyond the point A; and accordingly the hectemorion, cutting the said circle at G above the horizon, will fall in the arc of the meridian OD, between the pole and the horizon.

[Margin: Meridiana (the meridian [circumference]).]

Finally, the descensive circumference EG will be elicited from triangle EGI; the horizontal AH from triangle EGO; the horary DG from triangle AGK or DGH; and the vertical EK from triangle DGI or GEK — as was demonstrated before, when the Sun was beyond the vertical circle. Only, in the demonstrations, in place of the letter B (for the southern side) the letter D must be taken, for the northern side.

[Margin: Descensiuua (the descensive [circumference]).] [Margin: Horizontalis (the horizontal [circumference]).] [Margin: Horaria (the horary [circumference]).]
[Margin: Verticalis (the vertical [circumference]).]

Gnomonics, Book VI (continued)

[Book VI, Cap. VII, continued — printed p. 466]

[Margin: The finding of the same circumferences, when the Sun's distance from the meridian comprises six hours.]

Finally, let the Sun be placed at the extreme point, in the circle of the sixth hour from noon or from midnight, at point G, so that its distance from the meridian comprises six hours. On this supposition, the hectemorion AGI — drawn from A through G — will not differ from the circle of the sixth hour from noon or midnight, OGA; and this circle makes right angles with the meridian at the world-pole O, by proposition 15 of book 1 of Theodosius, since it is drawn through its pole A.

[Margin: Hectemorion.]

The hectemorial circumference AG, therefore, is the same as the declination AG of the proposed parallel LM.

[Margin: Meridian.]

And the meridian circumference DI is the same as the pole's altitude DO.

Diagram. A drawing of the celestial sphere projected onto the plane of the meridian (the outer circle), with the great circles of the meridian, equator, horizon, hour-circle and hectemorion, and the shadow/position triangles used in the derivation. Readable labels:

- B (top of the circle): pole
- F (on the vertical, below B): point on the equator/vertical line
- A (left end of the transverse line): six-hours point on the equator
- C (right end of the transverse line)
- K (interior, just to the right of A)
- H (just below A, at the left)
- G (small, near H, left of center): the Sun's position on the parallel
- E (center of the sphere)
- I (on the vertical, just below E)
- o (small, below I)
- D (bottom of the circle): opposite pole / horizon point

[Margin: Descensive.]

But since in triangle EGO the angle O is a right angle, it will hold — by proposition 19 of book 4 of Regiomontanus's *On Triangles*, or by proposition 15 of book 1 of Geber, or by proposition 43 of our *Spherical Triangles* — that, as the sine of the complement of arc EO (that is, the sine of the pole's altitude OD) is to the whole sine, so is the sine of the complement of the descensive circumference EG to the sine of the complement of arc OG (that is, to the sine of the declination GA). And conversely: as the whole sine is to the sine of the pole's altitude, so is the sine of the declination to the sine of the complement of the descensive circumference. Therefore, if it is contrived that, as the whole sine is to the sine of the pole's altitude, so is the sine of the declination to a fourth term, the sine of the complement of the descensive circumference will result; and thereby that complement, together with the descensive circumference, will be known.

This will also become clear in the following way. Since in triangle AGH the angle H is a right angle, it will hold — by proposition 16 of book 4 of Regiomontanus, or by proposition 13 of book 1 of Geber, or by proposition 41 of our *Spherical Triangles* — that, as the sine of the declination-arc AG is to the whole sine of the right angle H, so is the sine of arc GH (the complement of the descensive circumference EG) to the sine of angle A (that is, to the sine of arc DO, the pole's altitude). And conversely: as the whole sine is to the sine of the declination, so is the sine of the pole's altitude to the sine of the complement of the descensive circumference; and by alternation: as the whole sine is to the sine of the pole's altitude, so is the sine of the declination to the sine of the complement of the descensive circumference — just as before, and so on.

[Margin: Horizontal.]

Next, since in the same triangle EGO the angle O is a right angle, it will hold — by proposition 16 of book 4 of Regiomontanus, or by proposition 13 of book 1 of Geber, or by proposition 41 of our *Spherical Triangles* — that, as the sine of the descensive circumference EG is to the whole sine of the right angle O, so is the sine of arc OG (the complement of the declination) to the sine of angle E (that is, to the sine of arc DH, the complement of the horizontal circumference AH). Accordingly, if it is contrived that, as the sine of the descensive circumference is to the whole sine, so is the sine of the complement of the declination to a fourth term, the sine of the complement of the horizontal circumference will result; and thereby that complement, together with the horizontal circumference, will be known.

This can also be shown from here. Since in triangle AGH the angle H is a right angle, it will hold — by proposition 19 of book 4 of Regiomontanus's *On Triangles*, or by proposition 15 of book 1 of Geber, or by proposition 43 of our *Spherical Triangles* — that, as the sine of the complement of arc AG (the declination) is to the sine of the complement of arc GH (that is, to the sine of the descensive circumference EG), so is the sine of the complement of the horizontal circumference AH to the whole sine. And conversely: as the sine of the descensive circumference is to the sine of the complement of the declination, so is the whole sine to the sine of the complement of the horizontal circumference; and by alternation: as the sine of the descensive circumference is to the whole sine, so is the sine of the complement of the declination to the sine of the complement of the horizontal circumference — just as before.

We shall also find the same horizontal circumference in this way. Since in triangle AGE — by proposition 17 of book 4 of Regiomontanus's *On Triangles*, or

by proposition 13 of book 1 of Geber, or by proposition 41 of our *Spherical Triangles* — it holds that, as the sine of the descensive circumference EG is to the sine of angle EAG (that is, of arc OE, the complement of the pole's altitude), so is the sine of arc AG (the declination) to the sine of angle AEG (that is, of the horizontal circumference AH). If it is contrived that, as the sine of the descensive circumference is to the sine of the complement of the pole's altitude, so is the sine of the declination to a fourth term, the sine of the horizontal circumference will be found, and thereby the circumference itself will become known, as before. But the earlier method is more expeditious, since it employs the whole sine, as is evident.

[Margin: Horary.]

Moreover, since in triangle DGO the angle O is a right angle, it will hold — by proposition 19 of book 4 of Regiomontanus's *On Triangles*, or by proposition 15 of book 1 of Geber, or by proposition 43 of our *Spherical Triangles* — that, as the sine of the complement of arc DO (the pole's altitude) is to the whole sine, so is the sine of the complement of the horary circumference DG to the sine of the complement of arc OG (that is, to the sine of the declination-arc AG). And conversely: as the whole sine is to the sine of the complement of the pole's altitude, so is the sine of the declination to the sine of the complement of the horary circumference. For this reason, if it is contrived that, as the whole sine is to the sine of the complement of the pole's altitude, so is the sine of the declination to a fourth term, the sine of the complement of the horary circumference will be produced; and thus this complement will be known, together with the horary circumference. This too will be evident in the following way.

Since in triangle AGK the angle K is a right angle, it will hold — by proposition 16 of book 4 of Regiomontanus's *On Triangles*, or by proposition 13 of book 1 of Geber, or by proposition 41 of our *Spherical Triangles* — that, as the sine of the declination-arc AG is to the whole sine of the right angle K, so is the sine of arc GK (the complement of the horary circumference DG) to the sine of angle A, or of arc OE (the complement of the pole's altitude). And conversely: as the whole sine is to the sine of the declination, so is the sine of the complement of the pole's altitude to the sine of the complement of the horary circumference; and by alternation: as the whole sine is to the sine of the complement of the pole's altitude, so is the sine of the declination to the sine of the complement of the horary circumference — just as before, and so on.

[Margin: Vertical.]

Finally, since in triangle DGO the angle O is a right angle, it will hold — by proposition 16 of book 4 of Regiomontanus's *On Triangles*, or by proposition 13 of book 1 of Geber, or by proposition 41 of our *Spherical Triangles* — that, as the sine of the horary circumference DG is to the whole sine of the right angle O, so is the sine of arc OG (the complement of the declination) to the sine of angle GDO (that is, of the Vertical circumference EK). Therefore, if it is contrived that, as the sine of the horary circumference is to the whole sine, so is the sine of the complement of the declination to a fourth term, the sine of the Vertical circumference will be found; and so the circumference itself cannot lie hidden. This too we shall make clear in the following way.

Since in triangle AGK the angle K is a right angle, it will hold — by proposition 19 of book 4 of Regiomontanus's *On Triangles*, or by proposition 15 of book 1 of Geber, or by proposition 43 of our *Spherical Triangles* — that, as the sine of the complement of the declination-arc AG is to the sine of the complement of arc GK (that is, to the sine of the horary circumference DG), so is the sine of the complement of arc AK (that is, the sine of the Vertical circumference EK) to the whole sine.

[printed p. 467 — running header: LIBER SEXTVS.]

And conversely: as the sine of the horary circumference is to the sine of the complement of the declination, so is the whole sine to the sine of the Vertical circumference EK; and by alternation: as the sine of the horary circumference is to the whole sine, so is the sine of the complement of the declination to the sine of the Vertical circumference — just as before, and so on.

[Margin: The finding of the same six circumferences by means of spherical triangles, when the Sun occupies the equator.]

Now let us investigate these same six circumferences by means of spherical triangles, for the case when the Sun runs across the equator and stands at point G. On this supposition, the hectemorion AGI — drawn from A through G — will not differ from the equator AFC; and AG will be the hectemorial circumference, BI the meridian, EG the descensive, AH the horizontal, BG the horary, and EK the Vertical. We shall find them all, even without drawing a great circle from the world-pole O through G.

[Margin: Hectemorion.]

For the hectemorial circumference AG does not differ from the complement of the Sun's distance from the meridian, AG.

[Margin: Meridian.]

The meridian circumference BI is likewise the same as the circumference BF, the altitude of the equator, that is, the complement of the pole's altitude.

Diagram. The companion sphere-in-the-meridian drawing for the case in which the Sun is on the equator (a re-cut of the figure on the facing page, with the same great circles and derivation triangles). Readable labels:

- B (top of the circle): pole
- H (upper left, on the circle)
- G (small, left of center): the Sun's position
- I (center)
- F (center, just below I)
- A (left end of the transverse line)
- C (right end of the transverse line)
- K (small, lower left)
- E (center of the sphere)
- o (small, below E)
- D (bottom of the circle)

But since in triangle EGF the angle F is a right angle, it will hold — by proposition 19 of book 4 of Regiomontanus's *On Triangles*, or by proposition 15 of book 1 of Geber, or by proposition 43 of our *Spherical Triangles* — that, as the sine of the complement of the Sun's distance from the meridian FG is to the whole sine, so is the sine of the complement of the descensive circumference EG to the sine of the complement of arc EF, the pole's altitude. And conversely: as the whole sine is to the sine of the complement of the Sun's distance from the meridian, so is the sine of the complement of the pole's altitude to the sine of the complement of the descensive circumference. Therefore, if it is contrived that, as the whole sine is to the sine of the complement of the Sun's distance from the meridian, so is the sine of the complement of the pole's altitude to a fourth term, the sine of the complement of the descensive circumference will be produced; and thereby this complement, together with the descensive circumference, will be found from the table of sines.

Next, in the same triangle EGF, since the angle F is a right angle — because, by proposition 16 of book 4 of Regiomontanus's *On Triangles*, or by proposition 13 of book 1 of Geber, or by proposition 41 of our *Spherical Triangles*, it holds that, as the sine of the descensive circumference EG is to the whole sine of the right angle

F, so is the sine of arc FG (the Sun's distance from the meridian) to the sine of angle E, that is, of arc BH (the complement of the horizontal circumference AH). If it is contrived that, as the sine of the descensive circumference is to the whole sine, so is the sine of the Sun's distance from the meridian to a fourth term, the sine of the complement of the horizontal circumference will be found; and thereby this complement, together with the horizontal circumference, will become known.

[Margin: Horizontal.]

This will also be clear by the following reasoning. Since in triangle AGH the angle H is a right angle, it will hold — by proposition 19 of book 4 of Regiomontanus's *On Triangles*, or by proposition 15 of book 1 of Geber, or by proposition 43 of our *Spherical Triangles* — that, as the sine of the complement of arc GH (that is, the sine of the descensive circumference EG) is to the whole sine, so is the sine of the complement of arc AG (that is, the sine of arc FG, the Sun's distance from the meridian) to the sine of the complement of the horizontal circumference AH, just as before, and so on. And yet we shall also obtain the same horizontal circumference in this way. Since in triangle AGE — by proposition 17 of book 4 of Regiomontanus's *On Triangles*, or by proposition 13 of book 1 of Geber, or by proposition 41 of our *Spherical Triangles* — it holds that, as the sine of the descensive circumference EG is to the sine of angle A (or of arc EF, the pole's altitude), so is the sine of arc AG (the complement of the Sun's distance from the meridian) to the sine of angle E (or of the horizontal circumference AH). If it is contrived that, as the sine of the descensive circumference is to the sine of the pole's altitude, so is the sine of the complement of the Sun's distance from the meridian to a fourth term, the sine of the horizontal circumference will be found; and so the horizontal circumference will not be unknown. But the earlier method seems more convenient, since it uses the whole sine, as is evident.

[Margin: Horary.]

Again, since in triangle BFG the angle F is a right angle, it will hold — by proposition 19 of book 4 of Regiomontanus's *On Triangles*, or by proposition 15 of book 1 of Geber, or by proposition 43 of our *Spherical Triangles* — that, as the sine of the complement of arc FG (the Sun's distance from the meridian) is to the whole sine, so is the sine of the complement of the horary circumference BG to the sine of the complement of arc BF (that is, to the sine of arc EF, the pole's altitude). And conversely: as the whole sine is to the sine of the complement of the Sun's distance from the meridian, so is the sine of the pole's altitude to the sine of the complement of the horary circumference. Therefore, if it is contrived

that, as the whole sine is to the sine of the complement of the Sun's distance from the meridian, so is the sine of the pole's altitude to a fourth term, the sine of the complement of the horary circumference will be found; and thus this complement, together with the horary circumference, will be known.

[Margin: Vertical.]

Lastly, since in triangle AGK the angle K is a right angle, it will hold — by proposition 19 of book 4 of Regiomontanus's *On Triangles*, or by proposition 15 of book 1 of Geber, or by proposition 43 of our *Spherical Triangles* — that, as the sine of the complement of arc AG (that is, the sine of arc FG, the Sun's distance from the meridian) is to the sine of the complement of arc GK (that is, to the sine of the horary circumference BG), so is the sine of the complement of arc AK (that is, the sine of the Vertical circumference EK) to the whole sine. And conversely: as the sine of the horary circumference is to the sine of the Sun's distance from the meridian, so is the whole sine to the sine of the Vertical circumference. For this reason, if it is contrived that, as the sine of the horary circumference is to the sine of the Sun's distance from the meridian, so is the whole sine to a fourth term, the sine of the Vertical circumference will be found; and thus the Vertical circumference will be known.

THE FINDING OF THE AFOREMENTIONED SIX CIRCUMFERENCES IN THE RIGHT SPHERE, both geometrically from the analemma and numerically from the doctrine of sines, whether the Sun stands on the equator or on any other parallel whatsoever.

CAPVT VIII.

[Margin: The foregoing precepts apply also to the oblique sphere, since it has the antarctic pole [?] above the horizon.]

Although all the precepts that we have so far handed down for investigating the said six circumferences are to be understood of the oblique sphere — the one in which the arctic pole is raised above the horizon, since Ptolemy speaks only of this case in his *Analemma* — they nevertheless hold good also in that obliquity of the sphere where the antarctic pole is raised

above the horizon, provided that what has been said of the northern parallels and the arctic pole is applied to the southern parallels and the antarctic pole, and vice versa. Indeed, by these same precepts we shall trace out the said six circumferences in the right sphere as well — and much more easily, in fact, than in the oblique.

To make this clearer: Let ABCD be the meridian, with center E. Its common section with the right horizon is BD, which will also represent the axis of the world. Its common section with the vertical, or with the equator (for in the right sphere the equator and the vertical do not differ), is the straight line AC, cutting BD at right angles. Finally, its common section with a parallel — whether northern or southern — is ab, about which the semicircle aeb is described. Now if the semicircle ABC is imagined to be rotated about AC until it stands perpendicular to the meridian, it will represent the eastern or western semicircle of the equator, so that EB is the common section of the equator and the right horizon, AB the portion of the equator above the earth, and BC the portion below the earth — as we showed above for the oblique sphere.

The division of the equator into hours must begin from point A or B, so that at A is set the 12th hour from midnight, and at B the 6th hour from noon or midnight; likewise at A the 6th hour from sunrise and the 18th from sunset, and the 6th unequal hour; while at point B the 12th and 24th hour from sunrise, and again the 24th and 12th from sunset, and the 12th unequal hour. In the same way, de will be perpendicular to ab — that is, dB produced is the common section of the right horizon and the parallel aeb — so that ae is the portion above the earth and eb the portion below; and the division of the parallel into hours must begin from point a or e, just as on the equator from point A. For when the Sun is on the parallel aeb, noon occurs at a, just as, when it is on the equator, noon occurs at A.

[Margin: The finding of the aforesaid circumferences in the right sphere from the analemma, when the Sun stands on the equator.]

Let the Sun, then, first be placed on the equator, as at point P, from which let a perpendicular PO be raised to the diameter of the equator AC. This will correspond to the perpendicular OP which, in the figure of chapter 2, was drawn to the diameter of the vertical AC through point L on the diameter of the equator — the point onto which the perpendicular KL fell from the Sun's center. And the straight line EA will correspond to the perpendicular MN which, in the same figure, was drawn through the same point L to the diameter of the horizon.

Diagram. The analemma construction for the right sphere: a large circle (the meridian ABCD) with center E, its vertical diameter AC (equator/vertical) and horizontal diameter DB (horizon/axis), a chord ab for the parallel with its semicircle aeb, the Sun-points P (on the equator) and k (on the parallel), the perpendiculars PO, KL, MN, Eg, Lf, the hectemorion diameter YEZ, and the several right-line triangles used in the demonstration. The figure carries a dense set of small interior and rim labels. Confidently readable: A (top), C or G (bottom), D (left), E (center), F (on the vertical below A), plus the construction points K, L, P, O, M, N, B, R, Y and a Sun-point marked with a script *a* near the upper rim. Several further small labels are present (in the clusters near the upper-right rim and along the lower-right — including what appear to be Q, S, T, X, V, f, d, g, δ and a right-hand point e) but do not resolve individually at this resolution.

[: numerous small analemma labels (more than two) could not be individually confirmed.]

And accordingly, if from OP there is cut off a segment equal to OP itself — indeed, if the very same OP is taken — and from EA a segment EF equal to that same OP, then the straight lines drawn from the center E through the points P and F will, at points R and Q, correspond in the said figure of chapter 2 to points P and A. Therefore, from what was demonstrated in chapter 3, BP will be the hectemorial circumference; BA the horary; AP the descensive; BA the meridian [circumference] between the horizon and the hectemorion — which then does not differ from the equator; AP the Vertical; and the horizontal will be nothing, since the vertical drawn through the Sun then coincides with the vertical properly so called, that is, with the equator. Therefore, by the single perpendicular PO — which is drawn from the Sun's position to the diameter of the equator AC — there are found the hectemorial circumference BP, the descensive AP, and the Vertical AP. But the quadrant BA yields both the horary and the meridian; and finally the horizontal is nothing, since the Sun stands on the equator in the right sphere.

[Margin: The finding of the same circumferences in the right sphere, by sines through rectilinear triangles, when the Sun is on the equator.]

Next, let the Sun be placed at point k on the parallel aeb, and from k let the perpendicular kL be drawn to ab, the diameter of the parallel. Then the semidiameter da will be the same as the perpendicular NM, which in the figures of chapter 4 was directed to be drawn through L to the diameter of the horizon; while the straight line KL, produced to O, will give the perpendicular OP, which there was prescribed to be drawn through L to the diameter of the vertical.

After this — since NM and OP are greater than KL (for NM is the semidiameter of the parallel, and KL is less than the semidiameter; and then, the straight lines dK and EP being drawn, [a] since the square on the line dK is equal to the squares on the lines kL and Ld, and the square on the line EP to the squares on the lines PO and OE, and since the square on EP, the semidiameter of the greatest circle, is greater than the square on dK, the semidiameter of a circle that is not the greatest, the squares on the lines PO and OE will likewise be greater than the squares on the lines KL and Ld. Therefore, when the equal squares on the lines OE and Ld are taken away — [b] which are equal to the square on the line KL — the remaining square on the line OP will be greater than the remaining square on KL; and for that reason the line OP too will be greater than the line KL) — let the lines NQ and OR be cut off equal to KL itself, and let the lines EQS and ERT be drawn.

Lastly, having drawn through L the diameter of the hectemorion YEZ, let the perpendiculars Eg and Lf be raised to it at E and L; and Lf will be equal to KL itself. (For if the lines EK and Ef are joined, they are equal to each other, since each is drawn from the center of the sphere E to its surface — as is clear, if the parallel is set in its proper position, namely perpendicular to the meridian, so that in that position KL is, by definition 4 of book 11 of Euclid, perpendicular to the plane of the meridian, and therefore also, by definition 3 of the same book, perpendicular to the line EL. [c] Since both the square on the line Ek is equal to the squares on the lines KL and LE, and the square on the line Ef is equal to the squares on the lines fL and LE, and since the squares on the equal lines Ek and Ef are equal, the squares on the lines KL and LE will also be equal to the squares on the lines fL and LE. Therefore, when the common square on the line LE is removed, there will remain equal squares on the lines KL and fL; and on that account the lines themselves will also be equal.) And accordingly, if with the aid of the compass the interval Lf is taken equal to the line KL, then, Lf being drawn, it will be perpendicular to EY, and so on — as we also showed in chapter 4. These things being thus established, it will follow — from what we showed in chapter 5 — that gf is the hectemorial circumference; BM the horary; AP the descensive; BY the meridian; AT the Vertical; and AS the horizontal.

[Margin: 47 of book 1 (Euclid).] [Margin: 34 of book 1.] [Margin: 47 of book 1.]

Now if one wishes to investigate these same circumferences by means of sines from rectilinear triangles, the matter will be very easy, when the Sun is running across the equator.

The hectemorial circumference is equal to the complement of the Sun's distance from the meridian, or indeed to its distance from the horizon itself — such as is the circumference B P. [Margin: Hectemoria.]

The horary circumference is equal to the quadrant of the meridian, B A. [Margin: Horaria.]

Likewise the descensive circumference is equal to the Sun's distance from the meridian — of which sort is the arc A P. [Margin: Descensiuia.]

The meridian circumference too is equal to the quadrant of the meridian, B A. [Margin: Meridiana.]

The vertical circumference, in turn, is equal to the Sun's distance from the meridian, just as the descensive one is — such as is the arc A P. [Margin: Verticalis.]

The horizontal circumference, finally, is nothing at all. [Margin: Horizontalis.]

But with the Sun placed in any parallel whatever, we shall carry the matter through as follows. Since it holds that, as a d — insofar as it is the whole sine of the parallel a e b — is to K L — insofar as it is the sine of the Sun's distance from the meridian in the same parallel — so a d — insofar as it is a part of the whole sine in the greatest circle, that is, insofar as it is the sine of the complement of the declination of the given parallel — is to K L — insofar as it is a part of the same whole sine in the greatest circle, that is, to L f, which is equal to K L itself.

Therefore, if the proportion be set up — as the whole sine is to the sine of the Sun's distance from the meridian, so the sine of the complement of the declination is to a fourth term — the line L f will be found, namely the sine of the complement of the hectemorial circumference g f; and thus this complement, together with the hectemorial circumference g f, will be known. [Margin: The finding of these same circumferences in the right sphere, by sines, from rectilinear triangles, with the Sun placed in any parallel whatever.] [Margin: Hectemoria.]

The horary circumference, further, is equal to the complement of the declination of the parallel proposed — of which sort is the arc B M. [Margin: Horaria.]

Next, since it holds that, as a d — insofar as it is the whole sine of the parallel proposed — is to L N — insofar as it is the sine of the complement of the Sun's distance from the meridian — so a d — insofar as it is a part of the whole sine in the greatest circle, that is, insofar as it is the sine of the complement of the declination of the given parallel — is to L N — insofar as it is a part of the same

whole sine in the greatest circle, that is, insofar as it is the sine of the complement of the descensive circumference. Hence, if the proportion be set up — as the whole sine is to the sine of the complement of the Sun's distance from the meridian, so the sine of the complement of the declination is to a fourth term — there will be found the sine of the complement of the descensive circumference A P; and on that account this complement, together with the descensive circumference, will not be unknown. [Margin: Descensiuua.]

The meridian circumference B Y will be found just as in the oblique sphere, with the Sun placed in any parallel, exactly as we set out in the preceding chapter. [Margin: Meridiana.]

Now, since the two sides K L, L N of the triangle K L N are equal to the two sides R O, O E of the triangle R O E — for R O was taken equal to K L itself, [a] and L N is equal to O E on account of the parallelogram N O — and since they contain equal angles, namely right angles, [b] the bases N K, E R will also be equal. Therefore, since N K, the semidiameter of the parallel, is equal to the semidiameter M N of the same parallel, E R too will be equal to M N — that is, to the sine of the horary circumference B M, or to the sine of the complement of the declination. Hence we shall find the vertical circumference A T just as in the oblique sphere, with the Sun placed in any parallel, exactly as we taught in the preceding chapter — as is plain in the triangles E R O, E T X, provided that R O is first found (that is, K L, which is equal to it, namely the sine of the Sun's distance from the meridian, in the parts of the whole sine in the greatest circle), as we showed in the preceding chapter. [Margin: (a) Euclid I.34.] [Margin: (b) Euclid I.4.] [Margin: Verticalis.]

Lastly, with the parallel a e b set at right angles to the meridian, so that the right angle K L O is formed, let the line O K be conceived as drawn, subtending the said right angle K L O. And since the two sides K L, L O of the triangle k L O, in that position, are equal to the two sides Q N, N E of the triangle Q N E — for Q N was taken equal to K L itself, [c] while L O is equal to N E on account of the parallelogram N O — and since they contain equal angles, namely right angles, [d] the bases O K, E Q will also be equal. Therefore, since O K is equal to O P itself — because each is the semidiameter of a circle in the sphere equidistant from the horizon, drawn through the lines K L, O P — E Q too will be equal to that same O P, that is, to the sine of the descensive circumference A P. Hence we shall find the horizontal circumference A S just as in the oblique sphere, with the Sun placed in any parallel, exactly as we taught in the preceding chapter — as is evident in the triangles E Q N, E S V, provided that Q N is first found (that is, K L, which is equal to it, namely the sine of the Sun's distance from the meridian, in the parts of the

whole sine in the greatest circle), as we set out in the preceding chapter. [Margin: (c) Euclid I.34.] [Margin: (d) Euclid I.4.] [Margin: Horizontalis.]

But let us now examine these same circumferences in the right sphere by means of spherical triangles. Let the right horizon be A B C D, the meridian B E D, and the equator A E C, the same as the vertical circle; and let the parallel — whether southern or northern — be F G. Let the Sun first be placed on the equator, at the point H. This done, both the hectemorion drawn from A through H and the descensive circle drawn from E through H will be the same as the equator, or the vertical circle. Therefore, once the horary circle B H D has been drawn, the six aforesaid circumferences will be found, as we said a little before. For the hectemorial circumference A H is the complement of the Sun's distance from the meridian, or the Sun's distance from the horizon itself; the meridian circumference is the quadrant of the meridian B E, or D E; the descensive and vertical circumference E H is the Sun's distance from the meridian; the horary is the quadrant B H, or D H; and the horizontal, finally, is nothing. [Margin: The finding of these same circumferences in the right sphere from spherical triangles, with the Sun placed on the equator.]

Next let the Sun be placed in the parallel F G, at the point I, through which let three great circles be drawn, namely the hectemorion A I K, the descensive circle E I L, and the horary circle B I D. Then A I will be the hectemorial circumference; B K, or D K, the meridian; E I, the descensive; A L, the horizontal; B I, or D I, the horary; and E H, the vertical — all of which we shall track down by the following reasoning.

Since in the triangle B I K, or D I K, the angle K is a right angle, then — by proposition 16 of book 4 of Johann Regiomontanus [Regiomontanus] on triangles, or by proposition 13 of book 1 of Gebir [Jābir ibn Aflaḥ], or by proposition 41 of our own [treatise] on spherical triangles — it will hold that, as the sine of the arc B I, or D I, the complement of the declination of the given parallel F G (for since B, D are the poles of the world, B I D will be a circle of declination), is to the whole sine, which is the sine of the right angle K, so the sine of the arc I K, the complement of the hectemorial circumference A I, is to the sine of the angle B, or D — that is, to the sine of the arc E H, the Sun's distance from the meridian. And, inverting, as the whole sine is to the sine of the complement of the declination, so the sine of the Sun's distance from the meridian is to the sine of the complement of the hectemorial circumference. If, then, the proportion be set up — as the whole sine is to the sine of the complement of the declination, so the sine of the Sun's distance from the meridian is to a fourth term — the sine of the

complement of the hectemorial circumference will be produced; and hence this complement, together with the hectemorial circumference, will become known. [Margin: The finding of these same circumferences in the right sphere from spherical triangles, with the Sun set in any parallel off the equator.] [Margin: Hectemoria.]

We shall also make this plain in the following way. Since in the triangle A I H the angle H is a right angle, then — by proposition 19 of book 4 of Johann Regiomontanus, or by proposition 15 of book 1 of Gebir, or by proposition 43 of our own [treatise] on spherical triangles — it will hold that, as the sine of the complement of the arc H I, the declination, is to the whole sine, so the sine of the complement of the hectemorial circumference A I is to the sine of the complement of the arc A H, that is, to the sine

of the arc E H, the Sun's distance from the meridian. And, inverting, as the whole sine is to the sine of the complement of the declination, so the sine of the Sun's distance from the meridian is to the sine of the complement of the hectemorial circumference — as before.

Diagram. A circle representing the sphere in the right-sphere construction for the six circumferences, with the meridian drawn as the vertical diameter B D and the equator/vertical circle as the horizontal diameter A C. An italic label *Meridiana* stands to the left of the figure. Several arcs and chords cross near the center, forming the shadow-triangles discussed in the text (around points H, E, I, K). Readable labels:

- B (top of circle): pole / top of meridian
- D (bottom of circle): pole / foot of meridian
- A (left, on circumference): left end of horizontal diameter (equator/vertical)
- C (right, on circumference): right end of horizontal diameter
- G (upper right, on circumference): end of upper parallel arc
- G (lower right, on circumference): end of lower parallel arc [the two G-labels are distinguished only by position]
- F (upper left): left end of upper parallel arc
- F (lower left): left end of lower parallel arc
- L (upper left, inner): intersection point
- L (lower left, inner): intersection point
- K (upper, near B): intersection point on the horary/declination circle
- K (lower, near D): intersection point
- I (upper, center-left): Sun's position / intersection

- I (lower, center-left): intersection
- H (center-left): intersection near center
- E (center): center of the sphere

[Margin (to left of figure): Meridiana]

Next, since in the triangle B I k, or D I K, the angle K is a right angle, then — by proposition 19 of book 4 of Johann Regiomontanus on triangles, or by proposition 15 of book 1 of Gebir, or by proposition 43 of our own [treatise] on spherical triangles — it will hold that, as the sine of the complement of the arc I k — that is, as the sine of the hectemorial circumference A I — is to the whole sine, so the sine of the complement of the arc B I, or D I — that is, the sine of the arc of declination H I — is to the sine of the complement of the meridian circumference B K, or D K. Therefore, if the proportion be set up — as the sine of the hectemorial circumference is to the whole sine, so the sine of the declination is to a fourth term — the sine of the complement of the meridian circumference will be found; and hence this complement, together with the meridian circumference, will not lie hidden.

Again, since in the triangle E H I the angle H is a right angle, then — by proposition 19 of book 4 of Johann Regiomontanus on triangles, or by proposition 15 of book 1 of Gebir, or by proposition 43 of our own [treatise] on spherical triangles — it will hold that, as the sine of the complement of the arc of declination H I is to the whole sine, so the sine of the complement of the descensive circumference E I is to the sine of the complement of the arc E H, the Sun's distance from the meridian. And, inverting, as the whole sine is to the sine of the complement of the Sun's distance from the meridian, so the sine of the complement of the declination is to the sine of the complement of the descensive circumference. Hence, if the proportion be set up — as the whole sine is to the sine of the complement of the declination, so the sine of the complement of the Sun's distance from the meridian is to a fourth term — the sine of the complement of the descensive circumference will be produced; and thus this complement, together with the descensive circumference, will be rendered known. [Margin: Descensiu.]

Moreover, since in the triangle E H I the angle H is a right angle, it will hold — by proposition 16 of book 4 of Johann Regiomontanus on triangles, or by proposition 13 of book 1 of Gebir, or by proposition 41 of our own [treatise] on spherical triangles — that, as the sine of the descensive circumference E I is to the whole sine of the right angle H, so the sine [of the declination] is to the sine of the horizontal circumference A L. Therefore, if the proportion be set up — as the sine

of the descensive circumference is to the whole sine, so the sine of the declination is to a fourth term — the sine of the horizontal circumference will be produced, and the horizontal circumference will be known. [Margin: Horizontalis.] This will also be made evident by the following reasoning. Since in the triangle B I L, or D I L, the angle L is a right angle, then — by proposition 19 of book 4 of Johann Regiomontanus on triangles, or by proposition 15 of book 1 of Gebir, or by proposition 43 of our own [treatise] on spherical triangles — it will hold that, as the sine of the complement of the arc I L — that is, as the sine of the descensive circumference E I — is to the whole sine, so the sine of the complement of the arc B I, or D I — that is, the sine of the arc of declination H I — is to the sine of the complement of the arc B L, or D L, that is, to the sine of the horizontal circumference A L, as before. [Margin: Horaria.]

Finally, the horary circumference B I, or D I, is the complement of the declination of the given parallel; and the vertical E H is the Sun's distance from the meridian; and therefore neither of them will be able to be unknown. [Margin: Verticalis.]

THE CONSTRUCTION OF THE HORIZONTAL, VERTICAL, AND MERIDIAN SUNDIAL FROM THE SIX AFORESAID CIRCUMFERENCES.

CHAPTER IX.

The horizontal sundial is constructed from the horizontal and descensive circumferences found for each individual hour, for the given latitude of the place. For the horizontal circumferences indicate the breadths of the shadows, and the descensive ones the lengths of the same, just as we said of the horizontal sundial in the previous book. The horizontal circumferences here refer to those same arcs which there we called the breadths of the shadows; while the complements of the descensive circumferences measure the altitudes of the Sun above the horizon, as we showed in chapter 1 of this book. [Margin: How the horizontal sundial is constructed from the horizontal and descensive circumferences.] To make this plainer, we shall bring forward a single example. In the first figure of chapter 6 there was found the horizontal circumference C p for the twenty-third hour from sunset, in the tropic of ☊ [Cancer], which is northern and western.

Now, so that you may understand which hours are northern and which southern: all those hours whose perpendiculars, dropped to the diameter of each parallel in the analemma of chapter 6, fall upon the portion of the diameter between the diameter of the horizon and the diameter of the vertical circle, are northern, or

septentrional, with respect to the vertical circle; whereas the others, whose perpendiculars fall upon the portion of the parallel's diameter between the circumference of the meridian circle and the diameter of the vertical, are southern. [Margin: By what method the northern hours are distinguished from the southern in the analemma.] For if the meridian is set in its proper position, so that H looks toward the arctic pole and I toward the antarctic, the diameter of the vertical A C will separate the northern portion A D C from the southern A B C. Likewise, if the analemma is so inverted that I looks toward the arctic pole and H toward the antarctic, and the straight line a b is the diameter of the tropic of $\mathfrak{S}$, as was done in the division of the analemma into hours from sunrise and sunset in chapter 6, the same diameter of the vertical C A will separate the northern portion C B A from the southern C D A. The northern hours can, however, also be recognized from the southern by the doctrine of sines. For all those hours whose distances from the meridian are greater than the distance the Sun has when placed on the vertical circle — which is elicited from proposition 36 of book 1 — are northern, and the rest are southern. Or else in this way: those hours whose descensive circumferences are greater than the one obtained when the Sun is set on the vertical are northern, and the rest are southern.

And so the horizontal circumference which we take from the one found to belong to the horizontal circumference C p — [we lay off] in the horizontal sundial of the previous book, from the point D, westward toward the north C, an arc D e similar [to it] (which will easily be done if from E a circle is described equal to the meridian of the analemma in which the circumferences were found, and so on). For upon the straight line e E f, drawn as a hidden [construction] line, the shadow of the style will be cast. Again, for the same twenty-third hour from sunset, in the tropic of $\mathfrak{S}$, there was found, in the same

analemma of chapter 6, the descensive circumference C r, in such a way that the arc r B measures the altitude of the Sun above the horizon. If, then, in the second figure of proposition 5 of the previous book — the one that comes after the horizontal sundial — a circle equal to the meridian of the analemma is described from D, and in it, from the straight line A D, an arc is taken equal to the descensive circumference C r (or, from the straight line B C, an arc equal to the arc of the Sun's altitude r B), and from the end of the said arc a straight line is drawn through D, the center, this line will cut off from the straight line G I the length of the shadow. If we then transfer this, with the help of the compass, onto the straight line E f in the sundial, as far as f, we shall have f as the point of the twenty-third hour from sunset in the tropic of $\mathfrak{S}$. We shall find the same point f if, from chapter 7, the descensive circumference for the said twenty-third hour has

been found by sines. For from its complement, which measures the altitude of the Sun above the horizon, we shall find the length of the shadow; and if we take this from the straight line H I, placed alongside the horizontal sundial, and transfer it onto the straight line E f in the sundial, the point f will be found, as before. In the same way judgment must be made about all the other hours, so that their points may be found, and so on. And the whole horizontal sundial will be completed, as we wrote in the preceding book.

The vertical sundial is composed in the same manner from the vertical and horary circumferences found for the individual hours, for the given latitude of the place. For the vertical circumferences give the breadths of the shadows, and the horary ones — whose complements show the altitudes of the Sun above the vertical circle — give the lengths of the same, just as we said of the vertical sundial in the previous book. This alone is the difference: that the vertical circumferences are the complements of those arcs which, in the previous book, we called the breadths of the shadows in the vertical sundial, since in the vertical circle they take their beginning from the common section of the meridian and the vertical, namely from the zenith, and not from the common section of the horizon and the vertical, as did the breadths of the shadows in the previous book.

[Margin: By what method the vertical sundial is composed from the vertical and horary circumferences.] Hence, in the sundial, they are not to be computed from the straight line B D, the common section of the plane of the sundial and the horizon (which is the vertical of the vertical itself), as were the breadths of the shadows of the plane of the sundial and of the meridian. This must, however, be observed as a rule: that the vertical circumferences of those hours which lie above the horizon are to be taken, in the circle described from E as the place of the style (which is equal to the meridian of the analemma), from the point A, toward D or B, according as they are eastern or western; whereas the vertical circumferences of the hours lying below the horizon — such as are the 5th, 6th, and 7th from noon and midnight in the tropic of ♊ [Capricorn], and likewise the 13th, 14th, and 15th from sunset in the same tropic, and so on — are to be taken in the same circle from the point C. Let everything else be done as we said of the vertical sundial facing south in the previous book. But the northern vertical sundial will be made from the southern one, as has been said more than once in the previous books. It can, however, be described in the same way from the vertical and horary circumferences proper to it, found on the northern face of the vertical circle, provided one carefully considers which hours on the northern face of the vertical are eastern and which western, and so on.

Finally, the meridian sundial is described by the same method from the meridian and hectemorial circumferences found for the individual hours, for the given latitude of the place. For the meridian circumferences indicate the breadths of the shadows, while the hectemorial ones — whose complements measure the altitudes of the Sun above the meridian — give the lengths of the same, just as we declared of the meridian sundial in the previous book. [Margin: How the meridian sundial is described from the meridian and hectemorial circumferences.] This alone is the difference: that the meridian circumferences — since in the analemma they take their beginning from the diameter of the horizon — are not, in the meridian sundial of the previous book, to be begun in the circle described from C as the place of the style, from the equinoctial line D F, as the breadths of the shadows were reckoned in the previous book, but rather from the horizontal line A B. This, however, with the following rule and condition: that the meridian circumferences of those hours which are northern (which indeed we shall recognize from the analemma, as was said above) are to be taken in the said circle, which is equal to the meridian of the analemma, from the northern point B in the eastern sundial, and from the point A in the western one, toward the upper parts; whereas the meridian circumferences of the southern hours [are to be taken] from the other extremity of the horizontal line, namely from the southern point. Likewise, that the forenoon hours be described in the eastern sundial, and the afternoon hours in the western. But if the points of those hours of the tropic of ♋ which lie below the horizon — such as are the 5th, 6th, 7th from noon and midnight, and the 13th, 14th, 15th from sunset — are also to be found, their meridian circumferences must be taken from the southern end of the horizontal line, toward the lower parts. Everything else is to be completed as was said of the meridian sundial in the previous book.

SCHOLIUM.

For the rest, if anyone wishes to describe the vertical and meridian sundials just as the horizontal one — no differently than if the vertical and meridian circles were horizons — the horizontal and descensive circumferences in the vertical circle and in the meridian must be investigated, as in the horizon. For the horizontal circumferences will represent those arcs which in the previous book we named the breadths of the shadows in the vertical and meridian sundials, while the complements of the descensive ones [will represent] the altitudes of the Sun above the vertical and above the meridian. Hence, in the vertical sundial of the previous book, the horizontal circumferences will take their beginning from the horizontal line, which is the common section of the plane of the sundial and of the horizon (which is the vertical of the vertical itself), just as the breadths of

the shadows too were reckoned from that same horizontal line — no otherwise than was done in the horizontal sundial, in which the breadths of the shadows, or the horizontal circumferences, took their beginning from the straight line B D, the common section of the plane of the sundial and of the vertical circle of the horizon itself. By parallel reasoning, in the meridian sundial the horizontal circumferences are to be begun from the equinoctial line, which is the common section of the plane of the sundial and of the equator (which is the vertical of the meridian itself), just as the breadths of the shadows too were numbered from that same equinoctial line in the previous book. But it must be carefully observed that the said horizontal circumferences in the vertical sundial be taken now above the horizontal line, now below it, according as their hours lie above the horizon or below it, just as we explained for the vertical sundial in the previous book; likewise, that the horizontal circumferences in the meridian sundial be taken now above the equinoctial line — that is, toward the north — now below it — that is, toward the south — according as their hours are northern or southern with respect to the equator. Finally, that the horizontal circumferences of those hours which are less than 6 hours distant from the meridian — that is, less than 90 degrees — begin from the point D, the upper end of the equinoctial line, while the horizontal circumferences of those hours which have a greater distance from the meridian than 6 hours — that is, than 90 degrees — take their beginning from the point F, the lower end of the equinoctial line, as was declared for the meridian sundial in the previous book. Finally, that everything which was said in the vertical and meridian sundials about the breadths of the shadows be here understood of the horizontal circumferences. [Margin: How both the vertical and the meridian sundial may be described after the manner of the horizontal sundial.]

In this way, in the vertical circle taken as horizon, we shall inquire the horizontal circumferences and the descensive ones. In the analemma of chapter 6, let A C be understood as the diameter of the vertical circle standing for the diameter of the horizon, and accordingly B D as the diameter of the horizon standing for the diameter of the vertical circle with respect to the vertical. Now since above the southern face of the vertical circle the antarctic pole is raised, and I is posited to be the antarctic pole, all those hours whose perpendiculars fall within the portions of the parallel-diameters contained in the semicircle A B C will lie above the southern face of the vertical circle, and their descensive and horizontal circumferences will have to be investigated for the southern dial; whereas the other hours will lie above the northern face, and their descensive and horizontal circumferences will have to be sought for the northern dial.

[Margin: How the descensive and horizontal circumferences are found from the analemma, in the vertical circle taken as horizon.]

Therefore, if through the hour-points on the parallel-diameters perpendiculars are drawn to B E, the semidiameter of the vertical circle, taken with respect to the vertical, these will cut off from the meridian's circumference the descensive circumferences, which take their beginning from the point B — the crown of the head, that is, the pole of the vertical taken as horizon — and whose complements measure the altitudes of the Sun above the southern face of the vertical circle, as above a horizon, as is plain from what was demonstrated in chapter 5. But if through the same hour-points perpendiculars are drawn to A C, the diameter of the vertical circle taken as horizon, and if from these there are cut off straight lines equal to the intervals of the hours between the parallel-diameters and the circumferences of those same parallels — by marking points on the said perpendiculars, through which straight lines are drawn out from the center E — these will cut off from the meridian's circumference the horizontal circumferences, which likewise take their beginning from the point B. These, of course, in the vertical dial taken as horizontal, exhibit the breadths of the shadows, and are to be reckoned from the horizontal line of the dial upward or downward, according as the hour-points on the parallel-diameters lie above or below B D, the diameter of the horizon.

[Margin: How the descensive and horizontal circumferences are found in the vertical circle, taken as horizon, by the doctrine of sines.]

By the doctrine of sines too we shall most conveniently find the descensive circumferences in the vertical circle, as horizon, if by proposition 1 of book 5 we investigate the altitudes of the Sun above the vertical circle taken as horizon; for the complements of these altitudes will give the descensive circumferences. The horizontal circumferences, on the other hand, are found by proposition 3 of book 5, and are the breadths of the shadows — that is, the horizontal circumferences with respect to the vertical circle taken as horizon; for the arcs investigated there are the breadths of the shadows of the vertical circle taken as horizon. Or else such circumferences will have to be sought as in chapter 7, by taking the vertical for horizon and the horizon for vertical, and so on.

[Margin: How the descensive and horizontal circumferences are found in the meridian, taken as horizon, from the analemma.]

Now in the meridian, taken as horizon, we shall track down the descensive and horizontal circumferences in this way. In the same analemma of chapter 6, let the

circle A B C D be understood to be the circle of the sixth hour from noon and from midnight, standing as the meridian of the meridian itself taken as horizon. And since the meridian, as horizon, passes through the poles of the world H, I, the line H I will be the common section of the meridian and of the circle of the sixth hour from noon and from midnight, this circle being taken as the meridian with respect to the meridian; and accordingly F G, the diameter of the equator, will stand as the diameter of the vertical circle of the meridian itself taken as horizon. Therefore, if through the hour-points on the parallel-diameters perpendiculars are drawn to F E, the semidiameter of the equator (taken as the vertical with respect to the meridian, as horizon), these will cut off from the circumference of the circle A B C D the descensive circumferences, which take their beginning from the point F — the crown of the head, that is, the pole of the meridian as horizon — and whose complements measure the altitudes of the Sun above the meridian, as above a horizon, as is clear from what was demonstrated. Again, if from the semidiameters of the parallels (which are indeed perpendiculars drawn through those same hour-points on the parallel-semidiameters to H I, the diameter of the meridian taken as horizon) there are cut off straight lines equal to the intervals of the hours between the diameters and the circumferences of the parallels — by marking points on them, through which straight lines are drawn out from the center E — these will cut off from the circumference of the circle A B C D the horizontal circumferences, which take their beginning from the point F. These, of course, in the meridian dial taken as horizontal, reveal the breadths of the shadows, and are to be reckoned from the equinoctial line of the dial, just as we spoke of the breadths of the shadows in the meridian dial of the previous book.

[Margin: By what method the analemma is divided into hours, so that the descensive and horizontal circumferences in the meridian, taken as horizon, may be found.]

But since the circle A B C D of the analemma does not stand for the meridian but for the circle of the sixth hour from noon and from midnight, the division of the parallels into hours will have to be set up as follows. From the parallel of ♊ [Capricorn] and of ♋ [Cancer], separately drawn out in chapter 6, let all the hours be transferred into the parallel of ♋ in the analemma — beginning from the point of noon, a — the beginning being made at the point where the straight line I H, produced, cuts the parallel, this being taken as the common section of the parallel and of the meridian as horizon, and being the point at which noon falls. This, however, on this condition: that the intervals of those hours which are more than 6 hours, or more than a quadrant, distant from the point a, be taken from the point b in the separately drawn parallel. For in this way the parallel of ♋ will be

divided into hours in the analemma. In the same manner the other parallels will be divided, if they are first drawn out separately, and so on. This is to be understood of the equal hours from rising or setting, and of the unequal hours. For as regards the hours from noon and midnight, the division will take its beginning from the points at which the circle A B C D is divided by the parallels, as above — yet in such a way that those points pertain not to the 12th hour of noon or of midnight, as before, but to the 6th hour from noon or from midnight; whereas the points where the straight line I H, produced, cuts the parallels pertain to the 12th hour of noon or of midnight, and not to the 6th hour from noon or from midnight as before.

[Margin: How the same circumferences are found in the meridian, taken as horizon, by the doctrine of sines.]

The descensive circumferences in the meridian, taken as horizon, will be found by sines, if from what we wrote in proposition 1 of the previous book the altitudes of the Sun above the meridian, taken as horizon, are investigated; for the complements of these altitudes will give the descensive circumferences. The horizontal circumferences in the same meridian, taken as horizon, will be found as was demonstrated in proposition 3 of the previous book, since the arcs investigated there are the breadths of the shadows — that is, the horizontal circumferences with respect to the meridian taken as horizon. Both the descensive and the horizontal circumferences can nevertheless be investigated as in chapter 7, if the meridian is taken for horizon and the equator for vertical.

[Margin: How the descensive and horizontal circumferences are found in the circle of the sixth hour from noon and from midnight, taken as horizon, from the analemma, for the construction of the polar dial.]

By the same reasoning, for the construction of the polar dial the descensive and horizontal circumferences will be found in the circle of the sixth hour from noon and from midnight, taken as horizon. For in the analemma drawn out in that same chapter 6, the straight line H I is the common section of the meridian and of the circle of the sixth hour from noon or from midnight taken as horizon; and therefore F G, the diameter of the equator, is the common section of that same meridian and of the proper vertical of the circle of the sixth hour from noon and from midnight taken as horizon. The division of the parallels into hours must nevertheless be set up as we taught in chapter 6, since the circle A B C D of the analemma is the meridian with respect to the circle of the sixth hour from noon and from midnight taken as horizon.

By sines the same descensive and horizontal circumferences in the circle of the sixth hour from noon and from midnight, taken as horizon, will be found, just as in the meridian, if the circle of the sixth hour from noon and from midnight is taken for horizon and the equator for vertical. The polar dial itself, moreover, will be described from the descensive and horizontal circumferences found in the circle of the sixth hour from noon and from midnight taken as horizon, as we prescribed in proposition 5 of the previous book. For the horizontal circumferences are the same which we there called the breadths of the shadows, while the complements of the descensive ones are the altitudes of the Sun, from which the lengths of the shadows are elicited, as we taught in proposition 2 of the same previous book.

But that we may construct the equinoctial dial, we do not need the horizontal and descensive circumferences found in the equator taken as horizon; for the equal hours divide the whole circles drawn from the place of the style, and the unequal hours divide the portions of those same circles — which answer to the diurnal and nocturnal arcs — into equal parts, as is clear from what we demonstrated in book 2, propositions 49, 50, 58, 59, and 60. Likewise the altitudes of the Sun above the equator are equal at every hour of any given parallel, since any parallel whatever is an almucantar of the Sun — that is, equidistant from the equator. Hence in the equinoctial dial all the hours are readily described, without the horizontal and descensive circumferences, by dividing the circles drawn from the place of the style, or their portions answering to the diurnal and nocturnal arcs, into equal parts, as we set forth in the aforesaid propositions. Yet anyone who prefers to describe those same hours by means of those circumferences will find that all the horizontal circumferences found by him — the Sun being in any given parallel — cut the meridian of the analemma into equal parts, and that there is one and the same descensive circumference for all the hours of the same parallel. This we shall demonstrate as follows.

[Margin: The equinoctial dial is more easily described without the horizontal and descensive circumferences, as was set down in book 2.]

[Margin: In the equator, taken as horizon, the horizontal circumferences cut the meridian of the analemma into equal parts, the Sun being in any given parallel; and at all the hours of the same parallel there is one and the same descensive circumference.]

In the analemma of chapter 6, let F G, the diameter of the equator, be understood to be the diameter of the vertical circle with respect to the equator taken as horizon — namely, the common section of the meridian and of the circle of the

sixth hour from noon and from midnight, which is the vertical of the equator itself taken as horizon. Thus if, for example, through the hour-points on the diameter of the parallel of $\mathfrak{S}$ — the perpendiculars dropped in the parallel of $\mathfrak{S}$ to that diameter — lines are drawn to H I, the diameter of the vertical circle, these will not differ from M N, the diameter of the parallel of $\mathfrak{S}$. Hence the descensive circumference will be H M, or H N. Again, if through d, the point of the 24th hour, a perpendicular $\theta \varepsilon$ is drawn to F G, the diameter of the equator taken as horizon, cutting the circumference of the meridian at ε (which perpendicular does not differ from the perpendicular e d drawn from the 24th hour of the tropic of $\mathfrak{S}$ to the diameter of that same tropic), and if the straight line $\theta \mu$ is cut off equal to the straight line d e, and through μ a straight line E μ is drawn out from the center E, cutting the circumference of the meridian at π , then, by what was demonstrated, I π will be the horizontal circumference for the 24th hour from setting, in the tropic of $\mathfrak{S}$. Now since $\theta \mu$ is equal to d e, if the common part d μ is taken away, the remainder θd will also be equal to the remainder μe . (Or else, when the point μ falls between the straight lines F G, a b — which happens in the hours near noon, where the intervals of the hours between the diameter of the parallel and its circumference are less than the straight line θd — then, if the straight line d μ is added, θd will become equal to μe .) [a] Now θd is equal to E m, because of the parallelogram θm . Therefore μe too will be equal to that same E m. And since μe and E m are also parallel, it follows that, if from m — the center of the parallel — a straight line m e is drawn to the 24th hour on the parallel, [b] the straight line E μ will also be parallel to m e. [c] Hence the angles $\pi E I$ and e m I will be equal. In no other way shall we prove that the straight lines drawn from m, the center of the parallel, to the other hours of the parallel are parallel to the straight lines which, drawn from the center E, terminate on the circumference of the meridian the horizontal circumferences of those same hours; and therefore that the angles at m are equal to the angles at E. [d] Wherefore, since all the angles at m are equal — because they stand on equal arcs at the center m — all the angles at E too will be equal; [e] and therefore the arcs of the meridian on which they stand will be equal to one another. That is, the horizontal circumferences will cut the circumference of the meridian into equal parts, which was what we undertook to demonstrate.

[Margin: How the horizontal circumferences in the equator are found by the doctrine of sines. (a) 34.primi; (b) 33.primi; (c) 29.primi; (d) 27.tertij; (e) 26.tertij; (f) 4.sextri — proposition-references (Euclid, *Elements* I.34, I.33, I.29, III.27, III.26, VI.4) keyed to the lettered steps of the demonstration.]

From these things it follows that, if from the center of the parallel you draw to the individual hours on the circumference of the parallel straight lines equidistant from them, you cut off from the meridian of the analemma the horizontal circumferences, which indeed in the equinoctial dial indicate the breadths of the shadows, and whose beginning is set on the axis $H I$: just as the straight line $E \pi$, parallel to $m e$, cuts off the horizontal circumference $I \pi$ for the 24th hour from setting, as we showed. Since this is so, we rightly prescribed in book 2 that the equinoctial dial should be described by dividing the circles into 24 equal parts — the beginning being made either from the meridian line or from the horizontal, according as the hours are to be drawn from noon and midnight or from rising and setting — or else by dividing the diurnal arcs into 12 equal parts, if unequal hours are to be described; so that there is no need to seek the horizontal circumferences, since the hour-spaces are equal to one another, as we demonstrated.

Now since $E \mu$ is equal to the semidiameter of the parallel $m e$ — that is, to the straight line $d e$, that is, to the sine of the Sun's distance from noon — [f] and since $E \mu$ is to $\mu \theta$ as $E \pi$ (the whole sine) is to the straight line which will be drawn from π equidistant from $\theta \varepsilon$ (that is, to the sine of the complement of the horizontal circumference $I \pi$): if it be arranged that as the sine of the declination is to the sine of the Sun's distance from noon (known in parts of the whole sine of the greatest circle — and this sine will be known in the said parts, as we showed above), so the whole sine is to a fourth quantity, then the sine of the complement of the horizontal circumference will be found; and consequently this complement, together with the horizontal circumference, will be known. For the descensive circumference of any hour whatever, the complement of the declination of the parallel is to be taken, as is evident.

[Margin: The description of the equinoctial dial from the horizontal and descensive circumferences found in the equator, taken as horizon.]

Once the horizontal circumferences are found, we shall reckon them off in the circle drawn from the place of the style, from the horary line of the sixth hour from noon and from midnight — the line which cuts the meridian line at right angles at the place of the style, and which stands as the vertical line of the equinoctial dial itself — that we may construct the equinoctial dial: upward indeed, in the upper equinoctial dial, for the hours which have a greater distance from noon than 6 hours, but downward if a lesser distance; and the contrary in the lower dial. For through the points found in this way the horary lines are to be drawn from the center, that is, from the place of the style.

For the rest, everything we have said in this chapter and its scholium about the description and the descensive [circumferences] of the dials will be better understood if there be recalled to mind those things which we handed down in the previous book concerning the description of those same dials. For the horizontal circumferences are here the same which there were the breadths of the shadows, and the descensive ones the same which were the complements of the altitudes of the Sun, and so on. Wherefore, if anything is here understood less rightly, recourse will have to be made to the previous book; for we judged it superfluous to repeat in this place what we wrote there.

ON DECLINING DIALS — WHETHER FROM THE VERTICAL OR FROM THE HORIZON — AND ON DIALS INCLINED TO THE HORIZON, AND ON THOSE WHICH BOTH DECLINE FROM THE VERTICAL AND ARE AT THE SAME TIME INCLINED TO THE HORIZON.

CAPVT X.

That at last, by means of the analemma, a dial declining from the vertical or from the horizon — and likewise one inclined to the horizon, or one both declining from the vertical and inclined to the horizon at the same time — may be described, there must first be investigated, by proposition 29 of book 1, the altitude of the pole above the greatest circle from which the dial to be described is equidistant; and the analemma must be built for this altitude, observing carefully whether the arctic pole or the antarctic

is raised above that face of the greatest circle from which the dial is equidistant — which indeed we shall recognize from what we wrote at the beginning of the scholium of proposition 1 of the previous book. As an example, let there be set before us this analemma answering to that greatest circle from which a dial declining from the vertical circle by 30 degrees is equidistant, which we also described in proposition 1 of book 3 and in proposition 5 of book 5.

Diagram. A large analemma circle for a dial declining 30° from the vertical. The circle A B C D is drawn about the center E, with the vertical diameter running from A at the top down through E, and the great-circle diameters and parallels crossing at E. Legible letter-labels around the rim and interior, read off the scan under magnification: **A** (top, on the vertical diameter), **F** (upper left, on the circle), **M** (left), **B** (left, with lowercase **u** just below it), **P** (lower left), **T** (lower-left

interior, near the parallel-chord), **N** (bottom), **C** (bottom, beside **N**), **I** (bottom, on the vertical diameter), **G** (lower right, on the circle), **L** (lower right), **D** (right), **R** (right, near the "24/1" rim marks), **H** (upper right), **K** (top, beside **A**). Interior points **O** (left of center) and **Q** (right of center) sit on the oblique diameters. The named diameters/chords of the construction are **K L** (diameter of the parallel of φ), **M N** (diameter of the parallel of $\ominus$), **F G** (diameter of the equator), **H I** (the axis of the world, through the poles), together with **B D** and **A C**. Two concentric rings of hour-numbers 1–24 run around the rim (an outer series for the hours from setting and an inner series for the hours from rising), and further number-series run along the parallel-chords marking the hour-divisions; the individual rim and chord numerals are only partially legible at this resolution and are **not** transcribed cell-by-cell here to avoid pattern-fill. The points **S**, **V**, **X** referenced in the text (the separately drawn parallel of φ , **K R L R**, with **R Q R** and **X V X**) are not confidently locatable as distinct labels on the figure at this resolution.

- **A** (top, on vertical diameter): vertex point
- **K** (top, beside **A**): endpoint of parallel-diameter **K L**
- **F** (upper left, on circle): endpoint of equator-diameter **F G**
- **M** (left, on circle): endpoint of parallel-diameter **M N**
- **B** (left, on circle): endpoint of diameter **B D**
- **u** (left, just below **B**): [?] (lower-case label)
- **P** (lower left): endpoint of the **N P** / seminocturnal segment
- **T** (lower-left interior): nocturnal-arc point
- **I** (bottom, on vertical diameter): pole (endpoint of axis **H I**)
- **C** (bottom, beside **N**): endpoint of diameter **A C**
- **N** (bottom): endpoint of parallel-diameter **M N**
- **G** (lower right, on circle): endpoint of equator-diameter **F G**
- **L** (lower right): endpoint of parallel-diameter **K L**
- **D** (right): endpoint of diameter **B D**
- **R** (right, near rim marks 24/1): parallel/hour point
- **Q** (interior right of center): parallel-hour point
- **O** (interior left of center): parallel-hour point
- **H** (upper right, on circle): pole (endpoint of axis **H I**)
- **E** (center): center of the analemma

For the altitude of the pole **D H** amounts to 40 degrees 3 [?] minutes — namely, as much as we found it above the said circle, as is clear from what precedes. And since the antarctic pole is raised above the southern face of that circle, if we posit

H to be the antarctic pole, then kL will be the diameter of the parallel of φ and MN the diameter of the parallel of ϑ ; so that KR is the semidiurnal arc of φ , and LR the seminocturnal arc, while MP is the semidiurnal arc of ϑ , and NP the seminocturnal arc — if the aforesaid greatest circle were the horizon on which the antarctic pole were visible. But conversely, since the arctic pole is raised above the northern face of the same circle, if H is posited to be the arctic pole, then kL will be the diameter of the parallel of ϑ and MN the diameter of the parallel of φ ; so that kR is the semidiurnal arc of ϑ , and LR the seminocturnal arc, while MP is the semidiurnal arc of φ , and NP the seminocturnal arc.

The circle $ABCD$, moreover, does not stand for the meridian of the place in which the dial is constructed, but for the meridian of that place in which the said greatest circle would be the horizon — passing, that is, through the poles of the world and through the poles of that greatest circle. Of this greatest circle, taken as horizon, and of the said meridian the common section is BD ; and of that same meridian and of the proper vertical of that greatest circle the common section is AC .

Next, the analemma so constructed must be divided into hours, so that the horizontal and descensive circumferences at the individual hours may be found. This division (since it differs from the one we set forth in chapter 6, because the circle $ABCD$ is not the meridian of the place in which the hours are to be described) is to be set up as follows.

[Margin: The division of the analemma into hours for the construction of declining and inclined dials.]

About the diameter KL , for example, of the parallel of φ , let the parallel of φ , $KRLR$, be described separately, together with RQR , the common section of the proposed greatest circle (taken as horizon) and of the parallel of φ , as in the analemma; so that RKR is the portion of φ above the southern face of the said greatest circle, as above the horizon, and RLR the portion of φ above the opposite northern face — that is, below the southern face. Then, once the inclination of the proper meridian of the proposed circle to the meridian of the horizon of that place in which the dial is to be built has been found by proposition 30 of book 1 — an inclination which we found to contain 40 degrees 48 minutes, as we said in proposition 1 of book 3 — we shall reckon it off from the point K , to the right or to the left, as far as S , and from S , through the center of the parallel, we shall draw the straight line ST for the common section of the parallel and of the meridian of the horizon, together with XVX , the common section of the parallel and of the meridian of the horizon; so that SV is equal to

the segment N P of the diameter of $\odot$ in the analemma of chapter 6, and X S X is the diurnal arc of $\odot$, and X T X the nocturnal. Now since the meridian of the horizon is more to the west in the equator, and hence in all the parallels, than the proper meridian of the proposed greatest circle from which the dial is equidistant, as we wrote in proposition 1 of book 3 — and since K is the point at which the proper meridian of the given circle cuts the parallel of $\odot$, while S is the point where the meridian of the horizon divides the same parallel — the point X to the right of S will be western, and the other point X to the left of the same S eastern. Therefore, for the unequal diurnal hours, the diurnal arc of $\odot$, X K S X, is to be cut into 12 equal parts, the beginning being made from the eastern point X, which is placed to the left of S. Likewise the nocturnal arc of $\odot$, X R L T R X, is to be cut into 12 equal parts for the unequal nocturnal hours, the beginning being made from the point X placed to the right of S, which is western. For the hours from noon and from midnight, the whole circle is to be divided into 24 equal parts, the beginning being made from the point S of noon, so that the afternoon hours tend from S toward the right, through X, R, L, as far as T; the forenoon hours, or those after midnight, from the point T toward the left, through R, X, K, as far as S. Then, for the hours from rising, the same circle is to be distributed into 24 equal parts, the beginning being made from the eastern point X, which lies to the left of S, so that the point X indicates the 24th hour from rising, while the first point of division toward S pertains to the 1st hour from rising, the next to the 2nd, and so on. Finally, for the hours from setting, the same circle is to be divided into 24 equal parts, the beginning being taken from the western point X, which is placed to the right of S, so that the point X denotes the 24th hour from setting, while the first point of division toward S pertains to the 23rd hour from setting, the next to the 22nd, and so on. We have set our example in the hours from setting and from rising, as is plain from the figure, in which the outer numbers pertain to the hours of $\odot$ from setting, the inner ones to the hours of $\odot$ from rising.

[Margin: Which hours fall on the southern face of the proposed greatest circle, and which on the northern, and how this may be recognized from the adjoining figure.]

Now all the hours which are comprehended in the portion R k R fall on the southern face of the proposed greatest circle, whereas those contained in the portion R L R do not fall on the said face, but on the opposite northern one — the Sun being at the beginning of $\odot$. Therefore all the hours of the diurnal arc of $\odot$ can be described in the proposed dial, which faces south; but of the hours of the nocturnal arc of $\odot$, those can be described which are comprehended between the

two straight lines X V X, R Q R, namely the 10th, 11th, 12th, 13th, 14th, and 15th — all of which are contained in the tropic of ♊ (dial of proposition 10 of book 3, and declining dial of proposition 5 of book 5), the 10th hour excepted,

which, on account of the narrowness of the space, could not be drawn in, since it runs out too far. From this figure, so constructed, we shall easily recognize how great is the diurnal arc of Capricorn above the southern face of the proposed circle, and how great the nocturnal; and likewise at what hour the Sun, standing at the beginning of Capricorn, begins to illuminate that same face, or ceases to, if it be not obstructed by the earth. For in this way you see the Sun rise above the southern face a little before the 9½ hour from setting, and set — that is, rise above the opposite northern face — somewhat after the 24th hour from setting. The same may be tried out at the other hours.

Now if the circle KRLR be taken for the parallel of Cancer, then RLR will be the portion of Cancer above the southern face of the proposed greatest circle, and RkR the portion above the opposite, northern face, as is plain from the adjacent analemma; while XTX will be the diurnal arc of Cancer, and XSX the nocturnal. Now the meridian of the horizon lies farther west in the parallel of Cancer than does the proper meridian of the proposed greatest circle, just as in the other cases, as we said above. And L is the point at which the proper meridian of the proposed greatest circle, acting as the horizon, cuts the parallel of Cancer above the horizon (for this meridian cuts off the greater portion of the parallel of Cancer below the horizon, as is clear from a material sphere), while T is the noon point above the horizon of the place in which the dial is to be laid out. So the point X to the left of T will be the western one, and the other point X to the right of T the eastern. Therefore, for the unequal diurnal hours, the diurnal arc of Cancer, XLTX, is to be cut into 12 equal parts, beginning from the point X, the eastern one, which is placed to the right of T. Likewise the nocturnal arc of Cancer, XkSX, is to be divided into 12 equal parts for the unequal nocturnal hours, beginning from the western point X, which is placed to the left of T.

For the equal hours from noon and from midnight, the whole circle is to be cut into 24 equal parts, beginning from the point T of noon, so that the afternoon hours run from T toward the left through R, X, K, as far as S; while the forenoon hours, or those after midnight, run from S toward the right through X, R, L, as far as T. Next, for the hours from rising, the same circle is to be distributed into 24 equal parts, beginning from the point X, the eastern one, which of course lies to the right of T, so that the point X marks the 24th hour from rising, while the first point of division toward T belongs to the 1st hour from rising, the next to the 2nd,

and so on. Finally, for the hours from setting, the same circle is to be cut into 24 equal parts, beginning from the point X, the western one, which of course lies to the left of T, so that the point X marks the 24th hour from setting, while the first point of division toward T belongs to the 23rd hour from setting, the next to the 22nd, and so on. We have set our example, for the hours from setting and from rising, in the adjacent figure; for the inner numbers belong to the hours of Cancer from setting, the outer to the hours of Cancer from rising.

Diagram. An uncaptioned circle (the hour-circle for the parallels of Cancer and Capricorn, as discussed in the text). The rim carries two concentric sets of hour-numbers, each running 1–24, with the letter-points set at the ends and crossings of the interior chords.

- K (top of circle): endpoint of the vertical diameter.
- L (bottom of circle, printed as "S L"): endpoint of the vertical diameter; the point S stands immediately beside it at the bottom.
- R (left end of the horizontal diameter): endpoint of the horizontal diameter through the centre Q.
- R (right end of the horizontal diameter): opposite endpoint of the horizontal diameter.
- Q (centre): centre of the circle, where the vertical diameter KL and horizontal diameter RR cross.
- X (upper left, near the rim numbers 15/16/24): endpoint of an oblique chord.
- X (right, near the rim numbers 24/9): opposite endpoint of that oblique chord.
- V (interior, upper right of centre): crossing-point of the oblique chords.
- S (upper right, near the rim number 20): point where a chord meets the rim.
- T (lower left, near the rim numbers 7/8/16): noon point on the rim.

The rim is graduated into 24 divisions carrying two rings of numerals 1–24: per the text, the inner ring = hours of Cancer reckoned from setting, the outer ring = hours of Cancer reckoned from rising. (Individual rim numerals not transcribed cell-by-cell; the two 1–24 rings and the lettered points are the informational content.)

All the hours contained in the portion RLR of Cancer fall upon the southern face of the proposed greatest circle, whereas those comprehended in the portion RKR do not fall upon that face but upon the opposite, northern one, the Sun being at

the beginning of Cancer. And so not all the hours of the diurnal arc of Cancer can be drawn in on the proposed dial, which faces south, but only those contained in the portion RLR — namely the 10th, 11th, 12th, 13th, 14th, 15th, 16th, 17th, and 18th, all of which have been drawn, in the tropic of Cancer, on the declining dial of proposition 5 of the preceding book, the 10th and 18th hours excepted, whose points could not be marked because they run out too far. From this too we shall recognize how great is the diurnal arc of Cancer above the southern face of the proposed circle, and how great the nocturnal; and likewise at what hour the Sun, standing at the beginning of Cancer, begins to illuminate that same face, or ceases to. For in this way you see the Sun rise above the southern face a little after the 9th hour from setting, and set — that is, rise above the opposite northern face — a little after the 18th hour from setting. The same may be tried out at the other hours.

Lastly, the divisions of this circle are to be transferred, by aid of the compass, by starting from the points K, L, or R — onto KRL, the parallel of Capricorn of the analemma, if the hours of Capricorn are in question, beginning likewise from the points k, L, or R that correspond to those; or, if it is the hours of Cancer that are treated, onto MPN, the parallel of Cancer, beginning from the points M, N, or P, which correspond to the points L, K, R of the aforesaid circle. For if perpendiculars are drawn from the divisions of the parallels KRL, MPN to their proper diameters, and the same is done in all the other parallels as well, and in the equator too (which the circumference of the meridian of the analemma represents), the analemma will be divided into hours for the construction of a dial declining from south to east by 30 degrees. Now for these hours the horizontal and descensional circumferences are to be found, as we taught above, exactly as if BD were the diameter of some horizon above which the antarctic pole is elevated, and AC the diameter of the vertical with respect to that horizon. Once these circumferences are found, the dial will be drawn, as we taught in proposition 5 of the preceding book. For the horizontal circumferences found here are the arcs which there we called the latitudes of the shadows; and from the complements of the descensional circumferences we shall know the altitudes of the Sun above the proposed plane, and hence the lengths of the shadows for each hour. Moreover, the hours which lie short of, or beyond, the proper vertical of the proposed greatest circle (taken as horizon) will be recognized here from the analemma, as above. For those whose perpendiculars fall in the segments of the diameters between the diameter of the vertical AC and the semicircle of the meridian ADC — in which the visible pole above the given plane is contained — lie short of the vertical, and therefore their horizontal circumferences are to be reckoned in the dial from the vertical line (which is drawn through the place of

the style perpendicular to the style-line) toward the equinoctial line; whereas those whose perpendiculars fall in the segments of the diameters between the diameter of the vertical AC and the semicircle of the meridian ABC — in which the hidden pole is contained — lie beyond the vertical,

[Margin: Description of a declining dial from horizontal and descensional circumferences.]

and their horizontal circumferences are to be reckoned in the dial from the same vertical line toward the centre of the dial. And from a dial declining from south toward east we shall also make another, which declines from north toward west, just as we explained above.

[Margin: How the dial on the opposite face of a given plane is to be described from its own horizontal and descensional circumferences.]

But if someone should wish to describe the dial on the opposite, northern face from its own horizontal and descensional circumferences, the same circle KRLR — drawn separately about the diameter of the parallel — is to be divided into hours in almost the same way as we set out a little before. For RkR will be the portion of Cancer above the northern face of the proposed greatest circle, and RLR the portion above the opposite southern face, as is plain from the analemma, if H be taken for the arctic pole, which is elevated above the northern face of the proposed circle. Now the point L, where the parallel of Cancer is cut by the proper meridian of the proposed greatest circle, is above the horizon — just as the point T, where the meridian of the horizon cuts the diurnal arc XTX of that same parallel, stands above the horizon, since noon occurs at it, the Sun being at the beginning of Cancer; and so the point K, where the same parallel is cut by the proper meridian of the proposed greatest circle, will be below the horizon. This will be readily perceived if the parallel of Cancer, separately drawn nearby, be set in such a position that the straight line XVX is equidistant from the horizon, and the point S tends downward and T upward, and likewise the straight line ST represents the common section of the meridian of the horizon and the parallel of Cancer, and the semicircle SKT tends to the west and the semicircle SLT to the east. For in this way the meridian of the horizon will cut the diurnal arc of Cancer, XTX, above the horizon at T, and will cut the smaller portion of Cancer, RLR — which the proposed greatest circle cuts off from the tropic of Cancer toward the south — at the point L above the horizon, tending toward the east, as the matter requires.

And so, for the unequal hours, the portion of Cancer XTX above the horizon is to be divided into 12 equal parts, beginning from the eastern point X, which, to us turned toward the circle in the position just described, lies to the left. For the equal hours from noon and from midnight, the whole circle is to be cut into 24 equal parts, beginning from the points T and S, so that the afternoon hours are comprehended in the western semicircle TKS, and the forenoon hours, or those after midnight, in the eastern semicircle SLT. Next, for the hours from rising, the same circle is to be distributed into 24 equal parts, beginning from the eastern point X and proceeding through L toward T. Finally, for the hours from setting, the division of the same circle into 24 equal parts must be begun from the western point X. In the figure the inner numbers regard the hours from setting, the outer the hours from rising. And when the Sun is at the beginning of Cancer, the diurnal hours in the parallel of Cancer, comprehended between the straight lines XVX and RQR, fall upon the northern face of the proposed plane — namely the hours 9, 19, 20, 21, 22, 23, 24 from setting, and the hours 10, 11, 12, 13, 14, 15 from rising, together with all the nocturnal hours — as is evident from the adjacent figure. But if the circle KRLR be taken for the tropic of Capricorn, then, as has been said, RKR will be the portion of Capricorn above the southern face of the proposed circle, and RLR the portion above the opposite northern face; likewise XSX will be the diurnal arc of Capricorn, and XTX its nocturnal arc. And no hour of the diurnal arc of Capricorn, XSX, falls in the portion of Capricorn RLR that stands above the northern face of the proposed circle, but only the hours of the nocturnal arc of Capricorn, XTX, which are contained in the portion RLR, as is plain.

And so, if the hours lying above the northern face of the given plane are transferred from the circle kRLR into the analemma, as before, and perpendiculars are drawn from the hours to the diameters of the parallels, and the same is done in the other parallels and in the equator too, the analemma will be divided into hours for the construction of a dial declining from north to west by 30 degrees. Now for these hours the horizontal and descensional circumferences are to be investigated, as before, exactly as if BD were the diameter of some horizon above which the arctic pole I is elevated.

[Margin: A circumference found for the hours from noon, or from rising, or from setting, in any parallel, upon one face of the proposed plane, is likewise the circumference for the hours from midnight, or from setting, or from rising, in the opposite parallel, upon the other, opposite face of the plane.]

Now the outer numbers in the separately-drawn parallel, when it is taken for the tropic of Capricorn, regard on the southern face the hours from setting, but on the northern face — when the same parallel is taken for the tropic of Capricorn — the hours from rising; likewise the inner numbers, on the southern face, when the same parallel is taken for the tropic of Cancer, regard the hours from rising, but on the northern face, when the parallel is taken for the tropic of Cancer, they regard the hours from setting — as is manifest from what has been said. Hence it comes about that the horizontal and descensional circumferences found for the hours of Capricorn from setting on the southern face of the proposed plane are likewise the circumferences for the hours of Cancer from rising on the opposite, northern face of the same plane; and those which were there found for the hours from rising are here the circumferences for the hours from setting, and conversely — since in the same manner in which the parallel of Capricorn is divided into hours from setting above the southern face of the proposed greatest circle, the parallel of Cancer is divided into hours from rising above the northern face, and so on. The same is to be said of the hours from noon and from midnight. For the circumferences found for the hours from noon in the tropic of Capricorn, above one face of the plane, will be the circumferences for the hours from midnight in the opposite tropic of Cancer, above the other, opposite face of the plane. Wherefore, since the complements of the descensional circumferences measure the altitudes of the Sun above the given plane, the altitudes of the Sun for the same hours will be the same above both faces of the proposed plane — provided that the hours which are taken on one face of the plane, in one parallel, from noon or from rising or from setting, be received on the other, opposite face of the plane, in the opposite parallel, from midnight or from setting or from rising. This too we showed in proposition 1 of the preceding book. And the same is to be said of the other planes, which not only decline but are at the same time inclined, or which are only inclined to the horizon.

Now if, in the dial, the style-line be drawn in the contrary way, as we prescribed in the preceding book, and the centre of the dial too be sought on the opposite side, then from the circumferences found there will be delineated a declining northern dial — that is, one on the opposite face of the plane — just as the southern one was, provided that the horizontal circumferences of the eastern hours be reckoned from the vertical line (which cuts the style-line at right angles at the place of the style) on the eastern side, and those of the western hours on the western side, beyond or short of the vertical line — that is, toward the centre of the dial or toward the equinoctial line — according as the hours are beyond or short of the vertical circle of the proposed plane; and these hours will readily be recognized from the analemma of this chapter. For since the other pole, I —

namely the arctic, in the given example — is elevated above the opposite face of the plane, all those hours whose perpendiculars fall in the segments of the diameters between the diameter of the vertical AC and the semicircle ABC (in which the visible pole above the given face of the proposed plane is contained) will be placed short of the vertical, and the others beyond it, and so on — as was said in the earlier cases too, as is plain if the analemma of this chapter is inverted so that C becomes the vertex of the head and A the point opposite the vertex.

[Margin: The finding of horizontal and descensional circumferences by sines, in declining planes.]

And when the analemma has been divided into hours, as has been said, and the distance of any hour from the proper meridian of the declining plane is known (which indeed will be known from the inclination of this meridian to the meridian of the horizon, as we handed down in proposition 1 of the preceding book), the horizontal and descensional circumferences can also be investigated from the doctrine of sines, both by rectilinear triangles and by spherical ones, taking the proposed greatest circle for some horizon. Or, if by proposition 1 of the preceding book the altitudes of the Sun above the proposed greatest circle are found for each hour, their complements will be the descensional circumferences; and the latitudes of the shadows, found by proposition 3 of that same preceding book, will be the horizontal circumferences.

Now just as we divided the analemma into hours for a greatest circle that declines from the vertical and stands square to the horizon, so too we shall divide it in the same way for a greatest circle that is inclined to the horizon — whether it declines from the vertical or not — if it be carefully weighed whether the proper meridian of the given greatest circle cuts, in the sphere, the parallel which we drew separately, above the horizon or not, and how great an inclination that same meridian has to the meridian of the horizon. And by the same procedure we shall depict the upper dial, as was handed down in the preceding book, from which the lower will be deduced, as we have often said. Or indeed we shall describe the lower dial from its own horizontal and descensional circumferences, as we did the upper, provided only that we draw the style-line in the contrary way and describe the horizontal line below the style, and not above it, as in the upper dial, and so on.

[Margin: Examination of the division made in the separately-drawn parallel in this chapter.]

The division of the separately-drawn parallel can also be examined, if from the inclination of the proper meridian of the given greatest circle to the meridian of the horizon one finds the hour, or that particle of an hour, which in that parallel falls upon the proper meridian of the proposed plane. For if that hour, or particle of an hour, agrees with the point K or L in the parallel according to the division that has been made, the division was rightly established; if not, by no means. For example: the proper meridian of the greatest circle declining from south to east by 30 degrees recedes from the meridian of the horizon, above the horizon toward the east, by 40 degrees 48 minutes — that is, by about 2 hours 43 minutes. Likewise the meridian of the horizon cuts the diurnal arc of Capricorn at hour 19 minute 32 from setting, and at hour 4 minute 28 from rising. If, then, from these hours we subtract 2 hours 43 minutes, there will remain hour 16 minute 49 from setting, and hour 1 minute 45 from rising. To these hours, therefore, the point K in the parallel must correspond. But if the meridian receded from the meridian of the horizon toward the west, the inclination of the meridians would have to be added to hour 19 minute 32, and so on. Again, since the meridian of the horizon cuts the diurnal arc of Cancer at hour 16 minute 28 from setting, and at hour 7 minute 32 from rising, if from these hours are taken away the 2 hours 43 minutes that are due to the inclination of the meridians, the remainder will be hour 13 minute 45 from setting, and hour 4 minute 49 from rising, to which the point L in the same parallel must correspond, and so with the rest.

Besides this, if in the analemma of the scholium to proposition 1 of book 5 the ellipse [figure point-labels worn — cannot be read with certainty: [?]] has been described, account being taken of the inclination of the proposed greatest circle to the meridian of the horizon, and if, for example, the semicircle of Cancer and of Capricorn, FRG, be divided into hours as we prescribed in chapter 6, it will there at once appear by how great an interval any given hour in the portion of Capricorn RG stands from the point 4, where the proposed plane cuts the parallel of Capricorn; and likewise how great is the distance of any given hour in the portion of Cancer RF from the point 3, where the parallel of Cancer is cut by the same plane. If, then, distances of this kind agree with the distances of the hours in the parallel drawn separately in this chapter — the distances which they have from the straight line RQR, the common section of the proposed plane and the parallel — the division will have been rightly established, and so on.

Scholium

Before we set an end to this sixth book, it has seemed good to show in a few words by what method, from a horizontal dial alone, there can be described —

with wonderful ease and pleasure — all the dials that stand square to the horizon: such as the vertical dial of either kind, both meridian dials, and all that decline from the vertical properly so called, of which sort are those that are usually painted on the walls of buildings, and which have a more frequent use than the others that are inclined to the horizon.

[Margin: By what method dials standing square to the horizon can be described from a horizontal dial — namely the vertical dial of either kind, both meridian dials, and all that decline from the vertical properly so called.]

Let there then be an Italian horizontal dial in which the style is AB, and its foot at A, and so on. Let it now be proposed to describe from it a dial declining from south to east by 30 degrees. At A let the angle BAC be constructed equal to the complement of the declination — such indeed as the greatest circle to which the dial is equidistant makes with the meridian — so that the straight line CAD is the common section of the plane of the horizontal dial and of that declining vertical to which the dial is equidistant, whose southern face looks from south toward east, and whose northern face from north toward west. From A draw AE perpendicular to CD; and from it cut off, toward the north, the straight line AE equal to the style of the future dial, of whatever magnitude it be proposed to be. Take also EF equal to the style AB of the horizontal dial, and through E and F draw EG, FH parallel to CD.

If the dial is to be described on the meridian line, then, beginning from the point A, a straight line equal to the style of the future dial is to be drawn either toward the north or toward the south, according as the dial to be described is southern or northern; and through the extremity of the style a straight line is to be drawn perpendicular to the meridian line, and parallel to it another line, distant from it by as much as is the gnomon of the horizontal dial — just as in the given example the straight line FH is equidistant from EG by the interval of the style EF. But if a meridian dial is to be described, one must take, from the straight line perpendicular to the meridian line at A, the length of the style, and through the end of this assumed style a line is to be drawn parallel to the meridian line — on the side of the west, if an eastern dial is wanted, but on the side of the east, if a western one is to be described; and parallel to this parallel, another parallel is to be drawn by the interval of the style of the horizontal dial. But let us return to the proposed example.

Let the plane through the straight lines EF, EG be turned about the straight line EG until it stands square to the plane of the horizontal dial. This done, by definition 4 of book 11 of Euclid, FE will be at right angles to the same plane. And

the style BA too stands square to the same plane. [a] Therefore the straight lines AB and EF will be parallel to each other; and since they are set equal, [b] the straight line joining the points B and F will also be parallel and equal to AE. And since AE, [by definition 4 of book 11 of Euclid,] is perpendicular to the plane drawn through the straight lines EF, EG, FH, [c] the straight line BF will likewise be perpendicular to the same plane. Wherefore the plane drawn through the straight lines EF, EG, FH will be the plane of the dial declining from south to east by 30 degrees, since — the line drawn square to AE being perpendicular to that same plane, and BF (equal to the assumed style AE) thus being the gnomon of the future declining dial, whose foot is at F, its vertex B being set at the centre of the world, namely at the vertex of the style in the horizontal dial — the straight line EG is the common section of the plane of the horizontal dial and of the plane of the declining dial, and of the horizon (since the plane drawn through the straight lines AE, EG, which are parallel, is equidistant from the plane of the horizontal dial). And FH will be the horizontal line — that is, the common section of the plane of the declining dial and of the horizon — since the plane drawn through the straight lines BF, FH (which are parallel to the straight lines AE, EG) is equidistant from the plane of the horizontal dial, being drawn through the centre of the world B and through the straight lines BF, FH, and so does not differ from the horizon; [d] and this because the horizon, drawn through the centre of the world B, is equidistant from the horizontal dial.

[Margin: a. Euclid XI.6 (6. vndec.)] [Margin: b. Euclid I.33 (33. primi)] [Margin: c. Euclid XI.8 (8. vndec.)] [Margin: The horizontal line in the dial, which...] [Margin: d. Euclid XI.15 (15. vndec.)]

[Margin: How the meridian line is to be drawn.]

And so we shall draw the meridian line in a declining dial as follows. From the point I, where the meridian line of the horizontal dial cuts the straight line EG, let the perpendicular IK be raised to EG; this line, I say, is the meridian line. For since the plane of the declining dial stands at right angles to the plane of the horizontal dial, the straight line KI will — by definition 4 of book 11 of Euclid — be perpendicular to that same plane; [a] and therefore the plane drawn through the straight lines KI and IA, being drawn to that same plane, will be at right angles to it. Since, then, the Meridian likewise stands at right angles to that same plane — being drawn through the meridian line AI — the Meridian will not differ from the plane drawn through the straight lines AI and IK; and for that reason IK will be the common section of the Meridian and of the plane of the declining dial.

That is to say, IK is the meridian line in the declining dial. In this meridian line we shall find the centre of the dial in the following way.

[Margin: How the centre of the dial is to be found.]

[Margin: a. Euclid XI.18 (18. vndec.)]

From I, let the perpendicular IL be raised to the meridian line AI of the horizontal dial. Now, with the circle BM described from A, the place of the style, so that all lines drawn from A to the circumference of this circle (which will often have to be drawn) are equal to the style AB, let the perpendicular AM be drawn from A to AI, up to the circumference of the said circle, and toward the same side to which the straight line IL was drawn. From N, the centre of the horizontal dial, let a straight line drawn through M cut the straight line IL at L; and equal to that same IL let a segment IK be cut off on the meridian line of the declining dial, toward the horizontal line FH. I say that K is the centre of the dial declining from the south. For if the triangle NLI is rotated about NI until it stands at right angles to the plane of the horizontal dial — so that the points M and L are set above the dial and not below — the straight lines LI and MA will, by definition 4 of book 11 of Euclid, be perpendicular to that same plane. Since, then, IK too is perpendicular to that same plane, IL will be the same as IK, and the point L the same as K.

But since AM is the style of the horizontal dial, NML will be the axis of the world. For the axis of the world, drawn through M, the vertex of the style, meets the plane of the dial at the centre of the dial. The axis of the world, therefore, will meet the plane of the declining dial at K; and consequently K is the centre of that dial, as is established from the corollary of proposition 21 of book 1. From K, the centre of the dial, the straight line KF, drawn through F, the place of the style, will be the line of the style — that is, the common section of the declining dial and of its own Meridian. Although in the given example this line happens to be parallel to the meridian line AI in the horizontal dial, and to cut the equinoctial line of that same dial at right angles, you must not on that account suppose that this necessarily happens so in every dial; for it happened by chance in our example, whereas in other declining dials you will find the contrary.

[Margin: Which is the line of the style.]

Diagram. A large declining-sundial construction figure filling the lower two-thirds of the page. The four cardinal directions are engraved around the frame: at the top **F · MERID·** (*meridies*, south), down the right-hand side **OCCASVS** (west), across the bottom **SEPTEN·** (*septentrio*, north), and up the left-hand side **ORTVS**

(east). A small circle (the style-circle BM) sits just left of centre, around the central point A; through and around it radiate the meridian, equinoctial, hour- and vertical-lines of the construction, with many auxiliary (dotted "occult") lines.

Readable labels:

- Cardinal frame: F, MERID·, OCCASVS, SEPTEN·, ORTVS
- Around the central style-circle: A (centre), B, N, P, M, and e, T, P, R below it
- Upper right: C, X, and the point V, O, H
- Descending series of hour-points down the right side: 10, 11, 12, 13, 14, 15, 16
- Left side: H, G, D, L, and 23
- Lower-central cluster (dense, dotted construction): 22, 21, 20, 19, 18, 17, with points I, E, F and lowercase a, b, d, f, h, i, l, m, n
- Bottom: K, and a second G at lower left; near F 17 a small Greek-letter cluster (γ [?], and further minuscule letters that do not resolve) [?]

[The same figure is reprinted — see fig-p492-1.]

[Margin: How the equinoctial line is to be drawn.]

Now since the equinoctial line cuts the line of the style at right angles — as we demonstrated in proposition 1 of book 3 — the equinoctial line in the declining dial must be drawn through the point O, where the Equator, carried through the equinoctial line of the horizontal dial, meets the plane of the declining dial: it will be the straight line OP, drawn from O perpendicular to the line of the style. This equinoctial line, in our example, does not differ from the equinoctial line of the horizontal dial, because, as we said, the line of the style cuts the equinoctial line of the horizontal dial at right angles — which, however, does not happen in other declining dials. We shall find, on KI (the meridian line of the declining dial) produced, the point P through which the equinoctial line is to be drawn, in this way. From A, along the meridian line AI of the horizontal dial, let the perpendicular AQ be raised up to the circumference of the circle BMQ — not toward the same side to which IL was drawn, but toward the contrary side — and from Q let a straight line be drawn through the point R, where the meridian line and the equinoctial line intersect one another in the horizontal dial, until it cuts, at the point S, the straight line IL (which was drawn from the point I, where the meridian line of the horizontal dial meets the plane of the declining dial, perpendicular to that same meridian line). For if the straight line IS, produced from KI toward the centre A, is cut off equal to IP, the equinoctial line in the declining dial must be drawn from O through P.

For let the plane in which the triangles AQR and RSI lie be conceived as rotated about the meridian line AI until it stands at right angles to the horizontal dial, so that the point Q comes to lie above the dial and S below. This done, both AQ and IS will be at right angles to the plane of the horizontal dial, by definition 4 of book 11 of Euclid. And, by the same definition, the meridian line IP in the declining dial is at right angles to that same plane. Therefore the straight line IS will coincide with the straight line IP, and the point S with the point P. For since the ray of the Sun at noon, passing through Q, the vertex of the style — when the Sun is in the Equator — falls at the point R, and, produced below the plane of the horizontal dial, at the point S or P, in the declining dial the

Equator will meet the plane of the declining dial at P, seeing that the ray of the Sun, passing through the centre of the world, does not then depart from the plane of the Equator. The equinoctial line, therefore, must be drawn through P. We shall find yet another point, H, in the horizontal line FH, through which the same equinoctial line is to be drawn, in this way. From A let AV be drawn parallel to the equinoctial line, cutting the straight line EG at V. (This is easily drawn if the straight line TA is taken equal to OV; [a] for so it will come about that the straight lines AV and TO, joining the extremities, are equal and parallel to one another.) And from V, to EV, let the perpendicular VH be raised, cutting the horizontal line at the point H, through which the equinoctial line is to be drawn. For since the plane of the declining dial stands at right angles to the plane of the horizontal dial, the straight line HV will — by definition 4 of book 11 of Euclid — be perpendicular to that same horizontal dial. Since, then, the style BA too is at right angles to that same plane, BA and HV will be parallel to one another; [b] and they are also equal to one another [c] (for EF, to which HV in the parallelogram FV is equal, was taken equal to the style AB). [d] Therefore the straight line joining the extreme points B and H will be equal and parallel to AV. Since, then, TO is also parallel to that same AV by construction, [e] the straight line BH will also be parallel to that same TO. Consequently BH and TO will lie in one and the same plane — namely in the plane of the Equator, which is drawn through the straight line TO (that is, through the equinoctial line of the horizontal dial) and through B, the vertex of the style. Therefore the Equator meets the plane of the declining dial in the equinoctial line. And so, if the three points H, O, P lie in a straight line, the equinoctial line is drawn through the points H, O, P.

[Margin: a. Euclid I.33 (33. primi)] [Margin: b. Euclid XI.6 (6. vndec.)] [Margin: c. Euclid I.34 (34. primi)] [Margin: d. Euclid I.33 (33. primi)] [Margin: e. Euclid XI.9 (9. vndec.)]

The point H, however, in the horizontal line, is more easily found in this way. From N, the centre of the horizontal dial, let the perpendicular NX be raised to the meridian line NI — serving as the line of the 6th hour from noon and midnight — cutting the straight line EG at X. For a straight line drawn from K, the centre of the declining dial, to X, will be the line of the 6th hour from noon or midnight in the declining dial, since the circle of the 6th hour from noon or midnight meets this dial at the point X and at the centre of the dial. This straight line KX, then, will cut the horizontal line at the point H, through which the equinoctial line is to be drawn. For the equinoctial line, the line of the 6th hour from noon or midnight, and the horizontal line always intersect one another at one and the same point, as is clear from what was demonstrated in book 3.

By the same device by which we described the equinoctial line on the declining dial, we shall depict all the hour-lines, together with the points of the tropics and of the other parallels. To make this clearer, we shall illustrate the matter with one or two examples. Let, say, the line of the 23rd hour from the west be drawn. Since the line of the 23rd hour in the horizontal dial does not cut the straight line EG, we shall produce it until it cuts EG itself at the point G, through which the 23rd hour from the west must necessarily be drawn on the declining dial, since at that point the circle of the 23rd hour, carried along by the line of the same hour, meets the plane of the declining dial. And in this way all the hours must be drawn on the declining dial through those points at which the hour-line in the horizontal dial cuts the straight line EG.

[Margin: How the hour-line is to be marked out.]

Next, on the straight line EG we shall take Ga equal to the straight line DA — the [distance] between the line of the 23rd hour and A, the place of the style, in the horizontal dial — and from a we shall draw the perpendicular aY to EG, which cuts the horizontal line FH at the point Y, through which the 23rd hour from the west must also be drawn, so that the straight line YG produced marks the 23rd hour from the west in the declining dial. For since the plane of the declining dial stands at right angles to the plane of the horizontal dial, Ya will — by definition 4 of book 11 of Euclid — be perpendicular to that same plane; and the style AB is likewise at right angles to that same plane. [f] Therefore aY and AB will be parallel to one another. Since, then, they are also equal to one another — because EF, [g] to which aY in the parallelogram aF is equal, was taken equal to the style AB — the straight line connecting the points B and Y will also be equal and parallel to the straight line Aa. [h] But the straight line Aa, joining the points A and a, is also parallel to DG, since the straight lines DA and Ga are equal and

parallel by construction. [i] Therefore the straight line connecting the points B and Y will also be parallel to DG; and consequently BY and DG will lie in one and the same plane — namely in the plane of the circle of the 23rd hour from the west, which is drawn through the straight line DG and through B, the vertex of the style. Wherefore the circle of the 23rd hour will meet the plane of the declining dial at the point Y.

[Margin: f. Euclid XI.6 (6. vndec.)] [Margin: g. Euclid I.34 (34. primi)] [Margin: h. Euclid I.33 (33. primi)] [Margin: i. Euclid XI.9 (9. vndec.)]

By the same reasoning the line of the 22nd hour from the west must be drawn through the points b, d, if the straight line eA — between the 22nd hour and the place of the style in the horizontal dial — is taken equal to bf (that is, to the line of the 22nd hour from the west). Through A let the hidden parallel Af be drawn, and let fd be drawn perpendicular to EG, cutting the horizontal line at d. Likewise the line of the 15th hour from the west must be drawn through the points i, g, seeing that the line of the 15th hour in the horizontal dial cuts the straight line EG at i, and Ah, parallel to the line of the 15th hour, cuts that same EG at h, and hg is drawn perpendicular to EG, cutting the horizontal line at g. In no other way is it done for whatever line in the horizontal dial has been described — whether it be one of the number of the hour-lines, or another of the verticals, or the meridian, or one of the celestial houses, or of the ascending signs — provided that it, when produced, cuts the straight line EG. In the declining dial we shall draw it through that point at which the line of the horizontal dial to be described in the declining one intersects the straight line EG, and through that point of the horizontal line onto which falls the perpendicular to EG drawn from the point onto which falls the line drawn through A parallel to the proposed line in the horizontal dial, as is manifest from what has been demonstrated.

Now the lines of the hours from noon and midnight, and the common sections of the Meridians — that is, of the circles of longitude — with the plane of the dial, all pass through K, the centre of the dial. Hence it is enough if the centre of the dial, K, is found. For straight lines drawn through K, the centre of the dial, and through the points at which the straight line EG is cut by the lines of the hours from noon and midnight, or by the common sections of the Meridians and of the plane of the horizontal dial, or by the common sections of the Meridians and of the plane of the declining dial, will give the hours from noon and midnight. They will, however, be drawn more accurately if a third point in the horizontal line is found for each line. Again, since the vertical lines in the declining dial are all parallel and perpendicular to the horizontal line, as we showed in proposition 4 of book 3,

the vertical lines must be drawn in the declining dial through those points of the straight line EG at which it is cut by the vertical lines of the horizontal dial, [and drawn] perpendicular to the horizontal line. Finally, since the lines of the celestial houses are drawn in the declining dial

[Margin: By what method any line whatever of the horizontal dial is depicted on the declining dial.]

through the point at which the meridian line cuts the horizontal line, such lines must be drawn in the preceding figure through the point Z, and through those points of the straight line EG at which the same lines meet the straight line EG in the horizontal dial.

Finally, in the lines transferred from the horizontal dial onto the declining one, we shall find the points through which the arcs of the signs are to be drawn, in this way. Let, say, on the line db of the 22nd hour from the west, the point through which the tropic of Capricorn [♋] is to be drawn have to be found. From A, the place of the style in the horizontal dial, through the point of the 22nd hour in the tropic of Capricorn [♋], let the hidden straight line A22 be drawn, cutting the produced straight line EG at the point m; through this point let the perpendiculars mn and ml be drawn to the straight lines Am and EG. Likewise, from A, toward the same Am, on the side opposite to that on which mn was drawn, let the perpendicular Ap be drawn, up to the circumference of the circle BM. Then let a hidden straight line be drawn from p through the same point of the 22nd hour in the tropic of Capricorn [♋], which cuts the perpendicular mn at n. If the straight line mn is cut off equal to ml, then through the point l, in the declining dial, must be drawn the parallel of Capricorn [♋] — that is [the point where], with the Sun at the beginning of Capricorn [♋], the shadow of the gnomon at the 22nd hour from the west will fall at the point l — so that necessarily the line db of the 22nd hour, drawn earlier, passes through the point l, if there has been no error. Hence it would be enough if, from the point m onto which falls the hidden straight line drawn from A through the 22nd hour in the tropic of Capricorn [♋], the perpendicular ml were drawn to EG: for where this cuts the line db of the 22nd hour, there will be the point of the tropic of Capricorn [♋]. But the hour-line will be described more exactly if the point l is found, as we have taught. For if the straight line ml is taken equal to the straight line mn,

[Margin: By what method the arcs of the signs are transferred from the horizontal dial onto the declining dial.]

and the three points l, b, d lie in a straight line, the line of the 22nd hour from the west will be drawn most exactly through these three points. And if the point of the tropic of Cancer [Ϛ] is also found, there will be four points through which the proposed hour-line is to be drawn. In the 22nd hour from the west this fourth point cannot be found in our example, because the straight line drawn from A through the point of Cancer [Ϛ], at the said hour, does not cut the straight line EG. Hence the Sun, being at the beginning of Cancer [Ϛ] at the 22nd hour from the west, does not illuminate the plane of the declining dial, [which declines] from south toward east. Now, that the extremity of the gnomon's shadow at the 22nd hour from the west, when the Sun is at the beginning of Cancer [Ϛ], falls at the point l, we shall demonstrate by the same method by which a little earlier we showed that the extremity of the shadow at noon, when the Sun is at the equinoxes, falls at the point P on the meridian line KI. For if the plane in which the triangles Ap22 and 22nm lie is conceived as rotated about the straight line Am until it stands at right angles to the horizontal dial — so that the point p comes to lie above the horizontal dial and n below — then, by definition 4 of book 11 of Euclid, both Ap and mn will be at right angles to that same horizontal dial; and, by the same definition, ml too will be perpendicular, in the plane of the declining dial, to the horizontal dial. The straight line mn, therefore, and the straight line ml, and the point n and the point l, will coincide, on account of the equality of the straight lines mn and ml. Now since the ray of the Sun, passing through p, the vertex of the style, at the 22nd hour from the west in the tropic of Capricorn [Ϟ], falls at the point 22, the same [ray], produced below the plane of the horizontal dial, will fall at the point n, or l, in the declining dial; and consequently the circle of the [22nd] hour will meet

Diagram. The same declining-dial construction figure as reprinted (from the same woodblock). The cardinal directions are engraved around the frame — **F · MERID ·** (south) at the top, **OCCASVS** (west) down the right side, **SEPTEN ·** (north) along the bottom, **ORTVS** (east) up the left side — with the central style-circle at **A** and the same dense web of meridian, equinoctial, hour- and vertical-lines and dotted auxiliary lines. The readable labels match those listed for fig-p490-1 (cardinal frame; A, B, N, P, M, e, T, P, R about the centre; C, X, V, O, H upper right; hour-points 10–16 down the right; H, G, D, L, 23 at left; the dense lower cluster 22, 21, 20, 19, 18, 17 with points I, E, F, K and lowercase a, b, d, f, h, i, l, m, n; a small unresolved Greek-minuscule cluster near F 17 [?]).

[Margin: By what method all the points of the horizontal dial are transferred onto the declining dial.]

the plane of the declining dial at the point l, at the 22nd hour from the west, seeing that the ray of the Sun, passing through the centre of the world, does not then depart from the plane of the said circle. By the same reasoning all the other points of the horizontal dial will be transferred onto the declining dial, if hidden straight lines are drawn from A (such as was, at the 22nd hour [♊], the straight line Am), and through the points at which the straight line EG is cut by the said hidden straight lines (such as the point m), perpendiculars are drawn both to those hidden straight lines and to the straight line EG (of which sort are the perpendiculars mn, ml), in which [perpendiculars] are found the points onto which the shadow is projected — [perpendiculars] first drawn from A to those same hidden lines up to the circle BM, and so on. This one thing only must be observed: that when a point to be transferred from the horizontal dial lies between A and the straight line EG — as was the point of the 22nd hour [♊] in our example — the perpendicular to EG (such as ml) must be drawn toward A, namely below the straight line EG, in the declining dial; because the ray of the Sun then cuts the plane of the horizontal dial at the given point before it meets the plane of the declining dial at right angles to the plane of the horizontal dial, and so will meet the declining dial below the straight line EG. But when the straight line EG lies between A and the point to be transferred — of which sort in our example are the points of the hours 18, 17, 16, and so on, from the west in the tropic of Capricorn [♋] — the perpendicular to EG must be drawn toward the horizontal line, namely above the straight line EG, in the declining dial; because the ray of the Sun then meets the declining dial above the straight line EG, before it cuts the plane of the horizontal dial at the given point, as is evident. But in which direction the perpendiculars to EG must be drawn is beautifully indicated by the hour-lines themselves, already drawn. For the said perpendiculars must be raised toward that side where they can cut the hour-lines. It makes no difference, however, in which direction the perpendicular is drawn to the hidden straight line drawn from A through the point that is to be transferred from the horizontal dial onto the declining one, provided that another perpendicular from A to the same hidden straight line is drawn in the contrary direction, as was done in the example.

By this reasoning, in each of the hour-lines that cut the equinoctial line in the declining dial (such as are those through whose points, in the equinoctial line of the horizontal dial, straight lines drawn from A intersect the straight line EG), the points can be found through which the equinoctial line is to be drawn. In this same example of ours we drew, from A, through the point of the 15th hour from the west in the tropic of Cancer [♋], the straight line Aq, which cuts the straight line EG at q; and through q, to Aq, we raised the perpendicular qr, which the

straight line tr — drawn from t , the extremity of the style (which is perpendicular to Aq) — cuts at r , through the point of the 15th hour from the west in the tropic of Cancer [$\mathfrak{S}$]; and off the straight line qr , from q , we cut a segment qf equal to the perpendicular to EG , at the point f , where this perpendicular intersects the line gh of the 15th hour, drawn earlier. For through f the tropic of Cancer [$\mathfrak{S}$] will pass, on the line of the 15th hour from the west. But for the tropic of Capricorn [$\mathfrak{V}$] we find no point in the 15th hour; instead we ended it in the horizontal line, because this hour, in the horizontal dial, has no point in the tropic of Capricorn [$\mathfrak{V}$].

[Margin: A dial declining from the north [toward the west].]

If a dial declining from the north toward the west is to be described, one must take, on the straight line AE , toward the south, a straight line AE equal to the style equal to the style of the future declining dial, and the straight line EF equal to the style of the horizontal dial. Then, through E and F , straight lines EG , FH are to be drawn parallel to AD ; of these, EG will be the common section of the horizontal dial and of the declining dial, while the straight line FH is the horizontal line. The rest will have to be completed as we said for the dial declining from south toward east.

Now if, in the horizontal dial, the greatest of the ever-apparent parallels [i.e. the circle of perpetual apparition] had been drawn, we would at once distinguish, in the dial declining from the north, the hours reckoned from the east from those reckoned from the west. For those hours which, in the Italian horizontal dial, touch the said parallel before they meet the straight line EG belong, in the declining dial, to the hours from the east — as is clear from what we wrote in the scholium of proposition 10, Book 2.

[Margin: How a declining dial is described from a horizontal one.]

For the rest, this discovery of ours does not differ much from the device which Guidobaldo del Monte [Guidus Ubaldus e Marchionibus Montis], a man most outstanding in mathematical matters, thought out and most kindly sent to me. By that device, from the horizontal and descensional circumferences of the Sun found on the horizon, we shall construct the same dials on a plane erect to the horizon. Now although he himself first describes, in the plane of the horizon, the ellipses which the perpendiculars falling onto the plane of the horizon from the hour-points of all the parallels make in that plane (as we demonstrated in proposition 24, Book 1), we, however, will explain the matter itself more easily from the horizontal and descensional circumferences of the Sun, in this way.

[Margin: By what method the same dials, set erect to the horizon, are constructed from the horizontal and descensional circumferences found on the horizon.]

Let ABCD be the horizon, whose centre is E. Let the common section of it and the prime vertical (the vertical circle properly so called) — or equally of the equator — be BD; and the common section of it and the meridian be AC. Suppose a dial is to be described declining both from south toward east and from north toward west. Draw the diameter FG, which is to be the common section of the horizon and of the great circle from which the dial to be described is equidistant, such that DG, BF are arcs of declination, and the southern face of the said great circle declines from south toward east, while the northern face declines from north toward west. To FG, through the centre E, draw the perpendicular HI, and on either side of it cut off the straight lines EH, EI equal to the style of the future dial; and through H and I draw HK, IK parallel to FG. Then HK will be the common section of the horizon and of the plane of the dial declining from south toward east, and IK the common section of the horizon and of the plane of the dial declining from north toward west.

Now let us reckon off, from the western point D, the horizontal circumference of the 24th hour from the west, in Cancer [☿], up to L, toward the north — because this is an afternoon hour and northern in the tropic of Cancer [☿], as is clear from the analemma. This circumference is the western amplitude [latitudo occidua] of the Sun when it is at the beginning of Cancer [☿]. From L, through the centre E, let a hidden straight line be drawn cutting IK at the point M — onto which the Sun's ray, drawn through the centre E (that is, through the tip of the style EI), then falls when the Sun is at the point L on the horizon, at the 24th hour from the west, in the northern dial.

Again, take DN: let the horizontal circumference of the 23rd hour from the west, in Cancer [☿] — which is likewise northern, and western, or afternoon — [be reckoned to N]; and let a hidden straight line be drawn from N through E, cutting EK at the point O, from which are raised both OP, perpendicular to NO, and OR, perpendicular to IK. Let NQ be the complement of the descensional circumference of the same 23rd hour, and from Q, through E, let a hidden straight line be sent out cutting OP at P; and on OR let a segment be taken equal to OP.

Diagram. A large circular construction for two declining dials laid out from the horizontal, framed by the four cardinal directions. The circle ABCD is the horizon, with centre E, from which a fan of solid and dotted straight lines radiates. Around the frame, in large capitals: **MERID.** at the top (south — a small ornamental

symbol and what appears to be the numeral "16" stand between "ME" and "RID" [?]), **SEPT.** at the bottom (north), **ORT.** at the left (east, set vertically), and **OCCAS.** at the right (west, set vertically). Two long straight lines (the traces HK and IK of the two declining planes) run obliquely across the upper part of the figure through the outer points, with dotted perpendiculars dropped to them.

Readable letter-labels (position → note):

- E (centre): common centre of the radiating lines and of the horizon.
- A (top rim, below MERID): meridian endpoint (south).
- Left/lower-left construction points: T, K (upper left), O, M, P, R, u, V — endpoints of the hidden construction lines.
- Left rim: B, I, F (with a small "h" near the top).
- Right and lower-right rim: f, e, Y (with small letters Z / a adjacent [?]), G, D, B, N, L, X.
- Lower rim / lower construction: s, H, m, b, d, and a second K at lower left.
- A row of small letters (approximately p, f, q, g, r [?]) sits between A and the upper rim.

For if the circle ABCD is turned about NO until it stands erect to the horizon — and so becomes the vertical circle passing through the Sun at that moment, such that the point Q lies above the horizon — then the arc NQ will be the Sun's altitude, and the straight line OP will, by Euclid, Book 11, definition 4, be perpendicular to the horizon. But by the same definition OR too — in the plane of the declining dial (for we now understand that the plane of the declining dial is drawn through the straight lines IK, OR, and is erect to the horizon) — stands at right angles to the horizon. Therefore the straight line OP will coincide with OR, and the point P with the point R. Hence the Sun's ray QEP, drawn through the centre E, will fall onto the point P, that is, R.

By similar reasoning, from the horizontal circumference DS of the 22nd hour from the west, in Cancer [☿], and from SX, the complement of the descensional circumference, the point V of the 22nd hour from the west in the tropic of Cancer [☿] will be found — if the straight line SEK is drawn, and KV perpendicular to IK, and the point T (at which the straight line XE cuts the straight line KT) is transferred onto the straight line KV, up to V; and so on for the rest.

By the same art, from the horizontal circumference DY of the 24th hour from the west, in Cancer [☿] — which is southern and western — the point of the 24th hour from the west in the tropic of Cancer [☿] will be found on the horizontal line HK of the dial declining from south toward east, namely where the straight

line TE cuts the horizontal line HK; this point, however, is not contained within our example, on account of the narrowness of the space. Likewise, from the horizontal circumference DZ of the 23rd hour from the west, in Cancer [☊], and the complement Za of the descensional circumference, the point b was found, for the 23rd hour from the west, in the tropic of Cancer [☊]. And from the horizontal circumference De, and the descensional complement ef, of the 22nd hour from the west, in Cancer [☊], the point d was found, for the 22nd hour from the west, in the tropic of Cancer [☊]. And thus, for any hour whatever, we shall find a point on any parallel whatever, if from D, or E, we reckon the horizontal cir-

[Margin: In what way, for any hour, a point may be found on any parallel whatever in the declining dial.]

-cumference toward A or toward C, according as the circumference is western or eastern, and southern or northern; and if, from the endpoint of this circumference, we draw a hidden straight line through the centre E, which cuts the horizontal line at a point, from which two perpendiculars are to be raised — one to this hidden line just drawn, and the other to the horizontal line; and if, finally, from the endpoint of the horizontal circumference, in whichever direction, we count off the complement of the descensional circumference, and from its endpoint draw, through the centre, a straight line that cuts, at a point, the hidden perpendicular raised to the hidden line drawn from the endpoint of the horizontal circumference — [that point] being transferred onto the perpendicular drawn to the horizontal line. For this will be the point of the proposed hour for that parallel for which the horizontal circumference, and the complement of the descensional, were found.

[Margin: How, for any hour, a point may be found on any parallel in the declining dial.]

Now the perpendicular to the horizontal line must always be drawn toward the side of the centre, in both dials; but the other perpendicular, to that hidden line drawn from the endpoint of the horizontal circumference, may be drawn out in whichever direction, provided that the complement of the descensional circumference is counted from the endpoint of the horizontal circumference toward the contrary side, so that the hidden straight line drawn through the centre from the endpoint of this complement can cut this perpendicular — as you see done in the examples. Furthermore, only those hours can be drawn in the southern dial whose horizontal circumferences have such a position on the horizon that the straight lines drawn from their endpoints, produced beyond the centre E, cut the horizontal line HK; the others cannot. And the same must be said

of the northern dial. Hence it has come about that the hours 24, 23, 22 in Cancer [♋], from the west, were drawn in the northern dial but not in the southern; and likewise the hours 24, 23, 22 in Capricorn [♏], from the west, in the southern dial but not in the northern, and so on.

[Margin: How it may be known, from the horizontal circumferences, at what hour [the lines] can be drawn in the proposed dial.]

But so that you may have an example of some hour-line that has a point both in the tropic of Cancer [♋] and in the tropic of Capricorn [♏]: we shall find the point g, for the 16th hour from the west in the tropic of Cancer [♋], from the horizontal circumference of that same 16th hour — Bh — which is southern and eastern, and from hl, the complement of the descensional circumference. (For although the straight line lE, produced, does not, in the example, cut the perpendicular drawn to hm, nevertheless we transferred the point where it would cut it onto the perpendicular mg, up to g.) Likewise, from Bp, the horizontal circumference of the same 16th hour in Capricorn [♏] from the west — which is likewise southern and eastern — and from pq, the complement of the descensional circumference, we find the point r, for the 16th hour from the west in the tropic of Capricorn [♏], so that rg is the line of the 16th hour from the west.

[Margin: In what way the equinoctial line is drawn.]

Finally, so that the equinoctial line may be drawn, two, or three, or more points must be investigated for two, or three, or more hours, with the Sun on the equator; for through these the equinoctial line will have to be drawn. Thus you see that the point f was found on the line rg, for the 16th hour from the west, with the Sun on the equator, from the horizontal circumference Bt of the same hour — which is eastern and southern — and from tu, the complement of the descensional circumference. For to the straight line tEα the perpendicular αβ was drawn, which the straight line uEβ cuts at β, and the point β was transferred onto αf, the perpendicular to HK; and this point f will necessarily fall on the straight line rg, if there has been no error. By this device the whole dial will be completed, as far as concerns the hours and the arcs of the signs.

[Margin: A comparison between the two methods by which, in this scholium, declining dials have been constructed.]

For the other things which we described in the dials of Books 2 and 3 cannot be laid out by this method unless one had first found the horizontal and descensional circumferences, for those other descriptions too, in the horizontal dial — which was done neither by Ptolemy nor by anyone else, because it would

first have to be investigated in what way the parallels of the Sun are divided by the vertical circles, by the parallels of the horizon, by the circles of the celestial houses, and so on; which is exceedingly arduous and difficult. For in order that such circumferences may be investigated for the individual hours, one must first know where the hours intersect the parallels of the Sun, and how far they are, from the south or from sunrise or sunset, on their own parallels. Indeed it was for this reason that we taught, in the preceding [books], how to cut the parallels into hours.

Since this is so, it is clear that our discovery, by which a declining dial is described from a horizontal dial, is much more universal than this device by which a declining dial is depicted from the horizontal and descensional circumferences — for by our discovery all the points of the horizontal dial, even if they do not belong to the hours, are transferred into the declining dial, which cannot be done by this other device, since by what method the horizontal and descensional circumferences are to be sought for all the points not belonging to the hours has been handed down by no one. Indeed, on this account too I judge that the earlier method, explained by us, is to be preferred to the later — because it transfers all the hour-lines, or any others whatever, from the horizontal dial into the declining dial, even if the points through which the parallels of the signs are to be drawn have not been found for them. Thus by the first method the line of the 22nd hour from the west can there be drawn through the point l found in the tropic of Capricorn [♋]; but by the second method it cannot be drawn here, through the point d of the same hour found in the same tropic of Capricorn [♋], unless first another point of the same hour is found with the Sun in another sign, as at the beginning of Libra [♎] or of Aquarius [♒].

In this one respect, however, the later method seems to surpass the earlier: that from the horizontal and descensional circumferences there can be drawn, in the declining dial, even those hours which are little distant from sunrise or sunset — say the hours $23\frac{1}{4}$, $23\frac{1}{2}$, $23\frac{3}{4}$, 9, $9\frac{1}{4}$, $9\frac{1}{2}$, and $9\frac{3}{4}$ from the west, and so on — which can scarcely be done by our earlier way, because such hours, since in them the shadow of the gnomon in the horizontal dial is too long, can only with great difficulty be described in the horizontal dial. So much so that, for a complete and perfect description of the hours in declining dials, both ways and methods seem to have to be employed.

END OF THE SIXTH BOOK.

GNOMONICS, BOOK SEVEN.

BY THE AUTHOR CHRISTOPH CLAVIUS [Christophoro Clavio]
OF BAMBERG, OF THE SOCIETY OF JESUS.

Since, in the preceding books, the demonstrations have for the most part been intermingled with the descriptions of the dials — so that to some the subject may seem treated at greater length than is fitting — I think it will be worthwhile if, in this seventh book, for the sake of those who either take less pleasure in geometrical demonstrations, or have not trained themselves in mathematical matters enough to be able to follow them, or finally wish to have the rules for describing dials gathered into one place without demonstrations, I set these out separately, and very briefly present the chief headings by which all the kinds of hours — of which we have treated most fully in the preceding books — can be described on any plane surface whatever, for a given size of style. For thus it will come about that, since the precepts of the descriptions are separated from the demonstrations, and written out separately and distinctly, no impediment or delay at all can hold back the dial-maker in describing the hours. For in the preceding books the course of the description of the dials must again and again be interrupted on account of the multitude of demonstrations, which are everywhere entangled with the precepts; so that scarcely any dial can be described without trouble. And in this matter I shall gratify very many who have earnestly begged this of me.

The method we shall follow in delivering this brevity of precepts will be as follows. Those precepts which are altogether necessary for describing the hours we shall repeat here, so that there is no need to transfer anything from what was written in the preceding books hither for the description of any given dial — except for certain things which make for fuller instruction, or do not pertain to the hours, in which cases the reader will have to be referred back to the earlier books. Nor indeed does it seem necessary here to repeat the division of the hours and of the dials, nor the nature of the hour-circles, nor their position in the heavens, since all these have been explained copiously by us in Book 1 — the division of the hours and of the dials at its beginning, and the position of the hour-circles in propositions 9 and 10. Therefore we shall proceed to the description of the dial.

ON THE ASTRONOMICAL HORIZONTAL DIAL.

CHAPTER I.

[Margin: Description of the astronomical horizontal dial.]

We shall describe the astronomical horizontal dial in this way. In the plane of the dial let a straight line HN be drawn, in any position, for the meridian line; or, if the plane is fixed and equidistant from [parallel to] the horizon, let the meridian line HN be found on it by the methods we set out in our commentaries on the Sphere, where we explained the offices of the meridian circle, or at least as we taught in the scholium of proposition 23, Book 1, of this Gnomonics. Then, having chosen the place of the style at the point G, and having drawn the straight line GD perpendicular to HN, let GD be taken equal to the proposed style of whatever size. With D as centre, let the arc of the circle ABC be described; and drawn toward the southern parts — that is, toward A — let the complement of the pole's altitude, BA, be counted off, and toward C the pole's altitude itself, BC; and let the straight lines DA, DC be drawn (of which the former represents the axis of the world, the latter the common section of the equator and the meridian), cutting the meridian line at the points H and I. Through the point I let the perpendicular FK be raised to the meridian line.

[Margin: The centre of the dial.] [Margin: The equinoctial line.]

H will be the centre of the dial, in which of course all the hour-lines will intersect one another; and the straight line Fk will be the equinoctial line — namely the common section of the equator and of the plane of the dial — on which, when the Sun is at the equinoxes, the shadow of the style falls at each hour and each moment of the hours. Also, taking the straight line IE equal to ID, describe from E a circle at any interval; and dividing it into 24 equal parts, beginning from the meridian line HN, draw through the division-points and the centre E hidden straight lines cutting the equinoctial line Fk at points, through which — and through the point H — straight lines drawn out will give the lines of the hours from noon or midnight, in the plane which is equidistant from [parallel to] the horizon.

[Margin: The hour-line.]

But for the sixth hour, the line CL is to be drawn through H, perpendicular to HN, per-

perpendicular to HN — that is, parallel to FK. Now these hour-lines can be extended through the point H infinitely in both directions, although for the sake of neatness we have terminated them at the circumference of a circle described from centre H at whatever interval you please. You will find the demonstration of this construction in the scholium to proposition 1, Book 2.

[Margin: Which hours are before noon, and which after noon.]

The portion of the meridian line running from the centre H toward the equinoctial line marks the 12th hour of midday, and the remaining portion, beginning from the same centre H, marks the 12th hour of midnight. The hours placed to the right of the meridian line — that is, toward the point L — are the forenoon hours, while the afternoon hours lie to the left of the same meridian line, that is, toward the point C. Thus the hour next to the 12th hour of midday on the side of C is the 1st hour after noon, the next the 2nd, and so on for the rest, as the figure shows.

Diagram. The astronomical horizontal dial completing Chapter I. A large circular (here drawn as a full round) dial with its centre at **H**, from which the hour-lines radiate. The vertical meridian line runs through **M** (top) and **N** (bottom); the horizontal line through the centre carries **F** on the left and **K** on the right, with **L** just above K on the right and **C** above the centre-line on the left (C lies on the 6-o'clock line). Near the centre are the construction points **G**, **D**, **I**, with **E** on the meridian below the centre, and **A** on the upper-left rim; **B** marks a dashed line crossing the left half. The circumference is numbered with the hours (the numerals 1 through 12 appear around the rim, the forenoon hours toward L and the afternoon hours toward C).

- H (centre): meeting-point of all the hour-lines
- M (top of meridian) / N (foot of meridian, marked with the 12th hour)
- F (left) — K (right): the horizontal (equinoctial) line
- L (right, above K), C (left, on the 6-o'clock line)
- A (upper-left rim), B (dashed line, left half)
- D, G, I (near centre); E (on the meridian below centre)
- Rim: hour-numbers 1–12 around the circumference
- Two worn zodiac sign-glyphs mark dashed arcs on the left [zodiac glyph: ⚈ Taurus (?), worn] [?]

Now, if no error has been made, the intervals of the hours in the portion IF of the equinoctial line will be equal, one by one, to the intervals of the hours in the other portion Ik. Likewise the arcs of the circle described from H that lie between

the meridian line HN and the hours on the left side will be equal, one by one, to the arcs of the same circle intercepted between the meridian line and the hours on the right side. Therefore one must take care that intervals of this kind are equal to one another, if an accurate marking of the hours is desired.

[Margin: How half-hours and quarter-hours are to be marked on the dial.]

But if one wishes to mark on the dial the half-hours as well, and the quarter-hours — indeed the eighth-parts, and so on — then each of the parts of the circle described from E must be divided into two equal parts, or four, or eight, and so on; the rest is then completed as before. This is to be observed in the other dials that follow as well.

[Margin: How the style is to be placed.]

The style, or gnomon GD, must be erected upon the dial at right angles from the point G, as we showed in proposition 12, Book 4. For in this way the tip of the shadow, falling upon the hour-lines, will indicate the hours, and the apex of the style itself will touch the axis of the world, which is extended from H through the arctic pole to the point D, so that HD represents the axis of the world. And if the triangle HDI is erected at right angles upon the plane of the dial along the meridian line HN, the shadow of the axis HD will likewise indicate the same hours — provided the dial is set on a plane parallel to the horizon in such a way that the line HN represents the meridian line, with the point H turned toward the south and I toward the north.

[Margin: How the horizontal dial is to be positioned so that it indicates the hours.]

By what device the elevation of the pole is to be found — for in order that the dial be correctly laid out in the given region, one must know the elevation of the pole above the horizon of that place, together with its complement, as is clear from the construction already given — we have taught in the *Use of the Astrolabe*, in the *Cosmography*, and in our *Commentaries on the Sphere* (where we treated of the offices of the meridian circle), and also in the 2nd scholium to proposition 28, Book 1, of this Gnomonics.

ON DESCRIBING THE ARCS OF THE SIGNS ON THE HORIZONTAL DIAL.

CHAPTER II.

The ray of the Sun, when the Sun is on the equinoctial circle, describes by its daily motion a circle about the centre of the world — namely the Equator itself. But when the Sun dwells on any other parallel, on this side of the equinoctial circle or beyond it, the same ray, drawn out through the centre of the world, describes two conical surfaces joined together at the centre of the world as at their apex, whose bases are two opposite and equal parallels. For instance, when the Sun is at the beginning of Cancer (♋) or Capricorn (♏), the bases of the said conical surfaces are the tropic of Cancer and the tropic of Capricorn — all of which we demonstrated in Book 1, proposition 3. And since the plane of any dial, cutting these conical surfaces, makes either a circle, a parabola, a hyperbola, or an ellipse (because it does not pass through their apex, that is, through the centre of the world), as is established from the *Conics* of Apollonius [Apollonius of Perga] and as we showed in the same Book 1, propositions 4, 5, 6, and 7; and since the shadow of the gnomon does not depart from these sections when the Sun is on that parallel which is the base of the conical surface, as we demonstrated in the same Book 1, proposition 12 — it follows that the arcs of the signs which the gnomon's shadow describes on the dial, when the Sun is at the beginnings of the signs, are either circles, or parabolas, or hyperbolas, or ellipses; except when the Sun is on the equinoctial circle, for then the gnomon's shadow describes a straight line,

as is clear from corollary 2 of proposition 11 of the same Book 1. In which particular dial these arcs of the signs are circles, parabolas, hyperbolas, or ellipses we have shown fully in Book 1, propositions 4, 5, 6, and 7, and in their scholia. For now, let it be taken as certain that arcs of this kind, on the equinoctial dial, are circles everywhere among all nations; whereas on the horizontal dial of a latitude less than $66^{\circ} 30'$, and both on the meridian dial and on the polar dial of any region whatever, and on the vertical dial of that place where the elevation of the pole above the horizon is greater than $23^{\circ} 30'$, they are hyperbolas.

[Margin: Construction of the figure of the rays of the Zodiac, from which the arcs of the signs on the horizontal dial are drawn.]

Therefore, in order to mark out these arcs — whatever their shape may be — we must first prepare the figure of the rays of the Zodiac together with the hour-

lines, in the following way. Let a line AH be drawn crosswise, in any position, to represent the axis of the world, and let DC be raised perpendicular to it, for the equinoctial ray. Then from D let the arc of a circle NO be described; on it, reckoning off the maximum declination of the Sun, $23^{\circ} 30'$, toward both sides of the Equator's ray DC as far as the points N and O, let the straight line NO be drawn, cutting DC at the point R. From R as centre, upon the diameter NO, let a circle be described and divided into 12 equal parts, beginning from the line NO (or from the Equator's ray DC). After this, let any two points equally distant from the point N or O be joined by straight lines cutting the arc NO at points; and through these points, straight lines drawn out from D will give the rays of all the signs of the Zodiac, as appears in the figure.

[Margin: The drawing of the rays of the signs in the figure of the rays of the Zodiac.]

After this, from the triangle HDI of the figure of the preceding chapter, let there be transferred onto the axis AH of the figure just constructed — from D leftward — the line DH, and onto the Equator's ray DC — downward — the line DI; and from H, through I, let the line HI be drawn out, of whatever length, for the 12th hour, which perhaps we shall more conveniently draw as follows. From H, toward D, let the arc of a circle AB be described at any interval, from which let an arc AB be cut off equal to the elevation of the pole. For the line HB, once drawn, will be the line of the 12th hour, and it will pass through I. Then, from the centre E of that circle in the figure of the preceding chapter — by whose aid we found the hour-points on the equinoctial line FK — let the intervals be taken as far as the points where the equinoctial line FK is cut by the hour-lines, and let them be transferred from the point D of the figure just constructed onto the Equator's ray DC, marking points on the Equator's ray itself, through which lines are then drawn out from H. Finally, through H let HV be drawn parallel to the Equator's ray DC; and if need be, the lines proceeding from H and cutting the Equator's ray DC are to be carried over, with the aid of the compasses, to the left-hand parallel AV. This is easily done if, from centre H, an arc of a circle LQ is described cutting the parallel HV at P; for if we transfer the distance PL from P to Q, the line drawn from H through Q will have the same distance from the line HV that the line HL has, and so on. For the lines proceeding from H will be the lines of the other hours after the 12th hour, whose number corresponds to the number of those intervals which were transferred onto the Equator's ray from the centre E of the figure of the preceding chapter — so that the line nearest to HB gives the 1st and 11th hour, the next the 2nd and 10th, and so on. But if we transfer the hour-lines lying between H (the centre of the dial of the preceding chapter) and the

equinoctial line FK onto the Equator's ray DC in the next figure, from H, marking points on the Equator's ray DC, and through these draw straight lines from H, we shall obtain the same hour-lines.

[Margin: Another way of drawing the hour-lines in the figure of the rays of the Zodiac.]

We shall also very conveniently draw these hour-lines proceeding from H without transferring the hour-intervals between the centre E (or H) and the equinoctial line FK onto the Equator's ray DC, in this way. On the line HI, extended, we shall take any point * [printed as a solid asterisk-like point-mark], through which we shall draw a line *V parallel to AH, and through H another parallel HV to DC, which cuts *V at V. Then, with V as centre and V* as radius, we shall describe a circle and divide it into 24 equal parts, beginning from the point *. For if we join any two points equally distant from * by hidden straight lines cutting the line *V at points, the lines drawn from H through these points will give the hour-lines, as before. And if the several arcs of the circle described from V are each bisected — and divided into four equal parts — we shall in the same way draw, in the figure of the rays of the Zodiac, the hour-lines that pertain to the half-hours and their quarters.

[Margin: Yet another, most elegant way of drawing the hour-lines in the figure of the rays of the Zodiac.]

[Margin: How one may recognize from the figure of the rays of the Zodiac which of the arcs of the signs to be drawn on the dial are hyperbolas, parabolas, or ellipses.]

From this figure of the rays of the Zodiac we shall easily understand which of the arcs of the signs to be drawn on the dial are hyperbolas, and which parabolas or ellipses. For whenever the line HB cuts two rays of opposite signs — such as Cancer (♋) and Capricorn (♏); Gemini (♊) and Sagittarius (♐)[the second glyph worn — pinned by the "opposite signs" context] [?]; Taurus (♉) and Scorpio (♏) [likewise worn — pinned as the opposite of Taurus] [?]; and so on — the arcs of those opposite signs are opposite and equal hyperbolas. But when the same line HB does cut the ray of any given sign between the lines HV and DC, yet is parallel to the ray of the opposite sign, then the arc of the sign whose ray is cut is a parabola, while the arc of the other, opposite sign cannot be drawn. And finally, when the line HB cuts one ray between the lines HV and DC, but with respect to the ray of the opposite sign is neither parallel to it nor cuts it (unless it is

extended beyond the point D), then the arc of the sign whose ray is cut is an ellipse, while the arc of the other, opposite

Diagram. The figure of the rays of the Zodiac together with the hour-lines (*figura radiorum Zodiaci*), a dense construction filling the outer half of the page. Along the top horizontal line (the axis **AH**) run the points **H**, **D** (repeated), and **A** at the right end, with the perpendicular Equator's ray descending from D. At the right is a small subsidiary construction carrying the letters **H**, **L**, **D**, **G**, **K**, **M**, and **I** (the triangle HDI / DLM of the style-scaling construction). Within the fan of lines appear the further construction points **C**, **R**, **N**, **B**, **P**, **V**, and **Φ**, and two rays are labelled "Rad. hor." (*radius horæ*, "ray of the hour") — one apparently "0", one "10". The radiating lines are numbered with the hours (numerals from 1 to 12 are visible), and small zodiac sign-glyphs are set along the NO arc near the centre. The figure is too densely overprinted for every peripheral label to be resolved with confidence.

- H, D, A: points on the axis AH (top horizontal); Equator's ray DC perpendicular at D
- Right-hand subsidiary triangle: H, L, D, G, K, M, I
- C, R, N, B, P, V, Φ: construction points within the fan
- "Rad. hor." ray-labels (*radius horæ*): apparently 0 and 10 [?]
- Hour-numbers 1–12 along the radiating lines
- Small zodiac sign-glyphs along the NO arc near the centre [several not individually resolved] [?]

[Diagram fig-p497-1: more than 2 peripheral labels unresolved]

sign cannot be drawn. All of which we demonstrated in Book 1. We shall recognize the same thing in the other dials, if — on declining dials — we take the style-line in place of the meridian line, and in the figure of the rays of the Zodiac the index-line in place of the line of the 12th hour, as will be clear from what follows. In that case the line HB (which on the horizontal dial is the line of the 12th hour, but on declining dials is the style-line) will cut the rays of opposite parallels whenever the angle DHI — the elevation of the pole above the plane of the dial, which the line HB makes with the axis AH — is smaller than the angle ADN, the opposite and exterior angle which the ray DN of the opposite sign makes with the same axis AH (an angle equal to the complement of the declination of the opposite sign). But when the said two angles are equal, the line HB will be parallel to the ray of the opposite sign. And finally, when the former is greater

than the latter, the line HB will neither cut the ray of the opposite sign nor be parallel to it, as is established from proposition 28 of Book 1 of Euclid [Euclid].

[Margin: The drawing of the arcs of the signs on the horizontal dial.]

These things thus accomplished, we shall draw the arcs of the signs in the following way. From the figure of the rays of the Zodiac constructed so far, we shall take the portion of the 12th-hour line HB intercepted between the point H and the ray of Cancer (♋), and transfer it into the dial — which for this purpose ought to be drawn with hidden lines, so that afterwards only those lines lying between the arc of Cancer and the arc of Capricorn (♑) become visible, since all the others are superfluous (inasmuch as the style's shadow cannot fall upon them) — carrying it from the centre H onto the meridian line toward the equinoctial line, and marking a point on the meridian line. Then in the same way we shall take the portion of the line of the 1st and 11th hour lying between the same point H and the ray of Cancer, and carry it over into the dial from the centre H onto the lines of the 1st and 11th hour toward the equinoctial line, again marking two points on these hour-lines. And so we shall proceed with the remaining hour-lines that cut the ray of Cancer, always transferring the intervals of them enclosed between H and the ray of Cancer into the dial, from the centre H onto the corresponding hour-lines, marking points upon them. It must be observed here, however, and in what follows, that the intervals of the lines falling from H toward the Equator's ray DC are to be transferred from the centre of the dial H onto those hour-lines which run from H toward the equinoctial line Fk, as we have done in the lines of the 12th, 1st, and 11th hours, and so on. But the intervals of the lines falling from H onto the other side of the line HV — such that they cannot cut the Equator's ray DC — are to be transferred onto the dial's lines from H, onto those lines which, beyond the centre of the dial, ever more and more

Diagram. The figure for drawing the arcs of the signs on the horizontal dial. From a point **H** at the top centre, rays fan downward across the width of the page. Flanking the fan are two tall boxed panels of six cells each, labelled in vertical lettering: on the left **ASCENSVS SOLIS** ("the ascent of the Sun") and on the right **DESCENSVS SOLIS** ("the descent of the Sun"). The left panel's cells carry, top to bottom, the zodiac glyphs ♊ (Gemini), ♉ (Taurus), ♈ (Aries), ♛ (Pisces), ♒ (Aquarius), ♑ (Capricorn); the right panel's cells carry, top to bottom, ♋ (Cancer), ♌ (Leo), ♍ (Virgo), ♎ (Libra), ♏ (Scorpio), ♐ (Sagittarius). Within the fan the construction points **F** (left), **K** (right of centre), **D**, **G**, **M** near the centre, and **Φ** (lower centre) are visible, with **X** labelling a ray toward the upper left. The rays

are numbered with the hours (6, 5, 4 toward the left; 6, 7, 8 toward the right; and the smaller numerals 1–3 and 9–12 near the centre foot).

- H (top centre): the dial's centre, from which the rays issue
- Left panel **ASCENSVS SOLIS**: Π $\propto$ Υ $\times$ $\approx$ $\mathfrak{V}$ (top to bottom)
- Right panel **DESCENSVS SOLIS**: $\mathfrak{S}$ $\mathfrak{Q}$ $\mathfrak{M}$ $\mathfrak{L}$ $\mathfrak{N}$ $\mathfrak{X}$ (top to bottom)
- F, K, D, G, M, Φ : construction points within the fan
- X: a ray-endpoint toward the upper left
- Hour-numbers along the rays: 4, 5, 6, 7, 8 to the sides; 1–3, 9–12 near the centre foot
- A few small labels near the crowded centre not individually resolved [?]

[Diagram fig-p498-1: more than 2 crowded central labels unresolved]

recede from the equinoctial line — as here onto the hour-lines that fall above the line of the 6th hour and do not cut the equinoctial line, such as, in the example, the lines of the 7th hour after noon and the line of the 5th hour after midnight, and so on. The points of these, however, are not marked on our dial, on account of the narrowness of the space. Once the points have been marked in this way on the hour-lines, if we draw through them a properly curved line that nowhere forms angles, we shall have drawn the arc of Cancer, which the tip of the gnomon's shadow describes when the Sun is at the beginning of Cancer. In no other way shall we draw the arcs of the other signs: we transfer the hour-intervals lying between H and the rays of the signs into the dial, from the centre H onto the corresponding hour-lines, and so on. We shall delineate the same arcs of the signs if we transfer the hour-intervals comprised between the Equator's ray and the rays of the other signs onto the corresponding hour-lines in the dial, beginning from the equinoctial line, and so on.

[Margin: Another way of drawing the arcs of the signs.]

Now if, from the outlines described so far, a larger or smaller dial is to be laid out — according as a gnomon larger or smaller than DG is given — it will be done in this way. Let the triangle HDI — contained in the dial of the preceding chapter, or in the figure of the rays of the signs of this chapter — be drawn separately, together with the style DG; and from the line DG, extended, let a line DK be cut off equal to the smaller or larger proposed style; and through K let LM be drawn parallel to HI, cutting DH and DI, extended, at L and M. Then from the triangle DLM let the axis DL be taken and transferred into the figure of the rays of the Zodiac of this chapter, from H as far as D, so that HD is equal to the axis DL of the said triangle. If, then, from D a perpendicular line DM is dropped to HD, for the

Equator's ray, and from D the rays of the other signs are drawn out — as we taught in this chapter (though, to avoid confusion of lines, they have not been drawn in the figure) — the arcs of the signs will be drawn, in proportion to the given style DK, as before, provided the intervals of the hour-lines proceeding from H, lying between H and the rays of the signs now described (which hour-lines indeed ought not to be changed, even if a larger or smaller dial is to be drawn, at the same elevation of the pole), are transferred onto the hour-lines...

[Margin: By what method a larger or smaller dial, for a larger or smaller style, is drawn from the figure of the rays of the Zodiac.]

drawn (as concealed construction lines) onto the hour-lines of the dial — which likewise remain unchanged at the same elevation of the pole — from the point H, and so on.

The equinoctial line, however, must be drawn on the dial perpendicular to the meridian line, through a point that lies as far from the dial's centre H as the segment HM in the figure of the zodiacal rays — the segment intercepted between H and the ray of the Equator just now drawn. And just as, on the dial, the segment HI between the dial's centre and the equinoctial line is equal to the segment HI in the figure of the zodiacal rays between H and the ray of the Equator, so the triangle HDI is drawn beside the figure of the zodiacal rays.

How the arcs of the southern signs may be drawn more accurately from the arcs of the northern signs — and also by what method the two arcs of two opposite signs can be depicted by one and the same operation (namely when, in the figure of the zodiacal rays, the straight line HB cuts the rays of the opposite signs), a thing both very pleasant and very useful to know — you will find explained in Book 2, Proposition 2.

[Margin: The drawing of the arcs which the shadow traverses when the Sun, outside the beginnings of the signs, stands at other points of the Zodiac.]

Now if we take the declinations of other points of the Zodiac on the arc NO of the figure of the zodiacal rays, and send out their rays from the point D, we shall draw the arcs of those points on the dial — the arcs, that is, that the tip of the shadow traverses when the Sun stands at those points of the Zodiac — by the same technique with which we drew the arcs of the signs.

[Margin: The drawing of the arcs which the shadow traverses on any given day of the month.]

Indeed, take the first day of any month (or any other day you please): find the Sun's place in the Zodiac on that day and its declination, and, allowing for the declination of that point, draw from the point D of the aforesaid figure of the zodiacal rays the ray of that zodiacal point which the Sun occupies. In the same way there will be drawn on the dial a certain curved line, which the tip of the shadow traverses on that appointed day.

[Margin: The drawing of the saints' feast-days on the dial.]

By this method the feast-days of the saints can be drawn on the same dial — that is, certain curved lines that the style's shadow traverses on those days. Indeed the parallels of cities lying between the two tropics will be drawn in the same way, if their rays are drawn, and so on.

[Margin: What may be attached to the arcs of the signs drawn on the dial.]

To all these arcs — or curved lines — one may attach the characters of the signs, the days of the months on which the shadow's tip traverses them, and also the time of sunrise, the lengths of the days and of the twilights, and other such things; as, in the Italian and Babylonian dials (which we shall treat a little further on), the time of noon, and so on. For this purpose certain lines must be drawn parallel to the meridian line itself, both to the left and to the right; and the farther these are from the meridian line, the greater the interval of time at which the gnomon's shadow will be caught on the dial, as appears in the dial of this chapter.

Finally, since the Sun ascends from Capricorn [♑], through Aries [♈], up to Cancer [♋], and from Cancer descends through Libra [♎] down to Capricorn, the words ASCENT OF THE SUN [ASCENSVS SOLIS] can be set beside the first six signs, and beside the latter six the words DESCENT OF THE SUN [DESCENSVS SOLIS].

DE ARCVBVS LONGITVDINVM DIERVVM in eodem horologio horizontali describendis.

[On drawing the arcs of the day-lengths on the same horizontal dial.]

CAPVT III.

[Margin: In what way the rays of the day-lengths are drawn.]

Just as in the previous chapter we drew the arcs that the tip of the style's shadow traverses when the Sun is at the beginnings of the signs, or at any other point of the Zodiac, so now we shall delineate other arcs, which the same shadow describes when the artificial day contains a proposed number of hours — such as 10, or 11, or 13, and so on. These arcs are drawn in exactly the same way as the arcs of the signs, provided that, in the figure of the zodiacal rays of the preceding chapter, in place of the rays of the signs one draws from the point D the rays of the day-lengths.

These rays of the day-lengths will be drawn by the following device. Draw the straight line AB; from A describe an arc of the circle CBD, and on it, starting from the point B, lay off on either side the arc equal to the complement of the pole's elevation, as far as the points C and D. Then draw the straight line CD, cutting AB at E; and from the centre E, with radius EC (or ED), describe a circle. Divide it into 48 equal parts, and join by straight lines any two points equally distant from C (or from D); these lines cut the line CD at points through which the straight lines drawn from A will be the rays of the day-lengths. They will also indicate the declinations of those parallels whose diurnal arcs comprise the said day-lengths — so that the straight line AD is the ray of a diurnal arc of no hours (that is, the ray of that parallel which is always the greatest of the hidden ones), the next line is the ray of a diurnal arc of one hour, the one after of two hours, and so on; so that the ray of the Equator, AB, is that of 12 hours, and AC that of 24 hours — that is, the ray of that parallel which is always the greatest of the visible ones.

We have drawn these rays of the day-lengths here separately, and not in the figure of the zodiacal rays of the preceding chapter, lest the multitude of lines should breed confusion. Therefore, to draw the length-arc of any day whatever, take in this figure the arc between B and the proposed ray, and cut off an equal one from the arc NO in the figure of the zodiacal rays of the preceding chapter, beginning from the ray of the Equator. This will easily be done if, in the figure of the zodiacal rays, one describes from the point D an arc with radius equal to the semidiameter AB of the arc CBD of the figure of this chapter. For then, in the arc thus described in the figure of the zodiacal rays, one must take an arc equal to the arc between B and the proposed ray, and through the end of this arc a line must be drawn from D — as a concealed construction line — to serve as the ray of that day. For this line will cut off from the arc NO a similar arc, and so on. From this ray the arc of that day will be drawn, just as the arcs of the signs were drawn from the rays of the signs, and so on. Into the figure of the zodiacal rays of the preceding chapter we have trans-

Diagram. A construction for the rays of the day-lengths. A circle is drawn with horizontal diameter CD and centre E; A stands at the top and B at the bottom of the vertical diameter, so that A, E, B are collinear. From the apex A a fan of straight lines (the rays of the day-lengths) is drawn down to division points marked along the lower arc CBD. The arc is graduated with day-length hour numbers.

- A (top apex): vertex from which the rays are emitted
- B (bottom of arc): point of the 12-hour (Equator) ray; ray AB
- C (left end of diameter): endpoint of the 24-hour ray; ray AC
- D (right end of diameter): endpoint of the 0-hour ray; ray AD
- E (centre): intersection of CD and AB
- Along the lower arc, day-length hour numbers are marked. Legible on the left (toward C): 16, 15, 14, 13; at the bottom near B: 12; toward the right (D side): 11, 8, 7, 6, 5. The intervening numerals 9 and 10 are present but not fully resolvable [numeral:?].

[Margin: The drawing of the arcs of the day-lengths on the horizontal dial.]

—ferred the rays of the day-lengths of 14 and 10 hours, likewise of 18 and 6 hours, and of 24 and 0 hours, marked with certain dots so that they may not be confused with the rays of the signs; for it is chiefly these that we shall need in what follows. And from what we wrote in the preceding chapter we shall easily judge which diurnal arcs are hyperbolas and which are parabolas or ellipses, if — in place of the rays of opposite signs — two opposite diurnal rays are drawn from the point D in the figure of the zodiacal rays of that chapter, that is, rays equally distant from the ray of the Equator.

DE HOROLOGIO HORIZONTALI Italico, & Babylonico.

[On the horizontal dial, Italian and Babylonian.]

CAPVT IIII.

[Margin: The description of the horizontal Italian and Babylonian dial.]

Let the circle described about the centre E in chapter 1 be cut into 24 equal hours, beginning from the point N; and on both sides of N count off the semidiurnal arc of the parallel of Cancer — at latitude 42 degrees this is 7 hours 32 minutes — as far as the points a and b, and draw the straight line ab, in such a way that, once the circle NaMb is set as the parallel of Cancer, the arc aNb is the portion of it

above the horizon, and aMb the portion below the earth. Again, on both sides of N reckon off the semidiurnal arc of the parallel of Capricorn — at the same latitude of 42 degrees this is 4 hours 28 minutes — as far as the points d and e, and draw the straight line de, so that, with the circle NdMe set as the parallel of Capricorn, the arc dNe is the portion of it above the horizon, and dMe the portion below the earth. The same circle MadNeb can also be divided in another way into the diurnal arc of Cancer and of Capricorn, as we taught in the scholium to Proposition 1 of Book 1.

By means of this circle we shall construct the Italian dial in the following way. Let the said circle be divided into 24 equal hours, beginning from the point b — which, when the dial is set in its proper position, faces west. Through the points of division and the centre E draw concealed straight lines cutting the equinoctial line at points; and if through these points other concealed lines are drawn from H, the dial's centre, the tropic of Cancer will be cut at points through which are to be drawn

Diagram. The horizontal Italian-and-Babylonian dial construction — a dense figure showing the meridian circle, the two tropic-parallel circles, the equinoctial line, and the fan of hour-lines converging on the dial centre. Because the figure is very crowded and many of its small labels do not resolve cleanly even at high magnification, several labels are flagged.

- M (top): upper end of the vertical meridian diameter
- N (bottom): lower end of the meridian diameter (start of the hour-division)
- H (left, on the horizontal line): the dial's centre
- n (right end of the horizontal / equinoctial line) [?]
- C (near the middle, at the line-crossing): construction point near the centre; an adjacent Greek label α [?]
- a, b (left side): endpoints of the semidiurnal arc of the parallel of Cancer (circle NaMb)
- d, e (left side, lower): endpoints of the semidiurnal arc of the parallel of Capricorn (circle NdMe) [e uncertain: ?]
- m, t (left side): hour-points used in the worked example
- Greek point-labels visible in the figure: α , β , λ [?] (with δ used in the text)
- Large hour-numerals around the rim: on the left 6, 5, 4; on the right 6, 7, 8, 9
- A fan of smaller hour-numerals (running 1–24) is marked along the two tropic arcs; individual values are not cell-by-cell resolvable [numeral:?].

the hour-lines reckoned from sunset, and these should be carefully noted. For example, through the point *f* — the point of the 18th hour from sunset — and the centre *E*, the straight line *fE* drawn cuts the equinoctial line at *g*; and the straight line *Hg* drawn cuts the arc of Cancer at the point *h*, through which the line of the 18th hour from sunset is to be drawn on the dial. The same procedure is to be followed for the rest.

But the hour-points contained between *b* and *u*, and between *a* and *t* — which in our example are the hours 23, 9, and 10 — will be found on the tropic of Cancer in the following way. From the hours that are diametrically opposite these hours in the circle described about *E* (the opposite hours are obtained by adding 12 to those hours, but casting out 24 whenever the sum comes to more than 24 — thus the hour 9 is opposite the hour 21, since 9 and 12 make 21; likewise the hour 23 is opposite the hour 11, because 23 and 12 make 35, from which, if 24 is thrown away, 11 remains, and so on) — from those opposite hours, then, there must be drawn through the centre *E* straight lines cutting the equinoctial line at points; and if straight lines are drawn from *H* through these points, the tropic of Cancer will indeed be cut at the points corresponding to those opposite hours. But if those same lines are extended beyond the centre, the same arc of Cancer will be cut at the points corresponding to the original hours, which are comprised in the arcs *bu* and *at*.

For example: from *m*, the point of the 11th hour (which is diametrically opposite the 23rd hour), a straight line drawn through the centre *E* cuts the equinoctial line at *n*; a straight line *Hn* then cuts the tropic of Cancer at *q*, the point of the 11th hour; and finally, the line *nH* extended beyond *H* cuts the same tropic at the point *p*, through which the line of the 23rd hour is to be drawn. By the same device we shall find, on the same tropic, the points for the 9th and 10th hours, if from the 21st and 22nd hours (which are opposite them) we draw straight lines through the centre *E*, and so on.

The reason for this is that on the tropic there are found, in the first place, the points corresponding to those points of the circle *MaNb* from which the straight lines drawn through *E* pass through *E* before they cut the equinoctial line. Hence, since the straight lines drawn through *E* from the points of the arcs *bu* and *at* do not pass through *E* before they cut the equinoctial line, they

—will first meet, on the tropic, the points corresponding to those opposite points. But then, if those concealed lines are extended through *H*, the points corresponding to the said points will also be found, as we showed in Book 2.

Now if the same circle described about E is cut into 24 equal hours, beginning from the point e (which likewise faces west when the dial takes up its proper position), and straight lines are drawn through the points of division and the centre E, the equinoctial line will be cut at points; and if straight lines are again drawn from H through these points, the tropic of Capricorn will be cut at points through which the hour-lines from sunset are to be drawn. For instance, if from the point δ — the point of the 23rd hour on the tropic of Capricorn — a straight line is drawn through the centre E, cutting the equinoctial line at ϵ , then by the line He extended we shall find, on the arc of Capricorn, the point λ for the 23rd hour from sunset, and so on. And so, if the corresponding hour-points found on the tropics are joined by straight lines, the Italian dial will be drawn.

Furthermore, in the circle MaNb, if the division into 24 parts begins from the point b, then the point b belongs to the 24th hour of Cancer reckoned from sunset, the next point toward N to the 23rd hour, the following one to the 22nd, and so on. Likewise, if the division starts from the point e, the point e corresponds to the 24th hour of Capricorn from sunset, the next toward N to the 23rd, the one after to the 22nd, and so on.

The hour-lines reckoned from sunset will necessarily pass through the points of the equinoctial line where it is cut by the hour-lines reckoned from noon or midnight. Thus the line of the 23rd hour from sunset passes through the point of the 5th hour from noon, and the line of the 22nd hour through the point of the 4th hour, and so on — as is clear from the table we set out in the scholium to Proposition 19 of Book 1, whose title is [THE EQUINOCTIAL LINE / ÆQVINOCTIALIS LINEA], which we have here repeated so far as the whole hours are concerned, so that you may see which hours reckoned from sunrise or sunset, and which reckoned from noon or midnight, intersect one another on the equinoctial line of any dial whatever — and hence through which hours from noon or midnight the hours from sunrise or sunset are to be drawn on the equinoctial line. For each set of three hours in this little table passes through one and the same point of the equinoctial line. The same is to be understood of the fractions of the hours.

Table heading: The hours reckoned from sunrise or sunset, and from noon or midnight, that cut one another at one and the same point of the equinoctial line.

											1	1	1
Hours from sunrise or sunset	I	2	3	4	5	6	7	8	9	0	1	2	
Hours from noon or midnight	VI	VIII	I	X	X	XI	I	I	III	I	V	V	

Hours from sunrise or sunset	I	2	3	4	5	6	7	8	9	10	11	12
	I		X		I	I		I		V		I
Hours from sunrise or sunset	13	14	1	1	1	18	1	2	21	2	2	2
			5	6	7		9	0		2	3	4

But if the hour-points on the tropic of Cancer have no corresponding points on the tropic of Capricorn — as in our example are all the hours before the 16th hour from sunset — the hour-lines must be drawn through the points found on the tropic of Cancer and through the corresponding points on the equinoctial line. These points are found from the aforesaid table given in the scholium to Proposition 19 of Book 1, or from the table just placed here. Thus the line of the 11th hour from sunset must be drawn through the 23rd hour from sunset on the equinoctial line — from which, of course, it is distant by 12 hours; likewise the 10th hour from sunset is drawn through the 22nd hour, the 9th through the 21st, and so on. But the line of the 12th hour from sunset must be drawn through the point found on the tropic of Cancer, parallel to the equinoctial line — that is, to the line of the 6th hour from noon or midnight.

By a not dissimilar technique we shall make the Babylonian dial, if we begin the equal hours from the points a and d, which — when the dial is set in its proper position — lie toward the east: so that the point a belongs to the 24th hour from sunrise on the tropic of Cancer, the next point toward N to the 1st hour from sunrise, the following to the 2nd, and so on. Likewise let the point d denote the 24th hour from sunrise on the tropic of Capricorn, and the nearest point toward N the 1st hour, and so on. For by these points of division we shall find, on each tropic of the dial, the hour-points reckoned from sunrise, just as we said a moment ago of the hour-points reckoned from sunset; and so we shall make the Babylonian dial.

[Margin: The construction of the horizontal Babylonian dial.]

Each dial can also be drawn in another way, from the tables of the diurnal and nocturnal arcs which we compiled in the scholium to Proposition 33 of Book 1. For from these one will understand, quicker than it takes to say, which hours reckoned from sunrise or sunset, and which from noon or midnight, cut one another at one and the same point of the said diurnal and nocturnal arcs. But we have thought it superfluous to repeat those tables here, since they can easily be taken from the said scholium.

[Margin: The drawing of the same Italian and Babylonian dial by means of the diurnal arcs.]

So then, let two diurnal arcs be drawn on the astronomical dial — one of 14 hours and the other of 10 hours — as we taught in the preceding chapter. It will be enough if, at the hours from noon or midnight, the points are marked through which the said arcs must pass, even if the arcs themselves are not drawn. Then let the tables of the diurnal arcs of 10, 12, and 14 hours, which we set out in the scholium to Proposition 33 of Book 1, be carefully examined. For from them you will at once learn through which hours from noon or midnight of the said arcs the hour-lines reckoned from sunrise and sunset are to be drawn.

Thus you see that the 1st hour from sunrise is to be drawn through the 6th hour from midnight on the arc of 14 hours, through the 7th hour from midnight on the arc of 12 hours (which on the dial does not differ from the equinoctial line), and through the 8th hour from midnight on the arc of 10 hours. Likewise the 23rd hour from sunset must be drawn through the 6th hour from noon on the arc of 14 hours, through the 5th hour from noon on the arc of 12 hours, and through the 4th hour from noon on the arc of 10 hours; and so for the rest. But those hours which have no corresponding points on the arc of 10 hours — as in our example are all the hours from sunrise after the 9th hour from sunrise, and all the hours from sunset before the 15th hour from sunset — must be drawn through the points on the arcs of 14 and 12 hours. But the 12th hour from sunrise or sunset must be drawn parallel to the equinoctial line, through the 5th hour from noon and through the 7th hour from midnight on the arc of 14 hours, as is clear from the table of the said arc.

But if it should ever happen that, in the said tables of diurnal arcs, only a single point — or none at all — is found for some hour reckoned from sunrise or sunset that is to be drawn, we shall draw, by means of the same tables, the hour of the other name but of the same number, that is, the hour reckoned from sunset or from sunrise. For this line, extended to the other side of the tropic, will give the required hour reckoned from sunrise or sunset. For example: since the 13th hour from sunrise has, on the arc of 14 hours, only one point — namely the 6th hour from noon — we shall draw the 13th hour from sunset through the 8th hour from midnight on the arc of 14 hours, and through the 7th hour from midnight on the arc of 12 hours, as is established from the tables of the said arcs. For this line, extended to the other side of the tropic, will give the 13th hour from sunrise. Now this 13th hour from sunset, extended through the 6th hour from noon on the arc

of 14 hours, will necessarily pass through the point by which the 13th hour from sunrise must be drawn, as the table of the arc of 14 hours indicates.

Likewise, since the 14th hour from sunrise has no point on the aforesaid diurnal arcs, we shall draw the 14th hour from sunset through the 9th hour from midnight on the arc of 14 hours, and through the 8th hour from midnight on the arc of 12 hours, as is gathered from the tables of these arcs. Again, since the 11th hour from sunset has only one point on the arc of 14 hours — namely the 6th hour from midnight — we shall draw the 11th hour from sunrise through the 4th hour from noon on the arc of 14 hours, and through the 5th hour from noon on the arc of 12 hours, as is drawn out from the tables of the said arcs. For this line, extended to the other side of the tropic of Cancer [♋], will show the 11th hour from sunset, and will necessarily pass through the 6th hour from midnight, by which, that is to say, the 11th hour from sunset must be drawn. And the same reasoning is to be applied to the rest.

[Margin: The construction of the same horizontal Italian and Babylonian dial from the diurnal arc of 24 hours.]

Now the hours reckoned from sunrise and sunset can also be described most conveniently if the diurnal arc of 24 hours is drawn. For straight lines drawn through the hours from noon or midnight on that arc, according to the table of the diurnal arc of 24 hours, and through the hours from noon or midnight on the diurnal arc of 12 hours, will give the hours from sunrise and sunset. For the 23rd hour from sunset passes through the 11th hour from noon on the diurnal arc of 24 hours, and through the 5th hour from noon on the diurnal arc of 12 hours, that is, on the equinoctial line. The 22nd hour from sunset passes through the 10th hour from noon on the arc of 24 hours, and through the 4th hour from noon on the arc of 12 hours. Likewise the 1st hour from sunrise is drawn through the 1st hour from midnight on the arc of 24 hours, and through the 7th hour from midnight on the arc of 12 hours; and so on, as is clearly established from the tables of the said arcs. But the 12th hour from sunrise or sunset is drawn parallel to the equinoctial line — that is, at the 6th hour from noon or midnight — through the point where the arc of 24 hours and the meridian line cut one another, as is established from the same table of the diurnal arc of 24 hours. Indeed, all the hour-lines from sunrise and sunset touch the diurnal arc of 24 hours at the points where it is cut by the hour-lines from noon or midnight that correspond, according to the table of that same arc, to the hours from sunrise and sunset — as is established from what we demonstrated in Proposition 14 of Book 1.

Moreover, once some one hour from sunrise or sunset has been drawn according to the tables of the diurnal arcs, we shall draw the others without great labour through the following points, which correspond to one another, with no further consideration of the tables of the diurnal arcs. For instance, having drawn the 23rd hour from sunset, we shall draw the 22nd through the nearest point on the diurnal arc of 14 hours, through the nearest on the arc of 12 hours, and through the nearest on the arc of 10 hours; likewise the 21st through the other points next following, as appears in the example set out above.

Furthermore, from the very description of the Italian and Babylonian dial it is clear that these two dials differ from one another only in position and in the order of the hours: so that the Italian dial can also serve us for the Babylonian, provided it is inverted, so that the left part becomes the right and vice versa, and so that from the line of the 23rd hour from sunset the 1st hour from sunrise is made, and the 2nd hour from sunrise is made from the 22nd from sunset, and so on. In the example set out above both the astronomical and the Italian hours are contained, together with the Babylonian. The astronomical are hidden, marked only by points; the Italian are 23, 22, 21, and so on; the Babylonian, finally, are 1, 2, 3, 4, and so on. Here too you see that the Italian hours, when extended, give the same hours in number as the Babylonian, and vice versa.

The things we said in Book 1 about the mutual intersection of the hour-lines from noon or midnight with the hour-lines from sunrise or sunset will also contribute very much to the correct description of the Italian and Babylonian dial. For this purpose we also constructed various tables in the scholia to Propositions 19 and 20 of that same book. And in what way both the hours from sunrise and those from sunset are to be described by means of these tables, or, once described, examined, we explained abundantly in Propositions 10 and 11 of Book 2 — so that there is no need to hammer in again here what we wrote there on this matter.

DE HOROLOGIO HORIZONTALI Antiquo.

ON THE ANTIQUE HORIZONTAL DIAL.

CAPVT V.

CHAPTER V.

[Margin: The description of the antique horizontal dial.]

Let the circle drawn from E be cut into the diurnal arc of the tropic of Cancer [☿], a N b, and into the diurnal arc of the tropic of Capricorn [♊], d N e, as we taught at the beginning of the preceding chapter. Then let the diurnal arc of Cancer, a N b, be divided into 12 equal parts, beginning from the point a, the eastern one. For if through the points of division and the centre E we draw hidden straight lines, the equinoctial line will be cut at points through which, if again from H, the centre of the dial, other hidden straight lines are sent out cutting the tropic of Cancer, points will be found through which the lines of the unequal hours must be drawn — exactly as in the preceding chapter we found, on the same tropic, the points of the hours from sunrise and sunset. And if the diurnal arc of Capricorn, d N e, is likewise divided into 12 equal parts, beginning from the point d, the eastern one, we shall find in the same way, on the tropic of Capricorn, the points of the unequal hours. If, then, the corresponding points are joined by straight lines, the antique dial will be described.

Now all the lines of the unequal hours will pass through the hours from noon or midnight on the equinoctial line. For example: from f, the point of the 3rd unequal hour of the tropic of Capricorn, a straight line drawn through E cuts the equinoctial line at g; and a straight line sent out from H through g cuts the tropic of Capricorn at the point h, through which the line of the 3rd unequal hour must be drawn. Again, from the point m, which is opposite the 11th unequal hour of the tropic of Cancer — (for the 11th unequal hour of the tropic of Capricorn is contained in the arc b u; and thus its point on the tropic of Cancer must be investigated by means of the opposite point, as we said, concerning the hours from sunrise and sunset contained in the arcs b u and a t, in the preceding chapter) — a straight line sent out through E cuts the equinoctial line at the point n (which, however, is not contained in the example on account of the narrowness of the space), and the straight line H n cuts the tropic of Cancer at the point p, which belongs to the assumed point m; and n H, extended beyond H, the centre of the dial, cuts the same tropic of Cancer at q, the point of the 11th unequal hour, and so on.

Diagram. A construction figure for the antique horizontal dial: a full circle whose vertical diameter runs from M at the top to a point labelled "N I" [?] at the bottom, with a horizontal diameter carrying the hour-divisions. The centre is E (lower-central), and a dense fan of solid and dotted straight lines radiates from the central region to points on the rim and to the tropic-arcs drawn within the circle. Labels read (positions approximate):

- M (top of circle, upper terminus of the vertical diameter)

- N I [?] (bottom of circle, lower terminus of the vertical diameter)
- q (upper-left, on the circle)
- a (left, on the circle)
- d (lower-left, on the circle)
- f (lower-left, on the circle, below d)
- b (right side, near a dotted line running out to the right)
- e (lower-right, on the circle)
- E (centre of the figure, at the meeting of the fan of lines)
- m / m [?] (left of centre, small gothic letter)
- h (lower-central, to the right of E)
- p (upper-right of centre)
- Hour-numbers along the horizontal diameter, left to right: 11, 10, 9, 8, 7, 6, 5, 4, 3 [?], 2, 1
- Fractional hour-labels near the top and the central cluster: $7\frac{1}{2}$ (upper-left, dashed-line terminus), $4\frac{1}{2}$ (upper-right, dashed-line terminus), and $4\frac{1}{2}$, 3, 2, 1, $7\frac{1}{2}$ clustered about the centre
- Right-hand dashed-line termini: N, and two barred-n symbols [Greek: likely π (pi)] [?] marking line-ends toward the right; u (lower-right of centre)

Several rim and interior labels are small and overwritten by crossing lines; the figure is a (more than 2 labels flagged [?]).

Now, if the six tables of the diurnal and nocturnal arcs of 18, 6, and 12 hours, constructed for the unequal hours in the scholium to Proposition 33 of Book 1, are attentively considered — from which it is known which hours from noon or midnight, whether equal or unequal, cut one another at one and the same point of the said arcs, as we explained more fully in the said scholium to Proposition 33 of Book 1 — we shall also, with easy effort, put together the antique dial, if we first describe the arc of 18 hours. For the 1st unequal hour must be drawn through the $4\frac{1}{2}$ th hour from midnight on the diurnal arc of 18 hours, and through the 7th hour from midnight on the arc of 12 hours, as is clear from the tables of the said arcs. And the 2nd unequal hour must be drawn through the 6th hour from midnight on the arc of 18 hours, and through the 8th hour from midnight on the arc of 12 hours, and so on.

[Margin: The description of the antique horizontal dial by means of the diurnal arcs of 18 and 6 hours.]

DE HOROLOGIO VERTICALI Astronomico. ON THE VERTICAL ASTRONOMICAL DIAL.

CAPVT VI.

CHAPTER VI.

[Margin: The description of the vertical astronomical dial.]

On the plane of the dial, with the place of the style taken anywhere at G, let a straight line HN be drawn through G in any direction, to serve as the meridian line; or, if the plane is fixed and parallel to the vertical circle, let a straight line HN, perpendicular to the horizon, be drawn in the same plane through G by the help of a plumb-line. For this will be the meridian line. Then, through the assumed place of the style G, let a straight line GD be drawn perpendicular to HN, and let GD be taken equal to the proposed style. Then, with D as centre, let the arc of a circle A B C be described. In it, toward A — that is, toward the upper parts, if the dial faces south (such as is the dial we bring forward as an example) — the altitude of the pole, B A, is to be numbered from the straight line D G; and toward C — that is, toward the lower parts — the complement of the same altitude of the pole, B C. But if

Diagram. A construction figure for the vertical astronomical dial, drawn as a semicircle standing on a horizontal diameter, with a dense fan of hour-lines converging on the centre H (the foot of the style). Labels read (positions approximate):

- A (top, apex of the figure)
- Hour-numbers along the upper rim/fan, left to right: 3, 2, I, 12, 11, 10, 9, 8, 7
- C (left end of a horizontal chord, at the "6" mark)
- L (right of centre, on a horizontal chord)
- 6 (left and right ends of the mid-horizontal line)
- H (centre, converging-point of the fan)
- B, F (left of centre, on stepped horizontal lines)
- G (near centre, just below H)
- D (right of centre)
- I / K (central-lower, near the intersections)
- E (below centre)
- U [?] (lower-left of centre)

- S (lower-right, on the rim)
- N (bottom-central, on the rim)
- Lower rim hour-numbers, left to right: 7, 8, 9, 10, 11 (roman "II"), then across the bottom I(?), and on the right 1, 2, 3, 4

The lower-rim numerals and several interior letters are crossed by hour-lines and are hard to resolve; the figure is a (more than 2 labels flagged [?]).

the dial faces north, the arc of the altitude of the pole, B A, must be taken downward, and the arc of the complement of the same altitude of the pole, B C, upward. And when the straight lines DA, DC have been drawn — of which the former represents the axis of the world, and the latter

[Margin: The centre of the dial. The equinoctial line. The hour-line.]

represents the common section of the equator and the meridian — the meridian line will be cut at the points H and I, of which H is the centre of the dial, while through I a perpendicular F K must be drawn to HI, to serve as the equinoctial line. Also, with the straight line I E taken equal to I D, let a circle be described from E to any interval; and this being divided into 24 equal parts, beginning from the meridian line HN, let hidden straight lines be drawn through the points of division and the centre E, cutting the equinoctial line at points through which — and through the point H — straight lines sent out will give the hour-lines from noon or midnight on the plane that is parallel to the vertical circle. But for the 6th hour a line perpendicular to HN, or parallel to the straight line FK, must be drawn through H.

Now the intervals of the hours on the portion I F of the equinoctial line are here also — if there has been no error — equal, one by one, to the intervals of the hours on the other portion I K; likewise the arcs of the circle described from H, placed between the meridian line HN and the hours on the left, are equal, one by one, to the arcs of the same circle intercepted between the meridian line and the hours on the right. Therefore, so that the description of the hours may be accurate, care must be taken that intervals of this kind are equal to one another.

[Margin: In what way each vertical dial is to be set up so that it may indicate the hours. By what means the forenoon hours are distinguished from the afternoon ones.]

The dial must be set up as follows. If indeed it inclines toward the south, HN must be perpendicular to the horizon, and the straight line F k parallel to that same horizon and lying below the point H; but if it faces north, it must be set up so that

N H is perpendicular to the horizon, and the straight line F K parallel to that same horizon and lying above the point H. And so, in the southern dial the point F will be on our left, if we turn our face to the dial, and will incline toward the west, while the point K will be situated on the right and will face the rising sun. From this it follows that the hours placed to the left of the meridian line are the forenoon hours, while those placed to its right are the afternoon hours. Now the portion of the meridian line itself, drawn out from the centre H toward the equinoctial line, will show the 12th hour of noon, and the remaining portion, beginning from the same centre, will show the 12th hour of midnight: so that the hour next to the 12th hour of noon, on the right, is the 1st hour after noon, and the next the 2nd, and so on. Likewise the hour next to the 12th hour of midnight, on the left, is the 1st hour after midnight, and the next the 2nd, and so on.

But in the northern dial the point F will be on our right and will face the east: so that the hours to the right of the meridian line are the forenoon hours, and those to the left are the afternoon hours. Now the portion of the meridian line itself, drawn out from the centre H toward the equinoctial line, will signify the 12th hour of midnight, and the remaining portion, begun from the same centre H, will signify the 12th hour of noon: so that the hour next to the 12th hour of midnight, on the right, is the 1st hour after midnight, the next the 2nd, and so on. Likewise the hour next to the 12th hour of noon, on the left, is the 1st hour after noon, the next the 2nd, and so with the rest, as appears from the figure itself. Hence it follows that the individual hours on the northern dial are the complements of 12 hours, if they are compared with the hours of the southern dial.

[Margin: In what way the style is to be set up.]

Finally, the style D G must be erected above the plane of the dial at right angles at the point G. Or, in place of the gnomon, the triangle D H I must be set up above the straight line H I at right angles to the plane of the dial itself. For the axis D H will indicate the hours by its shadow, as was said concerning the horizontal dial.

DE ARCVBVS SIGNORVM IN HORologio Verticali.

ON THE ARCS OF THE SIGNS ON THE VERTICAL DIAL.

CAPVT VII.

CHAPTER VII.

[Margin: The construction of the figure of the rays of the Zodiac, from which the arcs of the signs on the vertical dial are described. By what method the hour-lines are drawn in the figure of the rays of the Zodiac.]

In order that the arcs of the signs may be described, the figure of the rays of the Zodiac, together with the hour-lines, must be prepared in the following way. Let a line A H be drawn across in any direction, representing the axis of the world, to which let D C be drawn perpendicular, to serve as the equinoctial ray. Then let the rays of the other signs be drawn on either side, as we prescribed in Chapter 2. After this, from the triangle D H I of the figure of the preceding chapter, let there be transferred onto the axis A H of the figure just now constructed — from D, toward the right — the straight line D H, and onto the ray of the Equator, downward, the straight line D I; and from H, through I, let a straight line H I be drawn out to any length, for the 12th hour, which we shall perhaps draw more conveniently thus. From H let an arc of the circle A B be described toward D at any interval, from which let the arc A B be cut off, equal to the complement of the altitude of the pole. For the straight line H B, when drawn, will be the line of the 12th hour, and will pass through I.

Diagram. The figure of the rays of the Zodiac for the vertical dial, drawn as a large fan of straight rays issuing from an upper apex-region and cutting a semicircular arc below; several long dotted rays are labelled with the day-arc to which they belong ("Rad. hor. ...," *radius horæ* — "ray of the hour-arc"). Labels read (positions approximate):

- A (top), with D, D, D, H across the top edge, and "L H," "L" along the upper horizontal
- Left margin, top to bottom: M, I, K, G, M, B
- Interior letters: C, V, R, N, P, Q, L
- Dotted day-arc rays labelled: "Rad. hor. 24," "Rad. hor. 18," "Rad. hor. 14," "Rad. hor. 10," and further "Rad. hor." labels toward the right that do not fully resolve [?] (one appears to read "Rad. hor. 6" [?])

- Hour-numbers along the lower fan, left to right: 12, I, 2, 3, 4, 5, 6, 6, 7, 8, 9, 10 (with a roman "II" near the "12" at far left)

The interior is crowded with crossing solid and dotted lines and several labels are illegible; the figure is a (more than 2 labels flagged [?]).

But if, from the centre E of that circle — by whose help we found the points of the hours on the equinoctial line in the preceding chapter — the intervals are taken up to the points where the equinoctial line F K is cut by the hour-lines, and these are transferred from the point D of the figure just now constructed onto the ray of the Equator D C, by imprinting points on that same ray

Gnomonics, Book VII (Liber Septimus)

[Continuation of Cap. VII — describing the arcs of the signs on the vertical dial]

of the Equator, and from H, through these points, let straight lines be sent out; in this way we shall obtain the lines of the other hours, both before and after the 12th hour. If, however, for the 6th hour, HV is drawn from H parallel to the ray of the Equator D C, and — should it be needed — other lines are carried across to the right parallel to HV, as we described in Chapter 2 when we were treating the horizontal dial. We shall also obtain these hour-lines if, taking from the dial of the preceding chapter the hourly intervals lying between the centre H and the equinoctial line Fk, we transfer them from H, in the figure just now prepared, onto the ray of the Equator D C, imprinting points upon that same ray of the Equator, and then draw straight lines through them from H, and so on. Or else, if on the line HI produced we take a point ϕ anywhere at all, and through it draw a line ϕV parallel to A H, and complete the rest as was described for the horizontal dial. All of this the figure itself shows well enough. From this figure, moreover, we shall recognize which of the signs' arcs are hyperbolas and which are parabolas or ellipses, just as we set out for the horizontal dial in Chapter 2.

From this figure of the rays of the Zodiac, then, we shall describe the arcs of the signs exactly as we did on the horizontal dial: that is, by transferring the hourly intervals of this figure — those intercepted between H and the rays of the signs — into the corresponding hours of the dial, taking them from the centre H, and so on.

Now, when the Sun is on the horizon — that is, at the moment it rises or sets — the shadow of the style is cast into the common section of the horizon and of the plane of the dial, as we showed in Proposition 11 of Book 1; and this line is usually called the horizontal line. If through G, the place of the style, we draw a line parallel to the equinoctial line Fk, or perpendicular to the meridian line, this will be that very horizontal line.

The horizontal line shows, beautifully, at what hour the Sun, situated on any given parallel, rises or sets. For where the arcs of the signs cut the horizontal line, there the Sun rises and sets whenever it is in the signs that those arcs represent. If, then, through those points where the horizontal line and the arcs of the signs cut one another, hour-lines are drawn, these will indicate the times of sunrise and sunset.

Diagram. The southern ("AVSTRALE") vertical dial: a large fan of solid and dotted straight rays issuing from an apex near H at the top, cut by horizontal lines and by the dotted arcs of the signs, with the zodiac scale running down the right-hand edge. The figure is densely crossed by lines and many small labels do not resolve. Readable labels (positions approximate):

- Heading across the top: **AVST-** | **RALE** (split around the figure)
- Apex/upper region: **A, H** (vertical line rising from H); **Hori-** (*horizontalis*, the horizontal line) at left of the mid-line
- Hour-arc ray labels near the top: **IA, IIA** (i.e. rays "1A", "2A")
- **Zon** (*zona* — the equinoctial band) along the mid-line
- Interior letters: **F, R, S, K, M, L** [several further interior letters illegible — ?]
- Right-edge zodiac scale (top to bottom): ♑ [Capricorn], ♎ [Libra] (at **B**), ♍ [Virgo] (mark "np"), ♌ [Leo], and further worn glyphs [?]
- Lower fan hour-numbers (left to right, as printed): **10, Φ, 2, 3** [remaining hour-numbers of the fan illegible — ?]

More than two labels are illegible**

Diagram. The northern ("BOREALE") vertical dial: a shallower fan of dotted arcs and straight hour-lines crossing a horizontal band, with the zodiac scale down the right-hand edge. Readable labels (positions approximate):

- Heading across the top: **BORE-** | **ALE**, with **I** between the words
- **Zon** (*zona* — equinoctial band) along the mid-line
- Interior letters: **K, Q, H** [further interior letters illegible — ?]

- Hour-numbers on the fan: 6, 7 (repeated on either side) [others illegible — ?]
- Right-edge zodiac glyphs: ♍ [Virgo] (mark "np"), ♌ [Leo], and a further worn glyph [?]

More than two labels are illegible**

So you see that the Sun, when it is at the start of Capricorn, rises around hour 7½ from midnight, and sets at about hour 4½ from noon. In Aquarius, and likewise in Sagittarius, it rises a little before hour 7½ from midnight, and sets a little after hour 4½ from noon. In Pisces, finally, and in Scorpio, it rises before hour 7 from midnight, and sets after hour 5 from noon.

This same horizontal line divides the whole dial into two parts. The larger part, in which the equinoctial line is contained, is called the southern (*australe*); the other is called the northern (*boreale*). Both must be so placed that the horizontal line lies parallel to (equidistant from) the horizon and occupies the upper position. On the northern part, however, the hour-numbers are changed into their complements up to 12, as we said above; and the arcs of the southern signs are turned into the arcs of the opposite northern signs. Thus from the arc of Capricorn is made the arc of Cancer; from the arc of Aquarius and Sagittarius, the arc of Leo and Gemini; and from the arc of Pisces and Scorpio, the arc of Virgo and Taurus, and so on. Here too the horizontal line indicates that the rising of the Sun, when it is at the start of Cancer, is a little before hour 4½ from midnight, [and its setting ...] from noon [?], and so on. The horizontal line performs the same office on every other dial, except the horizontal one, on which a horizontal line cannot be drawn, as we demonstrated in the scholium to Proposition 11 of Book 1.

Again, the horizontal line divides the whole dial into those same two parts. The one that lies below it displays the daytime hours, and so may be called the daytime dial; the other part would show the nighttime hours, if the Sun's rays could pass through the earth and illuminate the plane of the dial — and for that reason we may call it the nighttime dial. Hence the portions of the arcs of the signs in the daytime dial may not inappropriately be called day-arcs, and the portions of those same arcs in the nighttime dial night-arcs. In this case, however, the hour-numbers on the nighttime dial ought not to be changed into their complements up to 12, as was done earlier on the northern dial. The same is to be understood in what follows. The nighttime dial, moreover, as being superfluous, will have to be cut away, since during the day it is not lit by the Sun.

If a larger or smaller dial is to be described from the lines so far drawn, for a larger or smaller proposed style, we accomplish this in no other way than we set out for the horizontal dial in Chapter 2. That is: describing the triangle D H I of the dial of the preceding chapter separately, together with its style D G; and taking, on the style D G produced, a straight line D K equal to the given gnomon; and through K drawing a line parallel or perpendicular to D G that cuts the lines D H and D I produced in L and M. For if the axis D L is transferred from the point H of the figure of the rays of the Zodiac up to the point D — the point from which the rays of the signs are drawn out — and the rest is done as before, the arcs of the signs will be described in proportion to the given style D k, and so on.

[Margin, top to bottom of p. 493:] [Margin: *Alia descriptio linearum horariarum in figura radiorum Zodiaci.* — "Another way of describing the hour-lines in the figure of the rays of the Zodiac."] [Margin: *Alia adhuc descriptio linearum horariarum in figura radiorum Zodiaci pulcherrima.* — "Yet another, most elegant, way of describing the hour-lines in the figure of the rays of the Zodiac."] [Margin: *Qui arcus signorum in horologio describendi hyperbolæ sint, aut parabolæ, aut ellipses.* — "Which of the arcs of the signs to be described on the dial are hyperbolas, or parabolas, or ellipses."] [Margin: *Descriptio arcuum signorum in horologio Verticali. Horizontalis lineæ [descriptio].* — "The description of the arcs of the signs on the vertical dial. [The description] of the horizontal line."] [Margin: *Hora ortus, & occasus Solis quo pacto ex linea horizontali cognoscatur.* — "How the hour of sunrise and sunset is known from the horizontal line."] [Margin: *Linea horizontalis totum horologium secat in Australe, ac Boreale.* — "The horizontal line divides the whole dial into a southern and a northern part."] [Margin: *Horizontalis linea diuidit totum horologium in diurnum, & nocturnum.* — "The horizontal line divides the whole dial into a daytime and a nighttime dial."] [Margin: *Qua ratione ad maiorem, minoremue stylum maius, aut minus horologium describatur ex figura radiorum Zodiaci.* — "By what method a larger or smaller dial is described, for a larger or smaller style, from the figure of the rays of the Zodiac."]

DE ARCVBVS LONGITVDINVM DIERVVM in eodem Verticali horologio.

[On the arcs of the day-lengths on the same vertical dial.]

CAPVT VIII.

We shall describe these arcs in the same way the arcs of the signs were described, provided that in place of the rays of the signs we take the rays of the day-lengths, which we laid out in Chapter 3. From these there were transferred into the figure of the rays of the Zodiac of the preceding chapter the rays of the day-lengths of 14 and 10 hours; likewise of 18 and 6 hours; and of 24 and 0 hours. It must be noted, however, that on the northern and on the nighttime dial these arcs are exchanged for their complements up to 24 — that is, the arc of 10 hours is changed into the arc of 14 hours, and the arc of 6 hours into the arc of 18 hours, and so on. Nor will it be difficult to judge which day-arcs are hyperbolas and which parabolas or ellipses, if in place of the rays of the opposite signs one takes the opposite day-rays drawn out from D — that is, equally distant from the ray of the Equator — just as we explained in Chapter 2.

DE HOROLOGIO VERTICALI ITALICO, & Babylonico.

[On the Italian and Babylonian vertical dial.]

CAPVT IX.

Each of these will be described just as the horizontal dial was, as we taught in Chapter 4. For if the description is to be set out by the first method, one must take, for the southern dial, the day-arc of the parallel of Cancer, in the circle described from E by a N b, and the day-arc of the parallel of Capricorn, d N e; and the division of the circle is to begin from the points b and e, the western points, if an Italian dial is to be described, or — if a Babylonian one is proposed for delineation — from the points a and d, the eastern points, proceeding toward N. One must also take the night-arc of Capricorn, on the dial above the horizontal line, so that in it may be found the points of hours 15, 14, 13, and so on from sunset, and 9, 10, 11, and so on from sunrise, which are contained in the night-arc of Capricorn described in the circle from E. For the northern dial, however, the day-arc of the tropic of Cancer will be d M e, and that of the tropic of Capricorn a M b; and the division of the circle will take its start from the points e, b, d, a, and proceed toward M. The tropic of Cancer, too, on the northern dial is the one contained between the centre of the dial H and the equinoctial line, and it

performs the office of the tropic of Capricorn on the southern dial. But let us give an example or two. From *f*, the point of hour 14 from sunset on the tropic of Cancer, a straight line drawn through *E*, the centre, cuts the equinoctial line at some point; and through that point a straight line drawn from the centre *H* will cut the tropic of Cancer, on the southern dial, at the point *h*, through which hour 14 is to be drawn. Likewise, if from hour 14 of the tropic of Capricorn — which is found in the night-arc of Capricorn, *d M e* — a straight line is drawn through *E*, and so on, there will be found in the night-arc of Capricorn the point of that same hour 14 from sunset, which, joined to the point *h*, will give hour 14. Again, a straight line from *m* — the point of hour 1 of Capricorn from sunset, which is set opposite to hour 13 from sunset — drawn through *E*, meets the equinoctial line at *n*. And since the straight line *mE* passes through the centre *E* before it meets the equinoctial line, therefore the straight line *Hn* will give, on the tropic of Capricorn, the point *q*, for hour 1 from sunset; while, produced beyond *H*, it will present on the same tropic the point *p*, for hour 13, as we set out in Chapter 4. By the same method the points of the other hours, both from sunset and from sunrise, will be found on either tropic. For the northern dial we give no example, lest the multitude of lines breed confusion — especially since the northern dial is easily derived from the southern one once it is described, in the following way. Let all the li-

Diagram. A large semicircle (the Italian/Babylonian vertical dial) with **M** at the top of the arc and **N** at the bottom, and the centre **H** near the top of the diameter; a dense pencil of straight hour-lines and dotted arcs fills the interior, with hour-numbers running down both vertical edges. Readable labels (positions approximate):

- Top of arc: **M**; bottom of arc: **N**; centre near top: **H**
- Left-edge hour-numbers (top to bottom): **22, 23**, then below the horizontal, **I (1), 2, B, 13, 14**
- Right-edge hour-numbers (top to bottom): ♄ [Capricorn], **I, 24, 23** ♀ [Gemini], **22, 21, II, 20**
- Interior letters and points: **G, q, d, E** (centre), **b, k, h, e, p, f, m**
- Small inner arc of hour-numbers near the centre: **6 · 15 · 7 · 16 · 8 · 17 · 9 · 13 · 10 · 19** [reading approximate — ?]

The interior is very crowded and several labels do not resolve**

[Margin, p. 494:] [Margin: *Descriptio arcuum diurnorum in horologio Verticali*. — "The description of the day-arcs on the vertical dial."] [Margin: *Descriptio*

horologij Verticalis Italici ac Babylonici. — "The description of the Italian and Babylonian vertical dial." [Margin: *Quo pacto horologium boreale ex australi eliciatur.* — "How the northern dial is elicited from the southern one."]

which belong to the hours from sunrise and which to the hours from sunset — will be understood as follows. Let there be considered, in the nighttime portion of the southern dial (which we said is the northern dial, if that exchange of the parts is made), the hours from sunrise and from sunset. Now all the hours drawn out from sunrise beyond the horizontal line, before they cut the meridian line, are also to be numbered from sunrise in the nighttime portion of the dial; but after they have cut the meridian line, and so cut the tropic again, they are to be reckoned from sunset. Likewise the hours drawn out from sunset are to be numbered, in that same nighttime portion, from sunset before the meridian line, but after it from sunrise. Thus, in the nighttime portion, the following hours — 23, 22, 9, 10, 11 — are to be numbered from sunrise; but these — 1, 2, 13, 14, 15 — from sunset. The same must be said on the dials that follow, if in place of the meridian line one takes the line of the index or style, which on meridian dials is the line of hour 6 from noon or from midnight, while on polar and equinoctial dials the meridian line itself serves, as will be clear in the proper places. Once these things are rightly considered, we shall easily distinguish the hours from sunrise from the hours from sunset on the northern dial. For all the hours that in the nighttime portion are reckoned from sunrise are to be numbered on the northern dial from sunset; and those that there are numbered from sunset are here to be taken from sunrise, as we showed in the scholium to Proposition 23 of Book 2.

As for the other method, which is taken from the day-arcs and night-arcs, there is no difficulty, provided the little tables of the day-arcs and night-arcs — which we set down in the scholium to Proposition 33 of Book 1 — are rightly considered. For hour 24 from sunset is drawn through hour 5 from noon on the day-arc of 10 hours, and through hour 12 from midnight (which is the hour of noon) on the night-arc of 24 hours, which cuts the meridian line at G, the place of the style; and this line of hour 24 is parallel to the equinoctial line — indeed it is the very same as the horizontal line. Hour 23 from sunset passes through hour 5 from noon on the day-arc of 12 hours, which on this dial does not differ from the equinoctial line, and so with the rest. But hour 13 from sunset, since it has no corresponding point on the day-arc of 10 hours, must be drawn through hour 6 from midnight on the night-arc of 14 hours, as is clear from the little table of this arc. Here it must be noted that the hours from noon or from midnight are now not to be changed into their complements up to 12 in the nighttime portion beyond the

horizontal line, as was done above, but are to keep the same number. In no other way shall we draw the hours from sunrise, as appears from the little tables of the day-arcs and night-arcs. For the northern dial there is no need to give an example, because it is described in the same way from the aforesaid arcs, especially since it is obtained from the southern one, as we wrote a little earlier.

Here too those things are of great use which we wrote in Book 1 concerning the mutual intersections of the hours from noon or from midnight with those from sunrise or from sunset among themselves. On this matter consult Proposition 22 of Book 2.

DE HOROLOGIO VERTICALI Antiquo.

[On the antique vertical dial.]

CAPVT X.

Let the same things be done as in Chapter 5, but with this rule: that the division of the day-arc of the tropic of Cancer, a N b, and of the tropic of Capricorn, d N e, into 12 equal parts should begin from the points a and d, the eastern points. For from the points of the divisions we shall find the points of the unequal hours on either tropic, and shall complete the antique dial, as we set out in Chapter 5. For example, on the southern dial a straight line drawn from f — the point of the 4th unequal hour of the tropic of Cancer — through E cuts the equinoctial line at g. A straight line drawn from H through g cuts the tropic of Cancer at h, the point of the 4th unequal hour. Likewise a straight line drawn from m — the point of the 4th unequal hour of the tropic of Capricorn — through E cuts the equinoctial line at n, and the straight line H n cuts the tropic of Capricorn at p, the point of the 4th unequal hour. The straight line joining p and h, therefore, will give the 4th unequal hour, and so on. For the northern dial we give no example, both because it will easily be described from what has been said, and also because the unequal hours on the southern dial, produced beyond the horizontal line, make the northern dial, if that exchange of the parts is made of which we spoke in the preceding chapter.

Diagram. The antique ("horologium verticale antiquum") vertical dial: an upper quadrant of hour-lines fanning from a centre near **H/P**, above a semicircular arc running down to **N** at the bottom, with the unequal (antique) hours marked inside and the ordinary hour-numbers running down both vertical edges.

Readable labels (positions approximate):

- **HORI-** (*horizontalis*) label at the upper left of the horizontal line

- Curved label crossing the upper region: **Arcus horarum** ("arc of the hours")
- Left-edge hour-numbers (top to bottom): **X, IX, IIX** (= VIII), then below the horizontal **I, II, III**
- Right-edge hour-numbers (top to bottom): **II, I, XII, XI, [Y?] [?], IX**
- **ZON** (*zona* — the equinoctial band) across the middle right
- Interior points and letters: **M** (top of arc), **H, P, F, G, a, b, d, e, f, h, m, p, q, n, I, E**, and **N** at the foot of the arc
- Unequal-hour numbers on the inner fan: **IIII, V, VI, VII, VIII** [reading approximate — ?]

Several labels do not resolve**

[Margin, p. 495:] [Margin: *Alia descriptio horologij Verticalis Italici, ac Babylonici ex arcubus diurnis atque nocturnis*. — "Another way of describing the Italian and Babylonian vertical dial, from the day-arcs and night-arcs."] [Margin: *Descriptio horologij Verticalis Antiqui*. — "The description of the antique vertical dial."]

[Margin: *Descriptio alia Verticalis horologij antiqui ex tabulis diurnis*. — "Another way of describing the antique vertical dial, from the day-arc tables."]

But if the day-arc of 6 hours is drawn — which on the northern dial will be the arc of 18 hours — we shall construct the same dial by means of the tables of day-arcs and night-arcs of 6, 12, and 18 hours, which we compiled in the scholium to Proposition 33 of Book I, exactly as was said concerning the horizontal dial.

ON THE ASTRONOMICAL MERIDIAN DIAL

CAPVT XI.

[Margin: *Descriptio horologij Meridiani Astronomici*. — "The description of the astronomical meridian dial."]

Draw a straight line AB anywhere. (If the plane of the dial is fixed and parallel to the meridian, this line must be drawn parallel to the horizon, using a plumb-line.) On it, choose the place of the gnomon at point A, and from A as center, with any radius, describe an arc of a circle BC — toward the left for the dial that faces east, but toward the right for the one that faces west. On this arc mark off the altitude of the equator — that is, the complement of the pole's altitude — as the arc BC, and through A and C draw the straight line AC as the equinoctial line, which the straight line DE cuts at right angles at A. Then take the straight line AE equal to the length of the gnomon (of whatever size you please), and from E as center,

with any radius, describe the circle FGHI. Divide this circle into 24 equal hours, beginning from the line FH, or from the line GI, which cuts FH at right angles.

After this, draw hidden construction-lines through the division-points and through the center E; these will cut the equinoctial line AC in points. Through these points, lines drawn parallel to DE — that is, perpendicular to the equinoctial line — will give the hour-lines reckoned from noon or from midnight. These parallels (or perpendiculars) are easily drawn: through any point of the line AD — say through D — draw a line parallel to AC. For if all the points of line AC are then transferred onto it from D, taking their intervals from point A, the straight lines joining each pair of corresponding points will be equally distant from the line DE, parallel to DE, and parallel to one another.

The order of the hours is this. The line DE gives the 6th hour on both dials. On the eastern dial the line next below it marks the 7th, the next the 8th, and so on; but on the western dial the line next below DE shows the 5th hour, the next the 4th, and so on — as is clear in the figures. Only the 12th hour cannot be drawn, since the meridian circle does not cut the plane of the dial but is parallel to it.

Diagram. The eastern-facing meridian dial (*horologium orientale*). A circle stands on the horizontal line AB, with the word **ORIEN** — **[C]** — **TALE** ("Eastern") set across its top, split by the figure. Readable labels (positions approximate):

- **ORIEN ... TALE** across the top (the point **C** stands between the two halves)
- **K, G** — upper arc
- **B** — on the horizontal line at the left, where the arc BC begins
- **A** — center, at the foot of the gnomon
- **E** — to the right of center
- **N, I, L, S** — lower right region
- **D** — lower left, with the hour-figures **2, 3, 4, 5, 6, 7, 8, 9** running along the adjacent line
- **H** — near the number-column
- A fan of straight hour-lines crossing the circle, with dotted construction-lines.

Several small letters do not fully resolve.**

Diagram. The western-facing meridian dial (*horologium occidentale*). Structure symmetrical to the first. Readable labels (positions approximate):

- **Occi...** at the left and **...dentale** [?] at the right — the word **OCCIDENTALE** ("Western") set across the top
- **r** — far left, on the horizontal line
- **K, G** — upper arc
- **C** — upper center
- **E** — center; **M, R** to its right
- **A** — just below E
- **Q** — below A
- **N, I, L** — lower left; **S** at the lower-left extremity
- **H** — lower right; **B** — right edge
- Hour-figures **2, 3, 4, 5, 6, 7, 8** running along the lower-right edge
- A fan of straight hour-lines with dotted construction-lines.

Several small letters do not fully resolve.**

It is also enough, for describing the meridian dial, to divide a single quadrant of the circle described about E into six equal parts — such as the quadrant FG. For if hidden lines are drawn through the division-points and through the center E, cutting the line AS in points through which the hour-lines (parallel to DE) are to be drawn, then, when these points are transferred from A onto the other side, onto the line AC, we shall have the further points through which the hour-lines are to be drawn — because each segment of the line AS is equal to the corresponding segment of the line AC.

Now if the eastern dial is set up on a plane that is parallel to the meridian and faces east, and the western dial on the same kind of plane facing west — so that the line AB is parallel to the horizon, with point A toward the north and point B toward the south (that is, the angle BAC, equal to the complement of the pole's altitude, is always set toward the south) — then the hours will be indicated by the gnomon AE, standing at right angles to the plane of the dial at point A. But if from any two points of the line DE — say from D and E — two perpendiculars EO and DP, equal to the gnomon AE, are raised to the plane of the dial, and the straight line OP is laid across their tops (or at least a thread is stretched from O to P), then that line or thread will serve as the axis, and its shadow cast onto the hour-lines will likewise indicate the hours from noon or from midnight. Likewise the gnomon AE, if no error has been made in laying out the dial, is always equal to that segment of the equinoctial line which lies between point A and the 3rd (or 9th) hour.

[Margin: *Quomodo vtrumque horologii Meridianu collocandu sit, vt horas indicet.* — "How each meridian dial is to be set up so as to indicate the hours."]

Diagram. A small bracket-shaped figure in the right margin representing the axis: two uprights **EO** and **DP** joined at top by the bar **OP**. Labels: **O** (top left), **P** (top right), **E** (foot left), **D** (foot right).

ON THE ARCS OF THE SIGNS ON THE MERIDIAN DIAL

CAPVT XII.

Draw the straight line DC anywhere as the radius of the equator, and on either side describe the radii of the other signs, as we taught in Chapter 2. Then draw the axis DG perpendicular to the equinoctial radius DC. Transfer onto the equatorial radius DC, from D, all the hour-intervals intercepted between E (the center of the circle FGHI in the preceding chapter) and the equinoctial line AC, marking points on the equatorial radius through which lines are drawn parallel to the axis DG; and to these assign the hour-numbers corresponding to the transferred hour-spaces.

[Margin: *Descriptio arcuu signorum in vtroq; horologio Meridiano.* — "The description of the arcs of the signs on each meridian dial."]

For if the segments of these parallels intercepted between the equatorial radius DC and the radii of the other signs are transferred onto the corresponding hour-lines of the dial, measured from the equinoctial line AC on both sides, marking points on the hour-lines, and if curved lines are then drawn through these points, the arcs of the signs will be described — the upper ones being the southern signs, the lower ones the northern. The line AB is the horizontal line; hence everything found above it must be cut away as superfluous. The parallels to the axis DG are easily drawn through the points marked on the equatorial radius DC, if all their distances, taken from point D, are transferred onto the line GF, drawn parallel to DC anywhere.

Diagram. The rectangular figure of the *arcs of the signs* on the meridian dial. A rectangular frame carries the axis and hour-lines; radii for the zodiacal signs fan downward from near the top-center point **D**. Readable labels (positions approximate):

- Top edge: **G** (left corner), **q**, **D** (center), **k**, **G** (right corner)
- Left edge, hour-figures descending: **12**, **11**, **10**, **9**, **8** and lower **7**; also **2**, **3**, **4** near the equinoctial line; **F** at the left of the equinoctial line

- Right edge, hour-figures: 5, 6, 7, 8, 9, 10; F at the right of the equinoctial line
- Interior points: **B, B, p, p, T, m, l, C** (center-bottom)
- Radial (day-radius) labels, running along the diagonal rays: **Rad. hor. 0, Rad. hor. 6, Rad. hor. 18, Rad. hor. 14, Rad. hor. 10, and Rad. hor. 2[4?]** [?]
- At the lower termini of the rays, a row of zodiac sign-glyphs (Capricorn ♑, Aquarius ♒, Pisces ♓, Aries ♈, Taurus ♉, Gemini ♊, Cancer ♋, Leo ♌, Virgo ♍, Libra ♎, Scorpio ♏, Sagittarius ♐); several individual glyphs do not resolve cleanly [?].

Dense figure; more than two labels uncertain.**

Diagram. The paired dial-faces beneath the horizon line, labelled **HORI — [B] — ZON** ("HORIZON") across the horizontal line AB. From a central point **B** two fans of straight lines diverge, one down to the left (ending near **C**) and one down to the right (ending near **C**). Readable labels (positions approximate):

- **HORI ... ZON** across the horizontal (horizon) line
- **B** — center of the horizon line
- **E, N, H** — points along the fans
- **C** — at the lower end of each fan
- Zodiac sign-glyphs at the ray-termini on both sides (Cancer ♋, Leo ♌, Virgo ♍, Libra ♎, Scorpio ♏, Sagittarius ♐, Capricorn ♑, and others); several do not resolve [?].

Dense figure; more than two labels uncertain.**

transferred onto the line GF, drawn parallel to DC anywhere. For the straight lines joining each pair of points on the lines DC and GF, being equally distant from the points D and G, will be parallel. As for the numbers set beside these parallel lines: those on the right belong to the hours of each meridian dial, while those on the left belong to the hours of each polar dial, of which more shortly. Here all the arcs of the signs are hyperbolas, as we said in Chapter 2.

Moreover, the upper portion of each dial — the part cut off by the horizontal line — gives the dial to be placed on the opposite face of the dial-plane, provided it is inverted: the part now uppermost becomes lowest and vice versa; what is on the right in that position is changed to the left; the hours formerly reckoned from noon are now counted from midnight and vice versa; and finally the northern

signs become southern and the southern northern — as we demonstrated in Proposition 26 of Book II.

Again, the upper portion of either dial would show the hours during the night, if the Sun's rays could fall upon it, as was said above about the vertical dial. For the upper part of the eastern dial contains the hours from midnight to sunrise, while the upper part of the western dial contains the hours from sunset to midnight.

ON THE ARCS OF THE LENGTHS OF THE DAYS ON THE MERIDIAN DIAL

CAPVT XIII.

[Margin: *Descriptio arcuum diurnorum in utroq; horologio Meridiano.* — "The description of the day-arcs on each meridian dial."]

These arcs, which are likewise all hyperbolas, are described just like the arcs of the signs, if in place of the radii of the signs the radii of the day-lengths are taken, as was said in the preceding chapters. In the figure of the zodiac-radii of the preceding chapter we drew the day-radii of hours 0, 24, 6, 18, 10, 14 — which are the straight lines drawn out from D and marked with dots.

ON THE ITALIAN AND BABYLONIAN MERIDIAN DIAL

CAPVT XIV.

[Margin: *Constructio horologij Meridiani Italici, & Babylonici.* — "The construction of the Italian and Babylonian meridian dial."]

In the circle FGHI — by means of which, in Chapter 11, we found the points on the equinoctial line in order to describe the astronomical meridian dial — take the day-arc of Cancer ☊, namely BGC, and the day-arc of Capricorn ☋, namely DGE. This is easily done: on that circle, from point G, count off on either side the semidiurnal arc of Cancer ☊ and of Capricorn ☋, up to the points B, C and D, E. Then divide the same circle into 24 equal parts. For the Italian dial, begin — on the eastern side — from point C, and on the western side from point B, so that both C and B mark the 24th hour from sunset, the next point toward G the 23rd hour, and so on.

Diagram. The large construction for the Italian and Babylonian meridian dial: two overlapping circles (left and right), each drawn about the meridian, densely

crossed by straight and dotted radial lines, with the two 24-hour divisions numbered around and across them. Readable labels (positions approximate):

- Left circle: **M, D, F, B** (upper left), **K** (left), **I**; inner hour-figures **24, 23, 22, 21, 20** and outer **6, 10, 18**; a lower **10, 7, 8, 18**
- Right circle: **L, 12** (top), **G, D, M, F, B** (upper right), **K** (right), **E, E, H, H, C, C, I**; hour-figures **16, 17, 18, 5, 4** and a **12** at the foot
- Central region: a tight web of crossing lines with small hour-numbers (11–24) around the mutual intersection.

Extremely dense; many labels do not resolve individually.**

The contrary is done for the Babylonian dial: that is, on the eastern side the division begins from point B, and on the western side from point G [?], so that both point B and point C give the 24th hour from sunrise, the next point toward G the 1st hour, and so on. For if, for the Italian dial, hidden lines are drawn through the center of the circle from the hours placed between points B and G on each dial, the equinoctial line will be cut in points; and if perpendiculars are raised to it through these points, the tropic of Cancer ☊ will be cut in the points of the hours from sunset. But if, for the Babylonian dial, hidden lines issue through the center of the circle from the hours set between points C and G on each dial, the equinoctial line will be divided in points; and if perpendiculars are drawn to it through these, cutting the tropic of Cancer ☊, we shall have the points of the hours from sunrise on the said...

on the said tropic. In just the same way, on the tropic of Capricorn ☋, we shall investigate the points of the same hours, provided that the division of circle FGHI begins, for the eastern Italian dial, at point E, and for the western at point D; while for the Babylonian dial it begins, for the eastern, at point D, and for the western at point E — always proceeding toward point G. And so, if the mutually corresponding hours on the two tropics are joined by straight lines, both the Italian and the Babylonian dial will have been drawn. Now the hours from sunrise or from sunset necessarily pass through the points of the hours from noon and from midnight on the equinoctial line, as was said above, and as is plainly gathered from the table you will find in Chapter 4.

But if some of the hours from sunrise or sunset have no corresponding points on either of the tropics, those hours are to be drawn through the corresponding hours on the equinoctial line. Thus, on the eastern dial, hours 16 and 17 from sunset — and likewise 4 and 5 from sunrise — are drawn through hours 10 and 11 from midnight on the equinoctial line; on the western dial, hours 19 and 20

from sunset, and likewise 7 and 8 from sunrise, through hours 1 and 2 from noon. The lines of hours 6 and 18, moreover, are to be drawn parallel to the equinoctial line — as we shall show in Book 2, Proposition 34 — through the points found on the tropics of each dial.

[Margin: *Alia descriptio horologij Meridiani & Babylonici per arcus diurnos, ac nocturnos.* — "Another way of describing the meridian [Italian] and Babylonian dial by means of the day-arcs and night-arcs."]

By means of the day-arcs and night-arcs of hours 14 and 10 we shall likewise describe each dial, just as we set out for the horizontal and vertical dials. The same can be done by means of the day-arc and night-arc of the 24 hours. But it must be observed that, of the day-arcs and night-arcs set out in the scholium to Proposition 33, Book 1, one should take, for the eastern dial, only those hours from sunrise and sunset to which, in those same tables, the hours from midnight — not those from noon — correspond, since the latter are not contained in that dial; and for the western dial, those to which the hours from noon, not from midnight, correspond. For example, hour 14 from sunset we shall, on the eastern dial, draw through hour 2 from midnight on the night-arc of the 24 hours, and not through hour 2 from noon on the day-arc of the 24 hours. Likewise, hour 14 from sunrise we shall, on the western dial, draw through hour 2 from noon on the day-arc of the 24 hours, and not through hour 2 from midnight on the night-arc of the 24 hours; and so on.

[Margin: *Qua ratione ex horologio Italico fiat Babylonicum, et contra, in facie opposita plani horologij Meridiani delineandum.* — "By what method a Babylonian dial is made from an Italian one, and conversely, to be laid out on the opposite face of the plane of the meridian dial."]

As for the mutual intersections of the hours from noon or midnight with those from sunrise or sunset on the horizontal line, one must take into account what we wrote in Propositions 34 and 35 of Book 2.

Furthermore, it is evident from the figure of this chapter that the lines of the hours from sunset on the eastern dial have the same position that the lines of the hours from sunrise keep on the western dial. The same holds true of the hours from sunrise on the eastern dial and the hours from sunset on the western dial. Hence an eastern Italian dial drawn on the opposite face of the dial-plane, so that line answers to line, will be a western Babylonian dial; and a western Italian dial will be an eastern Babylonian dial, and conversely — provided only that the

individual hour-numbers are changed into their complements up to 24, as 9 into 15, and 3 into 21, and so on.

ON THE OLD [ANTIQUE] MERIDIAN DIAL

CAPVT XV.

Let both the day-arc of Cancer ☿, BGC, and that of Capricorn ♊, DGE, in circle FGHI, be divided — for each dial — into 12 equal parts. For by their means we shall find, on the same tropic, the points through which the unequal hours are to be drawn, exactly as in the preceding chapter we located the points of the hours from sunrise and sunset on these same tropics. The unequal hours, moreover, will pass through the hours from noon or midnight on the equinoctial line, as we taught in the case of the horizontal and vertical dial.

Diagram. The construction for the Old (Antique) meridian dial, drawn as two large overlapping circles (a left face and a right face about the meridian), each crossed by a dense web of straight and dotted radial lines, with the unequal hours numbered around and across them. Readable labels (positions approximate):

- Circumference letters (shared across the twin circles): **D** (top), **F** (upper left and upper right), **G** (top, on each circle), **B** (left and right flanks), **E E** (the doubled label at the shared central region), **H** (lower flanks), **C** (bottom of each circle), **I** (lower left / lower right), **S** (lower right).
- Interior/hour figures read on the left circle: **8, 9, 10, 4, 3, 2, 7** and **II** (= 11).
- Interior/hour figures read on the right circle: **2, 3, 4, 10** and **II** (= 11).

Extremely dense; many interior hour-figures and line-endings do not resolve individually.**

If two day-arcs are drawn, one of 18 hours and the other of 6 hours, we shall construct the same Antique dial in the way it was done above for the horizontal and vertical dial, from the tables described in the scholium to Proposition 33, Book 1.

It is clear, moreover, from the figure and the description of each dial that the lines of the unequal hours have the same position and situation on both dials. Therefore, once one dial has been drawn, if on the opposite face the same lines are drawn, answering exactly to the earlier lines, the other dial too will be obtained — the hour-numbers, however, must be changed into their complements up to 12, as 1 into 11, and 2 into 10, and so on.

[Margin: *Constructio eiusdem horologii Meridiani Antiqui ex arcubus diurnis. Quo pacto ex horologio Antiquo orientali fiat occidentale, & contra.* — "The construction of the same Antique meridian dial from the day-arcs. By what method a western dial is made from an eastern Antique dial, and conversely."]

ON THE POLAR DIAL, Astronomical.

CAPVT XVI.

[Margin: *Qua ratione ex horologio Meridiano Polare efficiatur. Quo pacto collocandum sit horologium Polare, vt horas monstret.* — "By what method a polar dial is made from a meridian one. In what way the polar dial must be set up so that it may show the hours."]

The polar dial does not differ from the meridian dial, which we described in Chapter 11, except in the number of the hours and in their order. For in this dial, on both sides of the straight line DE, one takes all the hours that can fall upon the plane of the dial, and the line DE itself is no longer the 6th astronomical hour but the 12th, as appears in the accompanying dial. For if this dial is so set up that the line CS is parallel to the horizon, the line DE lies in the plane of the meridian circle, point E faces south and D faces north, and finally point D is raised from the northern side according to the elevation of the pole — that is, if the line DE, together with the meridian line, is established in the plane of the horizon toward the [regions]...

Diagram. The polar astronomical dial: a broad figure with the meridian line DE running vertically (D at the top, E at the foot within a small graduated circle marked **12**), the horizontal line CS crossing it (C at the left, S at the right), the central intersection **A**, and a fan of straight and dotted hour-lines. Along the right and left edges the sign-arcs of the zodiac are labelled with sign-glyphs (day-parallels for the signs). Readable labels (positions approximate):

- Meridian/horizon frame: **D** (top), **E** (foot, in the circle, beside **12**), **C** (left), **S** (right), **A** (center), **B** (upper right).
- Interior points/figures: **N**, **K**, and hour-figures **4**, **7**, **8**, **9**, **10**.
- Right and left margins: a descending series of zodiac sign-glyphs marking the day-arcs; the individual glyphs are largely unresolved [?] (wavy Aquarius-like $\approx$ and Pisces-like $\bowtie$ forms on the left; Scorpio-/Libra-like forms on the right).

Dense, with many small edge-glyphs and interior figures unresolved.**

the pointer AE, standing at point A at right angles upon the plane of the dial, will indicate the angle of the pole's elevation of point D; or else the line OP, as we taught in Chapter 13 — the hours from noon and from midnight being kept in this order, namely that the hours between DE (the meridian line, which indicates the 12th hour of midday) and point C, toward the left, are counted from midnight, while those drawn toward point S are counted from noon. Only the 6th hour from noon or midnight cannot be drawn on this dial, since the circle of the 6th hour does not cut the plane of the dial but is parallel to it.

And so, if a polar astronomical dial is to be described, two straight lines CS and DE must be drawn on the proposed plane, cutting each other at right angles in A, of which DE represents the meridian line — to such effect that, if the plane is firm and stable and parallel to the circle of the 6th hour from noon or midnight, one must first draw, with the help of a level and a plumb-line, on the given plane the line CS parallel to the horizon, and then raise to it the perpendicular DE for the meridian line, cutting the former in A. Next, on the line DE, one takes the segment AE equal to the proposed pointer; and, having described a circle of any size from E, the rest is to be completed as we set out for the meridian dial in Chapter 11, and so on.

[Margin: *Descriptio horologij Polaris Astronomici.* — "The description of the polar astronomical dial."]

ON THE ARCS OF THE SIGNS AND OF THE LENGTHS of the days on the polar dial.

CAPVT XVII.

[Margin: *Descriptio arcuum signorum, et longitudinum dierum in Polari horologio. Horizontalis linea in horologio Polari, quomodo describatur. Horologium Polare Superius, & inferius. Item Diurnum, & nocturnum quod.* — "The description of the arcs of the signs and of the lengths of the days on the polar dial. How the horizontal line on the polar dial is to be drawn. The upper and the lower polar dial. Likewise which is the day-dial and which the night-dial."]

The arcs of the signs and of the lengths of the days, which are all hyperbolas, are described here just as on the meridian dial, from the figure of the zodiac-radii in Chapter 12 — provided you remember that the line which there was assigned to the 6th hour here represents the 12th hour, as we likewise noted there. The horizontal line is drawn as follows. From point B, where hour 9 or 3 intersects the equinoctial line, let an arc of a circle be described toward the meridian line,

upward. (I call the "upper" part that which lies above the equinoctial line when the dial is set in its proper position, so that the hours from midnight are to our left and the afternoon hours to our right.) Taking on that arc a portion equal to the complement of the pole's elevation, from its end let a straight line be drawn to hour 9, or 3, on the equinoctial line; this line will cut the line of the 12th hour at point D. Through D, a line drawn parallel to the equinoctial line will be the horizontal, dividing the whole dial into two parts, of which the larger — that in which the equinoctial line is contained — is called the upper or day part, and the other the lower or night part. In the lower part, however, the hour-numbers are changed into their complements up to 12, the meridian line signifying the 12th hour of midnight, and the arcs of the southern signs become the arcs of the northern signs, and so on. But if the same dial is taken as a night-dial, this change need not be made. The arcs of the southern signs are those which lie above the equinoctial line, proceeding toward the horizontal line; those of the northern signs are the ones drawn below the equinoctial line. An example is given in the preceding chapter.

ON THE POLAR ITALIAN AND Babylonian DIAL.

CAPVT XVIII.

[Margin: *Compositio horologii Polaris Italici, ac Babylonici.* — "The construction of the polar Italian and Babylonian dial."]

Let the day-arc of Cancer ☊, aFb, in circle FGHI, and the day-arc of Capricorn ☋, dFe (both of which are obtained if from point F the semidiurnal arc of Cancer ☊ and of Capricorn ☋ is counted off on either side, up to the points a, b and d, e), be divided into 24 equal parts — beginning, for the Italian dial, at the western points a, d, but for the Babylonian at the eastern points b, e, always proceeding toward F. For if hidden straight lines are drawn from the points of division through the center, the equinoctial line will be cut in points; and if perpendicular lines are raised to it through these, they will indicate on each tropic the points of the hours from sunset and sunrise, as was done on the meridian dial. But if some hours do not have...

Diagram. The polar Italian and Babylonian dial: a large circle FGHI (F at the top, G at the left, H at the foot, I at the right) crossed by a broad fan of straight and dotted hour-lines radiating outward on both sides, with the horizon line running across labelled **HORI** on the left and **ZON** on the right (i.e. HORIZON). The hours from sunset/sunrise are numbered along the rays; a tight interlaced web of lines fills the region about the center. Readable labels (positions approximate):

- Circumference letters: **F** (top), **G** (left), **H** (foot), **I** (right), with **C** on the upper right and **S** at the lower right.
- Interior points: **D, K, L, b** (lowercase), and **a/d** among the divisions.
- Left-side ray numbers: **23, 24, 12, 7, 8** and **II** (= 11).
- Right-side ray numbers: **24, 6, 23, 22, 13, II** (= 11), and **01** (= 10).
- Interior web figures read: **8, 9, 10, 12, 13, 14, 20, 21, 2, 3**.

Very dense; many interior figures and ray-endings do not resolve individually.**

points on either of the tropics — as is the case with those hours contained in the arcs aG, bI — they must be drawn through the points of the hours from noon or midnight on the equinoctial line. For all the hours from sunrise and sunset pass through the said hours, as is plain from the table in Chapter 4. The line of the 12th hour, however, both from sunrise and from sunset, must be drawn parallel to the equinoctial line through the point found on the tropic of Cancer ☿: the one belonging to the 12th hour from sunrise is found to the right of the meridian line, while the one indicating the 12th hour from sunset lies to the left.

These lines of the hours from sunrise and sunset, extended beyond the horizontal line, exhibit the same hours on the lower polar dial, if that portion of the dial cut off by the horizontal line is inverted in all its parts, as we said in Chapter 9 concerning the vertical dial.

We shall construct the same dial by means of the day-arcs and night-arcs of hours 10 and 14, and also of the 24 hours, with the help of the tables belonging to those arcs, as was done in the dials above. Here this alone is to be noted: that the lines of hours 6 and 18 from sunrise or sunset do not meet the day-arc and night-arc of the 24 hours, but are [Greek: ἀσυμπτότους (asymptotous, "asymptotic" — lines that never meet; the print sets omicron, not the vulgate ω)], as is clear from the corollary to Proposition 15, Book 1 — which we also stated in the case of the meridian dial.

By what method the same dial is drawn with the help of the line of the 12th hour from sunrise or sunset and of the horizontal line, that is, of the 24th hour from sunrise or sunset, may be sought from Propositions 46 and 47, Book 2.

[Margin: *Quomodo ex Polari horologio Superiori efficiatur Polare inferius. Constructio eiusdem horologij Polaris Italici ac Babylonici ex arcubus diurnis, nocturnisque.* — "How a lower polar dial is produced from an upper polar dial. The construction of the same polar Italian and Babylonian dial from the day-arcs and night-arcs."]

Gnomonics, Liber Septimus (continued)

On the Antique Polar Dial. Chapter XIX.

[Margin: *Cōstructio horologij Polaris Antiqui.* — "Construction of the antique polar dial."]

Just as in the preceding chapters, so here too we shall lay out the unequal hours. We take the day-arc — both that of Cancer ☊, aFb, and that of Capricorn ☋, dFe — on the circle FGHI and cut it into 12 equal parts, from which we may seek the points of the unequal hours on each tropic. This we shall likewise carry out with the help of the day-arcs and night-arcs of hours 18 and 6 [numeral:?].

Diagram. The antique polar dial for unequal (temporal) hours. A circle FGHI is drawn with F at the top, G at the left (on the horizon), H at the foot, and I at the right. A horizontal line runs across the circle carrying the label **HORI** on the left and **ZON** on the right (i.e. HORIZON). A broad fan of straight and dotted hour-lines radiates outward on both sides beyond the circle; the equal-hour Roman numerals **IX** (upper left), **I** (upper right), **XII** (right, beside ZON), **XI** (lower right), **I** (lower left) and **III** (foot) are set at the ends of the outer rays. Along the upper circumference, running from F toward the right, are the Arabic figures 6 (at F), 5, 4, 3, 2; running from F toward the left, 7, 8, 9, 10. Readable interior labels: G and lowercase a, b near the left of center, and a divided lower arc bearing the figures 8, 9, 10, 11 and 1, 2, 3, 4, 5 together with a row **III · V · VI · VII · VIII · IX**. A dotted ray at the lower right ends at X.

The interior is a very dense interlaced web of straight and dotted lines; many of the small ray-figures and interior divisions do not resolve individually at native resolution.**

The figure set beside makes this clear. There too, the lines of the unequal hours, when produced beyond the horizontal line, exhibit the lines of those same hours on the lower dial — provided that the portion of the dial cut off by the horizontal line is inverted in all its parts, as we taught in Chapter 9.

On the Astronomical Equinoctial Dial, by the Arcs of the Signs and the Lengths of the Days. Chapter XX.

[Margin: *Compositio horologij Aequinoctialis Astronomici.* — "Composition of the astronomical equinoctial dial."]

Draw a straight line AB to serve as the meridian line, that is, the line of the 12th hour from noon or from midnight, and let another straight line CD cut it at right angles in E, to serve for the 6th hour before and after noon. From E describe a circle of any size and divide it into 24 equal parts. For if straight lines are drawn out through the center E and through the points of division, an equinoctial dial will have been described. Indeed, if at E a style EF of any length is fixed perpendicular to the plane of the dial, and the dial itself is so placed that the line CD is parallel to the horizon and the line AB is set in the plane of the meridian circle (as the common section of the plane of the dial and of the meridian), and finally the point A on the noon side is raised — with point B leaning toward the north, C toward the east, and D toward the west — through the complement of the pole's altitude above the horizon (that is, so that AB together with the meridian line in the plane of the horizon makes, on the side of B, an angle equal to the complement of the pole's altitude): then the style EF will show the hours from noon or from midnight, this order being kept among them, that the hours to the right of the meridian line AB are numbered from midnight, while those to the left are numbered from noon.

[Margin: *Descriptio arcuum signorum, et longitudinum dierū in horoloio [horologio] aequinoctiali.* — "Description of the arcs of the signs and of the lengths of the days on the equinoctial dial."]

The arcs of the signs and of the lengths of the days, all of which are circles on this dial, will be described as follows. In the figure of the Zodiac rays of Chapter 12, take on the axis DG a straight line Dq to the left, or Dh to the right, equal to the style of the dial; and through q, or through h, draw a line qn (or hl) parallel to the equatorial radius DC, cutting the rays of the signs and of the lengths of the days at the points p, o, n, etc. Then if from the center of the dial E circles are described according to the intervals qp, qo, qn, etc., the arcs of the signs and of the lengths of the days will have been described — such that on the upper dial all the arcs are northern, the most northern being the one nearest to the center E, while on the lower dial all are southern, the one nearest the center E being the most southern. Therefore on the former dial the circle described according to the semidiameter qp will be the arc of Cancer ☊ [Greek/Latin zodiac gloss: Cancer], the next of Gemini ♊ and Leo ♌, and the third of Taurus ♉ and Virgo ♍; while on the latter the first will be Capricorn ♐, the next Sagittarius ♐ and Aquarius ♒, the third Scorpio ♏ and Pisces ♓. But by what arrangement the lower takes its origin from the upper, the horizontal line will disclose, which we shall now delineate.

[Margin: *Horizontalis lineae descriptio in horologio aequinoctiali.* — "Description of the horizontal line on the equinoctial dial."]

On the line of the 6th hour, CD, take a straight line El equal to the length of the style EF, and from l describe an arc of a circle toward the meridian line. If on this arc a portion equal to the pole's altitude is taken, and from the end of it a straight line is drawn to l, it will cut the meridian line AB at the point m; and the straight line drawn through m so as to cut the meridian line at right angles will be the horizontal line, dividing the whole dial into two parts. The greater part, in which the center E lies, is called the upper or diurnal,

Liber Septimus (continued)

diurnal, the other, the lower, is called nocturnal. On the lower dial, however, the numbers of the hours are changed into their complements up to 12, and the arcs of the northern signs are exchanged for arcs of the southern signs — but not so on the nocturnal dial. The equinoctial circle cannot be marked out on this dial, because it does not cut the plane of the dial but is parallel to it. Hence its common section with the plane of the dial, which ought to be a straight line, vanishes, as we demonstrated in Proposition 11 of Book 1.

Diagram. The astronomical equinoctial dial. A circle is drawn with **A** at the top and **B** at the foot (the vertical meridian diameter, AB), and **C** at the left and **D** at the right (the horizontal 6-o'clock diameter, CD); the left end is labelled **C 6** and the right end **6 D**. The center is **E**. An oblique horizon line crosses the figure carrying **HORI** on the left and **ZON** on the right; it meets the meridian at the interior point **m**, and the interior point **P** lies near it. Concentric inner circles (the arcs of the signs and of the lengths of the days) bear zodiac glyphs around their rims; among the clearly readable ones are Pisces ♓, Aquarius ♒, Virgo ♍, Cancer ♋, Gemini ♊, Taurus ♉ and Leo ♌. The outer rim is divided into 24 parts, labelled with Arabic hour-figures (2, 3, 4, 5 on the lower left; 1 and 12 at the foot near B; 7, 8, 9, 10 on the lower right; and further figures around the top) together with Roman hour-numerals **I** and **II** near the top.

The zodiac rim and the interleaved 24-part hour divisions are dense and partly overprinted; individual rim positions of the zodiac glyphs and several of the small hour-figures do not resolve cell-by-cell at native resolution.**

Now since, when the Sun is on the equator, the shadow of the style is infinite — and even a little before and after the equinoxes it is nearly infinite — the hour-lines on the upper dial must be produced beyond the circle of Taurus ♉ and Virgo ♍

℞, as far as the size of the plane on which the dial is described allows, so that on those days before and after the equinoxes the gnomon may be able to indicate the hours. Or else a circle of some particular degree near the equinoctial circle must be described — namely at 25° Virgo ℞ and 5° Taurus ☿ [?], or at 20° Virgo and 10° Taurus ☿ [?], and so on. The same is to be understood as needing to be done on the lower dial among the southern signs, always taking account of the size of the plane of the dial. This too must be understood of the Italian and Babylonian hours.

[Margin: *Quid agendum sit, vt vmbra styli horas indicet prope tempus aequinoctiorum.* — "What is to be done so that the shadow of the style may indicate the hours near the time of the equinoxes."]

For the rest, on the upper dial the portion EB of the meridian line indicates the 12th hour of noon, and the remaining portion EA the 12th hour of midnight. On the lower dial the matter stands in the contrary way: for the portion EB signifies the 12th hour of midnight, and the remaining portion EA the 12th hour of noon.

On the Equinoctial, Italian, and Babylonian Dial. Chapter XXI.

[Margin: *Cōstructio horologij Aequinoctialis Italici ac Babylonici.* — "Construction of the equinoctial Italian and Babylonian dial."]

Let the several arcs of the signs — or at least two of them, an interior and an exterior, which is enough — be divided into 24 equal parts, the beginning being made from the horizontal line, on the left side for the Italian dial and on the right side for the Babylonian. Then through the nearest points of these arcs, above or below the horizontal line, draw a straight line; likewise through the next points in sequence, and so on, until straight lines have been drawn through all the points. For these straight lines will indicate the hours from sunrise and from sunset on the upper dial, and thereby the upper equinoctial Italian and Babylonian dial will have been described, in which the number and order of the hours is this. The line nearest above the horizontal line, which indicates the 24th hour — that is, on the nocturnal dial (the part cut off by the horizontal line) — shows on the left the 1st hour from sunset, the next 2, and so on; so that the line nearest below the horizontal line on the same left side indicates the 23rd hour from sunset, and so forth. Again, the first line below the horizontal line on the right side shows the 1st hour from sunrise, the next 2, and so on, as is clear from the figure. These lines, produced beyond the horizontal line, form the lower Italian and Babylonian dial, if all the parts of the lower dial are inverted, as we said in the case of the northern vertical dial and the lower polar dial.

[Margin: *Alia descriptio horologij Aequinoctialis Itali[c]i & Babylonici per arcus diurnos nocturnosque.* — "Another description of the equinoctial Italian and Babylonian dial by means of the day-arcs and night-arcs."]

Each dial can also be described by means of the day-arcs and night-arcs of hours 10, 14, and 24, as was done in the preceding chapters. For example, the 23rd hour from sunset is drawn through the 6th hour from noon on the day-arc of 14 hours; and since the same line, carried beyond the day-arc of 24 hours (which touches the horizontal line at the point m), indicates when produced the 23rd hour from sunrise (as we demonstrated in Proposition 10 of Book 2), while the 23rd hour from sunrise passes through the 4th hour from mid-

Gnomonics

night on the night-arc of 10 hours — for this reason, so that the 23rd hour from sunset may be correctly drawn through the 6th hour from noon on the day-arc of 14 hours, the 4th hour from midnight must also be taken, corresponding to the 23rd hour from sunrise, on the night-arc of 10 hours. By the same reasoning the 22nd hour from sunset is drawn through the 5th hour from noon on the day-arc of 14 hours, and through the 3rd hour from midnight of the night-arc of 10 hours, which corresponds to the 22nd hour from sunrise. And so on continually, always taking one point on the day-arc of 14 hours for any given hour from sunset, and another on the night-arc of 10 hours — or likewise on the day-arc of 14 hours — for the same hour from sunrise, as the tables of the scholium to Proposition 33 of Book 1 will indicate. Thus you see that the 11th hour from sunset is drawn through the 6th hour from midnight on the day-arc of 14 hours, and through the 4th hour from noon on the same arc, which agrees with the 11th hour from sunrise. For by this reasoning the Italian dial is easily composed. In the same way the Babylonian will be made, if for any given hour from sunrise one point is taken on the day-arc of 14 hours and another on the night-arc of 10 hours — or likewise on the day-arc of 14 hours — for the same hour from sunset. Thus you discern that the 1st hour from sunrise passes through the 6th hour from midnight on the day-arc of 14 hours; and the 1st hour from sunset through the 8th hour from noon on the night-arc of 10 hours; likewise the 13th hour from sunrise through the 6th hour from noon on the day-arc of 14 hours, and the 13th hour from sunset through the 8th hour from midnight on the same arc; and so with the rest.

But each dial will be delineated much more easily with the help of the day-arc of 14 hours and the day-arc of 24 hours. For example, the 23rd hour from sunset passes through the 6th hour from noon on the day-arc of 14 hours, and through

the 11th hour from noon on the day-arc of 24 hours. Likewise the 8th hour from sunrise is drawn through the 1st hour from noon on the former arc, and on the latter through the 8th hour from midnight. Finally, on the lower dial the 17th hour from sunset is drawn through the 10th hour from mid-

Diagram. The equinoctial Italian and Babylonian dial. The circle has **C** at the upper left of the rim and **B** at the left where the horizon meets the circle; the center is **E**, with the interior point **D** just below the center. An oblique horizon line runs across, labelled **HORI** on the left and (on the right) **NoZ 24 / ZON**, marking the horizontal line as the 24th hour; the interior point **A** lies on it near the center-right. On the right, the rays are marked with the Babylonian hours from sunrise **II, I** below the 24 line. On the left, near **B**, run the hours **24 · XIII[?]**, **23 · XII**, **22 · XI**. The double outer rim carries paired hour-figures — Arabic Italian/Babylonian hours (**13, 15, 16, 17, 18, 19, 20, 21, 22, 23, 24** ...) beside Roman numerals (**III, IIII, V, VI, VII, VIII** ...) — and zodiac glyphs are interspersed around the rim.

The rim is a very dense double band of paired Arabic-and-Roman hour-figures with interleaved zodiac glyphs, and the interior is a tight web of straight and dotted hour-lines; the individual rim numbers and their positions do not resolve reliably cell-by-cell at native resolution.**

night on the day-arc of 10 hours, and through the 5th hour from midnight on the night-arc of 24 hours, and so on — as the tables of these arcs, described in the scholium to Proposition 33 of Book 1, teach. It must be noted, however, that the hours from noon or from midnight are the same, provided that those which on the upper dial are counted from noon are, on the lower, reckoned from midnight, and conversely. This indeed happens because of the inversion of all the parts of the lower dial, an inversion that is altogether necessary on the Italian and Babylonian dial. Hence, when above in Chapter 20 we taught that the hours from noon or from midnight must, on the lower dial, be changed into their complements up to 12, this is to be understood as holding if the aforesaid inversion of the parts is not made. But it will be better to derive the lower Italian and Babylonian dial from the upper, just as we set forth a little before.

[Margin: *Linea horarum ab or. & occ. tangent circulum horarum 24. in horis à meri. & med. noc.* — "The lines of the hours from sunrise and sunset touch the circle of 24 hours at the hours from noon and midnight."]

It must not be passed over here that the lines of the hours from sunrise or sunset touch the circle of 24 hours at the points where they are cut by the lines of the

astronomical hours, and thus that they are there cut by them at right angles, as we demonstrated in Propositions 58 and 59 of Book 2.

But here too one may observe the common intersections of the hours from noon or from midnight with those from sunrise or sunset, which they make on the horizontal line (that is, the line of the 24th hour) and on the line of the 12th hour from sunrise or sunset; and likewise the mutual intersections which the hours from sunrise or sunset make on the line of the 6th hour from noon or from midnight — as is plain from the tables set out in the scholium to Proposition 20 of Book 1.

On the Antique Equinoctial Dial. Chapter XXII.

[Margin: *Descriptio horologij Aequinoctialis Antiqui.* — "Description of the antique equinoctial dial."]

Let the several portions of the arcs of the signs which the horizontal line cuts off be divided, on each dial (both the upper and the lower), into 12 equal parts. It is enough, however, to do this on the inner

on the inner and outer dial. Then draw a straight line through the points nearest below the horizontal line, and do the same in turn for the succeeding points that correspond to one another. Once this is done, the antique dial will have been drawn. For the line nearest below the horizontal line — on the right-hand side, that is, on the upper dial, but on the left on the lower — will give the first unequal hour, the next the second, and so on. Here too the hours on the upper dial, drawn out beyond the horizontal line, give the same hours on the lower, provided all its parts are inverted, as was said above. Thus each line of the unequal hours passes through six points of the divisions of the arcs of the signs, three of which lie on the upper dial and three on the lower.

Diagram. A full circle representing the antique (unequal-hours) equinoctial dial. Its horizontal diameter is the horizon line: at the left end it is labelled **HORI** (with **12** just below it), and at the right end **ZON** (with **12**; the right-hand legend is set reversed/inverted, appearing as "1Z ZON", marking the inverted lower dial). Around the rim run the hour-figures of the dial; along the interior run dotted hour-lines carrying fractional hour-values.

- Horizon line: **HORI** (left), **ZON** (right), **12** at each end.
- Left rim, descending from the horizon: **1(I)**, then Roman **II**, then **10, 9, 8, 7, 6** (at bottom).

- Right rim, descending from the horizon: reversed **10(OI)** and **11[?]** above the horizon, then below it **1(I)**, **2**, **3**, **4**, **5**.
- Interior dotted hour-lines (left group): fractional values $7\frac{1}{2}$, **6**, $4\frac{1}{2}[?]$, **3**, $1\frac{1}{2}$, and near the centre **12[?]**, **10 $\frac{1}{2}$ [?]**.
- Interior dotted hour-lines (right group): $4\frac{1}{2}$, **6**, $7\frac{1}{2}$, **9[?]**, **10 $\frac{1}{2}$ [?]**.
- Top rim: a band of zodiac glyphs, worn and not reliably resolvable at native resolution — [Zodiac glyphs: ?].

The rim hour-figures, the interior fractional dotted-hour values, and the top-rim zodiac glyphs are a dense, partly worn cluster that does not resolve cell-by-cell; several labels are flagged.**

The antique dial can also be described easily by means of the diurnal arc of 18 hours and the nocturnal arc of 6 hours, just as was done in the cases above. This is gathered from the little tables drawn up for this use in the scholium to Proposition 33 of Book 1, and it appears clearly in the accompanying figure.

[Margin: *Alia descriptio horologij Aequinoctialis Antiqui per arcum diurnum horarum 18. & nocturnum horarum 6.* — "Another description of the antique equinoctial dial by means of the diurnal arc of 18 hours and the nocturnal arc of 6 hours."]

ON THE ASTRONOMICAL DIAL THAT DECLINES FROM A VERTICAL CIRCLE. CHAPTER XXIII.

[Margin: *Descriptio horologij Astronomici à Verticali declinantis.* — "Description of the astronomical dial declining from the vertical."]

Before all else, the declination of the plane on which the dial is to be described must be investigated, as we taught in Proposition 23 of Book 1 and in its scholium. Since we there discussed the declination and inclination of planes at length, there seems no need to say anything at all about it here. Once the declination has been found, we shall proceed to describe the dial on a plane that declines from the vertical, in this way.

On the plane of the dial, taking the location of the style anywhere at **K**, let two straight lines **AB** and **DF** be drawn through **K**, cutting each other at right angles at **k**; or, if the plane is fixed and vertical to the horizon, let the line **AB** be drawn through **K** parallel to the horizon by means of a level and plumb-line, and let **DF**, perpendicular to the horizon, cut it at right angles. Or, at any rate, in the first

place let the perpendicular be drawn, which the line **AB**, parallel to the horizon, cuts at right angles at **K**.

On **FD**, taking any length of the style **KF**, whether directed upward or downward, describe from **F**, toward **AB**, the arc **DH** — toward **B** if the wall or plane of the dial declines from south toward the east, or from north toward the west; but toward **A** if it deflects from south toward the west, or from north toward the east. Then, once the declination of the wall **DH** has been counted off (which in our example we set at 30 degrees from south toward the east), and **FH** has been drawn cutting **AB** at **E**, draw through **E** the line **CE** parallel to **FD**, that is, perpendicular to **AB**. For **CE** will be the meridian line, or the line of the 12th hour.

[Margin: *Linea meridiana*. — "The meridian line."]

Next, on the arc **DH** produced on the other side of the line **FD**, with the complement of the declination **DN** reckoned off, draw the line **FN**; or indeed draw the line **Fα** perpendicular to **FE**, cutting **AB** at **α**. For through **α** both the equinoctial line and the line of the 6th hour must be drawn. Take also on **AB** a segment **Eβ**, either to the right or to the left of the meridian line **CE**, equal to **EF**. From **β** describe an arc of a circle toward **CE** — upward, on a dial declining and deflecting from the north; on this arc, the altitude of the pole having been counted off starting from the line **AB**, draw from **β** to the end of the reckoning a line cutting **CE** at the point **C**, which will be the centre of the dial, in which all the hour-lines will meet.

[Margin: *Centrum horologij*. — "The centre of the dial."]

Therefore, drawing from **C** through **K**, the place of the style, the line **Ck** — which may be called the line of the style — and letting the line drawn from **α** cut it at right angles at **G**, the line **αG** will be the equinoctial line.

[Margin: *Linea styli*. — "The line of the style."]

[Margin: *Linea aequinoctialis*. — "The equinoctial line."]

After this, erect from **K** the line **KI** perpendicular to **CK** and equal to the style **KF**.

[Margin, later hand (× keyed into the text): *Errorem hic fuisse commissum colligis ex principio capitis primi libri tertij*. — "You may gather that an error was committed here from the beginning of the first chapter of the third book." (manuscript annotation)]

[Margin: *Axis mundi*. — "The axis of the world."]

For the line **CI** drawn will give the axis of the world, which the line **GI** joined to it will cut at right angles, if no error has been made. Now on the line of the style **CK**, taking a segment **GL** equal to **GI**, describe from **L** a circle of any size, and divide it into 24 equal parts, beginning from the line **LM**, which is drawn from **L** through the point **M**, where the equinoctial line cuts the meridian; and this line **LM** will necessarily cut the drawn line **Lα** at right angles, if no error has been made.

[Margin: *Linea horarum à mer. & med. noc.* — "The line of the hours from noon and from midnight."]

For if hidden straight lines go out through the centre **L** and the points of division — the lines emitted from **C** through which will give the hours from noon and from midnight — they do so in this order. On the dial that faces south, the portion of the meridian line from the centre **C** toward the equinoctial line marks the 12th hour of noon, and the remaining portion beginning from the same centre **C** marks the 12th hour of midnight. The lines preceding the meridian line on the left — that is, toward the parts of **A** — indicate the hours after midnight, or before noon; and those that follow the same line on the right — that is, toward the parts of **B** — show the hours after noon. Their order and number advance along the line **AB**, or the equinoctial line, from left to right. On the dial...

Diagram. The construction of the declining astronomical dial. A small circle at the upper centre is the origin of the world's axis, its centre labelled **C** (with lowercase **a** just above it); from **C** and from the style-vertex **F** a fan of straight hour-lines spreads downward across a horizontal line **AB**. The horizontal line runs **A** (left) to **B** (right). An arc of a circle (drawn partly dotted) sweeps through the lower-centre region and carries several construction points.

- **A** — left end of the horizontal line **AB**.
- **B** — right end of the horizontal line **AB**.
- **C** — centre of the small circle (centre of the world/dial), upper centre; **a** (lowercase) marked just above.
- **F** — style-vertex, at the convergence of the ray-fan, upper centre-left.
- **E** — on the vertical below **F**.
- **α** — centre-left, on **AB**.
- **β** — below centre, near **AB**.
- **G, K, M** — construction points at centre-left/left.
- **N** — lower left, on the dotted arc.
- **L, D, H** — points along the dotted arc (**L** left, **D** lower-left, **H** lower-centre).
- **I** — bottom centre.

- **z** — ray-label, centre-right; **S[?]** — ray-label, upper right.
- Hour-figures on the rays: right side **1, 2, 3, 4**; left side **6, 7, 8, 9**; bottom **10[?], 11, 12**.

(The exact hour attached to two of the outer rays and the reversed lower-rim figures do not resolve cleanly; those are flagged. Letter-labels A–N, α , β read confidently.)

that faces north, the portion of the meridian line from the centre **C** toward the equinoctial line indicates the 12th hour of midnight, and the remaining portion the 12th hour of noon. The lines preceding the meridian line on **AB**, to the left, show the hours before noon, and those on the right the hours from midnight; their order and number likewise advance from left to right along the equinoctial line, or the line **AB**.

Moreover, these same hour-lines are most conveniently drawn by the following method. From the point **F** let straight lines go out making with **FE** the same angles that the hour-lines make with the meridian line on the horizontal dial — namely, the line of the 6th hour, which is **F α** , a right angle, and so on. This is easily done if, from the centre of the horizontal dial, an arc of a circle is described cutting all the hour-lines, together with an equal arc from **F** toward the line **AB**. For if all the hour-intervals from that first arc, beginning from the meridian line, are transferred to this one, beginning from the line **FE**, the lines emitted from **F** through the points of this arc will be the hour-lines answering to the hour-lines on the horizontal dial.

[Margin: *Qua ratione lineae horariae ex horologio horizontali describantur.* — "By what method the hour-lines are drawn from the horizontal dial."]

Where, then, these lines cut the line **AB**, the lines drawn from the centre **C** [recte: *centro*; the print reads "cento"] through those points will give the hour-lines, as before. And in this way the earlier description can easily be examined and corrected, if some error has by chance been committed in it. Indeed, this latter method of drawing the hour-lines is very useful for drawing those lines which cut the equinoctial line either in no way at all, or scarcely at all except at the most remote points — such as, in the proposed example, the lines of the 4th and 3rd hours.

But should anyone doubt whether the hour-lines are drawn straight by this method, we shall demonstrate it briefly in this way. Let the triangle **α FE** be conceived as moved about the line **α E** until it stands perpendicular to the plane of the dial, so that **F**, the vertex of the style, becomes the same as the centre of the

world, and the triangle itself lies in the plane of the horizon. This being posited, all the hour-circles from noon and from midnight will be drawn through **F**, the centre of the world. Since, then, the meridian is drawn through the line **FE**, the circle of the 6th hour will be drawn through the line **Fα**. And since the common sections of the hour-circles and of the horizon at the centre of the horizon make angles equal to those which the common sections of the same circles and of the plane of the horizontal dial make at the centre of the dial — into which the axis of the world falls — as is clear from what we demonstrated toward the end of Proposition 1 of Book 3, and from what we demonstrated in Proposition 5 of Book 5 when we described the horizontal dial by means of the hour-arcs: it is evident that the hour-circles meet the declining dial at the points of the line **AB** into which fall the straight lines that make at **F** the same angles that the hour-lines make on the horizontal dial at the centre of the dial, and so on.

[Margin: *Quando puncta L, M, praecedentis horologii ...* — "When the points L, M of the preceding dial..." (continued in the note on the next page)]

Again, since the points **L** and **M** are sometimes so little distant from one another that a line — from which the division of the circle described from **L** must begin — can scarcely be drawn through them without error (for it may easily deflect to one side or the other, whence a sometimes considerable error will arise in drawing the hour-lines) — we shall do better if first, from **α**, through the cen...

centre **L** we draw a straight line. For the line **LM** will necessarily cut this at right angles, if no error has been made. The same must also be observed in the following declining and inclined dials. For by this method it will come about that the hour-lines are drawn most accurately, provided the said two lines have cut each other at right angles. Therefore this operation must be carefully examined before we go any further in describing the dial.

[Margin: *...parum inter se distant, quid agendum, vt accurate horae depingantur.* — "...are little distant from one another: what is to be done so that the hours may be drawn accurately."]

By the same method, if the line **Fα** happens to cut the line **AB** too far from the point **E**, we shall be able to draw from **F** any other hour-line besides the line of the 6th hour — one that makes with **FE** the same angle which that hour makes with the meridian line on the horizontal dial, and that cuts the line **AB** conveniently. For if, through the point where it cuts **AB**, we draw a line to **C**, the centre of the dial, and another line through the point where this line cuts the equinoctial and through the centre **L**, we shall have another line from which we

may most conveniently begin the division of the circle described from **L**. If, then, one point of division falls precisely on the line drawn through **L** and **M**, the operation will have been rightly set up; but if not, some error will have been committed, which you must correct before you pass on to other things.

[Margin: *Qua ratione diuisio circuli ex P, descripti aliunde possit inchoari quam à recta LM.* — "By what method the division of the circle described from **P** [so printed; expected *L*] may be begun from somewhere other than the line **LM**."]]

Therefore, if this dial is placed on a wall that declines 30 degrees from south toward the east, so that the line **AB** is parallel to the horizon and the line **FD** is perpendicular to it, and a style is fixed at the point **K** perpendicular to the wall and equal to the line **KF**; or if the triangle **CIG** is erected at right angles upon the line of the style **CK** — then the tip of the shadow projected from the vertex of the style, or the shadow of the axis **CI**, will indicate the hours from noon or from midnight.

[Margin: *Quomodo horologium declinans à Verticali collocandum sit, vt horas indicet.* — "How the dial declining from the vertical is to be placed so that it may indicate the hours."]]

In what manner a dial is to be laid out on walls that are little distant from the meridian circle, let it be sought from the scholium to Proposition 1 of Book 3.

[Margin: *Quando murus parum à Meridiano abest.* — "When the wall is little distant from the meridian."]]

Always, in these dials and in all the others that follow, the angle contained between the axis and the line of the style — such as here the angle **ICK** — is the measure of the altitude of the pole above the plane of the dial, as we showed in Proposition 1 of Book 3.

[Margin: *Altitudo poli supra planum declinans.* — "The altitude of the pole above the declining plane."]]

Now this same dial, declining from south toward the east, will also show the hours on the opposite face of the wall — that is, on a wall that declines 30 degrees from north toward the west — if it is so placed that the line **AB** is parallel to the horizon and the centre **C** is set below it, and the things that in that position are to our right become left, and conversely. But then the line **CEM** will indicate the 12th hour of midnight, not of noon, as on the dial facing south. Thus, when the dial declining from south toward the east, which we have described up to now, is turned toward us so that its upper part becomes the lower and conversely — that

is, the point **A** is to our right and **B** to our left — if on the opposite face of the dial all the linework is drawn so that each single line answers exactly to each single line, and again the point **A** becomes to our left and **B** to our right, then a dial will have been drawn declining from north toward the west by as many degrees as the one earlier described declines from south toward the east, to be placed on the wall as it lies. For by this method the centre **C** will be below the line **AB**, and the things that were earlier to our left (the dial being of course turned toward us so that **A** verged to the right and **B** to the left) will have been made right, and conversely.

Diagram. The finished declining astronomical dial. The centre **C** is at the top, and from it a fan of straight hour-lines spreads downward, crossing the horizontal line **AB** (**A** at left, **B** at right) and continuing to the lower margin. A dotted line runs obliquely across the lower right (the equinoctial line).

- **C** — centre of the dial, at the top, where the hour-lines converge.
- **A** — left end of the horizontal line; **B** — right, on the same line.
- **E** — on the horizontal line, centre.
- **I, K** — upper-left construction points below **C**.
- α — on the horizontal line, centre (lowercase).
- **M** — below **E**.
- **F** — at the bottom, on the meridian.
- **D** — lower left (foot of a ray to the lower margin).
- Hour-figures on the rays: left side **6, 7, 8, 9**; centre-bottom **10, 11, 12**; right side **1, 2, 3, 4** (and a dotted equinoctial line trailing to the lower right, marked $s[?] / \Omega$).

(All letter-labels **A, B, C, D, E, F, I, K, M, α** read confidently; two lower-margin ray markers are flagged.)

Being about to construct [recte: CONSTRVCTVRI; the print reads "CONSTVCTVRI"] a dial declining from north toward the east or the west, we shall describe a dial declining from south toward the opposite quarter by as many degrees as the one to be described declines. (For the declination of a dial facing north is always the same as that of one facing south, although they do not both decline toward the same quarters — because, when the one declines toward the east, the other declines toward the west, and conversely, yet by an equal number of degrees.) Thus, if a dial declining from north toward the west is to be described, we shall describe one declining from south toward the east; but if one declining from north toward the east, we shall describe one declining from south toward the

west. For from this we shall gather what is proposed, if all its parts are inverted, as has been said.

[Margin: *Quid agendum sit, quando horologium declinans à Septentrione describendum proponitur.* — "What is to be done when a dial declining from the north is proposed for description."]

Moreover, when any dial declining from south or north toward the east or west has been constructed, if all its linework is drawn on some other plane so that the things situated to the right of its meridian line become left, and those to the left come out right, a dial will have been made declining likewise from south or north toward the contrary quarter — so that, if the former declines toward the east, this one verges toward the west, and con-...

[Margin: *Qua ratione ex horologio declinante à meri. vel Sept. in or. vel occ. fiat declinans à mer. vel Sept in occ. vel ortum, & contra.* — "By what method, from a dial declining from south or north toward the east or west, one may be made declining from south or north toward the west or east, and conversely."]

and conversely. Such is the linework of any dial when it is described on the opposite part of the plane, so that its several lines correspond one to one. By this technique you see that here a dial has been made declining from south toward the west by 30 degrees, out of a dial declining by the same number of degrees from south toward the east.

Diagram. A declining astronomical dial (the mirror-image of the one on the preceding page — this one declines from south toward the west by 30°). The center **C** stands at the top; from it a fan of straight hour-lines spreads downward, crossing the horizontal base line and running to the lower margin. A dotted line runs obliquely across the lower right (the equinoctial line).

- **C** — center of the dial, at the top, where the hour-lines converge.
- **A** — left end of the horizontal base line.
- **E** — on the horizontal line, left of center.
- **B** — on the horizontal line, right of center.
- **α** — right end of the horizontal line.
- **I, K** — upper construction points just below **C**.
- **M** — below **E**.
- **F** — lower center, on the meridian line.
- **D** — lower left, at the foot of a ray to the margin.

- one small lowercase cursive point on the horizontal line between **E** and **B** [?].
- Hour-figures on the rays (read partially; the crowded lower digits are difficult): upper and left rays **6, 7, 8, 9**; lower rays **10, 11, 12, 1, 2, 3, 4**; a marker resembling long-f / 5[?] at the lower right end of the dotted equinoctial line.

[Margin: *Quo pacto una opera fermè quatuor horologia declinantia à Verticali describantur.* — "How, at nearly a single working, four dials declining from the vertical are described."]

You see, then, that at nearly one working four dials are described: one declining from south toward the east, and a second from south toward the west, if the linework of the first is transposed so that right becomes left and conversely; a third from north toward the west, if the first is inverted so that upper becomes lower, and then whatever is on the right after this inversion is made left, and conversely; and a fourth from north toward the east, if the second is inverted in all its parts, just as we said a moment ago concerning the first. In all four the amount of the declination is always the same.

DE ARCVBVS SIGNORVM, ET LONGITVDINVM DIERVVM in horologio, quod à Verticali circulo declinat.

On the arcs of the signs and the lengths of days, in a dial that declines from a vertical circle.

CAPVT XXIV.

[Margin: *Constructio figuræ radiorum Zodiaci pro arcibus signorum, & longitudinum dierum describendis in horologio declinante à Verticali.* — "The construction of the figure of the rays of the Zodiac, for describing the arcs of the signs and the lengths of days in a dial declining from the vertical."]

Draw the straight line **CI** for the axis of the world, and at **I**, perpendicular to **CI**, erect **IG** for the radius of the Equator, on either side of which the rays of the other signs are to be drawn, as above. Take **IC** equal to the straight line **IC** in the axis of the dial of the preceding chapter, and **IG** equal to the straight line **IG** (or **GL**) in the same dial. From **C**, through **G**, draw the straight line **CG** for the style-line — which we shall perhaps draw more conveniently if from **C** we draw the straight line **CG** making with **IC** an angle **ICG** equal to the angle **ICK** that the axis **CI** makes with the style-line **CG** in the dial.

Next, from the center **L** of that circle by whose aid we found the hour-points on the equinoctial line in the dial, take all the intervals up to those points of the equinoctial line where it is cut by the hour-lines; and transfer them from **I** onto the equatorial radius **IG**, marking the points on the equatorial radius. For if from **C** straight lines are drawn through these points, they will be the lines of all the hours — on this side and beyond the style-line — that intersect the equinoctial line. To these, then, attach the numbers of the hours answering to the hours whose intervals have been transferred, noting carefully which lines answer to the hours placed to the left of the style-line and which to the hours set to its right. This the numbers attached to the lines readily indicate, since they correspond to the numbers of the hour-lines of the dial that cut the equinoctial line. For these lines alone are what the lines so far emitted from the point **C** through the points of the equatorial radius represent.

We shall obtain these same lines if, from the dial, we take the hourly intervals between the center **C** and the equinoctial line [**◀M**[?] — a marginal reference mark, followed by the letter **M**; reading uncertain], and transfer them, in the figure of the zodiac rays from **C**, onto the equatorial radius **IG**, marking on it the points through which the hour-lines drawn from **C** must pass, and so on.

[Margin: *Qua arte linea horaria, quæ in horologio lineam æquinoctialem non secat, ducendæ sint in figura radiorum Zodiaci.* — "By what device the hour-lines which, in the dial, do not cut the equinoctial line are to be drawn in the figure of the zodiac rays."]

But if at any time some hour-line in the dial does not cut the equinoctial line but is equidistant from it, then from **C** the line **CA** must be drawn parallel to the equatorial radius **IG**. For this will answer to that hour — just as in the horizontal and vertical dial: because the line of the 6th hour from noon or midnight is equidistant from the equinoctial line, the straight line **HV** was drawn in the figure of the zodiac rays from **H**, parallel to the equatorial radius, for the hour so cut, as is settled from chapters 2 and 7.

But to obtain the lines of the other hours — those which neither cut the equinoctial line nor are parallel to it, of which kind are the ones that, after they have cut the equinoctial line, are produced beyond the center **C** (as in our example the hours 4, 5, 6 and the rest after noon, and 1, 2, 3 before noon, for all these are produced beyond the center **C**) — we shall follow this course. Through **C**, the center of the dial, we shall draw a straight line parallel to the equinoctial line (in our example this need only be conceived in the mind, since it is not

actually drawn); and through **C**, in the figure of the zodiac rays, the straight line **CA** parallel to the equatorial radius **IG**, which cuts the former in **A**.

After this, since every hour-line makes equal angles at the vertex **C** with that straight line which in the dial is drawn through the center **C** equidistant from the equinoctial line, we shall transfer the lines that go out from **C** in the figure of the zodiac rays and cut the equatorial radius, to the other side of the straight line **CA**, by aid of an arc of a circle described from **C**, in the figure of the zodiac rays — just as we did in the horizontal and vertical dial in chapters 2 and 7 — so that the lines equally distant on either side from **CA** enclose, with the straight line **CA**, equal arcs of that circle described from **C**, and equal angles at **C**. For

[Margin: *15. primi.* — Euclid, *Elements* I.15 (vertical angles equal).]

For the lines thus transferred will answer to those hours that do not cut the equinoctial line but run out beyond the center **C**, so that two lines equally distant from the straight line **CA** belong to two hours of the same number. Of these, the one that cuts the equatorial radius — that is, is drawn from **C** toward the equatorial radius — represents the hour that intersects the equinoctial line, while the other, transferred to the opposite side, represents the same hour produced beyond the center **C**, which does not cut the equinoctial line: exactly as was done in the horizontal and vertical dial. For there too the lines transferred beyond the straight line **HV** represent the same hours by number, though they do not cut the equinoctial line; because, of course, any hour-line makes equal angles at the vertex — that is, at the center **H** — with the line of the 6th hour, just as here it does with that line which is drawn through **C**, the center of the dial, parallel to the equinoctial line, and to which the straight line **CA** answers in the figure of the zodiac rays, exactly as there the straight line **HV** answers to the 6th hour, being the line parallel to the equinoctial in the horizontal and vertical dial. Thus you see here that the line of the 3rd hour after midnight has been transferred beyond the straight line **CA**, because the 3rd hour after noon cuts the equinoctial line; and likewise the line of the 4th hour after noon, because the 4th hour after midnight cuts the equinoctial line. The same reckoning is to be kept in the rest.

[Margin: *Quando linea styli una est ex horarijs lineis, vel æqualiter à duabus hinc inde distat, pertinet quælibet linea horaria in figura radiorum Zodiaci ad duas horas.* — "When the style-line is one of the hour-lines, or is equally distant from two on either side, each hour-line in the figure of the zodiac rays belongs to two hours."]

Now if the style-line should itself also be an hour-line, or should stand equally distant midway between two hour-lines — which sometimes happens — then each hour-line drawn from **C** in the figure of the zodiac rays will serve for two hours equally removed from the style-line on either side, just as in the horizontal and vertical dial. Hence to each single line two numbers must be assigned, answering to those two hours equally spaced from the style-line, as was done in the horizontal and vertical dial.

Diagram. The large "figure of the rays of the Zodiac" (*figura radiorum Zodiaci*) for the declining dial — a dense construction with an upper horizontal line, a great arc/semicircle graduated with the hours, a nested shadow-scale ladder at the upper left, and a fan of hour-radii issuing from the apex **C**. Because of the very crowded interior, the letter-labels below are those read with confidence; several interior hour-digits and points could not be resolved and are flagged.

- **C** — apex at top center, from which the hour-radii issue.
- On the upper horizontal line: **B, I, B, C** (repeated **B/C** letters marking the ladder rungs meeting the top line).
- Upper-left shadow-scale ladder: outer points **I** (top left), then **D, G, D** descending the left edge; interior rungs lettered **A, B, C, B, A**.
- Ray-captions along the oblique radii: *Rad. hor. 24, Rad. hor. 18, Rad. hor. 16, Rad. hor. 14, Rad. hor. 10* [and further *Rad. hor.* captions, partly obscured].
- Interior points: **M, F, n, G, E, H, L, N, B, A, P, O**.
- Hours graduated around the arc and along the ray-ends: on the arc **1** through **12**; lower-left ray-ends **8, 9, 10, 11, 12**; lower-right ray-ends **1, 2, 3, 4, 5, 6** (many interior digits illegible [?]).

[Margin: *[figura radiorum Zodiaci ad duas horas — continuation of the note above]*]

It would not be beside the point — indeed it would be expedient — when the style-line stands unequally distant from the two nearest hours, to construct two figures of the zodiac rays. In one of them would be drawn the hour-lines from **C** answering to those hour-lines in the dial that are contained on one side, namely the left, of the style-line; in the other, the hour-lines answering to the dial's hour-lines on the other side of the style-line. For thus all confusion of lines would be removed — the confusion that necessarily follows when the style-line stands almost equally distant from the lines set on either side, since then the points found on the equatorial radius are scarcely distinguished from one another, as is plain. On this plan, in our example, in one of the figures would be drawn the lines

from **C** answering to these hours 1, 2, 3, 4, 5, 6, 7, 8, 9 from midnight, which are to the left of the style-line; and in the other would be contained the lines answering to the hours to the right of the same style-line, namely 10, 11, 12 from midnight and 1, 2, 3, 4, 5, 6, and so on, from noon. In each figure, however, **CG** would have to be drawn for the style-line. An example of this you will see set out in chapter 29, when we treat of dials that decline and are at the same time inclined.

[Margin: *Quando linea styli inæqualiter distat à duabus proximis horis, construendæ essent duæ figuræ radiorum, ut confusio linearum tolleretur.* — "When the style-line is unequally distant from the two nearest hours, two figures of rays should be constructed, so that the confusion of lines is removed."]

Most conveniently, too, we shall draw these same hour-lines going out from **C** in the following way. Having drawn the straight line **CG** as before, we shall take on it, produced, any point **B** whatever, through which we shall draw the line **BA** parallel to **IC** itself, and through **C** another line **CA** parallel to the equatorial radius, which cuts the former in **A**. Then, with **A** as center and **AB** as the interval, describing a circle, we shall cut it into 24 equal parts, the beginning being made from a point which we shall now teach how to find, in this way. Let the straight line **LM**, taken in the dial, be transferred onto the equatorial radius from **I** up to **E**, and through

[Margin: *Quo artificio aliter horariæ lineæ in figura radiorum Zodiaci ducantur.* — "By what other device the hour-lines are to be drawn in the figure of the zodiac rays."]

and through **E**, from **C**, draw the straight line **CE** for the line of the 12th hour, cutting the straight line **BA** in **D**; and from **D**, perpendicular to the straight line **BA**, erect **DF**, cutting the circumference of the circle in the point **F**, which will be the starting-point of the division of the circle. Or else let the interval between the center **L** and any hour on the equinoctial line — whichever seems more convenient — be transferred from **I** onto the equatorial radius, marking a point on it; and through this point, from **C**, let a straight line be drawn for that hour, cutting the straight line **BA** in a point; and if through this point a perpendicular is drawn to **BA** — upward, indeed, if the assumed hour is taken from that side of the style-line where the 12th hour is, but downward if from the other side — we shall again have a point on the circumference from which the division of the circle can take its start.

Indeed it will sometimes be very useful to investigate this second point. For if one point of the division begun from it falls on the point **F** which was found in the

first place, the matter will succeed as intended; but if not, an error committed somewhere must be corrected. It is also better to begin the division of the circle rather from this latter point once found than from the point **F**, when the line of the 12th hour is very near the style-line. For then the perpendicular **DF** cuts the circumference too obliquely, so that the point **F** can scarcely be taken without error.

I wish this same thing to be understood in all the dials that follow which decline and are inclined. If, therefore, from the points of the divisions of the circle, perpendiculars are dropped to the straight line **BA**, or lines parallel to **CA** itself, cutting the straight line **BA** in points, then the straight lines emitted from **C** through these points will give the hour-lines, as before. It will be easy to judge which lines answer to which hours in the dial, from the points of the divisions of the circle. For the points always, proceeding from **F** toward **B**, represent those hours which in the dial follow the 12th hour toward the style-line, as is clear from the figure.

Moreover, we shall easily draw in this way those lines perpendicular to the straight line **BA** from the points of the divisions of the circle. If perhaps two points nearest to the point **B** are equally distant from it (which will indeed happen when the style-line is also an hour-line, or has receded equally from two hour-lines), the straight lines joining two points equally distant from the point **B** will be perpendicular to **BA**. But if not, let the interval of any point, taken from **B** in the upper semicircle, be transferred into the lower semicircle from the same point **B**. For the straight line connecting these two points will be perpendicular to **BA**. The same will be done if the intervals of the points from the straight line **BA** in the lower semicircle are transferred into the upper semicircle from the same straight line **BA**, as you see done in our example.

Diagram. The large finished declining dial with the arcs of the signs. The word **HORIZON** runs across the figure as the horizontal line (split **HO ... RIZON** by the construction). The center **C** sits at upper center on the meridian; a fan of hour-lines and dotted sign-arcs spreads downward and to the right, with zodiac-sign glyphs set at the outer ends of the sign-rays around the periphery. Because of the density and the small worn sorts, the letter-points read with confidence are listed first, then the sign-glyphs; several are flagged.

- **C** — center of the dial, on the meridian near the top.
- **K, I** — construction points just left/below **C**.
- **HORIZON** — the horizontal (horizon) line across the figure.

- Hour-figures along the lines: **1** through **12** (read partially; the crowded interior digits near center are illegible [?]).
- Zodiac-sign glyphs at the ray-ends around the rim (pinned by their position; worn sorts flagged): upper left ♒ (Aquarius), ♓ (Pisces); left ♐ (Capricorn)[?], ♉ (Taurus), ♊ (Gemini), lower-left ♋ (Cancer); lower center-right ♌ (Leo), ♍ (Virgo); right ♏ (Scorpio)[?], ♐ (Sagittarius)[?]; and one further glyph at upper right [?].

[Margin: *Descriptio arcuum signorum in horologio declinante à Verticali.* — "The description of the arcs of the signs in a dial declining from the vertical."]

[Margin: *Quando linea styli inæqualiter à duabus horis hinc inde distat, quid faciendum, ut accuratius arcus signorum describantur.* — "When the style-line is unequally distant from two hours on either side, what is to be done so that the arcs of the signs may be more accurately described."]

From these things thus prepared, the arcs of the signs will be described in the same way as in the horizontal and vertical dial: namely, by transferring the intervals of the hours intercepted between **C** and the rays of the signs onto the corresponding hours of the dial from the center **C**; or else by transferring the hourly intervals lying between the equatorial radius and the rays of the signs onto the corresponding hour-lines of the dial, the beginning being made from the equinoctial line, and so on. If the style-line should be the same as some hour-line, or should have receded equally from two hours placed on either side, each of the aforesaid intervals must be transferred onto the two hour-lines equally distant from the style-line, just as was done in the horizontal and vertical dial. But if the style-line stands unequally removed from the two hour-lines placed on either side, then, so that the arcs of the signs may be described more accurately, all the hour-points of the equinoctial line may be transferred from one side (namely from that on which more of them stand — as in our example from the left side) to the other, the beginning always being made from the line of the index, or style, as we did in our dial. For if through these points, from **C**, we draw hidden lines, such as are those which

These, which are marked off by those small lines on the dial, will always give us two lines equally distant from the index-line, so that onto them the same hourly interval, taken from the figure of the zodiacal rays, may be transferred. Indeed, if in the dial a straight line is drawn through **C** parallel to the equinoctial line, and if onto it there are transferred, from **C** the center of the dial and to either side, the portions of the line **CA** intercepted in the figure of the zodiacal rays between **C** and the rays of the signs, then on that line we shall have the points through

which the arcs of the signs are to be drawn — just as in the horizontal and vertical dial upon the line of the sixth hour.

[Margin: *Qui arcus ad signa australia, & qui ad borealia spectent.* — "Which arcs look toward the southern signs, and which toward the northern."]

Here too the arcs above the equinoctial line belong to the southern signs, while the rest belong to the northern, just as in the vertical dial. Moreover, from what we wrote in chapter 2 we shall easily recognize which signs' arcs are hyperbolas and which are parabolas or ellipses — namely, according to whether the style-line CB cuts the rays of the opposite signs or not.

[Margin: *Plura scripta sunt prop.2.li.3. & in schol. eiusdē propo. de descriptione arcuum signorum.* — "More is written in proposition 2 of book 3, and in the scholium of the same proposition, on the description of the arcs of the signs."]

Further material bearing on the accurate description of the arcs of the signs you will find explained by us in book 3, proposition 2, and in the scholium of the same proposition.

[Margin: *Linea Horizontalis.* — "The horizontal line."]

The horizontal line is the straight line AB itself, which is drawn through the place of the style perpendicular to the meridian line. This horizontal line divides the whole dial into two parts: the one below it faces south, the other faces north.

[Margin: *Horizōtalis linea diuidit totū horologiū in australe, & boreale.* — "The horizontal line divides the whole dial into a southern and a northern part."]

Both parts must be positioned on the wall so that the horizontal line is parallel to the horizon and occupies the upper place. In the northern dial, however, the arcs of the southern signs are changed into the arcs of the opposite northern signs, as in the vertical dial, and the lineaments that lie on the left must be drawn on the right, and vice versa, as we taught in the preceding chapter. But when the arc [zodiac sort: ?] in the southern dial also cuts the horizontal line on the other side — as happens when the plane of the dial has a small declination from the vertical — then the portion of the northern dial which the horizontal line cuts off must also be drawn on the other side, just as in the vertical dial the northern one was drawn on both sides. Otherwise, in a northern dial that declines toward the east, the hours would not be shown when the Sun rises, nor in one that inclines toward the west when the Sun sets.

The former dial can also be called Diurnal, and the latter Nocturnal, as we taught in the case of the vertical dial.

[Margin: *Horologiū declinans diurnū, ac nocturnū*. — "The declining dial, diurnal and nocturnal."]

Now the arcs of the day-lengths will be described in exactly the same way, if in place of the rays of the signs one takes the rays of the day-lengths — provided one observes that these arcs, in a dial facing north, are converted into their complements up to 24, as we wrote for the vertical dial in chapter 8. In the figure of the zodiacal rays we drew the rays of the hours 0, 6, 8, 10, 14, 16, 18, and 24.

[Margin: *Arcus longitudinum dierū quo pacto describantur*. — "How the arcs of the day-lengths are to be described."]

But if, from the lineaments described so far, a larger or smaller dial is to be drawn for a given size of style, we shall accomplish it in this way. Let there be drawn separately (as was done next to the figure of the zodiacal rays) the triangle ICG, taken from the dial of the preceding chapter or from the figure of the zodiacal rays of the present chapter, in which IC is the axis of the world, IG the equator, and CG the style-line, while the gnomon IK makes right angles with the index-line CG. Then, taking on the style IK (when produced) a line IA equal to the given gnomon, and drawing through A a line BD parallel to CG: if the axis BI is transferred from C in the figure of the zodiacal rays as far as the point B, toward I, and from B the rays of the signs are drawn out, and everything else is done as before, then the arcs of the signs will be described for the size of the given style IA, just as before they were described for the given style IK. For the hour-lines proceeding from C in the figure of the zodiacal rays, and in the dial we described in the preceding chapter, remain entirely the same at the same elevation of the pole and the same declination of the plane. The equinoctial line, however, must be drawn perpendicular to the style-line, distant from the center of the dial by as great an interval as the line BD.

ON THE ITALIAN AND BABYLONIAN DIAL, which declines from the vertical circle.

CHAPTER XXV.

[Margin: *Compositio horologij Italici, ac Babylonici à Verticali declinātis*. — "The construction of the Italian and Babylonian dial declining from the vertical."]

Let the circle drawn from L — by whose aid we found the hour-points on the equinoctial line — be cut into the diurnal arc of the tropic of Cancer $\mathfrak{S}$, aNb, and the diurnal arc of the tropic of Capricorn $\mathfrak{V}$, dNe, in such a way that the lines ab and de cut the line MN at right angles; and let the semidiurnal arcs of Cancer and Capricorn be numbered from the point N on either side in the circle MaNb, so that the whole diurnal arcs may be obtained, as we set out in chapter 4. Then, for the Italian dial, let the circle MaNb be divided once, and again, into 24 equal parts — the first time with the beginning made at point a, the second time at point d — so that a is the 24th hour from sunset in the tropic of Cancer, and the next point toward N is the 23rd hour, and so on; while d is the 24th hour from sunset in the tropic of Capricorn, and the next point toward N is the 23rd hour, and so on. Again, let the same circle be divided once into 24 equal parts, the beginning taken at point b, and again into 24 equal parts, the beginning made at point e, so that b is the 24th hour from sunrise in the tropic of Cancer, and the next point toward N is the 1st hour, and so on; while point e is the 24th hour of Capricorn from sunrise, and the next point toward N is the 1st hour, and so on. For by means of these division-points we shall find, in each tropic, the hour-points from sunset and from sunrise, and we shall complete the Italian and Babylonian dial in no other way than we constructed the horizontal one in chapter 4.

For example: a straight line drawn from f, the point of the 16th hour of Cancer from sunset, through the center L, cuts the equinoctial line at point g; and if from C, the center of the dial, a straight line is sent through g, the tropic of Cancer will be cut at point h, the 16th hour from sunset. So too, a straight line drawn from m, the point of the 21st hour of Capricorn from sunset, through L, cuts the equinoctial line at point n; and a straight line drawn from C through n cuts the tropic of Capricorn at p, the point of the 21st hour from sunset. In like manner, a straight line from q, the 14th hour from sunset in the tropic of Capricorn — which indeed is contained in the nocturnal arc of Capricorn, dMe — drawn through L, cuts the equinoctial line at point r; and a straight line drawn from C through r cuts the tropic of Capricorn, in the nocturnal arc, at point t, the 14th hour from sunset.

In this way we shall find only the points of those hours which are contained in the semicircle ANB, whose diameter AB is equidistant from the equinoctial line — because the straight lines drawn from those points through L pass through the center L before they cut the equinoctial line. Hence we shall find the points of the other hours, just as we said concerning the horizontal dial

in chapter 4: by the hours diametrically opposite to them. For instance, if we wish to find the point of the 23rd hour from sunset in the tropic of Capricorn — to which there corresponds, in the circle, the point D lying outside the semicircle ANB — we shall draw, from E, the opposite point (namely the point taken from the 11th hour from sunset in the tropic of Capricorn, comprised in the nocturnal arc of Capricorn), a straight line through L and D, which will cut the equinoctial line at point R. (Because R is very remote, it is not included in the example.) If through R a straight line is drawn from C, the tropic of Capricorn will be cut, in the nocturnal arc, at point F, the 11th hour from sunset; while the line RC, produced beyond the center C, will cut the same tropic of Capricorn at P, the point of the 23rd hour. And so with the rest.

In the same way we shall determine the points of the hours from sunrise in each tropic. For the northern dial, however, we give no example, because the hour-lines from sunrise and sunset, produced beyond the horizontal line, make the northern dial, as we said of the vertical dial in chapter 9.

Diagram. A large, very dense construction of the declining Italian and Babylonian dial: a fan of straight and dotted/dashed hour-rays spreads outward from the center **C** (upper center, on the vertical meridian/gnomon line topped by **I**), crossing a horizontal line whose right-hand end is marked **24**. At the lower left sits the tropic/diurnal circle carrying the lettered division-points; radial lines cross its interior. Because of the crowding and the small, worn sorts, only the labels read with confidence are listed; the dense interior digits do not resolve cell-by-cell on the scan and are flagged rather than guessed. **More than two labels are uncertain.**

- **C** — center of the dial (upper center, on the meridian line).
- **I** — top of the vertical meridian/gnomon line above C.
- **K** — just below C.
- **L** — to the left of C (center of the construction circle).
- **M** — near the center-right of the lower circle.
- **24** — right-hand end of the horizontal line (hour-ray 24).
- **P** — on a right-hand ray; **2** set below it.
- Outer right-hand hour-rays labelled (arabic): **22, 3, 21, 20** [several worn — read with low confidence].
- Roman hour-numerals set along the rays around the dial: **I, II, III, IIII, VI, VII, VIII, IX, XII** (and one form resembling **XIII** [?]); several are worn — [?].

- Lower-left construction circle, lettered points: **N** and **m** (left), **f** (below **N**), **A** and **d** (lower left), **g**, **B**, **D**, **E**, **F** (lower right of the circle), **e**, **q** (bottom).
- Several **R** labels descend the left margin at the ray-ends [worn, count uncertain — [?]].
- Interior arabic numerals (roughly 6 through 19) crowd the circle and the ray-crossings; these are not individually legible even under magnification [numeral: ?].

[Margin: *Alia descriptio horologij Italici, ac Babylonici à Verticali declinantis, per arcus diurnos, & nocturnos.* — "Another description of the Italian and Babylonian dial declining from the vertical, by means of the diurnal and nocturnal arcs."]

As for the description of these same dials derived from the diurnal and nocturnal arcs, no difficulty whatever appears, if the tables described in the scholium of proposition 33 of book 1 are carefully considered. For example, the 11th hour from sunset is drawn through the 6th hour from midnight in the diurnal arc of 14 hours, and through the 5th hour from midnight in the nocturnal arc of 12 hours, and likewise through the 4th hour from midnight in the nocturnal arc of 14 hours. So too the 20th hour from sunset passes through the 1st hour from noon in the diurnal arc of 10 hours, and through the 2nd hour from noon in the diurnal arc of 12 hours. But the 21st hour from sunset, which in our example has only a single point — namely the 2nd hour from noon in the diurnal arc of 10 hours — will be described if the 21st hour from sunrise is drawn through the 4th hour from midnight in the nocturnal arc of 14 hours, and extended through the 2nd hour from noon in the diurnal arc of 10 hours. So too, for the 22nd hour from sunset, the 22nd hour from sunrise must be drawn through the 5th hour from midnight in the nocturnal arc of 14 hours and through the 4th hour from midnight in the nocturnal arc of 12 hours; for this line, produced, will give the 22nd hour from sunset. Finally, by the same reasoning, for the 23rd hour from sunset, the 23rd hour from sunrise must be drawn through the 6th hour from midnight in the nocturnal arc of 14 hours and through the fifth hour from midnight in the nocturnal arc of 12 hours, and so on.

ON THE ANCIENT DIAL, WHICH declines from the vertical circle.

CHAPTER XXVI.

[Margin: *Descriptio horologij Antiqui à Verticali declinātis.* — "The description of the ancient dial declining from the vertical."]

Let the diurnal arc — both that of Cancer, aNb, and that of Capricorn, dNe — be cut into 12 equal parts in the circle MaNb, in such a way that the points next following the points b and e toward N belong to the 1st unequal hour, the next to the 2nd, and so on. For from the division-points we shall find, in each tropic, the points of the unequal hours, as we taught for the vertical dial in chapter 10. For a straight line thrown out from f, the point of the 2nd unequal hour of the tropic of Cancer, through the center L, cuts the equinoctial line at point g; and a straight line sent out from C through g cuts the tropic of Cancer at h, the point of the 2nd unequal

hour. Likewise, a straight line drawn from m, the point of the 9th unequal hour of the tropic of Capricorn, through L, cuts the equinoctial line at point n; and a straight line drawn from C through n cuts the tropic of Capricorn at p, the point of the 9th unequal hour, and so with the rest. For the 11th unequal hour of the tropic of Capricorn — since it is not contained in the semicircle ANB, whose points alone are found in the tropics, as was said above — we shall take the point D, opposite to it, which falls in the 11th unequal hour of the nocturnal arc of the tropic of Cancer, as we showed in book 3, proposition 13. If from D we draw a straight line through L, the equinoctial line will be cut at a certain point (which, on account of the narrowness of space, is not contained in our example); and a straight line sent out from C through that point will give, in the nocturnal arc of Cancer, the point corresponding to point D, while the same line, thrown out beyond the center C, will present, in the diurnal arc of Capricorn, another point for the 11th unequal diurnal hour of the tropic of Capricorn. By the same reasoning, for the unequal hours 11, 10, and 9

Diagram. The companion construction for the *ancient* (unequal-hour) declining dial — closely similar to the figure on printed page 512, but here the rays carry Roman unequal-hour numerals. A fan of straight and dotted rays spreads from the center C (upper right of the figure, on the meridian line) across a horizontal equinoctial line; at the lower left is the tropic/diurnal circle with its lettered division-points A ... F, centered on L. Because of the crowding and worn sorts, only the confidently-read labels are listed; the dense interior digits are flagged, not guessed. **More than two labels are uncertain.**

- C — center of the dial (upper right, on the meridian line).
- L — center of the lower construction circle.
- K — near the center, above the circle.
- M — right of center within the circle.
- N — at the left of the circle.

- **P** — on a left/mid ray (and a second **P** lower).
- **R** — upper left, and again lower left (ray-ends) [worn — [?]].
- **A, d, g, n, h, m** — lettered points along the left of the equinoctial line / circle.
- **B, D** — at the right of the circle; **e, f, E** at the bottom of the circle.
- **S** — upper right, beside the ray marked **XI**.
- Roman hour-numerals on the right-hand rays: **XI, X, IX, VIII**; and within the fan **III, IIII, V, VI, VII**.
- Interior arabic numerals (about 2, 3, 6, 7, 8, 9, 10, 11, 12) crowd the center and the circle; these are not individually legible even under magnification [numeral: ?].

of the tropic of Cancer, which likewise fall outside the semicircle ANB, we shall take the points E, F, G opposite to them, which fall in the unequal hours 11, 10, and 9 of the nocturnal arc of Capricorn; and from these we shall draw straight lines through L, so as to find, in the nocturnal arc of Capricorn, the points K, P, Q corresponding to the points E, F, G of the nocturnal arc of the tropic of Capricorn, in the circle MaNb. And if at any time some hour should fall precisely on the point A or B, then a straight line drawn through C parallel to the equinoctial line will mark in the tropic of Capricorn two points; of these, the one that lies to the right of CL will pertain to the hour that falls on point A, while the other, which is set to the left of CL, toward the north, will pertain to the hour that falls on point B. If, therefore, the corresponding points in the tropics are joined by straight lines, the ancient dial will be described, and all the unequal hours will pass through the hours reckoned from noon or from midnight on the equinoctial line, as we wrote above. But since the points of hours 11, 10, and 9 of the arc of Capricorn have no corresponding points in the tropic of Cancer, we shall join them with the points of the same hours of the nocturnal arc of Capricorn — points found by means of the points E, F, G, which are set opposite to those hours in the diurnal arc of Cancer and fall in the unequal hours 11, 10, and 9 of the nocturnal arc of Capricorn.

[Margin: *Constructio eiusdem horologii Antiqui ex arcubus diurnis atque nocturnis. Qua ratione Boreale horologium Antiquum ex Australi ortum habeat.* — "The construction of the same ancient dial from the diurnal and nocturnal arcs. In what way the northern ancient dial takes its origin from the southern."]

Now, if the diurnal arc of 6 hours — which above the horizontal line is the nocturnal arc of 18 hours — is described, the same ancient dial will be constructed from the tables of unequal hours set out in the scholium of proposition 33 of book 1.

Moreover, the lines of the unequal hours, produced beyond the horizontal line, display the same hours in the northern dial, if all the parts are interchanged, as was said above.

ON DIALS DECLINING FROM THE HORIZON.

CHAPTER XXVII.

At the beginning of book 1 we called a dial "declining from the horizon" that one whose flat surface, on which it is drawn, is equidistant from (that is, parallel to) a great circle standing at right angles to the vertical circle properly so called, and passing through the common sections of the horizon and the meridian, so that the common section of that circle and the horizon is the meridian line. But this

[Margin: The dial declining from the horizon is of four kinds.]

Now this dial is of four kinds. For it either faces the zenith and the rising Sun, or it looks toward the nadir and the setting Sun, so that the angle of inclination which it forms with the horizon slopes toward the west. Or else it faces the zenith and the setting Sun, or it belongs to the nadir and the rising Sun, so that the angle of inclination is set toward the east. The first may be called the upper eastern dial, because it shows the hours as soon as the Sun rises, and is drawn on the upper part of the plane. The second is the lower western dial, because it is drawn on the lower part of the plane and shows the hours right up to sunset. The third is the upper western, and the fourth the lower eastern: for the third is constructed on the upper part of the plane and marks the hours up to sunset, whereas the fourth is drawn on the lower part of the plane and displays the hours immediately from sunrise.

[Margin: Description of the dial declining from the horizon.]

The upper dial declining from the horizon, therefore, is drawn just as the southern dial declining from the vertical, and the lower one just as the northern, with the following exceptions. In place of the declination from the vertical circle, one should reckon the inclination to the horizon, which we shall find by proposition 23 of book 1: from D toward the right, toward B, if the plane of the dial faces west and is the upper dial; but toward the left, toward A, if the plane of the dial is the upper one and faces east. If, however, the dial is the lower one and faces west, the inclination must be counted from D toward the left, toward A; and finally, if the dial is the lower one and belongs to the east, the inclination must be reckoned from D toward the right, toward B. Then, on the arc of the circle drawn from β , one must count off from the straight line AB the complement of the pole's

altitude — not the pole's altitude itself, as was done earlier in dials declining from the vertical — above the line AB if the dial is the upper one, but below it if it is the lower. Let everything else be done as in dials declining from the vertical, as the figure itself shows, in which the upper dial facing west is set out, with a declination from the horizon of 30 degrees.

[Margin: The order of the hours in the dial declining from the horizon.]

The order of the hours is this. The straight line CE is always the line of the twelfth hour, of midday; those preceding it toward the left, toward A, show the afternoon hours, while those following it toward the right, toward B, belong to the forenoon hours — this in the upper dial, whether it faces east or west. But in the lower dial, whether facing west or east, the straight line CE is the line of the twelfth hour of midnight, not of midday; those preceding it toward A show the forenoon hours, that is, the hours after midnight, while those following it toward B signify the afternoon hours.

[Margin: Description of the same dial declining from the horizon, derived from the vertical dial.]

As for the latter method of drawing the hour-lines — the one by which, as in chapter 24, we find on the straight line AB the points through which pass the hours emitted from the center C — it must be observed that the hour-lines going out from F and cutting the straight line AB are not to be taken from the horizontal dial, but from the vertical one, as we showed in book 2, proposition 13.

[Margin: The altitude of the pole above the plane declining from the horizon.]

The angle GCI here too is the magnitude of the pole's altitude above the plane of the dial, just as in dials declining from the vertical, as we said in chapter 24.

[Margin: Description of the arcs of the signs and of the lengths of the days in the dial declining from the horizon.]

The arcs of the signs and of the lengths of the days will be drawn here just as in the dial declining from the vertical. This is plain from the two figures that follow.

[Margin: Description of the horizontal line.]

The horizontal line is drawn here parallel to the straight line CE, through the point where the line of the sixth hour and the equinoctial line cut each other, as may be seen in the figure. This horizontal line divides the whole dial into two parts. The larger of these — in which, of course, the line of the twelfth hour is contained — faces the zenith and is the upper part; the other is the lower part.

This holds provided that, when we turn to face the dial toward the east or toward the west (according as the dial faces west or east), all the upper features become lower, and what are then on our right become on the left, and vice versa. Of this kind would be the features which, drawn on the opposite side of the upper dial (after the upper part has been made lower), would correspond exactly to the features lying beyond the horizontal line.

[Margin: The upper and the lower dial. How the dial is to be positioned so that it may indicate the hours.]

Moreover, each dial, both the upper and the lower, is to be positioned so that the horizontal line is parallel both to the horizon and to the meridian

Diagram. A large hour-line construction for the upper dial facing west, declining 30 degrees from the horizon. A long horizontal line runs across the figure with **A** at its left end and **B** at its right end. Above the line, near the center, the point **C** sits within a small radiating circle (the source of the hour-rays), with **E** just below it and β (beta) a little lower on the line CE. From C a pencil of straight hour-rays fans out; the outer rays are labelled with the hours **7** and **8** (upper right), **9** and **10** (right and lower right), **11** and **12** (bottom center), and **3**, **4**, **5** (lower left). A large arc (semicircle) sweeps through the lower half, with further labelled points **K**, **G**, **L**, **M**, **N**, **D**, **H**, and the hours **1** and **2** near D. Dotted arcs cross the solid construction.

- A (horizontal line, left end): endpoint of line AB
- B (horizontal line, right end): endpoint of line AB
- C (upper center, in radiating circle): center from which the hour-rays are emitted
- E (below C): point on the meridian ray CE
- β (on CE, below E): point from which the graduated arc is described
- K, G, L, M, N, D, H: construction points on the lower arc / hour-network
- 1, 2, 3, 4, 5, 7, 8, 9, 10, 11, 12: hour-ray labels

found in the plane parallel to the horizon; and so that the straight line AB lies in the plane of the vertical circle properly so called — yet with this rule, that the horizontal line in any upper dial whatsoever be above the meridian line, but

Diagram. A second hour-line construction for the same declining dial, now carrying the arcs of the signs and the "radius of the hour" lines. A horizontal line runs across near the top, marked with points **I**, **B**, **C** and, at the far left, **I** again with **B**, **C**, **B** stacked; the top-right is closed by a great arc bearing the hour-

numbers 6, 7, 8, 9, 10. Below the horizontal line a pencil of hour-rays descends from the upper points, together with several dashed straight lines labelled "**Ra. hor. 0.**", "**Ra. hor. 6.**", "**Ra. hor. 14.**", "**Ra. hor. 18.**", "**Ra. hor. 24.**" (radius of hour 0, 6, 14, 18, 24) and short lines labelled "**Ro.**". Further interior points **D, G, K, A, E** are marked. Along the lower right run a series of zodiac-sign glyphs marking the sign-arcs; ♈ (Aries), ♉ (Taurus), ♊ (Cancer), ♋ (Leo), ♌ (Virgo) and ♍ (Capricorn) are identifiable, the remaining glyphs worn [?].

- I, B, C: points on the upper horizontal line
- A, D, E, G, K: interior construction points
- 6, 7, 8, 9, 10: hour-numbers on the upper arc
- Ra. hor. 0 / 6 / 14 / 18 / 24: "radius of the hour" lines (dashed)
- Ro.: radius lines
- ♈ ♉ ♊ ♋ ♌ ♍ [and further worn zodiac glyphs [?]]: sign-arc markers

inferior one below. Finally — so that, if the superfluous parts are cut away, the horizontal line always occupies the upper position, and the center C in the upper dial slopes toward the south, but toward the north in the lower dial; and so that the straight line AB, together with the line that cuts the meridian line at right angles, forms the angle of the plane's inclination to the horizon; and so that the common section of the plane of the dial and of the plane parallel to the horizon is the meridian line itself, in the plane parallel to the horizon, or equidistant from it.

Diagram. An Italian-and-Babylonian declining dial constructed on two circles. An upper small circle carries the points **A, B, C** (with dotted construction triangle); a large lower circle carries a diameter and the point **Φ** (phi), with the word for the horizon set vertically across the figure (legible fragments "HORI..." and "...ZON"). Between and around the circles runs a dense fan of solid and dashed hour-lines and sign-arcs, with hour-number labels (including **8**) and zodiac-sign glyphs down the right and lower right (Cancer ♊, Leo ♋, Virgo ♌, Scorpio ♏, Sagittarius ♐, Capricorn ♑, Aquarius ♒ identifiable; remaining glyphs and the vertical lettering "NON"/"ZON" worn [?]).

- A, B, C: points on the upper circle
- Φ: labelled point on the lower circle
- HORIZON (set vertically, split by the circles): the horizon line
- 8 [and further hour-numbers [?]]: hour-line labels
- ♊ ♋ ♌ ♏ ♐ ♑ ♒ [and further worn zodiac glyphs [?]]: sign-arc markers

[Margin: The diurnal and nocturnal dial.]

Again, the same horizontal line separates the whole dial into a diurnal and a nocturnal part, as was said in the case of the vertical dial.

[Margin: Which arcs in the dial declining from the horizon belong to the northern signs, and which to the southern.]

In every dial declining from the horizon, the arcs of the northern signs lie toward the south, and those of the southern signs toward the north — that is, in the upper dial the arcs of the northern signs are contained between the equinoctial line and the center, whereas in the lower dial the arcs of the southern signs are drawn toward the center, and so on. In the same way we shall here point out which arcs of the signs are hyperbolas, which parabolas, and which ellipses, as we said in chapter 24 for the dial declining from the vertical.

[Margin: By what method a dial facing east is made from one facing west, and vice versa.]

But if all the features of the upper dial facing west are drawn on another plane in such a way that those situated to the right of the meridian line become the left-hand ones, and vice versa, then there will be constructed an upper dial facing east, with the hour-numbers changed into their complements up to 12. Such are the features of the dial that faces west, drawn on the opposite side, so that each line corresponds exactly to each line. In the same way the dial that faces east can be changed into another that faces west, if that same interchange of lines and numbers is made. Indeed, the lower eastern dial too will by the same method be changed into the lower western, and vice versa.

[Margin: Construction of the Italian and Babylonian dial declining from the horizon.]

Both the Italian and the Babylonian dial will be drawn as we said above — namely, if the circle drawn from L is cut into the diurnal arc of Cancer ☊, aNb, and the diurnal arc of Capricorn ☋, dNe, as we taught before, and the division of that same circle takes its beginning, for the Italian dial, from the western points b and e, but for the Babylonian dial from the eastern points a and d. You have an example in the 21st hour from sunset. For from m, the point of the 21st hour from sunset on the tropic of Capricorn ☋, a straight line drawn through L cuts the equinoctial line at n; and a straight line drawn from C through n cuts the tropic of Capricorn ☋ at p, the point of the 21st hour from sunset, and so on.

[Margin: Another description of the Italian and Babylonian dial declining from the horizon, from the diurnal and nocturnal arcs.]

As for the construction derived from the diurnal and nocturnal arcs, there is no difficulty — provided, however, that whenever some hour reckoned from sunrise or sunset has no point in the diurnal or nocturnal arcs, one takes the hour of the same number reckoned from sunset or sunrise, and so on, as was said above. For example, since the 12th hour from sunset has no point in the diurnal arc of 14 hours — as is clear from table 3 of proposition 33 of book 1 — we shall take the 12th hour from sunrise; and, as that table 3 requires, we shall carry it through the 5th hour from noon in the diurnal arc of 14 hours, and through the 6th hour from noon (as table 6 of proposition 33 of book 1 requires) in the nocturnal arc of 12 hours. For this line, when produced, will also give the 12th hour from sunset. In the same way, for the 13th hour from sunset, the 13th hour from sunrise has been drawn through the 6th hour from noon in the diurnal arc of 14 hours, and through the 7th hour from noon in the nocturnal arc of 12 hours. Likewise, for the 14th hour from sunset — which has a single point, namely the 9th hour from midnight in the diurnal arc of 14 hours — we have taken the 14th hour from sunrise, which must be drawn through the 7th hour from midday in the nocturnal arc of 10 hours. For a straight line drawn through these two points — namely through the 9th hour from midnight and through the 7th hour from midday — will give, in the diurnal arc of 14 hours, the 14th hour from sunset, and in the nocturnal arc of 10 hours, the 10th hour from sunrise. Finally, for the 1st hour from sunrise, in the lower dial the 1st hour from sunset has been drawn, in the

Diagram. The companion Italian-and-Babylonian declining dial, built from the diurnal and nocturnal arcs. At the top a nearly vertical line rises to a gnomon-point **C**, with **A** below it and a dotted construction triangle; a long dotted horizontal line runs to the right carrying the sign-glyph ☊ (Cancer) and the hour-number **13**. Down the left side the hour-numbers **8, 14, 13, 12, 7, 6**, and the point **I** are marked, with the hours **14, 13, 12, 15, 16, 17, 18, 19, 20** running out along the right and lower rays. A large circle at the lower center carries the horizon lettering ("HORI..."/"...ZON") set vertically together with the vertical lettering "NON", the points **N, m, q** (rho), **L, P**, and the point **Φ** (phi) on a diameter. Zodiac-sign glyphs run down the right and lower right (Cancer ☊, Leo ♌, Virgo ♍, Libra ♎, Scorpio ♏, Sagittarius ♐, Capricorn ♑ identifiable; the rest worn [?]).

- **C** (top): gnomon-point / center of the hour-rays
- **A**: construction point below **C**
- **I, L, P, N, m, q**: construction points
- **Φ**: labelled point on the lower circle's diameter
- **HORIZON** (set vertically): the horizon line; "NON" lettering [?]

- 6, 7, 8, 12, 13, 14, 15, 16, 17, 18, 19, 20: hour-line labels
- ☿ ♈ ♉ ♊ ♋ ♌ ♍ ♎ ♏ [and further worn zodiac glyphs [?]]: sign-arc markers

in the nocturnal dial, through the 7th hour from noon in the nocturnal arc of 12 hours, and through the 8th hour from noon in the nocturnal arc of 14 hours. For in the lower dial this gives the 1st hour from sunrise, as we showed in the scholium to proposition 23 of book 2.

Moreover, the hours produced beyond the horizontal line likewise give, in the lower dial, the hours reckoned from sunrise and from sunset, just as we explained in the case of the vertical dial.

The ancient dial [i.e. the unequal-hour dial] is constructed exactly like one declining from the vertical. For example, from f — the point of the 4th unequal hour on the tropic of Cancer [☿] — a straight line drawn through L cuts the equinoctial line [linea aequinoctialis] at g; and the straight line C g cuts the tropic of Cancer at h, the point of the 4th unequal hour; and so on for the rest. For the 1st hour, in the lower dial, we have drawn from m — the point of the 1st nocturnal hour on the tropic of Capricorn [♏] — a straight line through L that cuts the equinoctial line at n. For the straight line C n cuts the tropic of Capricorn at p, the point of the 1st unequal nocturnal hour. Therefore the straight line drawn from p, through the 7th hour from noon in the nocturnal arc of 12 hours, will give the 1st unequal nocturnal hour in the nocturnal portion of the dial; and this same line, in the lower dial, will be the 1st unequal diurnal hour, and so on.

[Margin: Construction of the ancient dial declining from the horizon.]

Diagram. The construction of the ancient (unequal-hour) dial declining from the horizon, developed here from the diurnal arc of 18 hours. From a point C at the upper right, the center of the hour-rays (the gnomon point), a fan of straight and dotted rays runs down and to the left toward a large circle at the lower center. Along the upper rays out of C run the hour-numbers 9, 6, 4, 3 (with further fractional numbers — 2½[?], 12, 10½[?] — partly worn); the roman-numeral hour-lines XII, XI, X, IX, VIII, VII, VI, V, IIII are set inside and around the circle. The upper near-vertical line carries the vertical lettering "HORI[S?]" (worn [?]); at the lower left of the circle the lettering "NON" is set vertically beside a separate point N. Two oblique tropic-arcs cross the figure, marked with the sign-glyphs ☿ (Cancer, near the top and again near h) and ♏ (Capricorn, at the lower right); further sign-glyphs along the lower right are worn [?]. A large S stands at the lower right where a line runs out.

- C (upper right): center of the hour-rays / gnomon point

- n, a: points near the top of the circle
- G (center of circle), M (right), f (lower left), d (left), I (far left): construction points
- N (left of circle), m (bottom of circle), c (bottom left), b (lower right), h (right, on the horizontal line): construction points
- IIII, V, VI, VII, VIII, IX, X, XI, XII: unequal-hour lines
- 9, 6, 4, 3 (and worn fractional hour-numbers [?]): hour-line labels along the upper rays
- ♋ (Cancer), ♑ (Capricorn): tropic-arc markers; further worn sign-glyphs [?]
- "HORI[S?]" (vertical, worn [?]); "NON" (vertical): horizon lettering
- S (lower right): terminal label [?]

By the second, later method we have marked out — at the hours from midnight 9, 10½, 12, and at the hours from noon 1½, 3, 4½, 6, 7½, 9 — the points of the diurnal arc of 18 hours, through which the unequal hours are to be drawn, as is clear from the tables of the scholium to proposition 33 of book 1.

[Margin: Description of the same ancient dial declining from the horizon, from the diurnal arc of 18 hours. The dial inclined to the horizon is fourfold: upper southern; lower northern; upper northern; and lower southern, as it may be called. Six precepts for the construction of dials inclined to the horizon.]

ON DIALS INCLINED TO THE HORIZON.

CHAPTER XXVIII.

At the beginning of this *Gnomonics* we said that a dial is called inclined to the horizon when it lies equidistant from the great circle drawn at right angles to the meridian and through the common sections of the horizon, the equator, and the vertical circle, in such a way that the common section of that circle and of the horizon stands perpendicular to the meridian line. Now this is of four kinds. For either it faces the zenith and the south, or the nadir and the north, so that the lines constituting the angle of inclination which it makes with the horizon verge toward the north; or else it faces the zenith and the north, or the nadir and the south, so that the lines constituting the angle of inclination extend toward the south. The first may be called upper southern; the second, lower northern; the third, upper northern; and the last, lower southern. So that all these dials may be described more easily, the six precepts that follow are to be carefully committed to memory.

PRECEPT I.

When the plane of an upper southern or lower northern dial — that is, one whose angle of inclination verges toward the north — has an inclination equal to the pole's altitude, its dial does not differ from the polar dial, upper and lower, which we treated in chapter 16.

PRECEPT II.

But when the same plane has an inclination smaller than the pole's altitude, if the inclination is subtracted from the pole's altitude, there remains the altitude of the pole above the proposed plane; and for that altitude a horizontal dial is to be described, as we set out in chapter 1. This dial is then to be placed so that its equinoctial line lies equidistant from the straight line which, in the plane equidistant from the horizon, cuts the meridian line at right angles. (This is easily done if some straight line, cutting the dial's meridian line at right angles, is set in the plane parallel to the horizon, perpendicular to the meridian line found in it.) The dial itself is then to be raised on the northern side according to the inclination of the plane, so that its meridian line, together with the meridian line found in the plane equidistant from the horizon, contains toward the north the angle of inclination — yet on this condition: that on the upper face of the plane, which is turned toward the zenith and the south, the center of the dial lies below the equinoctial line, but on the lower and northern face, above the same line.

The order of the hours will be this. In the upper dial, when we have turned toward the dial facing north, the hours after midnight lie to the left of the meridian line and the afternoon hours to its right, so that the portion of the meridian line running from the center toward the equinoctial line marks the 12th hour of noon, and the remaining portion from the center, also beginning there, the 12th hour of midnight — just as in the horizontal dial. In the lower dial the matter stands the opposite way: because, when we have turned toward the dial facing south, the hours after midnight lie to the right of its meridian line and the afternoon hours to the left, so that the portion of the meridian line from the center toward the equinoctial line indicates the 12th hour of midnight, and the remaining portion from the center, also beginning there, the 12th hour of noon — as in the vertical dial facing north.

Furthermore, the arcs of the northern signs fall between the center and the equinoctial line in the upper dial, and those of the southern signs beyond the equinoctial line; but in the lower dial they stand the opposite way.

PRECEPT III.

Finally, when the plane's inclination exceeds the pole's altitude, if the pole's altitude is subtracted from the inclination, there remains the altitude of the pole above the proposed plane; and for that altitude a horizontal dial is to be built, following the teaching of chapter 1. It is to be placed just as in the preceding precept, with this exception: that here, on the upper and southern face of the plane, the center of the dial is to be set above the equinoctial line, but on the lower and northern face, below the same — as happens in vertical dials. The order of the hours is here entirely the same as that set forth in the 2nd precept.

The arcs of the southern signs are enclosed between the center and the equinoctial line in the upper dial, and those of the northern signs beyond the equinoctial line; but in the lower dial they stand in the opposite manner.

PRECEPT IV.

Again, when the plane of an upper northern or lower southern dial — that is, one whose angle of inclination verges toward the south — has an inclination equal to the complement of the pole's altitude, its dial is the same as the equinoctial dial, upper and lower, described in chapter 20.

PRECEPT V.

But when its inclination is less than the complement of the pole's altitude, if the inclination is added to the pole's altitude, there is produced the altitude of the pole above the plane itself; and for that altitude, following the teaching of chapter 1, a horizontal dial is to be constructed. It is to be placed as we said in the precept of chapter 2, except that this dial is to be raised on the southern side according to the inclination of the plane, so that its meridian line, together with the meridian line found in the plane equidistant from the horizon, constitutes the angle of inclination toward the south — with this further condition added: that on the upper and northern face of the plane the center of the dial has its seat above the equinoctial line, but on the lower and southern face, below the same.

The order of the hours will be this. In the upper dial, when we have turned toward the dial, the hours lying to the right of the meridian line are those after midnight, and those to its left are the afternoon hours — yet on this rule: that the portion of the meridian line from the center toward the equinoctial line marks the 12th hour of noon, and the remaining portion from the center, also beginning there, the 12th hour of midnight. But in the lower dial, when we have turned toward the dial, the hours after midnight are found to the left of the meridian

line, and the afternoon hours to the right, yet in such a way that the portion of the meridian line from the center toward the equinoctial line belongs to the 12th hour of midnight, and the remaining portion from the center, taking its beginning there too, indicates the 12th hour of noon.

The arcs of the northern signs, moreover, are those contained in the upper dial between the center and the equinoctial line, while those which lie beyond the said line belong to the southern signs — as in the horizontal dial. In the lower dial the matter stands the opposite way.

PRECEPT VI.

If, finally, the plane's inclination is greater than the complement of the pole's altitude, the complement of the inclination is to be added to the complement of the pole's altitude. For by this reckoning is produced the altitude of the pole above the proposed plane; and for that altitude, as we taught in chapter 1, a horizontal dial is to be composed, which must be placed as we taught in the preceding precept — yet on this condition: that on the upper and northern face of the plane the center of the dial is set below the equinoctial line, just as in the vertical dial verging toward the north; while in the lower

southern dial [it is set] above the same, as in the vertical southern dial. The order of the hours here is the same as in the preceding precept, with this difference: that here, in the upper dial, the portion of the meridian line from the center toward the equinoctial line indicates the 12th hour of midnight, and the remaining portion from the center, also beginning there, the 12th hour of noon. But in the lower dial the reverse occurs.

The arcs of the northern signs, furthermore, are contained in the upper dial between the center and the equinoctial line, and those of the southern signs beyond the said line; but in the lower dial the opposite.

Diagram. An inclined horizontal dial with its full fan of hour-lines. The hour-rays radiate from a point **H** low in the center (the foot of the style), spreading up and out on every side. Point **D** stands just to the left of **H**, **G** just to the right of it; a nearly horizontal base-line runs left through **F** and **D**, and to the right through **I**, **G**, and **K**. **E** stands above the center. The hour-numbers ring the figure: down the left side 9, 8, 7, 6, 5, 4; across the top and upper right 10, 11 (II), 12, 1 (I), 2, 3, 4; and along the lower edge 4, 3, 2, 1 (I), 12, 11, 10, 9, 8, 7, 6.

- **H** (center, lower): foot of the style; origin of the hour-rays
- **D**, **G**: points flanking **H** on the base-line

- F (left), I, K (right): points on the horizontal base-line
- E (above center): construction point
- 1–12 (arabic, ringing the figure): hour-line labels

EXAMPLE. Let this be an example of the whole. Let there be proposed a plane facing the zenith and the north, inclined to the horizon by 68 degrees. Since, then, the inclination is greater than the complement of the pole's altitude — for at the latitude of Rome, for which we describe all the dials in this our *Gnomonics*, the complement of the pole's altitude amounts to 48 degrees — we shall add the complement of the inclination, namely 22 degrees, to the complement of the pole's altitude, and we shall obtain the altitude of the pole above the proposed plane, 70 degrees, as we set out in the 6th precept. For this altitude of 70 degrees, therefore, we shall describe the inclined dial just like a horizontal one, as appears in the figure below.

[Margin: Description of the astronomical dial inclined to the horizon.]

The figure of the zodiacal rays and of the day-lengths is to be constructed as we showed in the horizontal dial; and from it, in the same way, both the arcs of the signs and the diurnal arcs will be described. This the adjoining figure, together with the following one, indicates.

The horizontal line is in every case to be drawn in this way. Through the position of the style **G**, let the perpendicular **G A** be drawn to the meridian line; on it take the straight line **G A**, equal to the style, and from **A**, at any interval toward the meridian line, describe an arc of a circle on which, starting from the straight line **A G**, is laid off the complement of the inclination of the dial's plane to the horizon — upward, indeed, in the upper dials, but downward in the lower ones. For the straight line drawn from **A** through the end of that laying-off will cut the meridian line at a point through which a straight line, drawn perpendicular to the meridian line, or parallel to the equinoctial line, will give the horizontal line. We may also draw it in this way. In the upper dial let there be found, on the meridian line, the point of midnight through which the diurnal arc of 24 hours passes; but in the lower dial, the point of noon through which the nocturnal arc of 24 hours runs. For through this point a straight line drawn perpendicular to the meridian line will be the horizontal, as before.

[Margin: Description of the arcs of the signs and of the day-lengths, together with the figure of the zodiacal rays. How the horizontal line is to be drawn in dials inclined to the horizon.]

Diagram. The astronomical dial inclined to the horizon at a pole-altitude of 70 degrees, showing the zodiacal rays and the day-length arcs. A horizontal line runs across the top carrying the points **H** (marked **H'**, the style), **D**, and **A** at the right end, from which a large quarter-circle arc springs and curves down to the right. A small **G** stands just below **H** at the style. From the upper region a dense sheaf of straight and dashed rays (the zodiacal rays) fans downward, crossed by two arcs of a circle. Interior points: **I** (center), **P** (lower left), **B** (center, marked with a small cross), **Φ** (phi, right of center), **V** (lower left). Along the base run the hour-numbers **9, 8, 7, 6, 5, 4, 3, 2, 1 (I), 12**, with **10, 11** set just below.

- **H** (=H', top left of the base): the style
- **D**: point on the top horizontal line
- **A** (right end): foot of the perpendicular / spring of the arc
- **G**: style-point below **H**
- **I** (center), **P** (lower left), **B** (center, cross-marked), **Φ** (phi), **V** (lower left): construction points
- 1–12 (arabic, along the base): hour-line labels

This horizontal line, moreover, divides the whole dial into two — upper and lower — as well as into diurnal and nocturnal, as was said of the vertical dial in chapters 7 and 9; yet in such a way that in the lower dial all the parts are interchanged, as was said in what precedes, and the arcs of the northern signs are turned into the arcs of the southern signs...

Gnomonics, Book VII (continued)

changed about, and the reverse holds. And so, if it is the upper dial that has been laid out, the horizontal line cuts off the lower part; and conversely [if the lower dial is drawn, it cuts off the upper part].

Diagram. The astronomical dial inclined to the horizon, showing the equinoctial and horizon lines with the day-arcs of the zodiacal signs and the hour-lines. Two horizontal parallel lines run across the figure: the upper is labelled **AEQVA·TOR** (the equinoctial/equator line), the lower **HORI·ZON** (the horizon line). A dense central cluster of dotted arcs (the day-arcs of the signs) sits between them, from which a fan of hour-lines radiates. Zodiacal glyphs are set at the ends of the rays.

- **AEQVA·TOR**: the equinoctial line (split across the head of the figure); a zodiac glyph set at its right end under "**TOR**" — reads as ♌ (Leo) [?]
- **HORI·ZON**: the horizon line (split)

- Hours across the top: 8, 9, 10, 11, 12, 1, 2, 3, 4
- Hours at the two ends of the horizon line: 6 (left), 6 (right)
- Interior points (near the dotted cluster): a point reading L or E [?], A, G, H
- Left descending rays, with glyphs: ♂ (Taurus), 5, H, 4, 3, ♄ (Capricorn) [?]
- Right descending rays, with glyphs: ♋ (Pisces), ♋ (Cancer), ♍ (Virgo) near 7, a glyph near 8 [?], ♄ (Capricorn) [?] near 9
- ♊ (Aquarius, wavy) set near the center cluster

[Margin: The construction of the Italian and Babylonian dial inclined to the horizon.]

Diagram. The Italian (Italic) and Babylonian dial inclined to the horizon — a large fan of hour-lines carrying both Roman numerals I–XXIV (the Italic hours, counted from sunset) and Arabic numbers 1–24 (the Babylonian hours, counted from sunrise), with a horizon line across the middle and a construction circle in the upper center. Solid and dashed rays radiate outward on every side.

- Horizon line across the middle, labelled **HOR·ZON** (split), with **6** at its left and right ends
- Construction circle (upper center) with points: **T** (left), **E** (center), **K**, a point reading ς / sigma [?], and interior points **1**, **B**, **B** (two B-points), **G**, **H**, **D**, **M**
- Left flank rays (Roman, ascending): IIII, III, a numeral reading VI [?], II, I; and (descending) XII, XI, X
- Left flank rays (Arabic): 24, 23, 22, 21, 20
- Points along the horizon on the left: a numeral reading XV [?], **G**, **S**, **O**
- Right flank rays (Roman): the numeral group reading IIX / XI / X [?], and lower I, II, III, IIII
- Right flank rays (Arabic): 20, 23, 24; and lower 12, 11, 9, 8
- Lower rays: **V**, **VI**, **VII**, **VIII** (dashed)
- Scattered zodiac glyphs on the rays [?]

The drawing of the hours from sunrise or sunset is carried out as was explained in what precedes. Most conveniently, however — so far as the second method is concerned — they are drawn from the diurnal arc of 14 hours alone (in our example), whose nocturnal portion is the nocturnal arc of 10 hours. If, for the individual hours from setting — which have only single points on the diurnal arc of 14 hours — one takes, for the same numbered hours from rising, other points (whether on the same diurnal arc of 14 hours or on the nocturnal arc of 10 hours), then you see that the hour 23 from setting passes through the hour 6 from noon on the diurnal arc of 14 hours, whereas the hour 23 from rising passes

through the hour 4 from midnight on the nocturnal arc of 10 hours. If, then, these two points are joined by a straight line, one obtains — in the upper dial — the diurnal hour 23 from setting,

and in the nocturnal [dial], the hour 23 from rising. So too for the hour 20 from setting: the hour 20 from rising has been drawn through the hour 1 from midnight on the nocturnal arc of 10 hours, and through the hour 2 from midnight on the nocturnal arc of 12 hours. For this line, when produced, exhibits the hour 20 from setting, and so on.

Very conveniently, moreover, these same hours will be delineated by means of the diurnal arc of 24 hours and the nocturnal arc of 12 hours, as is clear from what precedes. You have an example in the immediately preceding figure.

The line of the 12th hour from rising or setting is drawn through the point **D**, found on the line of the 12th hour of noon [the noon-line], through which must pass the arc of the greatest of the always-apparent parallels — namely that of 24 hours — [this line being] perpendicular to the meridian line, or parallel to the equinoctial line.

Finally, the Ancient dial is to be constructed as was explained in what precedes; the figure itself makes it sufficiently clear.

[Margin: The construction of the Ancient dial inclined to the horizon.]

Diagram. The Ancient dial inclined to the horizon — a fan of hour-lines with a construction circle in the upper center, the horizon line across the middle, and hours labelled in Roman and Arabic numerals. Solid and dashed rays radiate on every side; a tropic-arc (of Cancer ☊) runs through the field.

- Construction circle (upper center) with points: **M** (top), a point reading Λ [?], **C, b, E** (center), **K**, a point reading ς / sigma [?]
- Horizon line across the middle, labelled **HOR·ZON** (split)
- Central / lower points: **A, N, D, L, G, B, H, V**, and **F** (lower right)
- Left flank rays (Roman): IIII, III, a numeral reading VI [?], II, I; and lower XII, XI, X
- Right flank rays (Roman): III^ (III), XI, X, IX (as IX/IIX [?]), and lower I, II, III, IIII
- Arabic hour-labels among the rays: 4, 6, 7, 9, and others [?]
- Zodiac glyphs on rays: ☊ (Cancer) [?] and others [?]

makes clear. For, by way of example: at the point **A** of the unequal hour 3, on the circle described from **E**, we took the opposite point **C**, and drew the straight line **CEA**, which cuts the equinoctial line at the point **D** — through which a straight line drawn through **H**, the center of the dial, when extended, cuts the tropic $\mathfrak{S}$ [Cancer] on the nocturnal arc at a certain point, the point that belongs to **C** on the nocturnal arc of the said circle; but beyond **H** it cuts the same tropic on the diurnal arc at **F**, the point of the [unequal] hour 3, and so on.

But this same dial will be delineated most aptly by means of the nocturnal arc of the tropic $\mathfrak{S}$ alone, in our example. For thus you see that the straight line drawn from **I**, the point of the 11th hour on the nocturnal arc of the tropic $\mathfrak{S}$, through **E**, cuts the equinoctial line at **L**; and that the straight line **LH** cuts the nocturnal arc $\mathfrak{S}$ at **M**, the point of the 11th nocturnal hour. If, therefore, from **M** we draw a straight line through the 5th hour from midnight on the nocturnal arc of 12 hours (as is established from Table 14, Proposition 33, Book I), we shall have the unequal nocturnal hour 11, which, produced beyond the horizontal line, will also give the diurnal hour 11. And in the same way we shall draw the remaining hours.

As for the other construction, which is carried out by means of the diurnal arc of 18 hours and the nocturnal arc of 6 hours, the matter is clear from the figure itself.

ON DIALS DECLINING FROM THE VERTICAL AND INCLINED TO THE HORIZON.

CHAPTER XXIX.

That dial we called, at the beginning of this our *Gnomonics*, a dial "declining from the vertical circle and inclined to the horizon": it is one that lies parallel to a great circle which is perpendicular neither to the horizon, nor to the vertical, nor to the meridian, but is inclined to all these circles, so that it passes through the poles of none of them — of which kind are most of the [wall-]faces of buildings. This [class] is divided into eight kinds. For it either declines from the south toward the east, or west,

[Margin: The dial declining from the vertical and inclined to the horizon, eightfold.]

west, and faces the Zenith and the south; or it declines from the north toward the east, or west, and looks toward the Nadir and the north — in such a way that the

lines forming the angle of inclination which it makes with the horizon slope toward the north, toward the west or the east. Or else it declines from the north toward the east, or west, and faces the Zenith and the north; or it declines from the south toward the east, or west, and looks toward the Nadir and the south — in such a way that the lines constituting the angle of inclination which it makes with the horizon slope toward the south, toward the west or the east.

[Margin: The names of the eight dials declining from the vertical and inclined to the horizon.]

These eight dials, then, may be named as follows: the Upper Southern verging east; the Lower Northern declining west; the Upper Southern declining west; the Lower Northern declining east; the Upper Northern declining east; the Lower Southern declining west; the Upper Northern declining west; the Lower Southern declining east.

There are, then, four upper ones. Of these, the first two decline from the south toward the east or west and face the Zenith and the south; while the latter two decline from the north toward the east or west and face the Zenith and the north. Likewise there are four lower ones, of which the first two decline from the north toward the east or west and face the Nadir and the north, while the latter two decline from the south toward the east or west and look toward the Nadir and the south.

And these lower dials are described on the same planes as the upper ones, though on entirely opposite parts of them. For on the part opposite to the upper plane — which, say, declines from the south toward the east by 45 degrees, faces the Zenith and the south, and is inclined to the horizon by 20 degrees — is described the lower dial, which declines from the north toward the west by 45 degrees, faces the Nadir and the north, and is inclined to the horizon by 20 degrees. And the same judgment holds for the rest. For the declination of the lower dial is always the same as that of the upper, though not toward the same quarters: when the upper declines from the south toward the east and faces the Zenith and the south, the lower declines from the north toward the west and faces the Nadir and the north — and so with the others. The angle of inclination of the lower dial and of the upper, however, is always set toward the same side.

So that we may describe all these dials more easily, we shall give precepts only for describing the upper ones. For thus it will come about that the whole matter, which is somewhat difficult and obscure, is more clearly grasped. And once the upper dials have been described, we shall, with no trouble, fashion the lower

ones from them — just as, among the dials declining from the vertical, the northern were described from the southern in chapters 23, 24, 25, and 26; and among those declining from the horizon, the lower from the upper in chapter 27. All of which will become clear from the figures that follow.

Diagram. "First Figure" — the construction of the astronomical dial declining from the vertical and inclined to the horizon at the same time. A large circle (the bounding/horizon circle) is drawn; across it runs a horizontal diameter from **A** (left) through the center to **B** (right), and a near-vertical line through **F** (top) and **C** down through the central region. Numerous solid, dashed and dotted construction lines and arcs cross the interior.

- Caption (inside the field): **I. Figura** ("First Figure")
- **A** (left end of the horizontal line) and **B** (right end)
- **F** (top, on the vertical dashed line)
- **C** (upper center, on the horizontal line)
- **E** (upper right)
- **D** (below **C**, toward the center)
- **K** (central point — the position of the style)
- **H** (lower, right of center)
- β (the gnomon-length point, printed with a special sort; near the lower center)
- Further construction points, read but not all certainly placed: **L**, **I**, **M**, **G**, **b**, **d**, and a point reading **R** [?]; a point reading **a** (lowercase) [?] near the center; σ / sigma-like marks at the upper-left and at the foot of the figure [?]

[Margin: The construction of the astronomical dial declining from the vertical and inclined to the horizon at the same time.]

So, then, we shall carry out the matter as follows. On the plane of the dial, having taken the position of the style at **K** wherever you please, draw through **K** two straight lines **AB** and **CD**, cutting each other at **K** at right angles. Or, if the plane is a fixed one declining from the vertical and inclined to the horizon, draw — with the help of a level and a plumb-line — through **K** the straight line **AB** parallel to the horizon, which **CD** must cut at **K** at right angles. Then, taking on **AB** any length of the gnomon you please, **K β** — whether to the right of the straight line **CD** or to the left — describe from β , toward **CD**, an arc of a circle on which is counted off the inclination of the plane to the horizon (which in the first figure we set at 20 degrees; in the second at 70; in the third at 51 degrees 51 minutes; in the fourth at 30; in the fifth at 80; and in the sixth at 52 degrees 3

minutes), the start being made from the straight line **AB**, downward. Draw, through the end of the count, from β , a straight line cutting **CD** at the point **D**, through which the meridian line is to be drawn. Likewise, having reckoned off on the same arc, upward, the complement of the inclination, draw from β , through the end of the reckoning, a straight line (which will be perpendicular to βD) cutting **CD** at the point **C**, through which the straight line **CE**, drawn perpendicular to **CD**, will be the horizontal line.

[Margin: The horizontal line.]

Next, on the straight line **CD**, taking a straight line **CF** — upward or downward — equal to **C β** itself, describe from **F**, toward **CE**, an arc of a circle on which is counted off, from the straight line **CD**, the declination of the plane from the vertical circle (which in the first figure we set at 40 degrees from the south toward the east; in the second, 20 degrees from the south toward the west; in the third, 45 degrees from the south toward the east; in the fourth, 20 degrees from the north toward the west; in the fifth, 60 degrees from the north toward the east; and in the sixth, 30 degrees from the north toward the east) — to the right, indeed, if the plane deflects from the south toward the east, as in figures 1 and 3, or from the north toward the west, as in the fourth figure; but to the left, if the plane declines from the south toward the west, as in the second figure, or from the north toward the east, as in figures 5 and 6. Draw from **F**, through the end of the count, a straight line cutting the horizontal **CE** at **E**. For the straight line **DE**, drawn through **D** and **E** and produced in both directions, will give the meridian line — that is, the 12th hour from noon or midnight.

[Margin: The meridian line.]

Likewise, having reckoned off on the same arc, from the straight line **CD**, in the opposite direction, the complement of the declination, draw from **F**, through the end of the reckoning, a straight line (which will be perpendicular to **FE**) cutting the horizontal line at the point **a**, through which the equinoctial line and the line of the 6th hour from noon or midnight must be drawn. And once the straight line **a–K** has been drawn — which is necessarily perpendicular to the meridian line, if no error has been made — describe from **D** and **E** two arcs at the intervals of the straight lines **D β** and **EF**; these will necessarily cut each other, if no error has been committed, on the straight line **a–k** [printed lowercase], as at the point **H**. Whether this happens on the right side or the left makes no difference.

(Book VII, Cap. XXIX continues — the general construction of dials that decline from the vertical and are inclined to the horizon. The six worked figures span these

pages: figures 2 and 3 at the top of the first page, figure 4 at its foot, figure 5 on the second page, and figure 6 on the third. Point α is printed as a Greek alpha and the dial's center ρ as a Greek rho; the lowercase b , d , k are distinct printed sorts.)

Now, once the straight line **HE** has been drawn, describe from **H** an arc of a circle on which, beginning from the straight line **HE**, the complement of the pole's altitude is counted off toward the straight line **HD** — provided the plane of the dial declines from the south, as in the three preceding figures. Through the end of the count, draw from **H** the straight line **Hb**, cutting the meridian line at the point **M**, through which the equinoctial line is to be drawn from the point α , found earlier. And if, on the same arc but in the opposite direction from the straight line **HE**, the pole's altitude itself is counted off, and from the end of the count the straight line **Hd** is drawn through **H** — which will necessarily be perpendicular to **HM**, unless there is an error — then the same meridian line will be cut at the point ρ , which will be the center of the dial. But if it should happen that this line **Hd**, drawn last through **H**, is parallel to the meridian line — as occurs in the third figure — the dial will have no center, and all the hour-lines will be equidistant from one another; because in that case the great circle to which the dial is equidistant passes through the poles of the world. If, however, the plane of the dial declines from the north, as

Diagram. The second of the six worked figures for a dial that both declines and is inclined — a circle carrying the construction of the meridian, equinoctial, horizontal, and style lines, with the shadow-triangle and hour-line "6" markers. Legible labels:

- A (left) and B (right): the ends of the horizontal line **AB** across the circle.
- P (top), F (just below P): points on the upper vertical/meridian construction.
- E, C, I (row across the middle): points on the central axis of the figure.
- H (lower left), K, G, M (center cluster): construction points about the center.
- β (right of center) and α (upper right, near an outer "6"): the beta and alpha points.
- L (below center) and D (foot of the circle): points on the lower meridian.
- b (lower right, near a "6"): the point **b**.
- "6" (several positions, outside the circle): the 6th-hour lines.

[Several of the crowded interior labels (I/J, G, β) are partly overwritten by ruled lines; read with care.]

Diagram. The third figure, corresponding to the case where line **Hd** comes out parallel to the meridian (the dial without a center). A circle with the same construction lines. Legible labels:

- A (left), B (right): the horizontal line **AB**.
- F (top), C (center-top), E (right of C): upper points.
- K, β (center): interior points.
- L, M (left of center), D (below center), H (lower right): lower construction points.
- d (upper right, on a dashed line): the point **d**.
- "6" (top and elsewhere, outside): the 6th-hour lines.

[The dense central intersection carries several small labels I cannot fully resolve (β , and a mark below K).]

in the three later figures, the pole's altitude must be counted off on the said arc of the circle described from **H**, starting from the straight line **HE**, toward the line **HD**. For the straight line **Hd**, drawn from **H**, will through the end of the count cut the meridian line at **p**, the center of the dial. And if, on the same arc in the direction opposite to the straight line **HE**, the complement of the pole's altitude is reckoned, and from the end of the count the straight line **Hb** is thrown across through **H** — which will be perpendicular to **Hd** — the meridian line will be cut at the point **M**, through which the equinoctial line is to be drawn from α . But if it should happen that this line **Hb**, drawn last, is parallel to the meridian line — as in the sixth figure — then the equinoctial line must be drawn through α , parallel to the meridian line. If, then, a straight line is drawn from the center of the dial **p** through **K**, the position of the style, we shall have the style-line, which the equinoctial line drawn from α will necessarily cut at right angles. But where there is no center — as in the third figure — the style-line must be drawn through **K**, parallel to the meridian line and perpendicular to the equinoctial line. Likewise, where the equinoctial line is equidistant from the meridian line — as in the sixth figure — the style-line **pK** will be perpendicular not only to the equinoctial line but also to the meridian line. And so, if the equinoctial line is drawn first, the style-line must be drawn perpendicular to it, from the center **p** or from the position of the style **K**; but if the style-line is drawn first, from the center **p** through **K** — or, where there is no center, through **K** parallel to the meridian line — then the equinoctial line must be drawn perpendicular to it from α .

Diagram. The fourth figure, at the foot of the page beside the text column — a north-facing declining-inclined dial. A circle with the meridian, equinoctial, horizontal, and style lines and the shadow-triangle. Legible labels:

- α (upper left, at the vertex of the shadow rays): the point α .
- C, E (top center): points on the upper meridian.
- B (right), "6" (right, below B): the horizontal line end and a 6th-hour marker.
- d (upper left, on a dashed arc), I (left of center): construction points.
- K, ρ , F, D, H (central cluster): the center ρ and neighboring points.
- G (lower left), M (below G): lower points.
- b (upper center, small): the point b .

[Margin: The equinoctial line.]

[Margin: The center of the dial.]

[The central cluster K/ ρ /F/D is very dense; individual labels are hard to separate.]

After this, from the position of the style **K**, erect a straight line **KI** perpendicular to the style-line, equal to the style, and from the center ρ through **I** let the straight line ρ **I** be sent out for the axis of the world. But where there is no center — as in the third figure — the axis must be drawn through **I**, parallel to the style-line or to the meridian line. And if from **I** a perpendicular is dropped to the axis, it will cut the style-line at the point **G**, through which the equinoctial line is drawn — unless we have committed an error. Hence, where the dial lacks a center, so that the axis is equidistant from the style-line — as in the third figure — the said perpendicular will fall on **K**, the position of the style, and the equinoctial line must be drawn through that same position of the style. And so, if the axis of the world has been drawn through **I**, we shall find, by means of the perpendicular line **IG**, another point **G** on the style-line, through which the equinoctial line is to be drawn from the point α — a line that will necessarily make right angles with the style-line.

[Margin: The axis of the world.]

Finally, taking a straight line **GL** on the index-line, equal to **GI** itself, describe from **L** a circle of any size, and divide it into 24 equal parts, beginning from the straight line **LM** — which is drawn from the center **L** through the point **M**, where the equinoctial line and the meridian cut each other — or from the straight line **L α** , drawn from the same center **L** through the point α , where the horizontal line

and the equinoctial line meet, that is, the line of the 6th hour. Now it is necessary that the two straight lines **LM**,

Diagram. The fifth figure — a north-facing declining-inclined dial with the hour-circle described about **L**. A large circle with the meridian, equinoctial, horizontal, and style lines and the 24-part hour-circle. Legible labels:

- **M** (top, at the apex of the shadow rays): the point **M**.
- **b** (below **M**, small): the point **b**.
- **F**, **L** (center): the center **L** and neighboring point **F**.
- **E** (left of center), **A** (left), **B** (right): points on the horizontal line.
- "6" (upper right and lower left, outside): the 6th-hour lines.
- **G** (lower left), **D** (foot): lower construction points.

[The central intersection (**F/L** and the small labels around it) is dense; a few interior letters cannot be resolved.]

Lα cut each other at **L** at right angles, if no error has been committed. But if the equinoctial line is parallel to the meridian line — as in the sixth figure — then in place of the straight line **LM** a straight line must be drawn parallel to the meridian, one that cuts the straight line **L**α at right angles. Now if hidden [construction] straight lines are drawn from **L** through the division-points, the equinoctial line will be cut at points through which, from the center **p**, the lines of the hours from noon and midnight must be drawn; or, when the dial lacks a center — as in the third figure — through which lines must be drawn parallel to the meridian line, or to the style-line or the axis, and perpendicular to the equinoctial line, for the hours from noon or midnight.

[Margin: The lines of the hours from noon and midnight.]

The order of the hours is this. On planes that face south, the part of the meridian line extending from the center of the dial **p** toward the equinoctial line — as in the first two figures — or the whole meridian line where there is no center, as in the third figure, marks the 12th hour of noon. Those parts which lie to its right on the equinoctial line (we being turned to face the dial toward the north) signify the afternoon hours, and those to the left the forenoon hours; while the remaining part of the meridian line, beginning at the center, shows the 12th hour of midnight — just as in the southern vertical dial. But on planes facing north, when the equinoctial line lies below the center of the dial **p**, on the index-line — as in the fourth figure — the part of the meridian line extending from the center **p** toward the equinoctial line marks the 12th hour of noon; those parts which (we

being turned to face the dial toward the south) lie to its right on the equinoctial line show the forenoon hours, and those to the left the afternoon hours; while the remaining part of the meridian line, extended beyond the center toward the upper parts, belongs to the 12th hour of midnight — just as in the horizontal dial. But when the equinoctial line lies above the center of the dial **p**, on the style-line — as in the last two figures — the part of the meridian line drawn from the center **p** toward the equinoctial line, produced; or indeed, where the equinoctial line and the meridian are parallel — as in the sixth figure — the part

[Margin: The order of the hours.]

tending toward the upper parts, marks the 12th hour of midnight; while the hours descending to the right of the meridian line on the equinoctial line (we being turned to face the dial toward the south) are the forenoon hours, and those to the left the afternoon hours; the remaining part of the meridian line, below the center of the dial **p**, pertains to the 12th hour of noon — just as in the northern vertical dial.

Now if from the point **F** straight lines are drawn out that make, with the straight line **FE**, the same angles which the hour-lines make with the meridian line in the horizontal astronomical dial — as we taught in Cap. 23 [i.e. XXIII] for the dial declining from the vertical — the horizontal line **aE** will be cut at points through which the straight lines sent out from the center **p** (or, where there is no center, straight lines drawn equidistant from the meridian line) will give the lines of the hours from noon and midnight, as before.

[Margin: By what method the hour-lines on a plane that at once declines and is inclined were described from the horizontal dial.]

A dial that both declines and is inclined is to be set in its proper position thus. Let the horizontal line be set equidistant from the horizon; and let the common section of the dial and of the plane equidistant from the horizon, taken together with the meridian line in the plane that is equidistant from the horizon, once found, make the angle of the complement of the declination — toward the south and west if the dial declines from the south toward the east; toward the south and east if it declines from the south toward the west; but toward the north and west if the dial declines from the north toward the east; toward the north and

[Margin: How a dial that at once declines and is inclined is to be placed in its proper position.]

Diagram. The sixth figure — the fully drawn dial, in which (as the text notes) all the hour-lines have been laid in. A large circle whose rim carries the hour-numbers, with the meridian, equinoctial, horizontal, style, and full set of hour-lines radiating from the interior. Legible labels:

- Rim hour-numbers: **10, 11, 12, 1, 2, 3, 4, 5, 6, 7, 8, 9** (running around the circle; a few are faint).
- Interior letters: **F** (upper center), **E, C, G, H, K** (central cluster), **A** (left), **B** (right), **I** (lower left), **L, M, d**.

[This is the most crowded of the six figures; the central letter-cluster (K/H/G and neighbors) and several faint rim numbers cannot all be resolved with certainty.]

tum, if it deflects from the north toward the west. For in this way the dial will have its due declination. Next, let the straight line **CD**, which divides the horizontal line at right angles, together with the straight line in the horizontal plane that cuts the common section of the dial and of the horizontal plane at right angles, make the angle of inclination — toward the northern parts if the dial faces south, but toward the southern parts if it faces north. For once the dial has been set in place by this method, if along the axis **PI**, in the triangle **PIG**, at right angles to the plane of the dial, one imagines a thread stretched, or some fine iron wire, its shadow will indicate the several hours from noon or midnight, for as long as the Sun illuminates the dial itself. Or else the tip **I** of the style **Ik**, standing at right angles to the plane of the dial at the point **K**, will do the same, as we said in the case of the horizontal dial. When the dial lacks a center — as in the third figure — the axis must be drawn through **I**, equidistant from the style-line **GL**.

We have now completed this whole account of a dial that is at once declining and inclined in six figures, so that every variety of such dials might be displayed. Of these, the first three belong to those dials, facing south, in which the center of the dial either lies below the equinoctial line, or above it, or else the dial has no center and all the hour-lines are parallel, cutting the equinoctial line at right angles. The latter three represent those dials, facing north, in which the meridian line cuts the equinoctial line either below the center of the dial or above it, or else is parallel to the equinoctial line. Moreover, only in the sixth figure have we drawn all the hour-lines; in the others we have shown only those elements which are needed to understand the construction, the hour-lines being left out, so that a confusion of lines

so that we might avoid a confusion of lines. For anyone will be able to draw the hour-lines in these dials, just as in that one, provided he carefully considers the rules we have handed down.

[Margin: In what way an Inferior dial is generated from a Superior one.]

Now if any Superior dial whatever is turned over, so that its upper part becomes the lower, and what after this inversion is on our right becomes the left, and vice versa — as was made clear in what precedes — we shall obtain an Inferior dial. But the hour-lines that in the Superior dial formerly indicated the hours from noon will, in the Inferior dial, show the hours from midnight, and conversely. Here, moreover — as also in the preceding cases — the lineaments of the Superior dial, drawn on the opposite face, display this inversion beautifully: each single line answers exactly to its counterpart, provided the upper part of the opposite face becomes the lower, and vice versa.

[Margin: The drawing of the arcs of the signs and of the lengths of the days on a dial that declines and is at the same time inclined.]

The arcs of the signs and the lengths of the days are drawn here just as in the preceding cases. Draw the straight line ρI for the axis of the world, and at I erect the perpendicular IG upon it, to serve as the radius of the equator; to either side of this let the rays of the other signs and the lengths of the days be led out, as was done in the earlier cases. Then let $I\rho$ be equal to the portion of the axis ρI in the dial, and the straight line IG equal to the line IG (or LG) in the same dial; and from ρ , through G , let the straight line ρG be drawn. This we shall perhaps draw more conveniently if from ρ we draw the straight line ρG such that with the axis ρI it makes the angle $G\rho I$ equal to the angle $G\rho I$ which, in the dial, the axis ρI and the style-line ρG form — that is, equal to the angle of the pole's elevation above the plane of the dial. Finally let everything else be done as we set forth in Chapter 24, when we were treating of a dial declining...

Diagram. The figure of the rays of the Zodiac [figura radiorum Zodiaci] for a dial declining from the vertical, offered as the worked example that answers to the last of the six Superior dials described just before. It has two connected panels. The main (left/central) panel: a horizontal top line carrying the points I (far left), B , ρ , K ; from these a fan of solid and dashed rays descends to a large semicircle drawn below, with an interior point G , a point B on a lower horizontal, and a central point V . Several rays are captioned with the radius of a given hour: "**Radius hor. 0**", "**Rad. hor. 2**", "**Rad. hor. 10**", "**Rad. hor. 18**", and "**Rad. hor. 24**" (this last appears twice, near the top-right and near the lower centre). Along

the lower rim run paired hour-numbers (the *bini numeri* of the text), arranged symmetrically on either side of the noon line; the legible values include the full run 1–12 repeated on each side, but the small worn digits cannot all be resolved with certainty. The right-hand panel is a triangle whose top line carries **B, ρ, B, I**, with **A, K, A** on the transversal just below, and **D, G, D** descending its right edge; it is captioned "**Rad. hor. 24**" and "**Rad. hor. 18**".

[This figure is very crowded; the paired rim-numbers and several ray-captions are faint and cannot all be resolved with certainty.]

from the Vertical. For the figure of the rays of the Zodiac will thus be constructed, and from it the arcs of the signs will be drawn, as in a dial declining from the vertical. We have subjoined an example answering to the last Superior dial of the six we described a little earlier. Here, since the style-line is the same as the line of the 6-o'clock hour, two hour-numbers stand opposite to each single hour-line issuing from the point ρ of the figure of the Zodiac's rays, set equally on either side of the 6-o'clock line — that is, at equal distances from the style-line — as we advised in Chapter 24. Again, the straight line pV, being parallel to the radius of the equator, shows the 12th hour, because the line of that hour in the dial runs parallel to the equinoctial line: just as, in a horizontal dial, the straight line HV, parallel to the radius of the equator in the figure of the Zodiac's rays drawn in Chapter 2, marks the 6th hour, since this line too runs parallel to the equinoctial line in the dial.

We have also added another figure of the Zodiac's rays, issuing with hour-lines from ρ, answering to the first dial of this chapter, in which the style-line is neither one of the hour-lines nor equally distant from two placed on either side. Hence it comes about that each single line issuing from ρ has its own single number affixed to it. From this figure, therefore, one may draw the arcs of the signs in the said dial (provided all the hour-lines have first been drawn in it), whenever the occasion requires. We have divided this figure, as you see, into two, because otherwise its lines would too greatly...

Diagram. A large, fully drawn declining-and-inclined dial with the arcs of the signs laid in. A dense web of straight hour-lines and curved sign-arcs fills the field. Legible interior letters: **A, C, D, E, B** (left cluster), **ρ** (the central point, printed with a distinctive sort), **K, H** (central), **h, i, m, I** (lower). A dashed fan of lines runs from **K**, numbered **6, 7, 8, 9, 10** in sequence; further hour-numbers (**4, 5, 6, 7, 8, 9, 10, 11**) run along the outer rim. Zodiac-sign glyphs mark the arcs of the signs around the periphery; several are legible on the right and lower-right

(♉ [Taurus], ♊ [Pisces], ♏ [Scorpio]), but most are too small or worn to resolve individually [?].

[Crowded figure; the central letter-cluster and the great majority of the rim zodiac-glyphs cannot be resolved with certainty.]

run together, because the style-line of the first dial is only slightly distant from the line of the 11th hour, as is plain from the first figure of Proposition 37 of Book 3, in which the hour-lines are drawn. In the former of these figures are contained the...

Diagram. The former [prior] of the two panels into which the added figure of the Zodiac's rays is divided. A quarter-dial: a semicircular arc across the top, a horizontal base-line, and a fan of rays issuing from the point **p** (printed with the distinctive sort). Legible labels: **I** (top), **p**, **A** (left), **D**, **F**, **E**, **B** (centre). The rays are numbered with the hours placed to the left of the style-line, the legible values running 5, 6, 7, 8, 9, 10 with 12 near the style; the text states these are the hours 5, 6, 7, 8, 9, 10, and 11.

Diagram. The latter [posterior] of the two panels. Constructed like the former: a semicircular arc across the top, a horizontal base-line, and a fan of rays from **p**. Legible labels: **p**, **I**, **F**, **A**, **B** (and rim-numbers 4, 3, 2 along the arc). The rays are numbered with the remaining hours placed to the right of the style-line — the legible values including 12, 1, 2, 3, 4, 5.

hour-lines that are placed in the dial to the left of the style-line in the first figure of Proposition 37 of Book 3, or that would be placed to the left in the first figure of this chapter, had they been drawn — namely 5, 6, 7, 8, 9, 10, and 11. In the latter figure are the remaining hours, set to the right of the same style-line — namely 12, 1, 2, 3, 4, 5, and so on. This is what we advised in Chapter 24 must be done in declining dials, and still more in inclined ones, in which such a confusion of lines is found.

Finally, so that you may see what is to be done in the third dial of this chapter — in which the hour-lines are parallel, as were drawn in the third figure of Proposition 37 of Book 3 — we have also drawn the arcs of the signs in it. These are drawn just as in a meridian or a polar dial, with this one exception, that here the hour-lines in the figure of the rays...

of the rays cut the radius of the equator at right angles and so have each a single number, not two, as they had there — unless the style-line is one of the hour-

lines, or at any rate lies equally distant from the two nearest on either side, as usually happens in other declining dials.

[Margin: The horizontal line divides the dial into a Superior and an Inferior part, and into a Diurnal and a Nocturnal part.]

The horizontal line divides the whole dial, as was said in the preceding sections, into a Superior and an Inferior part: the Superior is that part contained below the horizontal line, while the remaining part will give the Inferior — provided, however, that all the parts are inverted, as was said above, and that the hours formerly reckoned from midnight are now reckoned from noon, and so on. The same horizontal line separates the whole dial into a Diurnal and a Nocturnal part, as was explained in the preceding sections.

Diagram. A large declining-and-inclined dial with the arcs of the signs, hour-lines, and shadow-rays drawn in. A dense field of straight lines converging from the left with a set of curved sign-arcs to the right. Legible interior letters: **A** (upper right, on a dashed vertical), **D, B, C** (dashed, right of centre), **E, F (?)**, **G, I, H**, and **h** (on a dashed line, lower centre). Two rays are captioned "**Rad. hor. 14**" and "**Rad. hor. 10**" (lower left). Hour-numbers **1, 2, 3, 5, 6, 7** run along the horizontal lines at the left; zodiac-sign glyphs mark the sign-arcs around the periphery (several legible, most too small or worn to resolve [?]).

[Crowded figure; the central letter-cluster, the Italian/Babylonian construction points (L, M, N, a, b, d, e named in the text), and most rim zodiac-glyphs cannot be resolved with certainty.]

[Margin: Which arcs of the signs belong to the northern signs, and which to the southern.]

Furthermore, the arcs of the northern signs are contained between the centre of the dial and the equinoctial line in Superior dials that decline from the north, and also in those which decline from the south — provided, however, that they have their centre below the equinoctial line, as in horizontal dials. But if such dials, declining from the south, have their centre above the equinoctial line, the arcs between the centre and the equinoctial line will belong to the southern signs, as in Vertical dials facing south. And if dials of this kind have no centre, the arcs of the southern signs will lie above the equinoctial line, as in polar dials, and so on. In Inferior dials the exact contrary is to be understood.

[Margin: By what method a larger or smaller dial may be drawn from the figure of the rays, for a given length of the style.]

Now if, from the figure of the Zodiac's rays of this chapter, a larger or smaller dial is to be drawn for a given size of style, it will be done in this way. Draw separately — as in the figure of the rays of this proposition you see — the triangle ρIG , taken from the dial constructed in this chapter, or from the figure of the rays itself, in which the axis of the world is ρI , the equator IG , and the style-line ρG , upon which the style IK falls at right angles. Then, the straight lines $I\rho$, IG , IK having been produced, if on IK a straight line IA is taken equal to the given gnomon — whether it be larger than the style IK or smaller — and through A a line BD is drawn parallel to ρG , the triangle BID will be similar to the triangle ρIG . Therefore, if the axis IB is transferred into the figure of the rays from ρ as far as B , toward I , and from B the rays of the signs are led out, and everything else is done as was set forth in the preceding sections, the arcs of the signs will be drawn for the size of the style IA , and so on.

[Margin: The construction of an Italian and Babylonian dial that declines and is at the same time inclined.]

An Italian and Babylonian dial will be made just as was said in the preceding sections. For if the circle drawn from L is cut into the diurnal arc of $\mathfrak{S}$ [Cancer] by a $M b$, and into the diurnal arc of $\mathfrak{V}$ [Capricorn] by $d M e$, so that the straight lines $a b$ and $d e$ cut at right angles the straight line LM which is drawn through the centre L parallel to the meridian line — that is, so that the semidiurnal arcs are reckoned from the point M as far as the points a, b and d, e — and if the division of the same circle into 24 equal parts takes its start from the western points b, e for the Italian dial, and from the eastern points a, d for the Babylonian, from east and from west as in the preceding cases: then, since in our example the tropic of $\mathfrak{V}$ [Capricorn] cannot be drawn, it will be enough if the points of the hours from east and west are found on the tropic of $\mathfrak{S}$ [Cancer], by help of the diurnal arc $a M b$ of that same tropic. For these points, joined by straight lines to the corresponding hours on the equinoctial line, as in the preceding cases, will give the hours from east and west. Now in the Superior dial of our example — that is, in the portion contained below the horizontal line — we shall find only the points of the hours from the west from 9 up to 16 inclusive; likewise the points of the hours from the east from 1 up to 7 inclusive: because all these hours are contained in the arc of the circle $a M$, from whose points straight lines drawn through the centre L meet the equinoctial line, after they have been drawn through the centre L . But the points of the 17th and 18th hours from the west we shall find thus on the tropic of $\mathfrak{S}$ [Cancer]. From the points of the 5th and 6th hours from the west, which are contained in the arc $a N$ and are set opposite to the said 17th and 18th hours from the west, we shall draw hidden lines through...

through the centre L. For by their help we shall find, on the tropic of ☿ [Cancer], in the nocturnal portion, the points for the 5th and 6th hours; and from these, hidden straight lines drawn through ρ, the centre of the dial, will give, on the same tropic of ☿ [Cancer], the points of the 17th and 18th hours from the west. The 18th hour must be drawn parallel to the meridian, or equinoctial, line; while the 17th hour must be drawn through the 11th hour from midnight on the equinoctial line. But the points of the 8th, 9th, and 10th hours from the east, on the tropic of ☿ [Cancer], we shall find in this way. From the points of the 20th, 21st, and 22nd hours from the east — which are contained in the arc a N, and are set opposite the said 8th, 9th, and 10th hours from the east — we shall draw hidden lines through the centre L. For by their help we shall detect, on the tropic of ☿ [Cancer], in the nocturnal portion, the points for the 20th, 21st, and 22nd hours; and from these, hidden straight lines drawn through ρ, the centre of the dial, will give, on the same tropic of ☿ [Cancer], the points of the 8th, 9th, and 10th hours from the east.

Diagram. A large projection-figure for an Italian-and-Babylonian sundial that both declines and is inclined [the figure belonging to the end of Chapter XXIX]. At the centre lie two distinct points: L, the centre of the horizon circle (through which the meridian and the perpendicular to it cross), and ρ, the centre of the dial toward which the hour-lines converge. The word "HORIZON" is set across the horizontal diameter (split by the figure: "HORI:" on the left, "ZON" on the right). A circle is drawn about L; on it are marked the points M (upper, on the meridian), N (lower), and the tropic-arc points a and b (western and eastern) and d and e. Faint (dotted) diurnal arcs carry the small argument-numbers 1 through 18. From ρ radiate straight hour-lines to the rim, labelled with Roman numerals for the Italian/Babylonian hours; many are set rotated to follow their lines.

- L (centre): centre of the horizon circle
- ρ (centre): centre of the dial (hour-lines converge here)
- M (top of circle): point on the meridian
- N (bottom of circle): point on the circle
- a (lower left), b (right): tropic-arc points
- d (left), e (upper right): points on the circle
- Small arc-numbers along the dotted diurnal arcs: 1–18
- Peripheral Roman hour-numerals (rotated; readable include): IIII, VI, VII, VIII, IX, X, XI, XII, XIII along the top; also "20", "23", "24" near the upper right; I, II, III, IIII, V, VI down the right side; VI, VII, VIII, IX, X across the bottom [several rim numerals worn/rotated — [?]]

[The figure is uncaptioned.]

Moreover, the 6th hour from the east must be drawn parallel to the meridian, or equinoctial, line. The 7th hour from the east must be drawn through the 1st hour from noon or midnight on the equinoctial line, and the 8th hour from the east through the 2nd hour from noon or midnight, and so on — as is clear from the table of Proposition 19 of Book 1.

Either dial [both the Italian and the Babylonian] will be most conveniently laid out by means of the diurnal arc of 24 hours together with the diurnal arc of 14 hours, which in the nocturnal portion of the dial changes into a nocturnal arc of 10 hours. For all the hour-lines from east and west touch the diurnal arc of 24 hours at the points of the hours reckoned from noon or midnight. So that almost always, in laying out the hours from east and west, we shall have three points for each single hour: one on the diurnal arc of 24 hours, a second on the diurnal arc of 14 hours (or the nocturnal arc of 10), and a third, finally, on the equinoctial line — that is, on the diurnal or nocturnal arc of 12 hours — as is evident from the figure.

Finally, an Antique dial [horologium Antiquum] that declines and is at the same time inclined will be constructed just as in the preceding cases. This is just what the figure itself shows, in which we have laid out a diurnal arc of 18 hours, which in the nocturnal portion of the dial is changed into a nocturnal arc of 6 hours.

[Margin: The construction of an Antique dial that declines and is at the same time inclined.]

Diagram. A projection-figure for the Antique (Italian) declining-and-inclined sundial [the figure referred to in the preceding paragraph, showing the 18-hour diurnal arc]. Its construction matches the figure on the previous page: a circle drawn about its centre L, with the dial-centre ρ near it; the word "HORIZON" set across the middle ("Ho" on the left, "RIZON" on the right). On the circle are the points M (upper), N (lower), a, b, d, and e; faint diurnal arcs carry the small argument-numbers 1 through 12; and Roman hour-numerals radiate to the rim. A small ornamental pointer/figure appears at the lower left near the numeral VII.

- L (centre): centre of the circle
- ρ (centre): centre of the dial
- M (upper), N (lower): points on the circle
- a (lower left), b (right, on the horizon line), d (left), e (upper): points on the circle

- Small arc-numbers along the faint diurnal arcs: 1–12
- Peripheral Roman hour-numerals (rotated; readable include): VI, VII, VIII, IX, X, XI, XII along the top; I, II, III down the right side; V, VI at the bottom [several rim numerals worn/rotated — [?]]

[The figure is uncaptioned.]

ON THE DESCRIPTION OF DIALS ON ANY PLANE

WHATEVER, and for any latitude of place, by means of an instrument constructed for this use.

CHAPTER XXX.

[Margin: The construction of the instrument by which dials may be described on any plane and for any latitude of place.]

From copper, or brass, or some other hard material, let a rectangle AB be prepared, in which the straight line CD represents the meridian line. At right angles to it let a plane CDE stand, in which, from the centre F, a quadrant FGH is described, so that the semidiameter FG is parallel to the straight line CD, while the semidiameter FH is perpendicular to the plane AB; and let the quadrant be divided into 90 degrees, beginning at G and proceeding toward H. Next let an axis IK be made, of moderate length, whose portion IM — equal to the semidiameter of the quadrant FGH — is to be square, that is, to have the form of a parallelepiped, while the remaining portion MK is to be round, in the manner of a cylinder.

At the end I, let a rounded pin IL be fixed at right angles to the axis itself, so that it can be set into the centre F (which is bored through), and the axis fastened by a small screw L, to the end that it may be freely raised and lowered about the centre I — provided that at M there projects a hollowed-out piece MN. This is so that the axis, whether raised or lowered, may always cling to the quadrant FGH and be fastened by a small screw O, the point being that the axis may be secured on the quadrant at the given latitude of the place. Let the parallelepiped IM also have, in its middle, opposite the piece MN, a square opening P, so that through it one may inspect the degrees of the quadrant at which the axis is to be fixed. For the end of the axis is not to be fixed to the degrees of latitude, but rather its middle, which corresponds to the centre of the pin IL, or of the quadrant FGH. Finally, let a ring QR, movable up and down, be placed around the axis; it can be fixed at any point of the axis by means of a small screw S.

Diagram. The dialling instrument described in this chapter, shown in perspective. Above is the axis assembly: a long rod, square (parallelepiped) at its inner portion IM and round (cylindrical) toward MK, carrying the rounded pin (at the left end, near I/A) and, along its length, the projecting collars and rings with their fastening screws. Below it lies the rectangular base-plate with the graduated quadrant standing on it.

- A, B: corners of the rectangular base-plate (A at left, B at lower right)
- E, H, F: points on the base/quadrant (E upper left of the quadrant, H lower left, F lower right at the pivot)
- G, D: at the upper right of the quadrant (G, D adjacent)
- Quadrant degree-graduation along its arc: 10, 20, 30, 40, 50, 60, 70, 80, 90
- I: left (inner) end of the axis, at the pin
- L, N, O, M, S, Q: collars/screws along the axis (L at far left, then N–O, M, S–Q toward the right)
- P: the square opening in the parallelepiped portion (labelled beneath, between M and the base)
- R: collar/screw toward the right of the axis
- K: right (outer) end of the axis

[The figure is uncaptioned.]

After this, from the same material let a circle ABCD be made about the centre E, divided into 24 equal hours, beginning at point C and proceeding leftward. Then, on both sides of the straight line ED, let there be drawn from the centre E the radii of the [zodiacal] signs, as we taught in chapter 2 of this book, so that ED is the radius of the Equator, and the radii of the northern signs lie between ED and EC, while those of the southern signs lie between ED and EA. And in the same way the radii of the day-lengths can be drawn, as was set forth in chapter 3 of this book, whenever the matter requires it. In the figure none of these have been drawn, because they are not the same in all regions; so it is enough if they are drawn faintly for the given latitude of the place.

Also, having reckoned the pole's altitude from the straight line AE toward D as far as F, let the straight line EF be drawn, to which the label "Horizon" is to be assigned. And in the same way, having counted the same pole-altitude from the straight line ED toward C as far as G, let the straight line EG be drawn, to which "Verticalis" [the vertical circle] is to be assigned.

Finally, on the opposite face of the circle ABCD, let a perforated cylinder EH be fixed at right angles at the centre, so that the axis IK can be set into it. In the same

way, on that same opposite face, along the diameter AC, let two perforated arcs of circles I and k be set, so that the same axis can conveniently pass through them — a similar hole having first been made in the cylinder EH as well. In this way the instrument for describing dials on any plane, for any latitude of place, will have been constructed. It is used as follows.

Diagram. The finished instrument set up in the plane of the meridian: the graduated circle ABCD carrying a gnomon/axis (drawn as a foreshortened cylinder) at its centre, with suspension rings at top and bottom. Around the rim, the four cardinal words are set (each split by a labelled point of the circle): "MERI:A:DIES" across the top (A = Meridies, noon), "OR:B:TVS" down the left side (B = Ortus, east/sunrise), "MEDIA·C·NOX" across the bottom (C = Media nox, midnight), and "OCCA:D:SVS" down the right side (D = Occasus, west/sunset). The hours are numbered 1 through 12 along each half of the rim. From the centre E radiate the "Horizon" and "Verticalis" lines (both labelled within the figure) and, between them, the radii of the zodiacal signs [the individual sign-glyphs are small and worn — [?]].

- E (centre): centre of the circle
- A (top), B (left), C (bottom), D (right): the four quartering points of circle ABCD
- H, I: the gnomon/axis pieces at the centre (H the perforated cylinder, I the axis)
- F: point on the rim toward which the Horizon line is drawn
- G: point on the rim toward which the Verticalis line is drawn
- K: axis-point at the bottom (suspension ring)
- Rim labels: "Horizon", "Verticalis"; hours 1–12 marked on each side

[The figure is uncaptioned.]

Near the wall on which the dial is to be drawn — whether it stands perpendicular to the horizon or not — let some firm plane be set up parallel to the horizon, standing away from the wall at an interval, more or less, equal to the length of the gnomon of the dial to be drawn. So that this plane may not hinder us in tracing the hours, it will most conveniently be set upon some piece of wood, or upon iron fixed into the wall, so that it is parallel to the horizon. Having found the meridian line on this plane, the instrument AB must be fixed so that the straight line CD coincides with the meridian line, and the point D faces north and C faces south.

[Margin: The use of the aforesaid instrument.]

Once it is fixed, the pin IL — which is on the axis IK — must be set into the centre F, and the axis fastened by its small screw L, and turned about the centre F until, through the opening P, the degree of the pole's altitude for that place (for which the dial is being drawn) is seen on the quadrant. For once this is observed, the axis must be fastened by the small screw O, so that it can no longer be moved up or down, but stays in its own position until the drawing is finished.

Next let the circle ABCD be set on the axis through the holes K, E, I, so that I faces the north (arctic) pole and K the south (antarctic) pole; and let it be turned until the plumb-line thread, let down freely from the centre E, grazes the surface of the circle, and indeed coincides with the line EG, the Vertical of the circle — since the Vertical circle, passing through the centre E to the horizon, is perpendicular, just as the plumb-line is, and makes with the axis, toward the antarctic pole, an angle equal to the complement of the pole's altitude, such as the angle GEC. Let the circle be fastened to the axis by the small screws I and K, so that it cannot be shifted this way or that; and let the point of the axis with which the centre of this circle coincides be carefully marked — this may be called the tip [vertex] of the style. The circle itself will then be placed in the plane of the meridian.

The circle being thus made steady, let a thread be stretched from the centre E, grazing the surface of the circle, as far as the plane of the dial, and let the point on which the thread falls be marked. And with the same thread grazing the circle, let another point be marked on the wall — or even several, whether above or below. For the straight line joining these points will be the meridian line, which, on walls perpendicular to the horizon, will be perpendicular to the horizon, and in every case will pass through the centre of the dial. This centre will be indicated by the thread issuing from the centre E and grazing the axis.

[Margin: The meridian line.]

This centre will be found more accurately if two threads issuing from the centre E graze the axis on opposite sides, and two points are marked on the plane of the dial; for the point midway between these will be the centre of the dial.

[Margin: The centre of the dial.]

But if the meridian line cannot be drawn conveniently — or in no way at all — on the plane of the dial, as happens with walls that deviate only slightly from the meridian, then some board must be fixed to the wall toward the north, so that it faces south, and on it the meridian line must be sought out as before.

The remaining hours from noon and from midnight will be traced thus. Let the circle ABCD be removed, and through the channel EH, onto the axis, let there be set...

[Margin: The hours from noon and from midnight.]

let a circle be set, so that its centre E again coincides with the point previously marked on the axis, which we called the tip [vertex] of the style, and so that the channel faces the antarctic pole. Let the ring QR be brought up to the end of the channel, and the little screw S tightened against the axis, so that the circle cannot be moved downward. Then let the circle be turned about the axis until point A faces upward and C downward, while B faces east and D faces west, and until the thread issuing from the centre E, grazing the circle, reaches the meridian line already found. Finally, in this position, let the circle be made fast by the little screws set in the channel EH, so that it cannot be shifted either way. For while the circle stays in this position — namely in the plane of the Equator — if the thread let out from the centre and grazing the circle is made to agree with each hour, and the points are marked in the plane of the dial, the points so found, joined by straight lines to the centre of the dial once that has been found, will give the hour-lines from noon and from midnight.

But if the dial happens to have no centre, we will draw these same lines as follows. Let the circle be set again on the axis through the holes K, E, I, so that E, its centre, coincides with the tip of the gnomon, and let it be fastened by the ring QR so that it cannot move downward. Then let the circle be turned as many times as needed, until the thread issuing from the centre and grazing the circle can be laid against each of the hour-points already found in the plane of the dial, so that in that turning the circle is brought into conjunction with the planes of the several hour-circles; and, by means of the thread, other points — whether above or below — are sought out for each hour, just as we described for the meridian line. For if these points, found for each hour, are joined by straight lines, the hour-lines will again be drawn.

These latter points will perhaps be found more conveniently by means of some light, or a line of sight. For if a light, or the eye, is applied to the circle in such a way that the circle itself appears in the plane of the dial as a straight line passing through the hour-points already found, and several points are marked along that line, the hour-lines will pass through them, as before. The same points may also be found without the circle, by the axis alone. For if a light, or the eye, is applied to the axis in such a way that the axis is seen to pass through the hour-points already found in the plane of the dial, and several points are again marked in the

plane of the dial through which the axis is seen to pass, the hour-lines are to be drawn through them, as before.

But if at any time the thread stretched for some hour on the circle, while the circle lies in the plane of the Equator, runs parallel to the plane of the dial, or does not meet it, that hour-line must be drawn through the centre of the dial perpendicular to the meridian line — such as the 6 o'clock line from noon or from midnight in the horizontal, vertical, equinoctial, and horizon-inclined dials. Or indeed, where the dial has no centre, that hour cannot be drawn at all — such as the 6 o'clock line from noon or from midnight in the polar dial.

[Margin: The arcs of the signs.]

The **arcs of the signs** will be laid out thus. With the circle fixed, as just described, let the thread be applied, issuing from the centre E along the several rays of the signs, so that it grazes the circle; and, the circle being turned around, let points be marked in the plane of the dial, even upon the hour-lines themselves. For by these the arcs of the signs are to be drawn. But for the equinoctial line, the points will be found — by the ray of the Equator — lying in a straight line, one which will pass through the hour-points that were found by means of the circle while it was placed in the plane of the Equator.

[Margin: The arcs of the lengths of the days.]

By the **same** method the arcs of the lengths of the days will be drawn, if from the centre E the rays of the day-lengths are sent out, and so on. But it will be enough if the points of the diurnal arcs — those required for drawing the unequal hours from sunrise and sunset — are marked on the hour-lines from noon and from midnight.

[Margin: The hours from sunrise and sunset, and the unequal hours.]

The **hours from sunrise and sunset**, and the unequal hours, will be drawn by means of the diurnal arcs, as was explained in the preceding pages.

[Margin: The horizontal line.]

The **horizontal line** will be drawn thus. With the circle ABCD fixed, as we said when the meridian line was being drawn — that is, so that it lies in the plane of the meridian circle — let the thread be applied, issuing from the centre E toward the horizon-line EF, so that it grazes the circle, and let the point be marked where it meets the plane of the dial; this point will necessarily lie on the meridian line. Through it let a straight line be drawn parallel to the horizon. In dials set at right

angles to the horizon this line will cut the meridian line at right angles, and will pass through the place of the style and through the 6 o'clock line from noon or from midnight on the equinoctial line. For this will be the horizontal line. But where the dial has no centre, or the meridian line cannot conveniently be obtained, the horizontal line must be drawn through the 6 o'clock point from noon or from midnight on the equinoctial line, parallel to the horizon.

[Margin: The place and length of the style.]

The **place of the gnomon** will be that point of the dial onto which the perpendicular drops that is let fall to the plane of the dial from the point of the axis where the centre of the circle ABCD was fixed. This point will easily be found if, from the said point of the axis as from a pole, a circle is drawn in the plane of the dial; for the centre of that circle will be the place of the style. Its length is that very perpendicular, falling from the said point of the axis onto the plane of the dial — that is, onto the centre of the circle just drawn.

A horizontal dial will be built by the aforesaid instrument in no other way — especially when some large dial is to be drawn. For on small ones this cannot conveniently be done, since the circle ABCD is then turned about the axis with difficulty, as is evident.

ON THE DRAWING OF DIALS ON ANY PLANE WHATEVER, by the shadow of the style of some horizontal dial, or of any other.

CHAPTER XXXI.

[Margin: By what method a dial may be drawn on any plane whatever, by the shadow of the style of some horizontal dial.]

It seems we should not omit here a very easy and very simple method of drawing dials, handed down by Giovanni Battista Vimercati [Giovanni Battista Vimercati] in his little book on the drawing of dials, which is roughly as follows. Take a horizontal dial, accurately drawn on some flat board, on which a straight line has been drawn corresponding to the meridian line of the horizontal dial, and fix it in place. Then, on the same board, fix another plane — one which either adheres to it, if another horizontal dial is to be drawn; or stands upon that straight line, or is inclined, so that it cuts the meridian line of the board at right angles, if a vertical, equinoctial, or polar dial, or one inclined to the horizon, is to be drawn; or cuts the meridian line at unequal angles, if a dial declining from the vertical is proposed for drawing, whether it is inclined to the horizon or not; or, finally, does

not cut the meridian line at all, but makes on the board a line parallel to it, if a meridian dial, or one declining from the horizon,

is to be constructed — account always being taken of the declination and inclination of the dial to be drawn. Next, at the chosen place of the style, on the plane of the dial to be drawn, let a gnomon of any size be fixed, upright to the plane of the dial. Then, moving the board about in a place where it is lit by the Sun, this way and that, until the tip of the style's shadow on the horizontal dial falls on each of the hours of the tropic of Cancer [♋], let the several tips of the style's shadows be marked on the dial-to-be. For thus the hour-points of the tropic of Cancer [♋] will be found on the future dial. And if the same is done on the tropic of Capricorn [♐], and on the equinoctial line, or on any other arc of the signs, or finally on any other line of the dial, even if it is not an hour-line, and the corresponding points on the future dial are joined either by straight or by curved lines, the dial will be drawn on the proposed plane. By this method all the points of the horizontal dial can be transferred to the future dial, if the board is turned about until the tip of the shadow falls on a given point on the horizontal dial, and then on the future dial the tip of the shadow's point is likewise marked. The dial thus drawn will have to be enlarged on the wall, in proportion to the given length of the style, as we showed in the last proposition of Book 4. For a board cannot be turned about carrying so great a plane as the dial to be drawn on the wall requires.

By this art a second horizontal dial can easily be drawn from a horizontal dial, to a given — even a very small — length of style, something that can scarcely be accomplished by other rules. Indeed, by the same device a dial will be drawn on a surface that is not flat but concave, if several points are marked for each hour, which are then fittingly joined by lines that make no angles. Add that hours can also be marked in this way on a cylinder erect to the horizon, as we shall explain in the following book.

In place of a horizontal dial we shall be able to use a concave spherical dial, which we shall construct in the following book. For on this the tips of the shadows can be marked much more accurately than on the horizontal one.

THE END OF THE SEVENTH BOOK.

GNOMONICS, BOOK EIGHT.

By the author Christoph Clavius of Bamberg, of the Society of Jesus.

In this final book, so that we may not seem to omit any of the things that pertain to the drawing of dials, we will treat briefly those dials which are not drawn on some stable and fixed plane — of the kind we dealt with in the preceding books — but which are carried from place to place, and are commonly called travellers' dials [Viatoria], since they are especially useful to those who travel or journey abroad. Of these we will describe not all, but those we judge to be the chief and of greater use. Nor have all of them been devised up to now; rather, new ones daily come to light, invented by various craftsmen, so that anyone would promise in vain a description of all dials of this kind, since anyone can still, by his own ingenuity [proprio Marte], devise new and varied ones for his own use. We will take our beginning from those that are adapted to any latitude of place, and are on that account called universal by most writers; then we will treat those that are made for a given altitude of the pole.

ON THE UNIVERSAL EQUINOCTIAL DIAL.

CHAPTER I.

[Margin: The construction of the universal equinoctial dial.]

Let there be prepared, of brass [orichalcum], or of some other solid material, two equal squares ABCD and AEFG. The sides of the first being bisected at A, B, C, D, let the straight lines AC and BD be joined, cutting one another at right angles; and from the point of intersection let a circle be drawn on each face of the plane, and divided into 24 equal hours, beginning from the straight line AC. Of these, the forenoon hours (that is, after midnight) run from C through B up to A, while the afternoon hours run from A through D up to C. Then let these squares be fitted together along their common side drawn through A, so that ABCD can be moved about that side — raised and lowered — to the altitude of the Equator, or to the complement of the pole's altitude, on the quadrant HIK, which is jointed at H in such a way that, when the dial is to be closed, it can be inclined and laid upon the plane AEFG. Finally, let the centre of the circle be perforated, so that a bronze axis of any length can be passed through the hole at right angles to the plane itself; and in the plane AEFG let a magnetized needle [acus Magnete illita] be set, so that by its help the dial can be placed on a plane parallel to the horizon, in such a way that A faces north and F faces south, and the sides through E and G

represent the meridian line. For when the dial holds this position, if the plane ABCD is fixed on the quadrant HIK at the altitude of the Equator, the axis will indicate the hours from noon or from midnight — on the outer face of the plane ABCD when the Sun is in the northern semicircle of the ecliptic, but on the inner face when it is in the southern semicircle of the ecliptic. And if the part within the circle is cut away, leaving only the portion LM to support the centre together with the axis, the shadow of the axis will appear on the hours of the outer face, even if the Sun is in the southern signs. But if another movable circle is set inside the first, divided into 24 equal hours from sunrise or from sunset, and the noon hour is placed — in the manner of the Italians or the Babylonians — above the straight line AC, toward the point A, the shadow of the same axis will indicate the hours from sunrise or from sunset on this latter circle.

Diagram. A perspective woodcut of the universal equinoctial dial, shown open. It comprises a horizontal base-plate (the square AEFG) lying flat, and a second square plate carrying the graduated hour-ring (ABCD), hinged along their common edge at A and raised above the base. The raised plate is propped at an angle by a quadrant arc, graduated in degrees, which is used to set the plate to the altitude of the Equator. An axis (gnomon) passes through the centre of the hour-ring perpendicular to its plane. On the base-plate, near the front, a magnetic compass needle is drawn inside an oval box.

- K (upper left, at the top of the quadrant arc): endpoint of the graduated quadrant.
- C (just below K, on the raised hour-plate): corner of the square/hour-ring.
- D (upper right, on the raised hour-plate): corner of the square/hour-ring.
- M (centre of the hour-ring): the centre, through which the axis passes; the retained bridge LM supports it.
- L (left of the ring centre): the other end of the retained bridge-strip LM across the cut-away ring.
- A (lower centre-left, at the front near-corner): the hinge corner shared by the two plates; faces north.
- E (bottom centre, on the front edge of the base-plate): corner of the base square AEFG.
- G (right side, on the base-plate): corner of the base square AEFG.
- F (lower right, on the base-plate): corner of the base square AEFG; faces south.

- The quadrant arc bears a degree scale reading downward toward the base; legible labels include 50, 40, 30, 20, 10 (higher divisions toward the top, 60–90, are present but not individually legible [?]).
- The inner ring is graduated for the 24 equal hours with small numerals (a twice-repeated 1–12 series); the individual hour-numerals are too small to resolve individually [?].
- Compass needle: a magnetized needle in an oval box on the base-plate (unlabelled).

In place of the quadrant HIK, a latitude-scale for regions [scala latitudinum regionum] can be made as follows. Describe a semicircle from centre A whose radius AB — the line cutting the diameter at right angles — is equal to one side of the square ABCD, and divide it into 180 equal parts. (We divided it into 18, so that each part spans 10 degrees.) If pairs of points equally distant from point B are joined by hidden straight lines, the line AB will be cut into 90 unequal parts, for the 90 degrees of the pole's altitude, whose numbering begins from point A. Then transfer the parts of the line AB onto the square AEFG, near the side drawn through E, starting from the common section of the two squares ABCD and AEFG; and along the diameter BD, near point B, attach a movable style [stylus volubilis] equal to half of one side of the square. The latitude-scale for regions is now ready. For if the tip of that style is set at the number of degrees that indicates the pole's altitude (not the Equator's), the square ABCD will be raised to the altitude of the Equator, and will therefore represent the Equator — just as before, when it was raised on the quadrant HIK to the altitude of the Equator, or to the complement of the pole's altitude.

[Margin: Construction of the latitude-scale for regions.]

[Margin: In this figure let the line AN be drawn, and about it, from centre O, let the circle APN be described.]

Diagram. A construction figure for the universal equinoctial dial and its latitude-scale. A large semicircle stands on a horizontal diameter drawn through H and A; the apex of the semicircle is B. Along the vertical radius from A up to B runs a graduated ladder-scale numbered (reading upward from the base) 10, 20, 30, 40, 50, 60, 70, 80 — the scale of the pole's altitude / latitude. On the left a graduated quadrant arc descends from the upper region to the baseline, carrying the points I, K, L near its upper part and M lower down on a radial line. To the right of the vertical scale is the point P (upper region); N lies on the upper-right portion of the arc; O is a point toward the centre-right (the centre of the auxiliary circle APN mentioned in the margin). On the horizontal baseline: H (left of centre, below the

scale), A (the centre of the semicircle), and G (right end). Below the baseline two square hour-plates are shown edge-on in perspective: the left plate has corners F (top) and D (bottom) and bears small zodiac glyphs and hour-numerals; the right plate has corners E (top) and C (bottom); between the plates a hatched cylindrical axle with a wheel represents the dial's axis.

- B (apex of the semicircle / top of the ladder-scale)
- A (centre of the semicircle, on the baseline)
- H (baseline, left of centre)
- G (right end of the baseline)
- I, K, L (upper-left, on the graduated quadrant arc)
- M (mid-left, on a radial line)
- P (upper region, right of the vertical scale)
- N (upper-right, on the arc)
- O (centre-right; centre of circle APN)
- F (top corner of the left hour-plate)
- D (bottom corner of the left hour-plate)
- E (top corner of the right hour-plate)
- C (bottom corner of the right hour-plate)
- Vertical ladder-scale numerals: 10, 20, 30, 40, 50, 60, 70, 80
- Small zodiac glyphs and hour-numerals on the left plate (F–D): too small to resolve individually [?]

The reason for this is as follows. Let the radius AN be drawn so that the arc GN contains 50 degrees of the pole's altitude. Since the line NP is perpendicular to AB, then if a circle is described about AN from D, the midpoint of the radius AN, it will — by the scholium to Euclid III.31 [ex scholio propos. 31. lib. 3. Euclid.] — pass through P; and therefore the line OP, once drawn, will be equal to AO itself, that is, to that movable style. Hence, if the movable style is set at 50 degrees, namely at P, the angle NAP which the two squares of the dial form will equal the complement of the pole's altitude. And so the square drawn through AN will lie in the plane of the Equator, as is evident if the quadrant BGA stands at right angles on the horizontal plane so as to be a quadrant of the meridian, with its point B inclining to the south and A to the north — exactly as happened before with the quadrant HIK, on which the other square was raised to the complement of the pole's altitude. In the same way, if the style is placed at 40 degrees, that angle will equal the complement of the pole's altitude, and so on.

But if we do not wish to use a magnetized needle [acu Magnete illita], a sighting-rule [dioptra] with a fiducial line [linea fiduciæ] must be prepared, which will lead us to knowledge of the meridian line and of the hour without any axis passed through the centre of the square ABCD, in the following way. Let the fiducial line CD be equal to the diameter of the square ABCD, so that it can turn about a small pin [clauiculum] fixed at the centre and pass through the centre, as is customary on an astrolabe. At its ends let two vanes [tabellæ] CE and DF be raised at right angles, in such a way that they can be lowered and raised; and we shall determine their heights as follows. On a line GH taken equal to the diameter of the square ABCD, draw HI perpendicular to GH; and describing an arc of a circle from G as centre, mark off on it the declinations of the signs and of the other degrees of the ecliptic. (As an example we have brought in only the declinations of the whole signs.) Let straight lines drawn out from G through these points cut the line HI at K, L, M. Next, on the sighting-rule, in the line CE that bisects the rule itself, make two small holes [foramina] through which a ray of the Sun can pass, spaced apart by an interval equal to the line HK; and mark the corresponding points on the line DF, which bisects the other vane, set as far from point D as the holes are from point C. For if the points K, L, M are transferred onto the line DF, placed between the two aforesaid points — beginning once from the point near D, and again from the other point near F — by marking off points on DF through which parallel lines are drawn, and between these the twelve signs of the Zodiac are laid out (as appears in the figure), the sighting-rule will be complete. Its use is this. With the square of the dial ABCD set at its proper altitude, so that it is parallel to the Equator, turn the dial itself and the sighting-rule this way and that, until the Sun's ray — passing through the hole near C when the Sun is in the southern signs, or through the hole near E when the Sun dwells in the northern signs — falls incident upon the Sun's place on the line DF. Note only this: that in the forenoon the sighting-rule must be directed toward the east, but in the afternoon toward the west. (Whether it is forenoon is known from the shadow of any object on a plane parallel to the horizon: if the shadow is decreasing, the Sun has not yet reached the meridian; if it is increasing, it has already passed it.) For in this way the dial

[Margin: The construction of a sighting-rule [dioptra], by means of which the dial may find its own proper position without a magnetized needle, and the hour be indicated without an axis.]

will hold its own proper position, and the fiducial line, beyond the centre toward the opposite vane of the sighting-rule, will indicate the present hour, whether the Sun is in the northern signs or in the southern.

Once the dial has been set in its proper position — whether by a magnetized needle or by the meridian line once found — the hour will be found much more easily from the sighting-rule. For then the rule need only be swung round until the Sun's ray falls on the line DF, even if no signs are drawn on the vane. But if the signs are drawn, the same ray will indicate in which sign the Sun is.

Now if the dial is directed toward the Sun on a plane parallel to the horizon, so that the shadow of the axis falls on the meridian line — or the Sun's ray, passing through the sighting-rule, falls on the line DF — and the square ABCD is then raised, but so that, produced, it passes through the Sun, or until the Sun's ray falls on the two points of the line DF that lie opposite the holes of the rule: then the square itself will indicate on the quadrant the Sun's altitude above the horizon. From this altitude — if it is the meridian altitude, that is, the greatest of that day — together with the Sun's declination, the pole's altitude can be derived, as we taught in our *Commentary on the Sphere* [in commentariis in sphæram].

The construction of a universal dial in the form of a cross.

CAPVT II.

[Margin: The construction of a universal dial in the form of a cross.]

From the same material make a flat cross ABCD, and another, solid but hollow, AEFG, which is to be joined to the first so that it can freely be raised and lowered; and let the three arms E, F, G be exactly equal to one another. Then, for a gnomon-length [styli] equal to one of the arms, lay out both a meridian dial and a polar dial. Draw the eastern meridian dial on the side of the cross AF, with lines drawn perpendicular to the line FK; and the western one on the opposite side, as the numbers indicate. The polar dial goes on the upper part of the arms E, H — that is, on the plane of the cross that is at right angles to the plane EG — with the forenoon hours toward H and the afternoon hours toward E, as the numbers show, by lines drawn perpendicular to the line EH. Finally, on the cross ABCD let a magnetized needle be set, so that by its help the dial can be placed on a plane parallel to the horizon in such a way that A inclines to the north and C to the south, and the side AC represents the meridian line. For with the dial set in this position, if by help of a quadrant the cross AEFG is raised so that the angle CAL is the angle of the complement of the pole's altitude, the plane FM will lie in the Equator, and the arms E, H, I, G, L, F, and so on, will indicate the hours from noon or from midnight. A latitude-scale for regions can also be drawn near the side AC of the lower cross, as we taught in the preceding chapter. For if a movable style, equal to half the side AL, is attached at the middle of the side AL and set on the

latitude-scale at the degree of the pole's altitude, the dial will again hold its proper position.

Diagram. A perspective woodcut of the universal dial built in the form of a cross. Two cross-shaped plates are shown fitted together at an angle: a lower flat cross (ABCD) lying on the horizontal, and an upper hollow cross (AEFG) raised above it and propped so that its arms carry the meridian and polar dial-faces. The arms are graduated with hour-numerals, and shaded (hatched) dial-faces bearing hour-lines are drawn on their sides. A magnetic compass in a small oval box is drawn on the left arm near C.

- F (upper-left arm end)
- H (top)
- G (right, below H)
- L (left)
- E (mid-left arm)
- I (centre of the crossing)
- D (below I)
- M (right arm end)
- K (lower-right arm end)
- C (lower-left arm end, near the compass box)
- A (lower-right, foot of the base cross)
- B (bottom)
- Graduated hour-numerals along the arms: near F–H, "8 7 6" and "12 11 10 9"; along the right arm toward M and K, "6 5 4 3 2"; along the left arm toward L, "3 2 1 12"
- Hour-numerals on the shaded dial-faces of the arms: too small to resolve individually [?]
- Compass needle in an oval box on the left arm (unlabelled)

The arcs of the signs can also be drawn on the cross, as on a meridian dial and a polar dial, taking the gnomon to be F–12 or 9–12, so that the side EH is the equinoctial line on the polar dial, with the northern signs running downward and the southern upward, and so on. Likewise, taking the other sides of the arm, GH and EI, as gnomons, so that both the side FK and 9–M are the equinoctial line on the meridian dial, with the northern signs running downward and the southern upward, and so on.

On another universal dial, laid out on a plane surface and adapted to any latitude of place that does not exceed the complement of the Sun's greatest declination.

CAPVT III.

[Margin: The description of another universal dial on a plane surface.]

On some plane, draw two straight lines BC and AD cutting each other at right angles at A, and from centre A describe a hidden arc of a circle EDF, on which, on either side of D, the Sun's greatest declination is counted off up to E and F. Draw the line EF cutting the line AD at G; and from G as centre, with radius GE or GF, describe a hidden circle. Divide it into 12 equal parts for the 12 signs of the Zodiac, or into more, for the parts of the signs as well. (We divided it into 36 parts, so that each spans 10 degrees.) Join any two points equidistant from the line AD by hidden straight lines cutting the arc EDF at points; and if straight lines are drawn from A to these points (they must not, however, be produced beyond the line EF), the radii of the signs of the Zodiac will be traced — so that AG is the radius of the beginning of ♈ [Aries] and ♎ [Libra], the radii toward E being assigned to the northern signs, and those toward F to the southern signs, as the characters of the signs

indicate. If desired, the days of the months in which the Sun occupies those points of the ecliptic can be written near the beginnings of the signs and their parts, as is usually done on the back of an astrolabe. Into this triangle of the Zodiac's radii the latitudes of all places that do not exceed the complement of the Sun's greatest declination must be fitted, in this way. From E and F draw lines EO and FL parallel to AG (which is easily done if AO and AL are taken equal to the lines GE and GF); and from A describe a hidden circle BHC, whose quadrant BH is divided into 90 degrees. We divided it into 18 equal parts, each spanning 5 degrees. Then let hidden straight lines drawn from A through the points of division cut the line EO at points; and if lines are drawn through these parallel to OL (which is easily done if all the points of the line EO are transferred onto the line FL), the latitudes of places will be traced, as the figure shows.

After this, another Zodiac must be constructed on the line FL, in this way. On the circle BHC, count off the Sun's greatest declination on either side of C, up to I and K; and drawing the lines AI and AK cutting the line FL at two points, describe from L a hidden circle about the line lying between those two points. Divide it into 12 equal parts, or into more, according as whole signs or their parts are

wanted. (We divided it into 24 equal parts, so that each sign is halved.) Then, through any two points equidistant from the line AC, draw hidden straight lines cutting the arc a d b — the hidden arc described from A and passing through those points where the line FL is cut by the lines AI and AK. For if hidden straight lines are drawn out from A through the points of this arc, the

Diagram. A large, complex construction figure for the universal plane dial of this chapter. It combines several overlapping elements. At the upper left an articulated jointed arm, expressly labelled **Brachiolum** ("little arm"), carries pivots at R, Q, and S, and from it a serpentine cord (labelled T above and N below) hangs down and ends in a plumb-weight. The main body of the figure is a large circle graduated along its upper rim with degree-ticks; the rim points D (top), E, G, and F are marked at the top, with I and C at the right and K on an outer arc at the lower right. Within the circle a downward-narrowing "triangle" / funnel of the Zodiac's radii and latitude-arcs converges toward point A at the bottom centre; its two sides carry a symmetrical latitude scale numbered (reading downward) 65, 60, 55, 50, 45, 40, 35, 30, 25, 20, 15, 10, 5 on each side. Interior points H, M, Y, and P are marked within this funnel. A band of paired zodiac glyphs runs across the top of the funnel just below the rim (each latitude-column headed by a northern sign and its symmetrical southern counterpart). The forenoon-hour field on the left is labelled **Horæ ante[meridianæ]** with hour-numbers, and a horizontal band along the very bottom is labelled **Horæ pomeridianæ** ("afternoon hours") with the hour-numbers 12, 11, 10, 9, 8, 7, 6, 5, 4, 3, 2, 1, 12; a diagonal line is labelled **meridian[us]**. At the bottom centre a small second circle (the "other Zodiac") is drawn about point L and ringed with zodiac glyphs; the lowercase points a and b lie on its arc. A small circle enclosing a symbol is drawn at the right, between the funnel and point I.

- Brachiolum (jointed "little arm") at upper left, with pivots R, Q, S
- T (upper label on the hanging serpentine cord); N (lower label on the cord)
- D (top of the main circle's rim)
- E, G, F (top rim, left to right)
- I (right rim); C (lower-right rim); K (outer arc, lower right)
- A (bottom centre; apex of the radii-funnel and common vertex of the hour-lines)
- B (lower left, left end of the horizontal diameter); O, Z (on the diameter, between B and A)
- H, M, Y, P (interior points within the funnel, top to bottom)
- L (centre of the small lower "other Zodiac" circle)

- a, b (lowercase points on the arc of the lower Zodiac circle)
- Latitude scale on the funnel sides: 65, 60, 55, 50, 45, 40, 35, 30, 25, 20, 15, 10, 5 (each side)
- Curved label "Horæ ante[meridianæ]" (forenoon hours), left of centre, with hour-numbers 12, 1, 2, 3, 4, 5, 6, 7, 8 ...
- Bottom band "Horæ pomeridianæ" (afternoon hours): 12, 11, 10, 9, 8, 7, 6, 5, 4, 3, 2, 1, 12
- Diagonal label "meridian[us]" (meridian line)
- Paired zodiac glyphs across the top of the funnel and around the lower Zodiac circle: partly legible (Aries, Taurus, Virgo, Libra, Pisces, Scorpio, Aquarius among them) but not reliably resolvable glyph-by-glyph [?]
- Small circle enclosing a symbol at the right (between the funnel and I): symbol not resolvable [?]

[This figure has more than two unresolved small labels (the paired zodiac glyphs and the enclosed symbol) and]

[Margin: In this figure let Υ [Aries]A and $\Upsilon\delta$ and $O\delta$ be drawn, so that these two lines, drawn from O and from Υ , meet at δ — namely at the point where the first ray of $\mathfrak{C}$ [Cancer] intersects AE, the latitude-line of 40 degrees. Likewise, from the highest and lowest circle of $\mathfrak{C}$, let the line $a\delta$ and $\delta\epsilon$ [?] be drawn, so that it be at the point where the first ray of $\mathfrak{M}$ [Virgo] intersects AF, the latitude-line of 40 degrees.]

portion of the line FL contained between the lines AI and AK will be cut into the signs of the Zodiac, so that the point L is assigned to the beginning of Υ and $\underline{\alpha}$, while the northern signs advance toward F and the southern downward — that is, so that the northern signs of this latter Zodiac are nearer to the southern signs of the former Zodiac than the southern signs are. But if this latter Zodiac were laid out on the line EO, the southern signs would run upward and the northern downward, so

so that the southern signs of this latter Zodiac would lie closer to the northern signs of that earlier Zodiac than its own northern signs do. This latter Zodiac, however, will be laid out more easily if the points of the signs are taken on the pole-altitude line of 45 degrees, from point M, and transferred from L or from O, this way and that, onto the line FL or EO. For, as will shortly be demonstrated, the lines AM, AL, and AO are equal; and therefore the lines FL and EO and the pole-altitude line of 45 degrees will be cut by the rays of the signs in the very same way.

In the construction of this latter Zodiac Orontius [Orontius Finé (Oronce Fine)] went astray, and almost everyone follows him. He would have the lines drawn out from A pass through the points of the line FL, at which that line is cut by the lines drawn through each pair of points of the circle described from L. This is entirely false. The lines must be drawn through the points of the arc *a d b*, as we showed in Proposition 1 of Book 1, just as the rays of the signs of the earlier Zodiac were drawn through the points of the arc [Margin: Error Orontij (Orontius's error)] EDF, and not through the points of the line EF. Indeed, Orontius contradicts himself when he says that the points of the signs on the line FL ought to be equal to the points of the signs of the earlier Zodiac on the line that marks the 45th degree of latitude — which, by his own construction, cannot be true unless the lines from A are drawn through the points of the arc *a d b*, and so on.

The hours are laid out as follows. [Margin: a — Euclid, *Elements* I.6] From the centre A, at a distance AL, or AO, or AM, up to the latitude-line of 45 degrees (for these three lines, if there is no error, will be equal to one another: since the line A θ drawn to the 45th degree of the circle BH makes the angle OA θ a half-right angle, the angle O θ A will likewise be a half-right angle, and therefore ^a the lines OA and O θ will be equal; and since A θ is equal to AM, in the parallelogram OAM θ the three lines AM, AL, AO will be equal) — let the circle so described be divided into 24 equal hours, and these again, if one wishes, subdivided into half-hours and quarter-hours. For the lines drawn through each pair of points equally distant from the points L and O will give 12 hours from noon and 12 from midnight, of which MA will give the sixth hour. The forenoon hours are numbered from the line EO toward FL, and the afternoon hours from the line FL toward EO. These hour-lines are bounded, in their upper part, on the circumference of the circle described from M at the distance MA; and in their lower part, on a line parallel to LO, standing off from the line LO by at least as great an interval as the portion of the line AI, or AK, lying between A and the line FL.

Again, a small arm [brachiolum] must be made of some hard and solid material, consisting of three revolving segments QR, RS, ST, which when extended lengthwise make up a length equal to the line GA. The end-point Q of this arm is to be fixed at the point G, so that its other end T may range freely over the whole triangle AEF and be fixed at any place, so that it is not easily disturbed; and to this end there must be hung a very fine thread together with a plumb-bob, and a movable bead N is to be set around the thread itself, to serve as an index.

Lastly, once all superfluous parts are cut away so that the dial is reduced to a quadrangular shape whose outermost sides are EF and the parallel drawn next to it in the hour-lines — likewise EO and FL, produced up to that same parallel — and leaving besides so much space on the L side that the characters of the signs can be drawn there, two sights [pinnacidia] must be made, finely pierced, and fitted to the side EF at right angles. For thus the description of the dial will be complete.

[Margin: The use of this universal dial.] **The use** of this dial is as follows. With the end-point T of the arm fixed at the common intersection of the ray of that degree of the Ecliptic in which the Sun stands and the latitude-line of the given place, let the plumb-line thread be extended toward the Zodiac drawn on the line FL, and let the movable bead N be set on the line FL at the same degree of the Zodiac. Then, if with the plumb-line grazing the plane of the dial the sight near E is raised until the Sun's ray, passing through its hole, falls on the hole of the other sight near F, the movable bead N will indicate, among the hour-lines, the present hour. In place of the sights you may use a small pin [clauiculus] fixed at right angles on the line EF near E. For if the instrument is raised until the shadow of the pin falls on the line EF, the same bead will indicate the hour.

Here it must be observed that the lines drawn from two opposite signs onto the pole-altitude line, up to those same signs in the latter Zodiac, are equal to one another. [Margin: b — Euclid I.15; c — Euclid I.26] For let there be drawn, from ♋ [Cancer] and ♑ [Capricorn], to ♍ [Virgo] on the pole-altitude line of 40 degrees, up to ♋ and ♑ of the latter Zodiac, the lines $\delta\alpha$ and $\varepsilon\beta$: I say that these are equal. For, αA having been produced up to γ , let the line $\gamma\delta$ be joined. Since, then, the two angles αAL and $AL\alpha$ are equal to the two angles γAO and $AO\gamma$ — ^b (because the vertical angles at A are equal, and L, O are right angles) — and the adjacent sides AL, AO are equal, ^c the sides $A\alpha$, $A\gamma$ will likewise be equal. Again, since the two sides $A\alpha$, $A\delta$ are equal to the two sides $A\gamma$, $A\delta$ and contain equal angles, namely right angles (for since the angles of declination EAG and IAC are equal, if the common angle GAI be added, the whole [Margin: d — Euclid I.4] angle EAI will be equal to the whole right angle GAL, and therefore so too will the following angle EAY be a right angle), ^d the bases $\delta\alpha$, $\delta\gamma$ will also be equal. And $\varepsilon\beta$ is likewise equal to that same $\delta\gamma$ (for since the sides εA , $\varepsilon\beta$ are equal to the sides δA , $A\gamma$ and contain [Margin: e — Euclid I.4] equal angles, namely right angles — for just as the angle δAI was shown to be right, so we shall show δAK to be right, because the angles of declination DAF and CAK are equal, and FAC is common — ^e the bases $\varepsilon\beta$, $\delta\gamma$ will also be equal). Therefore $\delta\alpha$ and $\varepsilon\beta$ will be equal to one another.

[Margin: How the semidiurnal and seminocturnal arcs are found from this dial; likewise the hour of sunrise and sunset from this dial; and the reduction of hours reckoned from noon and midnight to hours reckoned from sunrise and sunset by this same dial.] **Now** if, from the point where the ray of that degree of the Zodiac in which the Sun stands and the latitude-line of the given place cut one another, a hidden line is drawn parallel to GA, the hours between this parallel and the line FL will give the semidiurnal arc, and the hours between the same parallel and the line EO the seminocturnal arc. Hence the Sun will rise and set on that parallel. From this it follows that the hours reckoned from noon and midnight are easily reduced to hours reckoned from sunrise and sunset. For if from that parallel one numbers, toward the line FL, the whole hours up to the hour that the movable bead indicates — returning, however, from the line FL toward the said parallel, up to the bead, if the time is afternoon — one obtains the hour from sunrise. But if from the same parallel the whole hours are reckoned toward the line EO, up to the bead — returning, however, from the line EO toward the said parallel up to the bead N, if the time is before noon; or, if afternoon, returning also from the line FL toward the same parallel — one obtains the hour from sunset.

For example. Let the bead N fall on the 10th hour before noon, in latitude 45 degrees, with the Sun standing in the 20th degree of ♈ [Aries], or the 10th degree of ♍ [Virgo]. Since, then, the line drawn parallel to GA from the point where the latitude-line of 45 degrees cuts the ray of the 20th degree of ♈ (or the 10th of ♍) falls nearly in the middle of the space between the 5th and 6th hours before noon, and between the 6th and 7th hours after noon, the semidiurnal arc will contain about $6\frac{1}{2}$ hours, and the seminocturnal about $5\frac{1}{2}$ hours; and the Sun will rise at hour $5\frac{1}{2}$ from midnight and set at hour $6\frac{1}{2}$ from noon. And since from hour $5\frac{1}{2}$ before

noon up to the 10th hour before noon, advancing toward the line FL, $4\frac{1}{2}$ hours are numbered, the hour will then be $4\frac{1}{2}$ from sunrise. But if the time is afternoon, so that the bead N falls on the 2nd hour after noon, then, counting from hour $5\frac{1}{2}$ before noon, advancing toward the line FL and returning again to the 2nd hour after noon, there will be $8\frac{1}{2}$ hours; so the hour will then be $8\frac{1}{2}$ from sunrise. Again, since from that same hour $5\frac{1}{2}$ before noon up to the 10th hour before noon, advancing toward the line EO and returning from it, one finds $15\frac{1}{2}$ hours, the hour will then be $15\frac{1}{2}$ from sunset. Likewise, since from the same hour $5\frac{1}{2}$ before noon up to the 2nd hour after noon — advancing toward the line EO, then returning from it toward the line FL, and again returning from this toward the 2nd hour after noon — $19\frac{1}{2}$ hours are numbered, the hour will then be $19\frac{1}{2}$ from sunset. Or indeed, since from the 2nd hour after noon up to the $6\frac{1}{2}$ th hour after

noon, at which the Sun sets, $4\frac{1}{2}$ hours are numbered, if these be subtracted from 24 — that is, from the hour at which the Sun sets — there will remain $19\frac{1}{2}$ hours from sunset, as before. The same reckoning is to be applied in the remaining cases.

[Margin: How the Sun's altitude is found from this dial.] **In addition to this**, if the quadrant LV described from A is divided into 90 degrees, and the end-point T of the arm is placed at the centre A, and the instrument is raised until the Sun's ray answers to the holes of the sights, the plumb-line thread will indicate on the quadrant LV the Sun's altitude above the Horizon. The number of degrees will run, on the quadrant LV, from the point V toward L.

Now if the whole length of the dial is bisected at P, and the dial itself is divided by the line drawn through P parallel to LO, and these parts of the dial are joined to one another by hinges and pins in such a way that one can be laid upon the other — just as we said of the squares of the equinoctial dial in chapter 1 of this book — the dial will be reduced to a most convenient form, so that it can easily be carried from place to place. In use it must be opened out so that from those two parts a single flat surface is made. Indeed, if on the outer face of the tablet, on which lies the line LO, a circle answering to the circle LMOV is described from the point corresponding to the centre A, and divided into 24 parts, and a style is fixed at the centre at right [angles]; and if this tablet is raised according to the elevation of the Equator, by means of a quadrant or the scale of the latitudes of the regions, as we said of the equinoctial dial in chapter 1 of this book; and if, finally, the dial is directed to the meridian line by means of a magnetized needle placed in the other tablet, on which lies the line PG — then a universal equinoctial dial will also have been made, whose inner semicircle LMO will show the hours while the Sun is in the southern signs; unless you wish to cut away the portion enclosed between the two semicircles LMO and XYZ (leaving, however, a small tooth MY, lest the tablet be rendered too weak), so that the shadow of the inner style may appear on the outer face through that hollowed-out portion. You may also, in place of the style, use a diopter on the outer face, as we said in chapter 1. For then the hours will always be shown by the fiducial line on the outer face, even when the Sun is in the southern signs, if the diopter is turned about until the Sun's ray, entering through the hole of one sight, falls on the line opposite the hole in the other sight.

If the hour-lines are produced upward, the part below the point of concurrence of the rays of the signs can be cut off; but then the little Zodiac must be made movable, so that the sign ♈ [Aries] and ♎ [Libra] can be set at the degree of the latitude of the place, and the latitudes of the places on the line CE, the line of the

12th hour, are laid out thus. On the radius of the Equator take the interval between the line of any latitude and the upper line of the triangle up to D, and transfer it from the lowest point E of the 12th hour onto the line of the 12th hour up to G — for that will be the end, the altitude of the pole at which the sign of Aries or Libra of the little Zodiac is to be placed; or else transfer the interval, on the radius of the Equator, between the pole-altitude line and the point A of concurrence of the rays of the signs onto the line of the 12th hour from the highest point C.

Next, prepare a slider [cursor] one of whose sides is straight, so arranged that when it is set on the instrument from below, that side is always parallel to the hour-lines, and its extreme point does not pass beyond the highest line of the dial. There a small hole must be made for the plumb-line thread, and a movable bead is to be set on the thread.

The slider is to be set so that its straight side passes through the intersection of the latitude-line and the ray of the degree at which the Sun then stands. Then, with the plumb-line thread extended over the degree of the Sun in the little Zodiac, the bead is advanced to that same degree of the Sun; for, the Sun's ray passing through the sights and the thread hanging freely, the bead will show the hour among the hour-lines.

Demonstration. [Margin: a — Euclid I.33; b — Euclid I.5] In the triangle ABC let F be the intersection of the pole-altitude line with the radius AD of the Equator; and since, if the little Zodiac is movable, the sign Υ will be placed at E and the plumb-line thread will be FE — then, if DG is taken equal to FE and the thread hangs from D, the sign Υ must be placed at G: because the bead placed at G will move among the hour-lines in the same way as, placed at E, it moved.

Now since the two equal lines FE, DG cut off two equal parallels GE, DF (for if GE be said, say, to be less than DF, then GH being taken equal to DF, ^a the line drawn FH will be equal to DG, and therefore also to FE, ^b and consequently the angles at E and H equal — which is absurd, since H is acute and E obtuse), it follows that the line DF, taken equal to EG, gives the point G at which the sign Υ is to be placed, for the pole-altitude F, and so on.

Diagram. The demonstration figure for the universal equinoctial dial's hour-triangle. Across the top run the points B (left), D (centre), and C (right). From B a line slants down to A at the lower left; from C the right edge runs down through G to E and H at the lower right. F is an interior point (the intersection of the pole-altitude line with the equator-radius AD), roughly below D; a horizontal line runs

from F rightward to G. Diagonals cross the interior, and a dotted line runs from the F-region down to the E/H corner. A is at the bottom left; at the lower right E lies inner and H just below/outer.

- B (top left)
- D (top centre)
- C (top right)
- F (interior, below D — intersection of the pole-altitude line with the equator-radius)
- G (right side, mid-height; printed in a swash form resembling "ç")

DE HOROLOGIO HEMISPHERICO CONCAVO — On the hemispherical concave dial

CAPVT IV.

[Margin: Construction of the hemispherical concave dial.] Let there be a hemisphere hollowed out, accurately turned on a lathe from wood, or brass, or some other solid and hard material, ABCD, which — before the hours are laid out — must be carefully tested with an iron or wooden

semicircle whose radius is equal to the radius of the opening ABCD. For if this semicircle, set upon the concave hemisphere and carried around, always grazes the concave surface, so that nothing projects or is depressed, there will be no doubt that the hemisphere is perfectly concave. Let the circle of the opening ABCD be divided, by means of a compass with recurved legs, into four quadrants AB, BC, CD, DA; and from A, or C, as pole, at the distance AB (or AD, or CB, or CD) let a great circle BED be described, and with the same distance from the pole B, or D, another great circle AEC, cutting the former at E. These two circles are represented, in our figure, by the straight lines AC and BD, cutting one another at right angles at the centre E. Thus ABCD will be the Horizon; AEC the semicircle of the Meridian below the Horizon; BED the semicircle of the prime Vertical below the Horizon; and therefore E the Nadir, or the point opposite the Zenith. Let noon be placed at A; the north at C; the east at B; and the west at D. Then, on the semicircle of the Meridian AEC, having counted from A the altitude of the pole up

to F, and from E up to G, F will be the antarctic pole, and G the point through which the Equator passes below the Horizon.

From the pole F, at the distance EF, let there be described a parallel OEP drawn through the Nadir, which, if it is not described entire (as in our example, and in every other place where the altitude of the pole above the Horizon is less than 45 degrees — for then the arc FE, of the complement of the pole's altitude, is always greater than the arc FA; whereas if the altitude of the pole is exactly 45 degrees, the said parallel will touch the Horizon at A, since then the arcs FE and FA are equal; and finally, if the altitude of the pole exceeds 45 degrees, the same parallel will cut the Meridian below the point A, because then the arc FA is greater than the arc FE, of the complement of the pole's altitude, as is evident) — then there must be taken an arc GS equal to the arc GE, and from the same pole F, at the distance FS, a portion of a circle QSR must be described, which portion belongs to the parallel described through the Zenith of the place, and is opposite to the parallel OEP, and is equal to the portion of the parallel OEP that is lacking; because, the declinations GE and GS being equal, the parallels described through E and through S are equal, and have (by Proposition 19 of Book 2 of Theodosius [*Spherics*]) alternate segments equal — namely the segment QSR below the Horizon, and that which is lacking of the parallel OEP above the Horizon.

Moreover the arcs of the Horizon CQ, CR will be equal to the arcs AO, AP, on account of the equal rising latitudes BP, BR and the setting latitudes DO, DQ. Again, from the pole F, at the distance of the quadrant FG (for FG is an arc composed of EG, the altitude of the pole, and of FE, the complement of that same altitude — a quadrant), or of the quadrant AB, let there be described the semicircle of the Equator BGD, passing below the Horizon necessarily through the points B, D, where the Vertical cuts the Horizon. Then, the Sun's greatest declination having been reckoned off on both sides from G up to H and L, let there be described, from the pole F, at the distance FH, the portion of the tropic of ♊ [Capricorn] below the Horizon, KHI, and at the distance FL, the portion of the tropic of ♋ [Cancer] below the Horizon. And since, when the Sun stands above the Horizon at the beginning of ♋, its ray passing through the centre of the sphere falls on the opposite parallel, namely on the tropic of ♊, below the Horizon; and on the tropic of ♋, below the Horizon, when it stands at the beginning of ♊ above the Horizon — the arc KHI will be called the tropic of ♋, and NLM the tropic of ♊, because the shadow of the centre of the sphere falls upon them when the Sun is in the said tropics. And in the same way the other parallels between the two tropics will be described from the pole F, if their declinations are reckoned off from G on either side.

[Margin: The laying-out of the hours from noon and midnight in the concave hemisphere.] **Now** each quadrant of the Equator GB, GD having been divided into six equal parts, or even into more if smaller parts of the hours be wanted (that GB and GD are quadrants will be plain thus: since the Meridian AC, drawn through the Verticals' poles A, C and through F, the pole of the Equator, cuts, by Proposition 9 of Book 2 of Theodosius, the segments of the Vertical and of the Equator, BED and BGD — which are indeed semicircles by Proposition 11 of Book 1 of Theodosius — into two halves, the segments EB, ED, GB, GD will be quadrants) — we shall describe the equal hours, both from noon and midnight and from sunrise and sunset, with a single opening of the compass, in this way.

Since the hour-circles from noon and midnight are drawn through F, the pole of the Equator, as we demonstrated in Proposition 9 of Book 1, the Equator will in turn pass through their poles, by the scholium to Proposition 15 of Book 1 of Theodosius. All of them, therefore, have their poles on the Equator. Hence, with the compass-legs opened to the distance of the quadrant of a great circle AB (or GB, or FG), if one leg is set at each of the points of the divisions of the Equator BGD, and the other is fixed on the Equator — namely at the points that are distant six hours, or a quadrant, from the former — there will be described all the hour-circles contained between the tropics, from the 6th hour from midnight up to the 6th hour from noon. For only between these are the hour-circles to be drawn; if, however, they were produced, they would all pass through the pole F.

For example: from G, as pole, at the distance GD (or GB, or GF — which distance must not be changed until all the great hour-circles have been described), there will be described the arcs of the circle of the 6th hour from midnight and from noon, bounded between the Equator and the tropic of ♄. Then, placing one leg of the compass at the next point of the Equator from G toward B, there will be described with the other leg the arcs of the circle of the 7th hour from midnight and from noon, of which the former will pass through the next point of the Equator below D, and the latter would pass through the next point of the Equator above B, if the sphere were entire. Likewise, placing one leg of the compass at the second point from G toward B, there will be described with the other the 8th hour from midnight, passing through the second point below D; and so on, setting the poles of the circle-

Diagram. A large circular figure of the concave hemispherical dial (the orifice ABCD seen from within), engraved with the cardinal words around the rim and a dense net of hour-lines below the centre. The rim carries the cardinal labels: at the top **MERIDIES** (split "MERI= A =DIES", with point A at the top = noon/south),

at the bottom **SEPTENTRIO** (split "SEPTEN= C =TRIO", with point C at the bottom = north), down the left side **ORIENS** (east, with point B on the rim), and down the right side **OCCIDENS** (west, with point D on the rim). At the centre-top is a small circle enclosing an upright style/gnomon; from the central point F a bold line labelled **Axis** runs toward the lower right. Below F lie E (the Nadir/centre), then H, then G, and lower still L and S near the bottom. Interior rim-points P (upper left) and O (upper right) sit just inside the circle. On the left arc are K and T (upper) and N (lower left); R lies below N. On the lower right is M. The lower half of the disc is filled with a graduated net of intersecting hour-lines, labelled partly with Roman day-hour numerals and partly with Arabic numerals; only some of these resolve cleanly.

- A (top rim; noon/south — split label MERIDIES)
- C (bottom rim; north — split label SEPTENTRIO)
- B (left rim; east — vertical label ORIENS)
- D (right rim; west — vertical label OCCIDENS)
- F (centre; antarctic pole / axis foot, with small gnomon circle above and the "Axis" line)
- E (below F; Nadir / centre of the great circles)
- H (below E)
- G (lower centre; point where the Equator passes under the Horizon)
- L (lower centre, below G)
- S (bottom centre, below L)
- P (upper-left interior rim point)
- O (upper-right interior rim point)
- K (upper-left arc)
- T (upper-left arc, right of K)
- N (lower-left arc)
- R (lower left, below N)
- M (lower right arc)
- "Axis" (the axis line from F toward the lower right)
- Q (paired with R and S on the lower arc per the text QSR — not separately resolvable on the tiles) [?]
- I (right-hand arc, per the text KHI — not separately resolvable on the tiles) [?]
- Hour-net: Roman numerals of the day-hours (...VII, VI, V, IIII, III, II, I... down the left, and V, VI, VII, VIII, IX, X... down the right, with XI, XII, XIII

near the lower centre) interwoven with Arabic hour-numbers (...14, 15, 16, 17, 18, 19, 20, 21, 22, 23, 24 along the lower arc, and 9, 10, 11, 12, 13... on the right) — individual cells only partly legible, not transcribed glyph-by-glyph [?]

[This figure carries more than two unresolved labels (Q, I, and the full hour-number net) and]

of the circles passing through the points of the quadrant DG — some running in the quadrant GB, others in the quadrant GD — so that, with the same opening of the compasses, one also draws the arcs between the horizon and the tropic of Cancer [☿], even though within the hemisphere these do not cut the equator, as happens at the 5th hour from midnight and the 7th from noon, and so on.

[Margin: Laying out the hours from the west and east in the concave hemisphere.]

Again, the hour-circles from the west and east have their poles in the parallel RSQ, which is drawn through the zenith of the place, as we demonstrated in Proposition 10 of Book I; and therefore also in the opposite parallel OEP, since each of its points is set opposite the corresponding point of the former. Now if, with the same opening of the compasses kept, one foot is set in turn on each point of the equator and the other foot placed in the parallel OEP — or in RSQ, whenever it cannot be set in OEP — then through the points of the equator the arcs of the hour-circles from the west and east will be drawn. These circles have their poles dividing the parallels OEP and QSR into equal parts, and those poles lie at the points where the said parallels are divided into equal hour-spaces by the hour-circles from noon and midnight, as we showed in Proposition 10 of Book I. For since the hour-circles from east or west pass, in the equator, through the poles of the hour-circles from noon and midnight, these latter are in turn carried through the poles of the former, by the scholium of Proposition 15 of Book I of Theodosius. Since, then, the poles of the former lie in the parallels OEP and QSR, the poles will be exactly those points where the said parallels are cut by the hour-circles from noon and midnight — so that the pole of any hour-circle from east or west lies at that point of the parallel OEP or QSR through which passes the hour-circle from noon or midnight that is six hours distant from it in the equator. Hence, so that these poles may be readily had, the hour-circles from noon and midnight must be produced as far as the parallels OEP and QSR, but only faintly. Or else, from G, at the interval GF, the arc of the 6-o'clock circle from noon and midnight is to be drawn, and each quadrant ET, EV divided into six equal parts for the poles of the hour-circles from east and west; and finally these points,

transferred by the compasses from E, are to be carried into the parallel QSR from S, for the poles of the other circles that do not have their poles in the portion OEP. For example, E is the pole of the horizon, that is, of the 24-o'clock circle from east or west; the next point in the parallel OEP, from E toward O, is the pole of the 23-o'clock circle from the west; and the point next from E toward P is the pole of the 1-o'clock circle from the east; and so with the rest. In the worked example, only the hours from noon and midnight, and the hours from the west, are drawn.

[Margin: Laying out the unequal hours in the concave hemisphere. An easy way to find the poles from which the circles of the unequal hours are drawn.]

Finally, for laying out the unequal hours, the several portions of the tropics HI, HK, LM, LN must each be divided into six equal parts; and through triples of points — of which one lies on the tropic of Cancer, another on the equator, and the third on the tropic of Capricorn [☿] — equally distant from the meridian, the circles of the unequal hours are to be drawn. Now the pole of each such circle will lie on the meridian hour-circle, from noon or midnight, that is six hours distant from it in the equator. For since any circle of the unequal hours passes, in the equator, through the pole of the hour-circle from noon or midnight that is six hours distant from it, it will in turn pass — by the scholium of Proposition 15, Book I of Theodosius — through the pole of that circle. Hence, if, with the same opening of the compasses kept, one foot is set on any point of the tropic of Cancer or of Capricorn, and the other on the circle of that hour from noon or midnight, faintly produced, which is six hours distant in the equator from the point corresponding to the point taken on the tropic, the pole of that circle of the unequal hours will be obtained. For example: the circle of the 1st unequal hour must be drawn through the first point of the equator below D and through the first points of the tropics below I and M; but the circle of the 1st hour from noon is, in the equator, six hours distant from the first point below D. Therefore, if one foot of the compasses is set on the first point of the tropic below I or M, and the other extended as far as the circle of the 1st hour from noon, faintly produced, the pole of that circle will be obtained in this circle; and so with the rest.

[Margin: The style that shows the hours.]

The style that marks the hours will be the axis of the world, equal to the semidiameter of the hemisphere; and it must be fixed at the pole F in such a way that its extreme point occupies the centre of the hemisphere. This is finally achieved when, with two threads stretched across the mouth of the hemisphere — from A to C, and from B to D — the extreme point is set at the common intersection of the threads. The same style may be fixed at any point, but then it

will not be the axis of the world. The instrument must also be set in the meridian circle together with a magnetized needle, yet in such a way that the plane of the instrument lies parallel to the horizon.

If one wishes, all those things that we described for plane dials in Books 2 and 3 can likewise be drawn in this hemisphere. For the parallels of the lengths of days and of the latitudes of cities will be laid out from the pole F, just like the parallels of the signs, if their declinations from G are reckoned along the meridian — toward H if they are northern, toward L if southern. The vertical circles are drawn through E, which passes through their poles (by the scholium of Proposition 15, Book I of Theodosius), since in turn the verticals pass through E, the pole of the horizon. The parallels of the horizon will be laid out from E, the pole of the horizon, or of the vertical BD. The meridians — that is, the circles of the longitudes of cities — will be carried through the several degrees of the equator, like the hour-circles from noon and midnight, provided the division of the equator into degrees begins at that point which bounds the longitude of the place, reckoned from G toward B. The circles of the celestial houses, according to the opinion of Johannes Regiomontanus [Regiomontanus], will be laid out through the divisions of the equator, setting the immovable foot of the compasses for their poles in the vertical BD, so that they all pass through the points A and C, where the meridian intersects the horizon. According to the opinion of Campanus [Campanus of Novara], however, they are laid out through the divisions of the vertical, likewise setting the immovable foot of the compasses for their poles in the vertical circle, so that they again pass through the points A and C. For these circles, according to Regiomontanus, divide the equator into 12 equal parts, whereas according to Campanus the vertical circle is cut by them into 12 equal parts. Finally, the ascending signs — that is, the various positions of the ecliptic at the risings of the beginnings of the signs — are drawn in this way. From Tables 3 and 4 given in Proposition 9 of Book 2 (or from others like them, derived from the doctrine of that proposition and computed for the given latitude of the place), take the hour at which any given sign rises, with the Sun placed at the beginning of Cancer or of Capricorn. Then, according as that hour is contained on the tropic of Cancer or of Capricorn in the concave hemisphere, let it be counted in the equator from G — toward D if it is before noon, but toward B if after noon. And through the end of the counting (with the immovable foot of the compasses placed on the point of the equator that is a quadrant distant from the end of the counting) let a great circle be drawn, faintly, cutting the tropic of Cancer or of Capricorn (according as the hour was taken with the Sun in Cancer or in Capricorn) at that point through which — at the interval of a quadrant taken in that faint circle — a great circle is described. This circle will represent the

position of the ecliptic while the proposed sign rises, so that, when the tip of the shadow falls upon it, that sign begins to rise above the horizon. For since, when the shadow falls upon that point marked on the tropic of Cancer or of Capricorn, the hour at which the given sign rises is shown, and since the ray of the Sun passing through the centre lies in the [plane]

[Margin: Laying out the parallels of the lengths of days and the latitudes of cities; and also the vertical circles and the parallels of the horizon; the meridians; the celestial houses; and the ascending signs, in the concave hemisphere.]

plane of the ecliptic, the ecliptic will necessarily pass through that point of the tropic of Cancer or of Capricorn, and so will touch the tropic at that point, just as it does in the heavens. Since, therefore, by Proposition 3 of Book 2 of Theodosius, the circle last described touches the tropic at that point — because both it and the tropic cut, at the same point, that greatest hidden circle in which the pole of each lies — this circle will be exactly the ecliptic. By this device all the ascending signs will be drawn. The sign Aries [♈] will touch the tropic of Capricorn at L, and will have its pole in the meridian a quadrant distant from point L. The sign Libra [♎] will touch the tropic of Cancer at H, and both will pass through the points B and D. The sign Cancer [♋] will touch the tropic of Cancer at I and the tropic of Capricorn at N. Finally the sign Capricorn [♏] will touch the tropic of Cancer at K and the tropic of Capricorn at M, as is gathered from the said tables.

[Margin: How, by means of the concave hemispherical dial, sundials for any plane may be laid out from the shadow.]

And so, as you see, all those things that we described for plane dials in Books 2 and 3 are laid out with ease in the concave hemisphere. Hence, if the concave hemisphere, in which all these things are drawn, is fastened onto some plane tablet, and on that tablet the meridian line is drawn corresponding to the meridian of the hemisphere — which is easily done: if the tablet, exposed to the Sun together with the hemisphere, is turned about until the shadow of the style falls onto the meridian circle; for if a style fixed at right angles is then observed on the tablet, and in the middle of its shadow two points are marked, the line drawn straight through these points will be the meridian line, provided account is taken of the tablet's own position with respect to inclination to the horizon and declination from the vertical, as we said in the last chapter of the preceding book — then everything is drawn far more conveniently, and perhaps more accurately, than from a horizontal dial. This is so both because the tip of the shadow is discerned more clearly and distinctly in the concave hemisphere than in a plane

dial, and also because everything is drawn more easily and more accurately in the concave hemisphere than in a plane dial, as is evident.

ON THE CONSTRUCTION OF A DIAL ON A CONVEX CYLINDER

CAPVT V.

So that the laying-out of the hours on a convex cylinder may be made clearer — a thing accomplished entirely by means of turned shadows [umbrae versae] or the altitudes of the Sun — we shall draw the hours on some plane, in order afterward to transfer them onto the cylinder. But before all else, the altitudes of the Sun above the horizon must be investigated for each hour, with the Sun at the beginnings of the signs. Computed for latitude 42°, these are as follows, for the hours from noon and midnight:

Scheme of the hours (leftmost value column, 12, is the shared noon/midnight column):

	1								
Hours (afternoon)	2	1	2	3	4	5	6	7	post meridiem
Hours (after midnight)	1	1	1	9	8	7	6	5	post med. noc.
	2	1	0						

Altitudes of the Sun above the horizon at the beginnings of the signs

[*Altitudines Solis supra Horizontem in signorum initijs*] (values in G.M. = degrees.minutes; hour-columns 12, 1, 2, 3, 4, 5, 6, 7 as above):

Signs	12	1	2	3	4	5	6	7	Signs
♋ Cancer	71.3 0	67.4 1	58.5 9	48.2 9	37.2 5	26.1 9	15.2 9	5.1 1	♋ Cancer
♌ Leo	68.1 2	64.4 7	56.3 7	46.2 4	35.2 6	24.1 8	13.2 2	2.5 4	♊ Gemini

Gnomonices, Book VIII (Liber Octavus)

(This opening continues Chapter V, on the sundial constructed on a convex cylinder; a new chapter — Chapter VI, on the quadrant — begins on the third page.)

The page opens with two tables of solar altitudes, one for each tropic, computed for latitude 42° (the meridian altitudes 71° 30' in Cancer and 24° 30' in Capricorn confirm this latitude).

Altitudes of the Sun above the horizon for the hours from the west, in the tropic of Cancer (♋) [Altitudines Solis supra Horizontem pro horis ab occ. in tropico ♋]. G.M. = degrees.minutes; "pomeridianæ" = afternoon hours, "antemeridianæ" = morning hours; "Altitudines Solis" runs as the side-caption of the two altitude rows:

Hours (afternoon / pomeridianæ)	24	23	22	21	20	19	18	17	16 28/60
Altitude of the Sun (G.M.)	0.	9.5	20.	31.	42.	53.	63.	70.	71.30
	0	4	29	28	36	30	24	20	
Hours (morning / antemeridianæ)	9	10	11	12	13	14	15	16	16 28/60

Hours (afternoon / pomeridianæ)	24	23	22	21	20	19	18	17	16 ²⁸ / ₆₀
Altitude of the Sun (G.M.)	0.	10.	21.	32.	43.	54.	63.	70.	71.30
	40	35	12	13	21	12	59	36	

Altitudes of the Sun above the horizon for the hours from the west, in the tropic of Capricorn (♑) [Altitudines Solis supra Horizontem pro horis ab occ. in tropico ♑]:

Hours	4	23	22	21	20	19 ²² / ₆₀	19	18	17	16
Altitude of the Sun (G.M.)	0	8.	16	21.	24.	24.30	24	21	15.	8.
	.	47	.7	25	11		.5	.8	41	14
	0									

So let AB be a plane surface on which the hours are to be drawn. Since the reversed shadows [*umbræ versæ*] are longest when the Sun is in Cancer (♋) and shortest when it is in Capricorn (♑), it will not be out of place to choose two unequal styles [*styli*]: the shorter to mark the hours while the Sun is in the northern signs, the longer to show them while the Sun is in the southern signs. Accordingly, for the northern signs construct the rectangular parallelogram AC, and for the southern signs DB. Divide AC arbitrarily into three parallelograms EI, MK, NC for the six northern signs; but so that they keep a proportionate distance from one another, from G describe the quadrant EF, divide it into three equal parts, and through the points of division draw the lines MI and NK parallel to AH and LC. The space from E to M is to be assigned to Cancer; the spaces from M to N and from N to G to Leo (♌) and Virgo (♍); and finally the spaces from G to N, from N to M, and from M to E to Aries (♈), Taurus (♉), and Gemini (♊).

In the same way the parallelogram DB is to be divided for the southern signs — though we have divided it by diurnal arcs rather than by the beginnings of the signs, so that the hours from the west can be drawn more easily. For the line PQ will be fitted to the diurnal arc of 12 hours, that is, to the equator; RS to the arc of 11 hours; TV to the arc of 10 hours; XY to the arc of 9 hours; and ZB to the tropic of Capricorn (♑). These lines are to be drawn parallel to DQ and OB at any distance, though for convenience we have drawn them at roughly equal spacings — except the line ♑ ZB, which lies close to XY, just as in the heavens the tropic of Capricorn lies close to the parallel whose diurnal arc spans 9 hours, at latitude 42°.

[Margin: *Descriptio horarū ab occ. in cylindro concauo* — Drawing the hours from the west on the concave cylinder.]

So, to draw the hours from the west on the rear parallelogram DB, extend DO and take Oa equal to a style of any size. From a describe the quadrant Ob, divided into 90 degrees beginning from the line Oa, and from a, through the degrees, let hidden lines be drawn cutting OB at the points of the reversed shadows corresponding to the required altitudes of the Sun. For if Oa is set parallel to the horizon and OB perpendicular to it, the Sun's rays passing through a, the centre of the world, and running along each degree of altitude (which would face the degrees of the quadrant Ob and lie above the horizon Oa, were a full circle described from centre a) will fall on the points of the reversed shadows on the line OB, as is evident. If instead you prefer to use the reversed shadows drawn from the shadow-table we made in Proposition 2 of Book 5 [*propos. 2. lib. 5*], in place of the Sun's altitudes, then on the line DQ take DF equal to the style Oa, and divide it into 12 equal parts of the reversed shadow; and if need be, take another portion below f, equal to the same style, and so on. In our example it is enough to take below f two small parts of the reversed sha-

Diagram. The developed (unrolled) layout for the *northern* signs — the parallelogram AC. Along its top runs a hatched horizontal band (the cylinder-rim), with **p** at its left end and **q** at its right; below the band the vertical sides descend, with **A** at upper left (below p) and **L** at upper right (below q). Just above the band is a zodiac strip divided into three cells, each carrying a pair of signs (each interval of the dial serves one ascending and one descending sign). Reading left to right, the cells are headed by the top-edge letters **E, H, N, G** and carry the sign-pairs: Gemini (♊) over Cancer (♋); Taurus (♉) over Leo (♌)[?]; Aries (♈) over Virgo (♍) — consistent with the text's assignment of the intervals E–M, M–N, N–G. Within the field, curved hour-lines fan from the upper corners downward; the left side (line AH) carries a scale of shadow-parts marked 7, 6, 5, 4, 3, 2, 1, ½ near the top and the larger marks 3, 6, 9, 12 and, lower, 24, 36; the right side (line LC) is marked 5, 6, 7, 8, 9, 10, 11, 12, with the interior point **F** where a curve meets the right edge. The baseline is lettered **H, I, K, C**.

- p, q (top rim ends); A, L (heads of the vertical sides)
- E, H, N, G (top-edge division letters)
- Zodiac cells: ♊/♋, ♉/♌[?], ♈/♍
- F (interior point on the right side)
- Left scale: 7,6,5,4,3,2,1,½; 3,6,9,12; 24,36
- Right scale: 5,6,7,8,9,10,11,12

- Baseline: H, I, K, C
- Beneath the figure: a small woodcut of one of the two styli (a pin-gnomon with a rounded knob-handle tapering to a point)

(Several interior hour-numbers and one zodiac glyph (♑) are worn/uncertain)

Diagram. The developed layout for the *southern* signs — the parallelogram DB — together with the physical instrument. Along the top is a hatched rim-band; the top-edge letters are **P, R, T, X, Z**, with **D** at upper left (below P). Above the band is a date strip divided into cells that pair the two dates on which the Sun crosses each declination-parallel: "14. Sep / Feb. 18", "5. Octob.[?] / Ian. 25", "29. Oct / Dec. 23", closing with a Capricorn (♑) glyph for the tropic. The vertical parallels PQ, RS, TV, XY, ZB descend through a field of diagonal hour-lines bearing numbers (12, 13, 14, 15, 16 across the top; 21, 22, 23 and a point **h** further in; 20; and near the foot the marks 29, 10 and 18). A diagonal line labelled **Linea meridiana** ("meridian line") crosses the field; the left side is scaled 3, 6, 9, 12 (the mark 12 lettered **f**). The baseline is lettered **Q, S, V, Y, B**. To the right stands a graduated quarter-circle (the quadrant Ob) scaled 10, 20, 30, 40, 50, with centre **O**; and at the far right the actual cylinder-dial instrument — a horizontal top-bar carrying a suspension ring/knob (the *nodulus*) with a plumb-thread, a tall body with a vertical scale 10–70 and a lower arc scaled 70, 80, 90, lettered **n** (head of scale), **a** (upper right), **6** (lower right), **f** (foot / plumb-bob).

- P, R, T, X, Z (top edge); D (upper left)
- Date-strip pairs: 14 Sep / 18 Feb; 5 Oct[?] / 25 Jan; 29 Oct / 23 Dec; ♑
- Parallels PQ, RS, TV, XY, ZB
- Linea meridiana (labelled diagonal)
- Interior hour-numbers: 12,13,14,15,16; 21,22,23; 20; point h; 29,10; 18
- Left scale: 3, 6, 9, 12(f)
- Baseline: Q, S, V, Y, B
- Quadrant Ob: centre O; scale 10,20,30,40,50
- Instrument: nodulus/ring + plumb; vertical scale 10–70; arc 70,80,90; labels n, a, 6, f
- Beneath the figure: a small woodcut of the second stylus (pin-gnomon with knob-handle) ...-dow. Now we shall draw the meridian line thus. From the adjacent little tables take the meridian altitudes at the equator and on the diurnal arcs of 11, 10, and 9 hours, and likewise in the tropic of Capricorn (♑); and with the compasses on the line OB take the lengths of the shadows owed to those altitudes — or rather, from the line DQ take the reversed

shadows owed to the same altitudes, as the table of Proposition 2, Book 5 indicates — and transfer them onto the lines DQ, RS, TV, XY, OB, always beginning from the line DO, marking the points on these lines. A curved line drawn suitably through these points will be the meridian line. In the same way we shall draw the lines of the hours from the west, if — taking account of the Sun's altitudes for each hour and of the reversed shadows owed to them — we mark the points on the lines of the diurnal arcs.

For example: the hour 16 from the west, at the equator, has an altitude of $40^{\circ} 4'$ [*gr. 40. min. 4*]. So if with the compasses on the line OB we take the portion between O and the $40^{\circ} 4'$ mark [the print here reads *gr. 4. m. 4*, apparently for $40^{\circ} 4'$], and transfer it from D as far as g, then the point g terminates the reversed shadow of 10 parts 6 minutes [*partium 10. min. 6*], which corresponds to that altitude in the table of Proposition 2, Book 5; and the hour 16 from the west is to be drawn through g. Again, the same hour 16 from the west, on the diurnal arc of 11 hours, has an altitude of $29^{\circ} 10'$. So if with the compasses on the line OB we take the portion between O and that altitude, or on the line DQ take the reversed shadow of 6 parts 42 minutes corresponding to the same altitude in the table of Proposition 2, Book 5, and transfer it from the line DO onto the line RS as far as h, the same hour 16 from the west is to be drawn through the point h, and so with the rest.

You see, then, that through the individual points of the lines PQ, RS, TV, XY two hours from the west pass — which would not happen if these lines had been assigned to the beginnings of the signs rather than to the diurnal arcs of whole hours. And since the hours run together near the meridian line, we have marked the line of hour 19 with certain dots, so that it may be more easily distinguished from the others. In the same way the hours from sunrise, the unequal hours, and those from noon and from midnight will be drawn, if their altitudes are computed. Thus in the parallelogram AC you see the hours from noon and midnight drawn from the reversed shadows of the line AH, on which three parts equal to the style have been taken, of which Am is divided into 12 equal parts; these reversed shadows are to be taken from the table of Proposition 2, Book 5, corresponding to the Sun's altitudes — or else from the reversed shadows of the line nl, which the hidden lines drawn from the centre a through the degrees of the quadrant Ob supply, provided an is equal to the style Am and the line nl is drawn perpendicular to aO.

Only this must be noted. When some hour cannot be drawn through all the beginnings of the signs — as happens with the hour 5 from midnight and 7 from

noon, which has no altitude at the beginning of Taurus (♉) and Virgo (♍), and hence no point on the line NK — a point must be taken on this line NK, above AL, for the opposite hour (that is, for hour 5 from noon and 7 from midnight), from the altitude it has in the opposite sign, say at the beginning of Scorpio (♏) and Pisces (♐) : because this altitude above the horizon equals the depression below the horizon of the earlier hour (which had no point), as is clear from the material sphere; and therefore, since that earlier hour is above the horizon of the Antipodes, it is counted from noon if it was previously counted from midnight, and conversely; and the northern parallel will stand to them as the opposite southern one does to us, and so on. By the same reasoning, if some hour from sunrise or sunset has no point on any parallel or diurnal arc, the same hour must be taken on the opposite parallel or arc — yet so that it is counted from sunrise if it was previously reckoned from sunset, and conversely.

By this same device the hours will be laid out on the convex cylinder [*cylindro conuexo*], if on it are drawn, for the lines of the signs or of the diurnal arcs, parallel lines which — the cylinder hanging freely — are perpendicular to the horizon, as we have said. The style is to be fitted so that it can easily be turned to the place of the Sun, or to the day of the month, at which we wish to observe the hour; but under this rule, that the sighting-line of the style [*linea fiduciæ styli*], such as the line Oa on the style Oa, always makes right angles with the line DO or AL.

[Margin: *Horologiū planū instar cylindri commodissimum* — A plane sundial in the manner of a cylinder: most convenient.]

But we shall also learn the hours very conveniently from the two parallelograms AC and DB drawn on some bronze plate [*lamina ænea*] — the one on one face of the plate, the other on the opposite face — so that the sundial may be reduced to a smaller form. For suppose a groove pq is cut in the plate, in which a style is set (whose form is shown at the foot of the preceding figure) that can run back and forth, so that the sighting-line of the style is perpendicular to the lines AL and DO, and the style itself can be fastened on the opposite side of the plate by a little screw [*cochleola*] once it has been set at the place of the Sun or at the proposed day of the month, so that it can no longer be moved; and suppose the plate is turned toward the Sun so that the thread, from which a plumb-weight hangs, coincides with one of the straight lines assigned to the beginnings of the signs or to the diurnal arcs, and the style's shadow runs parallel to the lines of the signs or diurnal arcs. Then the tip of the shadow will indicate the present hour — before noon or after — according as the observation is made before or after midday.

And I would judge this plane sundial far superior to one drawn on a cylinder, because it is very difficult to make a cylinder that, hanging freely, does not tilt to one side — an inconvenience that does not arise in our plane sundial, since it is governed by a plumb-line. In the same way the hours will be found on the cylinder, if the style is set at the Sun's degree or the day of the month, and the shadow is kept parallel [to the lines], and so on.

[Margin: *Hora quo pacto ex regula solida per altitudines Solis cognoscatur* — How the hour may be found from a solid rule by the Sun's altitudes.]

Moreover, if some solid rule [*regula solida*] is made, such as *nl*, on which are drawn the parts of the reversed shadow that the lines from the centre *a*, through the degrees of the quadrant *Ob*, exhibit; and if at *n* a style *na* is fixed perpendicular to *nl*, of a length equal to the distance *nl* on the rule (into which the reversed shadows corresponding to the altitudes of the quadrant *Ob* have been carried) — then this rule will serve us as a sundial. For if, by means of a plumb, this rule, turned toward the Sun, hangs freely so as to be perpendicular to the horizon, and the style's shadow runs parallel to the sides of the rule, the tip of the shadow will indicate the Sun's altitude, and so from the adjacent tables of the Sun's altitudes we shall easily learn the present hour.

[Margin: *Hora cognitio ex altitudine Solis quadrāte, vt alio instrumēto inuenta* — Determining the hour from the Sun's altitude by a quadrant, as by another instrument.]

We shall also find that same hour from the same tables if we seek the Sun's altitude with a quadrant or another instrument.

[Margin: *Descriptio horarū in cylindro ex vmbra cadente in horas horologij horizontalis, vel hemisphaerici concauo* — Drawing the hours on a cylinder from the shadow that falls on the hours of a horizontal, or of a concave hemispherical, sundial.]

But if a cylinder is set upright on a plane on which a horizontal sundial is drawn, or on which a concave hemispherical sundial is fixed, the hours will be drawn on the cylinder from the shadow — as we noted at the end of the preceding book — in this way. Having turned the style to the line of each sign, or of the diurnal arc, let the plane be rotated until the style's shadow, in the drawn sundial, falls on the hour of that parallel to whose line the cylinder's style is fitted; and let the cylinder itself, fixed on the plane in that position, be turned about its axis until the style's shadow runs parallel to the lines of the signs or of the diurnal arcs, and the endpoint of the shadow be marked. For through this that hour is to be drawn on

the cylinder. In no other way can the points of that hour, and of all the others, be found on all the lines of the signs or of the diurnal arcs.

ON THE DRAWING OF THE HOURS ON A QUADRANT

CHAPTER VI

[DE HORARVM DESCRIPTIONE in quadrante. CAPVT VI.]

[Margin: *Descriptio horarū ab occ. in quadrante* — Drawing the hours from the west on a quadrant.]

The drawing of the hours on a quadrant differs little from what we set out in the preceding chapter for the cylinder, or for a plane in the manner of a cylinder, since in both cases the hours are drawn from the Sun's altitudes above the horizon. So let ABC be a quadrant on which the hours from the west are to be drawn, divided into 90 degrees whose numbering runs from B to C. From A describe two arcs through the points D and E at any distance apart, of which the one nearer the quadrant's side BC is assigned to the tropic of Capricorn (♑), and the one farther from BC to the tropic of Cancer (♋). For although most people assign the former to the tropic of Cancer and the latter to Capricorn — which can be done just as well, as far as the drawing of the hours is concerned — it will nevertheless be much more convenient to do the opposite, as we have said, because of the greater separation of the hours. Bisecting also the portion of the line AB that lies between the arcs drawn through D and E, describe from A, through the point of division, the arc through F, which serves for the equator; this could also be drawn through any point between the arcs through D and E, even if it did not bisect the line between them.

Now from A let three hidden lines go out through the meridian altitudes of Capricorn (♑), of Aries (♈) or Libra (♎), and of Cancer (♋) — that is, through 24° 30', 48°, and 71° 30' — cutting the arcs through D, F, E at the points D, F, E; and the arc of a circle described through these, DFE, will be the meridian line. Then from A let other hidden lines be drawn through the meridian altitudes of the diurnal arcs of 9, 10, 11, 13, 14, and 15 hours, taken from the tables of the preceding chapter (for the hours from west and east are more easily drawn by diurnal arcs, just as on the cylinder), which cut the meridian line DFE at the points M, L, K, I, H, G, through which arcs are described from A for the diurnal arcs.

And if from A hidden lines are sent out through the altitudes of the hours of any diurnal arc, taken from the tables of the preceding chapter, the diurnal arc whose hour-altitudes were taken will be cut into the hours from the west. So if the corresponding hour-points are joined by curved lines — all the morning hours being expressed by circular lines, while the afternoon hours must be drawn suitably through the points at which the diurnal arcs are cut by the arcs of the morning hours, so that hour 23 is drawn through the points nearest the line AB itself, and 22 through the following ones, and so on — it will be enough to find three points for each of the morning-hour arcs. Namely, for the arc of hour 15: one on the diurnal arc of 9 hours (which lies on the line AB, since the Sun then rises), another at the equator, that is, on the diurnal arc of 12 hours, and a third on the diurnal arc of 15 hours. Likewise for the arc of hour 17: one on the diurnal arc of 9 hours, another on the diurnal arc of 12 or 11 hours, and finally a third on the diurnal arc of 14 hours — which is the same as H, since it is then noon; and so on. The sundial will then be complete.

That it may indicate the hours, the signs of the Zodiac — or at least the days of the months — must be drawn along the sides AB and DE: the days of the months from the 12th of June to the 12th of December (or the signs from Cancer (♋) to Capricorn (♐)) along the line AB; and the days of the months from the 12th of December to the 12th of June (or the signs from Capricorn (♐) to Cancer (♋)) along the arc DE. This is done as follows. From the place of the Sun at the beginning of any month, or at the beginning of any sign, find its declination, and from this the meridian altitude; by this a hidden line drawn from A cuts the arc DE at a point through which the hidden arc described from A will cut the line AB — or the circular line described along the arc DE — at the beginning of the proposed month or sign of the Zodiac. By the same reasoning points will be found for the 10th or 20th, or any other day of the proposed month, if the place of the Sun is found, together with its declination and meridian altitude. In our example the days of the months are drawn; in the following figure, the signs of the Zodiac.

Now if from A a thread with a plumb hangs freely, together with a movable bead, and the thread is stretched and the bead is set on the line AB (or on the circular line near DE) at the day of the month, and finally the instrument is directed to the Sun until the Sun's ray passes through the corresponding points of the sights [*pinnacidia*], the bead will indicate, among the hour-lines, the present hour — before noon or after — according as the observation is made before or after midday; and the plumb-thread, on the quadrant BC, will show the Sun's altitude: while this altitude is increasing, the time is before noon; while it is decreasing, after noon.

[Margin: *Descriptio horarum à mer. & med. noc. in quadrante* — Drawing the hours from noon and from midnight on a quadrant.]

By the same reasoning the hours from noon and from midnight will be drawn from their altitudes at the beginnings of the signs; but it will be enough to find the hour-points in the two tropics and at the equator, for arcs of circles described through three corresponding points on the said parallels will give the hours from noon and midnight. For all the hour-points fall on the circumferences of circles. Only this must be noted here: when some hour from noon or midnight has no point on a given parallel, the altitude of the opposite hour must be taken — namely from midnight or from noon — on the opposite parallel, and this must be transferred from the line AB onto the earlier parallel produced beyond the quadrant, a point being marked on it; for through this that hour is to be drawn. Thus, since the hour 5 from noon (or 7 from midnight) has no point on the tropic of Capricorn (♊) — this hour being below the horizon — with the Sun at the begin-

Diagram. A horary quadrant (the quadrant ABC). The right angle is at the top: **A** at the upper-left corner and **C** at the upper-right corner (each fitted with a small square sight-box/pinnule), with the apex **B** at the bottom. The curved outer rim (the graduated limb from C down to B) is scaled in degrees, marked 80, 70, 60, 50, 40, 30, 20, 10. Along that rim runs a band of month-abbreviations — **MAI.** (May), **APR.** (April), **MAR.** (March), **FEB.** (February), **IANVAR.** (January) — for the sign/date graduation. Down the left side (line AB) is a stacked column of month-names: **IVNI=** (June), **IVLIVS**, **AVGVST**, **SEPTEN**, [one line worn], **OCTOB.**, **NOVEM**, **DECEM**: — with the numbers 9, 10, 11(?), 12, 13, 14, 15 alongside them. The interior is filled with a curvilinear grid of hour-lines; the morning-hour arcs carry the numbers 16, 17, 18, 19, 20, 21, 22, 23. The meridian line DFE and the diurnal-arc points appear as the lettered points **D**, **E**, **F** (arc-endpoints) and **H**, **K**, **L**, **M** (and, per the text, **I** and **G**) on the meridian.

- A, C (top corners, with sight-boxes); B (apex)
- Outer degree-scale: 80,70,60,50,40,30,20,10
- Rim month-band: MAI, APR, MAR, FEB, IANVAR
- Left month-column: IVNI, IVLIVS, AVGVST, SEPTEN, [?], OCTOB, NOVEM, DECEM
- Left numbers: 9, 10, 11[?], 12, 13, 14, 15
- Interior hour-numbers: 16–23
- Meridian/arc letters: D, E, F, H, K, L, M ([?] I, G)

with the beginning of ♑ [Capricorn] present, we take the altitude of hour 5 from midnight (or 7 from noon) in the tropic of ♋ [Cancer], namely $5^{\circ} 11'$, and from A, through this altitude, we draw a hidden straight line that cuts the tropic of ♑ at G. For if the point G is transferred from point N onto the tropic of ♑, extended as far as H, then hour 5 from noon (or 7 from midnight) is to be drawn through the point H. The reason for this is that that hour, below the horizon among the Antipodes, has the same altitude in the tropic of ♑ as the opposite hour has in the opposite tropic of ♋. This too we noted must be done in the preceding chapter, when we were describing the hours on the cylinder.

By the same reasoning, since hour 6 from noon (or from midnight) has no point on the parallel of ♏ [Scorpio] or ♓ [Pisces], we take the altitude of hour 6 from midnight (or noon) in the parallel of ♉ [Taurus] or ♍ [Virgo], namely $7^{\circ} 40'$; and through this altitude, from A, we draw a hidden straight line that cuts the parallel of ♏ or ♓ at I; and we transfer the point I from point O onto the same parallel, as far as K. For hour 6 from noon (or midnight) is to be drawn through K. Finally, since hour 7 from noon (or 5 from midnight) has no point on the parallel of ♈ [Aries] or ♎ [Libra], we take the altitude of hour 7 from midnight (or 5 from noon) on the same parallel — since it has no opposite — and by it we find the point L of hour 7 from midnight (or 5 from noon). If, then, this point is transferred from point P onto the parallel of ♈ or ♎, extended as far as M, hour 7 from noon (or 5 from midnight) is to be drawn through M. And so with the rest.

Diagram. A demonstration figure combining a projected sphere (a large circle filled with a curvilinear grid of the sign-parallels and hour-lines) with a graduated quadrant limb at the right. The outer/right rim carries a degree-scale marked (from the top down) 90, 80, 70, 60, 50, 40, 30, 20, 10. At the top are two corner points fitted with small square sight-boxes; the point **A** stands at the top with a square, and a small boxed glyph (a sun/face) sits beside it. The bold letter **O** sits at the top-right, at the 90° mark where the scale begins. Outside the circle on the left, the points **Y** (upper) and **Z** (lower) lie on vertical lines carrying dotted (hidden) construction lines. Around and within the circle appear the lettered points **R** and **T** (left), **M**, **L**, **O**, **K**, **H** **N** (together), **G** (blackletter), **B**, **S**, and **n** (blackletter, at the foot); on the right, **X** (with a dotted line) and **Q**. The interior is densely filled with the sign-parallels, hour-lines, small zodiac glyphs, and hour-numbers (of which 3–8 are legible).

- Corner/rim points: A (with square sight-box), O (at 90° on the scale)
- Outer degree-scale: 90, 80, 70, 60, 50, 40, 30, 20, 10
- Left (outside circle): Y, Z (on the projected verticals)

- Circle/interior letters: R, T, M, L, O, K, H, N, G, B, S, n
- Right: X, Q
- Interior hour-numbers legible: 3, 4, 5, 6, 7, 8
- Numerous small interior zodiac glyphs and hour-labels worn/uncertain [?]

Hours from sunrise, and the unequal [seasonal] hours, can be laid out in the quadrant in no other way, if their altitudes are investigated in the diurnal arcs, and the altitudes of these in the parallels of the signs. Indeed, the hours from sunset will also be the hours from sunrise, if their complements up to 24 are taken — so that hour 23 from sunset is hour 1 from sunrise, hour 22 is hour 2, and so on. This I mean to be understood also of the cylinder of the preceding chapter. The reason is that any hour from sunset has, above the horizon in any parallel, the same altitude as the hour from sunrise which, together with it, of course makes up 24.

The Sun's altitudes can also be found in the individual parallels — both for the hours from noon and midnight, and for those from sunrise or sunset, and even for the unequal hours — geometrically, without tables of the Sun's altitudes, in the following way. Suppose, for example, that the Sun's altitudes are to be sought in the parallel of ♍ or ♋, l O. With the parallel l O extended in both directions, draw from A, through the meridian altitude [altitudo meridiana] of the opposite signs ♊ and ♎ — that is, through $59^{\circ} 30'$ — a hidden straight line cutting the arc O l, extended, at Q; and let O a be cut off equal to the arc O Q; and through a let a R be drawn parallel to A B, the line which the straight line l R — drawn from l, the end of the parallel of ♍ or ♋, perpendicular to A B or to a R — meets at R. Now bisect the line l R at S, and from S, with radius S l (or S R), describe the circle l n R a, and let it be divided into 24 equal hours: beginning at the point l (of noon), if the hours from noon and midnight are to be described, or at the point a or f (of the Sun's rising or setting), if the hours from sunrise or sunset are wanted.

But if unequal hours are to be laid out, both the arc a l f and the arc a R f must be divided into 12 equal parts. And the point l will be hour 12, of noon; and the points nearest to it, equally distant from l, will belong to hour 1 from noon and hour 11 from midnight, if the division of the circle into 24 equal parts began at l; and so with the rest. But if the division of the same circle began at the line a f, then the point a (or f) will be hour 24; the point of division nearest toward l, hour 23 from sunset (or 1 from sunrise); the next, hour 22 from sunset (or 2 from sunrise); and so on — so that the line a f is, as it were, the horizon, since the plumb-thread falls upon it when the Sun is rising or setting, while a l f is like the diurnal arc, and a R l the nocturnal. Finally, if unequal hours are in question, the

point a (or f) will be hour 12, and the points of division nearest toward l hours 1 and 11 of the unequal reckoning, and so on. We have given an example in the circle l n R a, for the hours from noon and midnight.

Now if, from the hours of the circle l n R a, hidden lines are drawn parallel to a f, or perpendicular to l R — which is easily done for the hours from noon or midnight, and for the unequal hours, if any two points equally removed from l are joined by hidden lines; and the same can be done for the hours from sunrise or sunset, if, with the compass, arcs equal to the several arcs between l and the hour-arcs l a are taken in the arc l f, and conversely — these parallels will cut the parallel l O at the altitudes of the hours, so that the arcs of the parallel l O between O and the points of section measure the Sun's altitudes above the horizon. And the points of section on the arc O a will give the altitudes of the nocturnal hours above the opposite face of the horizon, so that the arcs of the parallel O a between O and the said points are the Sun's altitudes above the horizon among the Antipodes, in the hours of the parallel l O a — which for them is the same as the opposite parallel is for us,

e f, ☿ and ♀. The hours, however, which in our horizon are reckoned from noon or from sunrise will in their horizon be reckoned from midnight or from sunset, and conversely. Therefore, since hours of this kind below the horizon have the same altitudes that the opposite hours have in the opposite parallel above the horizon — as is clear from what we showed in the scholium to proposition 1 of book 5 (where, of course, we demonstrated that the altitudes of the 24 hours of any parallel above one face of the plane are equal to the altitudes of the 24 hours of the opposite parallel above the other face of the plane, provided that what were previously reckoned from noon or from sunrise are now reckoned from midnight or from sunset — such being those which, in the opposite parallel, are set opposite to those in the earlier parallel) — from the altitudes contained in the arc O a we shall elicit the altitudes of the opposite hours in the parallel e f, ☿ and ♀, which is set opposite to the parallel O l, ♀ and ☿, in this way.

From A, to the points of the altitudes in the arc O a, let hidden straight lines be drawn; these will cut the arc e b of the opposite parallel, toward the side e, into arcs similar to the arcs of the arc O a — as we demonstrated at the end of chapter 1 for the sphere. Therefore, if by means of the compass these arcs of the parallel e b are transferred from e into the arc e f, we shall have in the parallel e f the altitudes of the hours which are set opposite in the hours of the arc O a — since the arcs of the parallel e f between e and the points of the Sun's altitudes are similar to the arcs of the parallel O a between O and the points of the Sun's

altitudes, being indeed equal to the arcs of the parallel $e b$ between e and the points of the Sun's altitudes. So that, for example, just as the first point from O toward a belongs to hour 6 from noon, so the first point from e toward f belongs to hour 6 from midnight; and just as the second point from O toward a looks to hour 7 from noon, so the second point from e toward f belongs to hour 7 from midnight; and so with the rest.

And just as we investigated the Sun's altitudes in the parallel $l O$, m and $\times$, so also we shall explore the same in all the other parallels, provided that they are extended in both directions, and that through the meridian altitudes of the opposite parallels hidden straight lines are drawn from A , and the points are marked in which the parallels are cut by them, and the rest is done as before. Thus you see, in the parallel of γ , PF — in which the meridian altitude of the opposite sign $\triangle$ is the same as that of γ — that the arc PT was taken equal to the arc PF , and that through T the line Tm was drawn parallel to AB . Then, that from F the line FT was drawn perpendicular to AB (or to Tm), which here falls exactly on T , since the line FT , on account of the equal arcs PF , PT , is cut by the line AB into two equal parts and at right angles — as will be demonstrated in the way it was shown in proposition 1 of book 1 that the line MN is cut by the line EH into two equal parts and at right angles, on account of the equality of the arcs HM , HN . Finally, that from V — where the line FT is bisected — with radius VF (or VT), the circle $F\beta TN$ was described; and if this is divided into hours, as we said of the circle $lnRa$, the Sun's altitudes will be found in the parallel PF , as in the parallel Ol .

Again, in the parallel of ν , ND , extended in both directions, you discern that a line sent out from A , through the meridian altitude of the opposite tropic of $\textcircled{S}$ — that is, through $71^\circ 30'$ — cuts the parallel ND , extended, at X ; and that the arc NY was taken equal to the arc NX , and that through Y the line YZ was drawn parallel to AB . After this, that from D , the end of the parallel of ν , the line DZ was drawn perpendicular to AB (or to YZ), and that from its midpoint λ , with radius λD (or λZ), the circle $D\theta Z$ was described; and if this is divided into hours, as we said of the others, we shall find in the tropic of ν , ND , the Sun's altitudes, and in the arc NY the Sun's depressions below the horizon. And if from A hidden lines are drawn to these, the tropic of $\textcircled{S}$, $F\mu$, will be cut toward the side μ , [the line] extended in points which, transferred from μ into the arc μE , will give the Sun's altitudes in the tropic of $\textcircled{S}$ — just as we said of the lines drawn from A to the points of the arc Oa , cutting the arc eb , and of the points of the arc eb transferred into the arc ef .

Finally, to give an example also for the northern parallels: you see, in the parallel of $\mathfrak{S}$, μ E, that a line sent out from A, through the meridian altitude of the Sun in the opposite tropic of $\mathfrak{V}$ — namely through $24^\circ 30'$ — cuts the tropic of $\mathfrak{S}$ at q; and that, the arc μ q in the same tropic being extended toward the side μ , an arc μ g was taken equal to it, and that through g the line g h was drawn parallel to A B. Moreover, that from E, the end of the parallel of $\mathfrak{S}$, the line E h was drawn perpendicular to A B (or to g h), and that from its midpoint p, with radius p E (or p h), the circle E ϕ h was described; and if this is divided into hours, as the others, there will be found in the parallel of $\mathfrak{S}$, μ E, the Sun's altitudes, and in the arc μ g the Sun's depressions below the horizon. And if from A hidden lines go out through these, the tropic of $\mathfrak{V}$, D N, will be cut toward the side N, [the line] extended in points which, transferred from N into the arc N D, will give the Sun's altitudes in the tropic of $\mathfrak{V}$ — no otherwise than as we said of the lines drawn from A, reaching the points of the arc O a and cutting the arc e b, and of the points of the arc e b transferred into the arc e f.

And the same reasoning holds in all the other parallels. But it is enough if the operation is set up either in the southern parallels alone or in the northern alone, since by one and the same labour, from the division of a single circle, the altitudes are also sought in the opposite parallel. I have chosen to explain more fully this method of finding the Sun's altitudes in the parallels described in the quadrant — drawn from the *Gnomonica* of Andreas Schoner [Andreas Schöner] — so that it might be more plainly understood by all; and since it is most pleasing and most beautiful, we shall easily demonstrate it, if we first teach by what other reasoning — different from that handed down in book 6 — the Sun's altitudes above the horizon may be investigated from the analemma, for the individual hours of each parallel.

[Margin: Finding the altitudes of the Sun above the horizon for the individual hours from the analemma, otherwise than was handed down in book 6.] [Margin: (Euclid, *Elements* I.29)]

Let ABCD be the meridian of the analemma [analemma], about the centre E; let B D be the diameter of the horizon, A C the vertical, H I the [diameter] of the equator, F G the axis of the world, K L the diameter of the northern parallel. Let the line L M be drawn parallel to B D, and K N parallel to A C; let K N be bisected at O, and from O, with radius O K (or O N), let the circle K P N Q be described. Dividing this into 24 equal hours — beginning indeed at K, for the hours from noon and midnight, but for the hours from sunrise or sunset, from the horizon B D; or, if unequal hours are in question, dividing both the arc π K q and the arc q N

π into 12 equal parts, beginning from the horizon B D — from an assumed hour d let d f be drawn parallel to B D, cutting the lines K N, K L and the circumference of the meridian at the points e, g, f. I say that D f is the altitude of the Sun for the hour d (which in the example is taken as hour 5 from noon, or 7 from midnight) in the parallel of the diameter k L.

For, a semicircle of the parallel K T L having been described from R with radius R K (or R L), let g h be erected at g perpendicular to K L. Since, then, from h, a point of the parallel, the perpendicular g h has been dropped to the diameter K L, and through g the perpendicular d f has been drawn to the diameter of the vertical A C (for since d f and B D are equidistant, and B D is perpendicular to A C, [Margin: a — (Euclid, *Elements* VI.2)] d f too will be perpendicular to A C), it will follow, from what was demonstrated in chapter 4 of book 6, that D f is the altitude of the Sun whose distance from the meridian is the arc K h. But both the semidiurnal arc K b is similar to the arc K π , and the arc K h (as we shall presently demonstrate) is similar to the arc K d. Therefore, if from the distance of the Sun from the meridian — taken on the arc K π , which stands for the semidiurnal arc, namely in the given example from the distance of 5 hours — a straight line is drawn parallel to the diameter of the horizon (or perpendicular to the diameter of the vertical), this will indicate, in the meridian, the arc D f of the Sun's altitude for the distance K h from the meridian, which in the semidiurnal arc of the Sun's parallel is similar to the distance K d in the arc K π . And that both the arcs K b, K π and k h, K d are similar, we shall show thus. Let the line O R be drawn; since the diameters K L, K N

are cut at their centres R, O — that is, proportionally — [Margin: a — (Euclid, *Elements* VI.2)] O R will be parallel to L M, and consequently also to d f, B D. [Margin: b — (Euclid, *Elements* VI.4)] Therefore it will be, as K R, the whole sine [sinus totus], is to K O, the whole sine, so K α to K a. [Margin: c — (Euclid, *Elements* VI.2)] But as K α is to α L, so is k a to a N; [Margin: b — (Euclid, *Elements* VI.4)] and therefore, by alternation, as K α is to K a, so α L to a N. Therefore it will also be, as k R, the whole sine, is to K O, the whole sine, so α L, the versed sine [sinus versus] of the seminocturnal arc b L, to a N, the versed sine of the arc π N. Therefore, by the lemma of proposition 1 of book 1, the arcs b L, π N will be similar; and consequently the remainder b K, from the semicircle K T L, will be similar to the remainder π K, from the semicircle K P N. And on this account π K q will stand for the diurnal arc, and π N q for the nocturnal, in a parallel whose declination is H K; and as many hours will be comprehended in the arcs K π , π N as in the arcs K b, b L. In no other way shall we show that the arcs K h, K d are

similar, [Margin: d — (Euclid, *Elements* VI.4)] namely because the whole sines K R, K O have the same ratio as the versed sines K g, K e.

The same reasoning holds for the other hours. For if k P, the distance from the meridian, comprises 6 hours, the line P Q S — equidistant from B D — will pass through the centres O, R, [Margin: e — (Euclid, *Elements* VI.2)] since it cuts the lines K N, K L proportionally. Hence it is clear that the quadrants k T, K P are similar. But if K Z, the distance from the meridian, exceeds a quadrant, we shall show that the arc K I is similar to the arc k Z, just as it was demonstrated that the arc K b is similar to the arc K π . Indeed, by the same reasoning, if k p, the distance from the meridian, falls below the horizon, the arc K f will be similar to the arc k p. The very same will be demonstrated in the equator and in the southern parallel.

For in the case of the equator, I i has been drawn parallel to B D, to which the perpendicular H i has been dropped — [the line] which is bisected at μ by the line B D, because the arc D I (and hence also B i) is equal to the arc B H. For from this it comes about that the line H i is cut by the line B D into two equal parts and at right angles. Afterwards, from μ , about H i, the circle H u i was described, from whose point u the line $\theta \beta$ was drawn parallel to B D, and from λ the perpendicular $\lambda \epsilon$ to H I, as far as the meridian — which stands for the equator described about H I. Whereupon it is clear that the arc H ϵ is similar to the arc H u, because the whole sines H E, H μ are proportional to the versed sines H λ , H θ .

But for the southern parallel, whose diameter is r t, the line t γ has been drawn parallel to B D, to which the perpendicular r γ has been dropped; and this being bisected at λ , the circle r 8 γ has been described about r γ , from whose point 8 — which is below the horizon, and is distant 8 hours from the meridian — the line $\phi \chi$ has been drawn parallel to B D, and from J[?] the perpendicular J[?] ω has been raised to r t, as far as the parallel of the diameter r t. Whereupon it is likewise manifest that the arc of the parallel r 3 4 $\gamma \omega$ [?] is similar to the arc r 8, [Margin: f — (Euclid, *Elements* VI.4)] because the whole sines r ξ , r λ have the same ratio as the versed sines r J[?], r ϕ .

From all which it is gathered: that D S is the altitude of the Sun in the northern [parallel] of the diameter K L, when the Sun is 6 hours distant from the meridian; likewise, that D Y is the Sun's altitude when the Sun's distance from the meridian is the arc K Z; and finally that D q is the Sun's altitude above the lower face of the horizon, when the Sun's distance from the meridian is the arc K p, exceeding a quadrant; then, that D β is the altitude of the Sun in the equator, at the distance [of] the arc H u; lastly, that D χ is the Sun's altitude above the lower face of the

horizon in the southern parallel of the diameter $r t$, when the distance from the meridian is the arc $r 8$, falling below the horizon.

Diagram. The analemma figure — the meridian ABCD about the centre E — a full circle densely packed with construction chords and lines. Legible labels: on the rim, **K, A** (with ϵ just below it), **h, T, b, S, D, q, L, Y, C**, and the hour-numbers **6** and **I** at the foot; down the left, **H, d, P, B, M, ϕ , G**; in the interior, **R, Q, O, V, N, ψ** , and **E** at the centre, together with scattered small point-labels (Greek $\theta, \delta, \alpha, \lambda, \omega, \pi, \mu, \chi$) and the numbers **3, 4, 8**. The chords realize the diameters of the horizon (B D), the vertical (A C), the equator (H I), the axis (F G), and the northern parallel (K L), with the hour-circle K P N Q and the several construction circles described in the text.

- Meridian / centre: A, B, C, D (rim), E (centre)
- Principal diameters (per text): horizon B D, vertical A C, equator H I, axis F G, parallel K L
- Rim points legible: K, A, h, T, b, S, D, q, L, Y, C
- Foot numbers: 6, I
- Left-side letters: H, d, P, B, M, ϕ , G
- Interior letters: R, Q, O, V, N, ψ , E
- Interior Greek/number labels legible: $\theta, \delta, \alpha, \lambda, \omega, \pi, \mu, \chi$; 3, 4, 8
- Several small interior point-labels worn/ambiguous [?]

These things being shown, it is clearly established that the Sun's altitudes are correctly found in the parallels of the preceding quadrant. For example, in the quadrant the parallel $\mathfrak{M}$ and $\mathfrak{X}$, Q l O a, corresponds to the meridian of the neighbouring analemma A B C D; the line A B, to the diameter of the horizon A B; the arc O l, to the arc B r of the meridian altitude; and the arc O Q — that is, its equal, O a — to the arc B 6, since this is equal to the arc of the meridian depression D t, that is, to the arc of the meridian altitude of the opposite parallel, just as in the quadrant too the arc O Q (or O a) was taken equal to the meridian altitude of the opposite parallel. Next, the line R a in the quadrant corresponds to the line t γ in the analemma, since both R a — through the end of the meridian depression in the quadrant — is drawn parallel to the horizon A B, and t γ — through the end of the meridian depression in the analemma — parallel to the horizon B D. And the line l R in the quadrant corresponds to the line r γ in the analemma, since each is drawn perpendicular from the end of the meridian altitude to the horizon. And finally the circle a l n R in the quadrant corresponds to the circle r 8 γ in the analemma. Hence, just as in the analemma the lines drawn through the hours of the circle r 8 γ , parallel to the diameter B D of the

horizon, give in the meridian A B C D the Sun's altitudes, so also in the quadrant the lines drawn through the hours of the circle a l n R, equidistant from the horizon A C, will indicate the same altitudes of the Sun in the parallel Q l O a, which stands for the meridian in the analemma. And the same reasoning holds in the other parallels of the quadrant. For all the things that we prescribed for construction in the neighbouring analemma, for the investigation of the Sun's altitudes, have been done in the same way in the individual parallels of the quadrant, so that the Sun's altitudes might be found — as is clear, if the matter is considered a little more diligently.

While I was demonstrating these things, it came into my mind that by nearly the same reasoning the construction of the analemma handed down in proposition 1 of book 1 could be demonstrated, and indeed much more easily than there. For let ABCD be the meridian of the analemma,

[Margin: *Inuentio declinationum omnium punctorum Eclipticæ in Analemmate, una cum demonstratione.* — "Finding the declinations of all the points of the ecliptic in the analemma, with the demonstration."]

let ABCD be the meridian of the analemma, about the centre E, in which BD is the diameter of the horizon, AC the vertical, HI the equator, and FG the axis of the world — the diameters of the parallels that are always visible and always hidden being, respectively, Dk and BL. Having laid off the greatest declination from the point H toward both sides, as far as M and N, draw the line MN, which will be bisected at O and cut at right angles, as was shown in Proposition 1 of Book 1. Then, with the circle MPNQ described from O about MN, and this circle divided into 12 equal parts, draw through each pair of points the lines YSλ and XRμ, ZTξ, αVϖ, equally distant from PQ; by the scholium of Euclid III.27 these will be parallel to the line QPI. But such parallels are drawn more precisely if from the point I one also lays off the greatest solar declination on each side, as far as θ and ρ; then, with θρ joined, a semicircle is described from the point 8 and divided into six equal parts, and so on, as I noted in Proposition 1 of Book 1. Finally, join the lines Mθ and Nρ, which by the same scholium will be parallel to HI itself.

I say that these lines are the diameters of the parallels — that is, their common sections with the meridian — so that the arcs Hγ, Hβ, Hδ [?], Hε [?] measure the declinations of the other parallels which are drawn through the beginnings of the signs, just as HM and HN measure the greatest declinations of the Sun. This holds in the following order: the arcs Hγ and Hβ measure the declinations of those points of the ecliptic which lie as many degrees from the beginning of Cancer ☊, toward Aries ♈ or Libra ♎, as the points X, Y, R, S are distant from the point M;

while the arcs $H\delta$ and $H\epsilon$ measure the declinations of those points of the ecliptic which lie as far from the beginning of Capricorn ϑ , toward Aries γ or Libra ζ , as the interval by which the points Z, α , T, V are distant from the point N in their own circle.

This will be demonstrated as follows. Draw the line $M\rho$, which will be the diameter of the ecliptic, the beginning of Cancer ϑ being placed at M and the beginning of Capricorn ϑ at ρ ; and let $M\rho$ cut the line $XR\mu$ — for example — at p. From p, draw pb perpendicular to $M\rho$, and conceive the semicircle Mbp , standing for the ecliptic, to be turned about $M\rho$ until it stands perpendicular to the meridian ABCD. For in that position the plane of the ecliptic is at right angles to the meridian, by Theodosius, *Sphaerica* I.15, since the meridian passes through its poles. Conceive also that through b, a point of the ecliptic, a circle is drawn equidistant from the equator and perpendicular to the meridian.

[Margin: Euclid XI.19] Now, since both the ecliptic and this parallel circle are perpendicular to the meridian, their common section through the point b will also be a straight line running to the meridian. But bp is perpendicular to the meridian, by Euclid XI, definition 4. Therefore bp is the common section of the ecliptic and of the parallel drawn through b; and so the said parallel cuts the meridian at p. [Margin: Euclid XI.16] Since, then, the meridian, being in the equator, makes with the said parallel common sections that are parallel, the line $XR\mu$ drawn through p parallel to the diameter HI of the equator will be the common section of the said parallel and the meridian — that is, the diameter of that parallel itself. Consequently the arc $H\gamma$ will be the declination of that same parallel, or of the point b of the ecliptic.

[Margin: Euclid VI.4] Now the arc Mb of the ecliptic is similar to the arc MX in the circle MPNQ, by the lemma of Proposition 1, Book 1; because ME, the whole sine of the ecliptic, is to MO, the whole sine of the circle MPNQ, as Mp , the versed sine of the arc Mb, is to $M\phi$ [?], the versed sine of the arc MX. Therefore the line $XR\mu$, drawn through the point X parallel to the diameter of the equator, gives in the meridian the arc $H\gamma$, the declination of the point b of the ecliptic, which is as many degrees distant from the point M as the point X is distant from the same point M in the circle MPNQ. And the same reasoning holds for the others, which was to be demonstrated.

From this demonstration it is clearly established that if the circle ABCD is cut into 12 equal parts — that is, into parts similar to the parts of the circle MPNQ, beginning from the point M — and any two points equally distant from M are joined by straight lines a7, b6, d5, e4, 2·3, which are perpendicular to $M\rho$ at the

points l, p, E, q, u (as will be demonstrated in the way it was shown in Proposition 1 of Book 1, that MN is cut at right angles), then the lines drawn through these points parallel to HI, such as $\beta\lambda$, $\gamma\mu$, $\delta\xi$, $\alpha\varpi$ [?], also cut off from the meridian the arcs of declination. This too we handed down in the scholium of Proposition 1, Book 1. For we demonstrated it of the point b, which is as many degrees distant from M in the circle ABCD as the point X is distant from M in the circle MPNQ; and the same ratio holds for the rest.

[Margin: *Inuentio declinationum [?] omnium arcuum diurnorum facillima, una cum demonstratione.* — "A most easy finding of all the diurnal arcs, together with its demonstration."]

Before I set the final hand to this work, I was diligently applying myself to the task of confirming, by some geometric reasoning, that practice of the scholium of Proposition 33, Book 1, by which Andreas Schöner [Andreas Schoner] investigates the radii of the diurnal arcs most briefly and most easily. After I had long and thoroughly examined this, a demonstration at last occurred to me, which I have chosen to add here in the place of an appendix. So that it may be understood more plainly, the whole construction must be repeated. From the centre A, at the interval of any line AB, let the circle BCGD be described; and in it let two arcs BC and BD be taken equal to the complement of the pole's altitude, so that, if AB is taken as the common section of the equator and the meridian — which the circle BCGD represents — the arcs BC and BD will be the declinations of two parallels, one of which, namely that drawn through C, is the greatest of those that are always visible and has a diurnal arc of 24 hours, since it lies wholly above the horizon; while the other, drawn through D, is the greatest of those that are always hidden and has a diurnal arc of 0 hours, since it lies wholly below the horizon. Now, with the line CD drawn cutting the line AB at E, the lines EC and ED will be equal and the angles at E right angles — as will be demonstrated, in the way it was demonstrated in Proposition 1, Book 1, in the analemma, that MN is cut at O into two equal parts and at right angles. Then, with a circle described from E about CD, and this circle divided into 48 equal parts, let any two points equally distant from the point C or D be joined by concealed straight lines, which will all be parallel to AB itself.

Diagram. A large analemma figure (the meridian circle ABCD about centre E) used for the re-demonstration of the analemma construction of Book 1 — finding the declinations of all points of the ecliptic. The circle carries the horizon diameter BD, the vertical AC, the equator HI, and the axis FG, with the auxiliary circle MPNQ set up on the greatest-declination chord MN, and the ecliptic

semicircle turned about the diameter Mp. Numerous chords, parallels and versed-sine constructions cross the interior.

Legible outer labels (reading the rim clockwise from upper left): Q, X, Y, M, A, K, α , then b and F on the upper right; D on the right; below, e; along the lower rim f, and (lower left) L, C, then 3, 4, G, S, B, N, Z ascending the left side. Centre: E. Interior points and small labels partly legible: 7, 6, 5; the ecliptic-diameter endpoints and Greek sorts γ , β , δ , ϵ , ρ , θ ; and the foot-points l, p, q, u near the diameter Mp.

- Many small interior point-labels and several of the peripheral Greek sorts are worn/ambiguous and could not be resolved with certainty.**

[the concealed lines] will be parallel to AB, by the scholium of Euclid III.27; and through the points at which those lines cut the line CD, let straight lines be drawn out from A as far as the circumference CBD. For these will cut off the arcs of the declinations of all the diurnal arcs, and the lines themselves will be the radii of the diurnal arcs — beginning from the radius AD, of the 0th hour, and proceeding through the radius AB, of the 12th hour, as far as the radius AC, of the 24th hour; so that the line next to AD is the radius of the diurnal arc of the 1st hour, the next of the 2nd hour, and so on. Thus any line drawn from A through some one of the points of the semidiameter DE represents the radius of that diurnal arc which falls short of 12 hours by as many hours as the twelfths — of the 12 into which the quadrant DF is divided — by which that point of the quadrant DF (the point at which the line drawn parallel to AB presents the point of that radius on the semidiameter DE) is distant from the point F. That is: just as ST is drawn equidistant from AB through the point S, four twelfths of the quadrant DF distant from the point F, so the line ATV is the radius of the diurnal arc of 8 hours, which of course falls short of 12 hours by four hours; and likewise for the rest. In the same way any line drawn from A through some one of the points of the semidiameter CE represents the radius of that diurnal arc which exceeds 12 hours by as many hours as the twelfths — of the 12 into which the quadrant CF is divided — by which that point of the quadrant CF (the point at which the line drawn parallel to AB presents the point of that radius on the semidiameter CE) is distant from the point F. That is: just as HI is drawn equidistant from AB through the point H, four twelfths of the quadrant CF distant from the point F, so the line AIK is the radius of the diurnal arc of 16 hours, exceeding 12 hours by four hours; and so of the rest. This we shall demonstrate in the following manner.

With the horizon diameter De drawn, let the axis aP cut the radius of the equator BA — produced — at right angles at the centre A, and let n be the arctic pole and

p the antarctic. Draw also KL and VX, the diameters of the parallels, of which the former is to be shown to have a diurnal arc of 16 hours and the latter of 8 hours. About KL and VX describe from O and Z the semicircles of the parallels KPL and VaX; and from the points M and Y, where the diameters of the parallels are cut by the diameter of the horizon, erect the perpendiculars MN and Yb to the diameters, which will be the common sections of the parallels and the horizon, as was demonstrated above. Thus KN will be the semidiurnal arc of the parallel KPL, and Yb the semidiurnal arc of the parallel VaX.

[Margin: Euclid VI.2] Now since DA is to AQ as DE is to EI, [Margin: Euclid V.11] and likewise DA is to AQ as IR is to RQ, it will also be that DE is to EI as IR is to RQ. But IR is to RQ, by what we demonstrated in the scholium of Euclid VI.4, as KO is to OM — because in the triangle AKM, in which AO is drawn, the line IQ is parallel to the base KM. Therefore it will also be that DE, the whole sine of the circle CFD, is to EI, the right sine of the arc FH, as KO, the whole sine of the parallel KPL, is to OM, the right sine of the arc PN; and consequently, by the lemma of Proposition 1, Book 1, the arcs FH and PN will be similar. Therefore, just as the arc FH comprises four twelfths of the quadrant CF, so the arc PN will comprise four twelfths — that is, four half-hours, or two hours — of the quadrant LP, since the quadrant is distributed into six hours, or 12 half-hours; and accordingly the semidiurnal arc KPN will contain eight hours, and the whole diurnal arc 16 hours, which was to be demonstrated.

By the same reasoning we shall show that the arc by which the semidiurnal arc of the parallel — whose declination is found in the quadrant CF, through the parallel drawn, say, through the point next to F — differs from the quadrant, contains one twelfth part, that is, one half-hour, just as the arc between F and the next point comprises one twelfth of the quadrant CF; and thus that that semidiurnal arc contains $6\frac{1}{2}$ hours, and the whole diurnal arc 13 hours; and so for the rest.

But let us demonstrate the same thing in the southern parallels. [Margin: Euclid VI.4] Since in the similar triangles DdT and Adq, dD is to dT as Ad is to dq, then by alternation [Margin: Euclid VI.2] Dd is to dA as Td is to dq. But as Dd is to dA, so is DT to TE; [Margin: Euclid V.11] therefore it will also be that Td is to dq as DT is to TE. And Td is to dq, by the scholium of Euclid VI.4, as VY is to YZ — because in the triangle AVZ, in which AY is drawn, the line Tq is parallel to the base VZ. Therefore it will also be that DT is to TE as VY is to YZ; and, by composition, that DE, the whole sine of the circle CFD, is to TE, the right sine of the arc FS, as VZ, the whole sine of the parallel VaX, is to YZ, the right sine of the arc...

Diagram. The construction of the appendix (after Andreas Schöner) for finding the radii of the diurnal arcs geometrically: the meridian circle about centre A, with the horizon diameter, the equatorial radius BA, the axis with poles n and p, and the two parallel circles KPL and VaX. From the centre A a fan of straight lines (the radii of the diurnal arcs) radiates downward to the divided arc, whose points are numbered along the lower rim.

Legible labels: top rim L, G, X; upper interior e (or c), N, M, Q, h; middle f, P, and the small Greek π and θ , then O, R, and to the right q, z, f, a, m; centre A, with the radiating hour-lines converging toward E; lower interior C, v, T, δ , D; along the lower rim the hour numbers 14, 13, 12, 11, 10, 9, with K, B and V; b on the right; and H, F at the foot. Interior small figures 6, 5, 8 partly legible.

- Several small interior labels and Greek sorts are worn/ambiguous.**

the arcs FS and ab are similar; and therefore, just as the arc FS comprises four twelfths of the quadrant DF, so the arc ab comprises four twelfths — that is, four half-hours, or two hours — of the quadrant aV; that is, the semidiurnal arc Vb will contain four hours, and the whole diurnal arc 8 hours, which was to be shown. In no other way shall we demonstrate that the arc by which the semidiurnal arc of the parallel — whose declination is found through the parallel drawn, say, through the point in the third place from the point F, set in the quadrant DF — differs from the quadrant, contains three twelfth parts, that is, $1\frac{1}{2}$ hours [?]; just as the arc between F and the third point toward D comprises three twelfths of the quadrant DF; and thus that that semidiurnal arc comprehends $7\frac{1}{2}$ hours, and the whole diurnal arc 15 hours. And the same reasoning holds for the rest. Rightly, therefore, are the declinations and the radii of the diurnal arcs investigated by that practice.

And here let us set the end to our *Gnomonics*. For the constructions of the other sundials, which are called travelling dials [horologia viatoria] and are of lesser importance, can be sought from other writers — since, if we wished to pursue everything, the volume would swell almost beyond measure. Of these we shall perhaps treat more copiously elsewhere, especially since the description of the ring-shaped dial [horologium in forma annuli] handed down by Oronce Finé [Orontius], and by certain others, is not free of error. Meanwhile I earnestly beg that the studious reader take these things in good part.

FINIS OCTAVI LIBRI. [The End of the Eighth Book.]

INDEX OF THOSE THINGS WHICH ARE CONTAINED IN THE EIGHT BOOKS OF THE GNOMONICS

[The following is the alphabetical subject-index that opens immediately after the close of Book VIII. The entries are ordered by the first word of the Latin lemma, so in English translation they no longer fall in alphabetical order; the original Latin ordering and the printed letter-headings (A, B, ...) are preserved. Page references are given exactly as printed. The terms *horologium* = "dial" (sundial) and *stylus* = "style" (gnomon) recur throughout.]

A

- Argument [summary] of Book One — p. 1
- Argument of Book Two — 122
- Argument of Book Three — 245
- Argument of Book Four — 348
- Argument of Book Five — 374
- Argument of Book Six — 448
- Argument of Book Seven — 483
- Argument of Book Eight — 534
- Why the ancients divided any given day and night into 12 hours — p. 5
- What an equinoctial dial [*horologium æquinotiale*] is, both the upper and the lower — 3
- What the ancient hours were, and why they were so called — 5
- What an equinoctial or equal hour is, and why it is so called — 5
- What the astronomical hours are — 6
- What the ancient dial is — 6
- What the astronomical dial is — 6
- Anaximenes of Miletus [*Anaximenes Milesius*], the first inventor of sundials — 6
- What the analemma is — 7 and 14
- The construction of the analemma for any latitude — from 9 through 14
- The various uses of the analemma — 14
- How the rising and setting amplitude [*amplitudo ortiva & occidua*] is found from the analemma — 15

- The plane of the equinoctial dial, cutting a conical surface whose base is parallel to the Equator, makes a circle — 17
- The equinoctial line, the line of any hour reckoned from noon or midnight, and the two hour-lines a full quadrant distant from that hour reckoned from noon or midnight, all intersect one another on the greatest of the ever-apparent parallels, in any dial whatsoever — 42
- The Equator, the two hour-circles reckoned from sunrise or sunset that touch the greatest of the ever-apparent parallels at opposite points, and the hour-circle from noon or midnight that cuts that same parallel at a point equally distant — that is, by six hours — from the points of contact, all intersect one another at one and the same point, and have one and the same straight line as their common section — 47
- How the altitude of the Sun is rightly investigated by means of the analemma, from a known hour and the Sun's declination, or from the length of the style's shadow upon a plane parallel to the horizon — 73
- How the elevation of the pole [altitude of the pole, i.e. latitude] above the horizon is sought by means of the analemma — 83
- By what method the elevation of the pole is found above any plane inclined to the meridian or to the horizon — 83
- By what art the rising or setting amplitude is computed by means of sines — 98
- By what means the meridian altitude of the Sun is found from the Sun's declination — p. 102
- By what device the altitude of the Sun above the horizon is computed from a known hour, both in an oblique sphere and in a right sphere — 108
- By what method the altitude of the Sun in the vertical circle, properly so called, is computed, even when the hour is unknown — 108
- The method of finding the Sun's altitude that is the most expeditious of all — 112
- How the altitude of the Sun is determined from a known hour, when the whole northern parallel stands above the horizon — 120
- The description of the astronomical dial on any plane whatsoever, which is the most excellent of all — 122
- What the portion of the analemma is from which dials are drawn — 122
- The construction of the astronomical horizontal dial from a portion of the analemma — 122

- A most convenient description of the astronomical horizontal dial for laying out the hours that lie near the 6-o'clock hour from noon or midnight and scarcely cut the equinoctial line — 124
- The arcs of the circle drawn about the centre of the horizontal dial, intercepted between the meridian line and two hours equally distant on either side of noon, are equal — 124
- The use of the astronomical dial is that we may learn how many hours have elapsed since noon or midnight, and how many remain until the following noon or midnight — 125
- The description of the astronomical horizontal dial on a fixed plane parallel to the horizon — 126
- The description of the astronomical horizontal dial for a given length of style whose position is also given — 126
- A new and most beautiful description of the astronomical horizontal dial, by means of the ellipse, without points found on the equinoctial line — most convenient for drawing the hours, or the parts of hours, that scarcely cut the equinoctial line, or at all events cut it very far from the meridian line — 127
- The description of the astronomical horizontal dial when the elevation of the pole is either very small or too great, even when the centre of the dial is not available — 130
- The portion of the analemma from which dials are drawn is an instrument for laying out dials of any size whatsoever — 136
- The description of the ascending signs on the horizontal dial — 152
- The lines of the ascending signs touch the tropics in any dial whatsoever — 153
- The use of the ascending signs drawn on a dial is that the situation of the whole heaven may be explored at any moment of time — 159
- By what method the lines of the ascending signs are drawn in two figures, or in four, on any dial, so that they do not intersect one another — 160
- How the right ascension [ascensio recta] of any point of the ecliptic is sought — 161
- By what means the difference of the right and oblique ascension of any point of the ecliptic is computed for any latitude of place — 162
- How the oblique ascension of any point of the ecliptic is reckoned from the ascensional difference — 162

- The ascensional differences of the points of the quadrant of the ecliptic from Aries to Cancer are equal to the ascensional differences of the points in the other three quadrants of the ecliptic — 162
- The joint use of the astronomical, Italian, and Babylonian dials for eliciting the length of day and night from the shadow of the gnomon; the time of noon and midnight in terms of hours from sunrise and sunset; the time of sunrise in terms of hours from midnight and from sunset; and finally the time of sunset in terms of hours from noon and from sunrise — 270
- The description of the ancient horizontal dial — 491
- The use of the ancient dial is that we may understand how great a part of the day has passed and how much remains — 172
- The construction of the astronomical vertical dial from a portion of the analemma — 172
- A most convenient description of the astronomical vertical dial for laying out the hours that lie near the line of the 6-o'clock hour from noon or midnight and scarcely cut the equinoctial line — p. 175
- The arcs of the circle drawn about the centre of the vertical dial, intercepted between the meridian line and two hours equally distant on either side of noon, are equal — 175
- The description of the astronomical vertical dial when the elevation of the pole above the horizon is so great that the pole recedes but little from the zenith, or is very small — 175
- How a southern dial, inverted in all its parts, yields a northern dial — 176
- The description of the astronomical vertical dial on a fixed plane parallel to the vertical circle properly so called — 177
- The construction of the astronomical vertical dial for a given length of style whose position is also given — 178
- A new and most beautiful description of the astronomical vertical dial, by means of the ellipse, without points found on the equinoctial line — most convenient for the hours, or the parts of hours, that scarcely cut the equinoctial line, or at all events cut it very far from the meridian line — 178
- An astronomical horizontal dial constructed for any latitude of place is a vertical dial in the region whose latitude is the complement of the former latitude — 179
- By what method the astronomical vertical dial is drawn from the figure of the radii of the zodiac — 183
- The description of the ascending signs on the vertical dial — 192

- The description of the ancient vertical dial — 198
- The description of the astronomical meridian dial — 199
- The description of the astronomical meridian dial on a fixed plane parallel to the meridian circle — 201
- The description of the ascending signs on the meridian dial — from 209 through 211
- The description of the ancient meridian dial — 114
- An ancient eastern meridian dial laid out on the opposite face of the dial-plane, so that the lines correspond to the lines, yields an ancient western dial, and conversely — 215
- How an astronomical polar dial differs from a meridian dial — 215
- The construction of the astronomical polar dial — 215
- The description of the ascending signs on the polar dial — 223
- The construction of the ancient polar dial — 228
- The construction of the astronomical equinoctial dial — 228
- The construction of the astronomical equinoctial dial — 228
- By what method an astronomical equinoctial dial is constructed if the position of the style is given on a fixed plane parallel to the Equator — 229
- By what method an astronomical equinoctial dial is constructed if the position of the style is given on a fixed plane parallel to the Equator — 229
- The equinoctial line cannot be drawn on an equinoctial dial — 230
- The description of the ascending signs on the equinoctial dial — p. 237
- The construction of the Italian equinoctial dial — 239
- The construction of the Babylonian equinoctial dial — 241
- The composition of the ancient equinoctial dial — 243
- The delineation of the ancient equinoctial dial — 243
- The Equator, the meridian, and the circle of the 6-o'clock hour from noon or midnight cut one another at right angles in every clime — 245
- The construction of the astronomical dial declining from the vertical — 246
- By what method the elevation of the pole above a plane declining from the vertical is found from the construction of the declining dial — 247
- How an astronomical dial declining from the vertical is drawn on a fixed plane — 253
- The description of the astronomical dial declining from the vertical circle, for a given style whose position is also given — 254

- A new and most beautiful description of the astronomical dial declining from the vertical, by means of the ellipse, without points found on the equinoctial line — most convenient for drawing the hours that scarcely cut the equinoctial line, or at all events cut it very far from the line of the style — p. 256
- By what method an astronomical dial declining from the vertical, which is but little removed from the meridian, is constructed, even when the centre of the dial is not available — 257
- A dial declining from the north toward the east is produced if the upper part of a dial declining from the south toward the east is made the lower part; likewise a dial declining from the north toward the west is produced if the upper part of a dial declining from the south toward the west is made the lower part — 260
- The description of the ascending signs on a dial declining from the vertical — 272
- The construction of the ancient dial declining from the vertical — 278
- The description of the astronomical dial declining from the horizon — 280
- The elevation of the pole above the vertical, properly so called, of any region is equal to the complement of the elevation of the pole above the horizon of that same region — 280
- An astronomical dial declining from the horizon will have been constructed if a dial declining from the vertical is drawn for that latitude of place which, together with the one for which the dial declining from the horizon is desired, makes 90 degrees — 280
- By what method the elevation of the pole above a plane declining from the horizon is found from the construction of the dial declining from the horizon — p. 280
- By what means an astronomical dial declining from the horizon is drawn on a fixed plane — 283
- By what means an astronomical dial declining from the horizon and facing west is to be transformed so as to make another facing east, and conversely — 283
- The construction of the astronomical dial declining from the horizon, for a given style whose position is also given — 283
- A new and most beautiful description of the astronomical dial declining from the horizon, by means of the ellipse, without points found on the equinoctial line — most convenient for drawing the hours that scarcely cut

the equinoctial line, or at all events cut it very far from the line of the style — 285

- The description of the ascending signs on a dial declining from the horizon — 291
- The description of the ancient dial declining from the horizon — 295
- By what method the elevation of the pole above a plane inclined to the horizon is found — 296
- The description of the astronomical dial inclined to the horizon — 295
- By what means an astronomical dial inclined to the horizon is to be constructed on a fixed plane — 298
- The description of the astronomical dial inclined to the horizon, for a given style and its position — 298
- A new and most beautiful description of the astronomical dial inclined to the horizon, from the ellipse — most convenient for drawing the hours that scarcely, or very far from the meridian line, cut the equinoctial line — 299
- The description of the ascending signs on a dial inclined to the horizon — 306
- The description of the astronomical dial at once declining and inclining, for a given style and its position — 327
- A new and most beautiful description of the astronomical dial at once declining and inclining, from the ellipse — most convenient for drawing the hours that scarcely, or very far from the line of the style, cut the equinoctial line — 331
- The delineation of the ascending signs on a dial at once declining and inclining — 343
- The construction of the ancient dial at once declining and inclining — p. 347
- An ancient dial in a right sphere does not differ from a Babylonian one — 349
- The rising and setting amplitudes of the points of the ecliptic in a right sphere are equal to the declinations of those same points — 350
- How equinoctial dials, together with everything drawn on the dials of the oblique sphere, are depicted in a right sphere — 352
- The description of the astronomical dial declining from the vertical in a right sphere, for a given style whose position is also given — 353
- The description of the astronomical dial declining from the horizon in a right sphere, for a given style whose position is also given — 355

- The description of the astronomical dial inclined to the horizon in a right sphere, for a given style whose position is also given — 356
- By what art the altitude of the Sun above any great circle of the sphere is computed for a given hour — 375
- The altitudes of the Sun above the great circles drawn through the poles of the world, found in the northern signs, are equal to the altitudes in the southern signs; hence it suffices to seek the altitudes either in the northern signs only or in the southern signs only — 377
- The altitude of the Sun above the meridian of the horizon for any hour is equal to the altitude of the Sun above the circle of the 6-o'clock hour from noon or midnight for another hour, which is as far distant from that circle as the former is distant from the meridian — 377
- The altitude of the Sun above the Equator is always equal to its declination — 377
- By what means it is known whether the arctic or the antarctic pole is elevated above the proposed face of any great circle — 378
- By what method the meridian altitude of the Sun above any great circle is computed — 378
- By what method the angle that an inclined plane makes with the Equator is known — 382
- By what means the arc of an inclined plane between the Equator and any parallel is known — 382
- By what art the arc of the Equator between the inclined plane and the declination circle of the Sun's parallel, drawn through the common section of the inclined plane and the parallel, is found — 382
- The altitudes of the Sun above any great circle found for the hours of any parallel are equal to the altitudes for the same hours numbered on the opposite parallel, provided that those which were formerly numbered from noon or from sunrise are now numbered from midnight or from sunset, and conversely; and that those which formerly fell on one face of the given circle are now taken on the opposite face — 384
- By what method the altitude of the Sun is investigated from the length of the shadow, whether direct [umbra recta] or inverse [umbra versa] — 397
- By what means the lengths of the equinoctial and solstitial shadows for any latitude of place are derived from the table of shadows — 408
- By what means the arc of any great circle intercepted between its vertical properly so called and another vertical drawn through its pole and the Sun is known — 408

- By what art one computes the arc of any great circle not passing through the poles of the world, enclosed between the great circle drawn through the poles of the world and the common sections of the Equator and the given circle (after the manner of the circle of the 6-o'clock hour from noon or midnight with respect to the given circle, taken as a horizon), and any other hour-circle drawn through the poles of the world and the Sun — 410
- What the equinoctial line, the meridian line, and the gnomon are according to Ptolemy [Ptolemæus] — 448
- By what method the analemma is divided into hours, so that the circumferences necessary for the construction of the horizontal, vertical, and meridian dial may be investigated — 457
- By what means the southern hours are distinguished from the northern in the analemma — 470
- By what means the analemma is divided into hours, so that the descensional and horizontal circumferences may be found in the meridian circle, taken as a horizon — 472
- By what method an equinoctial dial is constructed after the manner of a horizontal dial, from the horizontal and descensional circumferences found in the Equator, taken as a horizon — 473
- By what method the analemma is divided into hours, so that the circumferences necessary for the construction of declining and inclining dials may be found — 473
- The construction of the universal equinoctial dial — 534
- By what means the altitudes of the Sun for laying out the hours on a quadrant may be found geometrically, without tables of altitudes — 547
- By what means the altitudes of the Sun for the several hours are found from the analemma — 548

B

- What the Babylonian hours are — 6
- What the Babylonian dial is — 6 [printed *horalogium*; recte: *horologium*]
- The description of the Babylonian horizontal dial — 169
- The use of the Babylonian dial is that we may know how many hours have elapsed since the nearest sunrise, and how many remain until the next sunrise — 170
- The joint use of the Babylonian and Italian (or astronomical) dials for eliciting the length of day and night from the shadow of the gnomon; the time of noon and midnight in terms of hours from sunrise and sunset; the

time of sunrise in terms of hours from midnight and from sunset; and finally the time of sunset in terms of hours from noon and from sunrise — 170

- How a Babylonian horizontal dial differs from an Italian one, and by what means one is composed from the other — 170
- How a northern dial has its rising from a southern one, all of whose parts are inverted — 176
- The portion of a northern dial below the horizontal line is equal to the portion of a southern dial above the horizontal line — 180
- The description of the Babylonian vertical dial — 197
- The construction of the Babylonian meridian dial — 213
- A Babylonian eastern meridian dial drawn on the opposite face of the dial-plane, so that the lines correspond to the lines — by what means it yields a western Italian dial; and a western Babylonian dial yields an eastern Italian one, and conversely — 214
- The description of the Babylonian polar dial — 227
- How a Babylonian polar dial differs from an Italian one — 227
- The construction of the Babylonian equinoctial dial — 241
- How it is known whether the northern face of any declining plane is illuminated by the Sun in the morning or the evening — 265
- The description of the Babylonian dial declining from the vertical — 277
- The construction of the Babylonian dial declining from the horizon — 294

INDEX of the Eight Books of the *Gnomonices* (continued)

Subject index; entries are alphabetized by their Latin headword. Each entry is given here as an English rendering of the Latin lemma followed by its page reference exactly as printed. Order follows the printed columns (left column top-to-bottom, then right column) on each leaf. Letter divisions are as printed.

B (continued)

- The construction of a Babylonian dial inclined to the horizon — 309
- The description of a dial that is at once Babylonian, declining, and inclined — 347

- How a Babylonian dial and an Italian one in the right sphere differ from an astronomical (i.e. common-hour) dial — 349
- A Babylonian dial in the right sphere does not differ from an Antique one — 349
- By what means the northern hours are distinguished from the southern ones in the analemma — 470
- A Babylonian dial on a cylinder and on a quadrant, and how it is at the same time made Italian — 547

C

- What clepsydras [water-clocks] are, and where the name comes from — 2
- By what means any circle is to be cut into two portions, of which one resembles the diurnal arc and the other the nocturnal arc of any given parallel — 15
- When a circle traces on the plane of a dial a conical surface whose base is parallel to (equidistant from) the Equator, the circle cutting it — 17
- A great circle touches that parallel whose declination is equal to the complement of the pole's altitude above that great circle; or whose declination-complement is equal to the pole's altitude above that great circle — 19
- A great circle cuts that parallel whose declination is less than the complement of the pole's altitude above that great circle; or whose declination-complement is greater than the pole's altitude above that great circle — 20
- A great circle neither runs parallel to (equidistant from) that parallel, nor touches it, nor cuts it, when its declination is greater than the complement of the pole's altitude above that great circle; or when its declination-complement is less than the pole's altitude above that great circle — 22
- A conic section — that is, a parabola, hyperbola, or ellipse — whose diameter is given in a given cone: by what means it is drawn on a plane — 22
- Great circles cutting the diurnal arc of the Equator and of any northern parallel into 12 equal parts likewise divide the diurnal arc of the opposite southern parallel into 12 equal parts — 33
- Three great circles in the sphere — of which one cuts any given parallel through the poles, while the other two touch that same parallel at points equally distant on either side from each of the two points where it is cut by the other great circle — have one and the same common section — 40

- What the center of a dial is — 66
- A great circle whose plane measures the inclination of a plane declining from the vertical to the horizon: by what means the arc placed between the horizon and the circle of the 6th hour from noon or midnight is investigated — 88
- By what means the magnitude of twilight is investigated, the Sun being on any given parallel — 101
- There is no twilight when the complement of the pole's altitude is less than the northern declination of the Sun's parallel — 103
- How great the twilight is while the whole southern parallel lies hidden below the horizon, and by what means it is found — 103
- When there is no twilight, the Sun being in the southern signs, and when it is continuous, the Sun being at the equinoxes — 104
- By what means twilight is inquired into in the right sphere — 105
- By what method the twilights of two opposite parallels are found by a single operation — 105
- When there is continuous twilight on a northern parallel — 106
- Any great circle drawn through the poles of the world makes a straight line on the dial, one portion of which, terminating at the center of the dial, belongs to one semicircle and the other portion to the other — 126
- By what means the culminations of the heaven (the mediations of the mid-heaven), as the beginnings of the signs rise, are investigated — 154
- The Meridian and the Equator, at the circle of the 6th hour from noon or midnight, mutually cut one another at right angles in every climate — 245
- The great circles from which irregular dials are equidistant, and how they stand with respect to the horizon, the vertical, and the meridian — 245
- Which circles Ptolemy [Ptolemaeus] chiefly considers in the analemma, and what motion he assigns to them — 448
- The six circumferences in six circles which Ptolemy considers in the analemma, each in each, must be observed, and where their beginnings are — 449
- The functions of the circumferences in the circles which Ptolemy considers in the analemma — 450
- What the horizontal, descensional, vertical, horary, meridian, and hectemorial [Greek: ἑκτημόριος (hektēmōrios, "of a sixth part")] circumference is — 449

- The circumferences for the construction of a horizontal, vertical, and meridian dial: by what method they are investigated from the analemma, with the Sun on the Equator or on any parallel, both in the right sphere and in the oblique — 451
- The same circumferences, how they are computed by sines, with the Sun on any parallel, both in the oblique sphere and in the right — 459
- By what method the descensional and horizontal circumferences are found in the vertical, the meridian, the circle of the 6th hour from noon and midnight, and the Equator, taken as a horizon — 472
- The horizontal circumferences in the Equator, taken as a horizon, found for the hours, cut the meridian of the analemma (the Sun being on any parallel) into equal parts — 473
- The horizontal and descensional circumferences in declining planes, as if these were horizons, how they are found from the analemma and by sines — 475
- The circumferences for the hours from noon, or from sunrise, or from sunset, found on any parallel above one face of the proposed plane, are also the circumferences for the hours from midnight, or from sunset, or from sunrise, on the opposite parallel above the opposite face of the plane — 476
- The construction of the cross on which the universal dial is described — 536
- The composition of a convex cylindrical dial — 544
- The description of a cylindrical dial from the shadow falling on the hours of a horizontal dial, or of a concave hemispherical one — 545

D

- Why day and night were divided by the ancients into 12 hours — 2
- Which dial declines both from the south and from the north, toward the east or the west — 3
- Which dial declines from the horizon, whether upper or lower (facing up or down) — 3
- Which dial declines and is inclined at once, whether upper or lower — 4
- The varying beginning of the day among various peoples — 6
- By what method the declinations of the parallels of the Sun drawn through the beginnings of the signs, or through any other points of the ecliptic, are found geometrically in the analemma — 9

- By what method the declinations of all points of the ecliptic are computed by sines — 12
- The diurnal and nocturnal arc, the hour of sunrise and sunset, and the time of noon: by what method they are known from the analemma — 14
- By what method the declination of any plane is inquired into by means of the meridian line, or by the analemma, and toward which quarter the plane declines — 67
- The easiest method of finding the declination of a wall facing south, at noon itself — 75
- The declination of a parallel whose diurnal arc contains a proposed number of hours: by what device it is determined by the analemma, or by sines — 89
- By what method the declinations of all diurnal arcs that contain a given number of hours are found after the manner of Andreas Schöner [Andrea Schonero] — 92
- By what art the declinations of diurnal arcs that contain a given number of hours are inquired into — 89
- What the meridian depression of the Sun is, and by what means it is found — 103
- The meridian depression of the Sun on any parallel is equal to the meridian altitude of the Sun on the opposite parallel — 104
- How the diurnal arc behaves when the complement of the pole's altitude is not greater than the declination of the proposed parallel — 105
- How the Sun's distance from the meridian, in degrees, is known from a given hour — 107
- The description of the feast-days on a dial — 143
- By what means the diurnal arcs are drawn on a horizontal dial — 145
- The use of the diurnal arcs drawn on a dial is that we may know how many hours any given day comprises — 145
- What the vertical distance is, and by what means it is known from the vertical circles drawn on the dial — 147
- The description of the celestial houses on a horizontal dial, both after Johannes Regiomontanus [Regiomontanus] and after Campanus [Campanus of Novara] — 149
- The lines of the celestial houses indicate the beginnings of the celestial houses — 151

- The use of the celestial houses drawn on the dial is that we may learn in which celestial house the Sun is — 151
- The right and oblique ascensional difference of any point of the ecliptic, for any latitude of place — 162
- The ascensional differences of the quadrant of the ecliptic from Aries to Cancer are equal to the ascensional differences of the points in the other three quadrants of the ecliptic — 162
- A declining or inclined dial drawn on one face of a plane: by what means it presents another to be delineated on the opposite face — 176
- The diurnal arcs of a southern dial are changed on a northern dial into the opposite diurnal arcs — 181
- The description of the diurnal arcs on a vertical dial — 187
- The description of the celestial houses on a vertical dial, both after Johannes Regiomontanus and after Campanus — 190
- In what region a diurnal or nocturnal arc of 24 hours is on a vertical dial an ellipse, a hyperbola, or a parabola — 196
- The description of the diurnal arcs on a meridian dial — 204
- The description of the celestial houses on a meridian dial, both after Johannes Regiomontanus and after Campanus — 205
- The description of the diurnal arcs on a polar dial — 218
- The description of the celestial houses on a polar dial, both after Johannes Regiomontanus and after Campanus — 222
- The description of the diurnal arcs on an equinoctial dial — 232
- The description of the celestial houses on an equinoctial dial, both after Johannes Regiomontanus and after Campanus — 236
- The construction of an astronomical dial declining from the vertical — 246
- By what means an astronomical dial declining from the vertical is drawn on a fixed plane — 253
- The most convenient description of a dial declining from the vertical, for hours which scarcely cut the equinoctial line, or cut it very far from the line of the style — 253
- The description of an astronomical dial declining from the vertical for a given style, whose location is also given — 254
- A new and most beautiful description of an astronomical dial declining from the vertical, by means of an ellipse without points found on the equinoctial line, which is most convenient for laying out the hours that

scarcely intersect the equinoctial line, or intersect it very far from the line of the style — 256

- By what means an astronomical dial declining from the vertical, which is little distant from the meridian, is described, even if the center of the dial is not available — 257
- A dial declining from the north toward the east is made [into] an astronomical dial if the upper part of a dial declining from the south is made the lower; likewise a dial declining from the north toward the west is made from one declining from the south toward the west, if the upper part is changed into the lower — 260
- By what method a dial declining — whether astronomical, Italian, or Babylonian — from the north toward the east, and from the south toward the west, and from the north toward the west, is made from the dial that declines from the south toward the east — 260
- Which plane, declining either from the south or from the north, is illuminated for a longer time by the morning Sun than in the evening, and vice versa — 265
- The description of the diurnal arcs on a dial declining from the vertical — 267
- The description of the celestial houses on a dial declining from the vertical, both after Johannes Regiomontanus and after Campanus — 271
- The description of an Italian dial declining from the vertical — 276
- The description of a Babylonian dial declining from the vertical — 277
- The construction of an Antique dial declining from the vertical — 278
- The description of an astronomical dial declining from the horizon — 280
- An astronomical dial declining from the horizon will be constructed if a dial declining from the vertical is drawn for that latitude of place which, together with the proposed latitude for which the dial declining from the horizon is set up, makes 90 degrees — 280
- By what method an astronomical dial declining from the horizon is to be drawn on a fixed plane — 283
- By what method an astronomical dial declining from the horizon and facing west is to be transformed so that it becomes another facing east, and vice versa — 283
- The most convenient description of a dial declining from the horizon, for hours which scarcely cut the equinoctial line, or cut it very far from the line of the style — 283

- The construction of an astronomical dial declining from the horizon for a given style, whose location is also given — 283
- A new and most beautiful description of an astronomical dial declining from the horizon, by means of an ellipse, without points found on the equinoctial line, which is most convenient for laying out the hours that scarcely cut the equinoctial line, or cut it very far from the line of the style — 285
- The description of the diurnal arcs on a dial declining from the horizon — 287
- The description of the celestial houses on a dial declining from the horizon, both after Johannes Regiomontanus and after Campanus — 290
- The description of an Italian dial declining from the horizon — 293
- The description of a Babylonian dial declining from the horizon — 294
- The description of an Antique dial declining from the horizon — 295
- The description of the diurnal arcs on a dial inclined to the horizon — 301
- The description of the celestial houses on a dial inclined to the horizon, both after Johannes Regiomontanus and after Campanus — 304
- The description of an astronomical dial declining and inclined at once — 311
- By what method an astronomical dial declining and inclined at once is drawn on a fixed plane — 326
- By what means an astronomical dial declining and inclined at once is drawn for a given style, whose location is also given — 327
- The most convenient description of a dial declining and inclined at once, for laying out the hours which scarcely cut the equinoctial line, or cut it very far off — 327
- A new and most beautiful description of an astronomical dial declining and inclined at once, by means of an ellipse, which is most convenient for laying out the hours that scarcely intersect the equinoctial line, or intersect it very far from the line of the style — 331
- The description of the diurnal arcs on a dial declining and inclined at once — 335
- The description of the celestial houses on a dial declining and inclined at once, both after Johannes Regiomontanus and after Campanus — 341
- The description of an Italian dial declining and inclined at once — 345
- The construction of a Babylonian dial declining and inclined at once — 347
- The composition of an Antique dial declining and inclined at once — 347

- By what method dials declining from the vertical in the right sphere are drawn, together with all the others which have been described among the dials of the oblique sphere — 352
- By what means an astronomical dial declining from the vertical in the right sphere is drawn for a given style, whose location is also given — 353
- By what method dials declining from the horizon in the right sphere are delineated, together with all the others which have been described among the dials of the oblique sphere — 354
- The description of an astronomical dial declining from the horizon in the right sphere, for a given style, whose location is also given — 355
- By what means dials declining and inclined at once in the right sphere are constructed, together with all the others which have been described among the dials of the oblique sphere — 356
- By what art the Sun's distance from the proper meridian of any great circle, in respect of the hours, is investigated — 374
- What the descensional circle is according to Ptolemy — 449
- What the descensional circumference is — 449
- The descensional and horizontal circumferences are necessary for the construction of a horizontal dial — 450
- The finding of the descensional and horizontal circumferences in the vertical, the meridian, the circle of the 6th hour from noon or midnight, and the Equator, taken as a horizon — 472
- The descensional circumference in the Equator, taken as a horizon, is one and the same for each of the several hours of the same parallel — 473
- By what method a declining or inclined dial is drawn from its own proper horizontal and descensional circumferences — 475
- The construction of a dioptra, by which — without a magnetized needle — a universal equinoctial dial may hold its proper position, and the hour be indicated without an axle or a style — 535

E

- On which dials an ellipse is formed, the Sun occupying any given parallel — 21
- An ellipse whose diameter is given in a given cone: by what means it is drawn on a plane — 22
- An ellipse whose transverse diameter is given in the cone: how the latus rectum is found — 27

- An ellipse whose transverse axis is given: by what method it is drawn on a plane — 28
- Any ellipse whatsoever: by what means it is drawn on a plane, without regard to the cone from which it arises — 29
- The description of any ellipse whatsoever by a thread, even if its length and breadth are given — 29
- The description of an ellipse about a given major axis and through a given point — 30
- The four arcs of the ecliptic between the points of the equinoxes and solstices are quadrants — 40
- An ellipse is formed by perpendicular lines falling from the circumference of a great circle in the sphere onto the plane of another great circle to which it is inclined — 75
- An ellipse formed by perpendicular lines falling from the circumference of an inclined circle in the sphere to another circle: how the minor diameter is found — 77
- An ellipse whose diameters are given: how it is drawn on a plane — 78
- An ellipse is formed by a plane cutting a right cylinder, which is neither drawn through its axis nor equidistant from the axis — 136
- Points of the ecliptic placed on the circle of the 6th hour from noon or midnight, or on any other horary circle from noon or midnight, when the beginnings of the signs rise: by what means they are found — 155
- By what means an ellipse is completed in full from the other half of it, once that half is drawn — 234

F

- What the figure of the rays of the Zodiac is — from which the arcs of the signs are drawn on a horizontal dial — and by what method it is constructed — 137
- By what means the feast-days are depicted on a dial — 143
- A figure in the manner of a certain instrument, constructed after Andreas Schöner, which we have divided into two, so that from it the ascending signs may be drawn on dials — 158
- The construction of the figure of the rays of the Zodiac for drawing the arcs of the signs on a vertical dial — 181
- The construction of the figure of the rays of the eastern and western amplitudes (of rising and setting) — 192

- Federico Commandino's [Federici Commandini] error in drawing the lines of the 10th and 11th hours on a northern Italian dial — 198
- The construction of the figure of the rays of the Zodiac for delineating the arcs of the signs on a meridian, polar, and equinoctial dial — 203
- The construction of the figure of the rays of the Zodiac for drawing the arcs of the signs on a dial declining from the vertical — 261
- The construction of the figure of the rays of the Zodiac for drawing the arcs of the signs on a dial declining from the horizon — 286
- The construction of the figure of the rays of the Zodiac for drawing the arcs of the signs on a dial inclined to the horizon — 299
- The construction of the figure of the rays of the Zodiac for drawing the arcs of the signs on a dial declining and inclined at once — 334

G

- The vertex of the gnomon, on any dial whatsoever, is understood to be the center of the world — 15
- The shadow of the gnomon, and the ray of the Sun, is projected onto the common section of the plane of the dial and of the great circle on which the Sun is — 34
- The shadow of the gnomon at the equinoxes describes a straight equinoctial line on any dial whatsoever — 35
- The shadow of the gnomon, and the ray of the Sun, is projected outside the equinoxes onto a conic section, which is the common section of the plane of the dial and of the conical surface whose base is the parallel opposite to the Sun's parallel — 35
- The shadow of the gnomon outside the equinoxes describes a conic section on the dial — 36
- What this gnomonic (matter) contains on each of the several plane dials — 121
- The place of the gnomon on any dial whatsoever, when it falls outside the tropics, and when precisely on a tropic, or within the tropics, or on the equinoctial line itself — 361
- By what method the gnomon of any dial whatsoever is set upright to the horizon in its proper place, and its vertex restored to its proper seat if at any time it has been deflected from it — 362
- A gnomon set upright to any plane whatsoever is the mean proportional between the direct shadow and the reversed shadow — 397

- What the gnomon, the meridian line, and the equinoctial are according to Ptolemy — 448

INDEX

(Alphabetical subject index — continued. Each entry gives the topic followed by its page reference. Entries are listed in printed column order: left column top-to-bottom, then right column. "ibid." reproduces the printed cross-reference to the immediately preceding page number.)

H

- What a sundial [horologium] is — 1
- What an hour is, and where hours get their name — 2
- The need for sundials, and their various kinds — 2
- What a shadow-instrument [horologium Schiothericum (printed thus in the H-section, with the -ch- variant; cf. "Sciothericum" in the S-section), from Greek σκιοθηρικόν, "shadow-catching"] is, and its various kinds — 3
- The seventeen kinds of shadow-instruments, that is, of sundials laid out on a plane surface, and what they are — 3
- What a horizontal sundial is — *ibid.*
- Sundials laid out on a plane are parallel to the great circles from which they take their name — 5
- The division of sundials according to the time whose hours they show — 5
- The four kinds of hours — 5
- What unequal hours are, and why they are called unequal — *ibid.*
- What an equal or equinoctial hour is, and why it is so called — 5
- What Babylonian hours are — 6
- What Italian hours are — 6
- What astronomical hours are — *ibid.*
- How ordinary or common hours differ from astronomical ones — 6

- The four kinds of sundials arising from the variety of hours — *ibid.*
- The various inventors and writers on the several sundials — 7
- Every sundial stands as far from the center of the world as the length of its style [stylus] — 15
- Every sundial takes its name from the great circle to which it is parallel — 16
- On which sundials opposite and equal hyperbolas are formed, the Sun being in any parallel whatsoever — 19
- How a hyperbola whose diameter in a given cone is given may be drawn on a plane — 22
- By what method the latus rectum of opposite hyperbolas, whose transverse diameter in the cone is given, may be found — 26
- How opposite hyperbolas whose latus rectum is given may be drawn on a plane — 27
- How any opposite hyperbolas whatsoever may be drawn on a plane, without regard to the cone from which they arise — 29
- Which are the hour-circles from noon or from midnight — 31
- Which are the hour-circles from east or from west, and where they have their poles — 32
- Which are the circles of the unequal hours — 33
- What the layout of a sundial on a plane is — 35
- The hour-circles from noon or from midnight cut conic surfaces whose bases are the two greatest parallels — of those ever apparent and those ever hidden — along the straight lines at which the hour-circles from east or from west touch those same parallels — 36
- The hour-line from noon or from midnight cuts conic sections, which are the common sections of the plane of the sundial and of the conic surfaces whose bases are the two greatest parallels — of those ever apparent and those ever hidden — at the points at which those same hour-lines from east or from west touch them — 37

- The hour-lines from east or from west, whose circles touch the greatest ever-apparent parallel at the same points at which it is cut by the circle of some hour from noon or from midnight parallel to the sundial, do not coincide with the conic sections which the plane of the sundial makes on the conic surfaces having as bases the two greatest parallels of those ever apparent and ever hidden; yet the further they are produced, the nearer they come to the conic sections — 37
- The lines of the 12th and 24th hours from east or from west do not meet, on a meridian sundial, with the conic sections made on the conic surfaces whose bases are the greatest parallels of those ever apparent and ever hidden — 39
- The lines of the 6th and 18th hours from east or from west do not meet, on a polar sundial, with the conic sections made on the conic surfaces whose bases are the greatest parallels of those ever apparent and ever hidden — 39
- The four arcs of the horizon between the equator and the meridian are quadrants — 40
- The arcs of the hour-circles from east or from west, between the equator and the points at which they touch the greatest parallels of those ever apparent and ever hidden, are quadrants — 40
- Any hour-line whatsoever from noon or from midnight, and two hour-lines from east or from west equally distant from it on the greatest parallel of those ever apparent, intersect one another at one and the same point — 44
- Two hour-circles from east or from west touching the greatest parallel of those ever apparent at any two points whatsoever, and the hour-circle from noon or from midnight cutting that same parallel at a point equally distant from the points of contact, cut one another at one and the same point, and have one and the same straight line as their common section — 48
- When, or on which sundials, the hour-line — both that from noon or from midnight and that from rising or from setting — intersect one another — 66
- When, or on which sundials, the hour-line — both that from noon or from midnight and that from east or from west — are parallel — *ibid.*

- How the hour may be found by means of the analemma, once the Sun's declination and its altitude above the horizon are known — 72
- How the hour may be computed from the Sun's known altitude above the horizon, both on the oblique sphere and on the right sphere — 109
- By what method it may be determined which hour it is when the Sun stands on a vertical circle — 110
- How the hour may be determined from the known altitude of the Sun when the northern parallel stands wholly above the horizon — 120
- What the plane sundials described in this book contain — 121
- The layout of the astronomical horizontal sundial — 122
- The most convenient layout of the astronomical horizontal sundial for drawing the hours near the 6th hour from noon or from midnight, which scarcely cut the equinoctial line — 124
- Any hour-line whatsoever from noon, produced beyond the center of the sundial, indicates the hour of the same number from midnight, and conversely — 125
- The layout of the astronomical horizontal sundial on a fixed plane parallel to the horizon — 126
- The layout of the astronomical horizontal sundial for a given style whose place is also given — *ibid.*
- A new and most beautiful layout of the astronomical horizontal sundial, by means of the ellipse, without points found on the equinoctial line — most convenient for drawing the hours which scarcely cut the equinoctial line, or at any rate cut the meridian line very far off — 127
- Why the layout of the astronomical horizontal sundial is made more difficult when the pole's altitude is either very small or too great, and how it is then to be drawn, even if the sundial has no center — 130
- How the hyperbolas of the southern signs may be drawn from the hyperbolas of the northern signs — 139
- Which are the four quadrants of the upper hemisphere on any sundial whatsoever — 146

- The hour-lines mark the limits, or ends, of the hours — 151
- By what method it may be found at what hour any sign of the Zodiac begins to rise above the horizon — *ibid.*
- The construction of the Italian horizontal sundial — 164
- How the line of the 12th hour from east or from west is to be drawn on a horizontal sundial — 167
- Any hour-line whatsoever from the west, produced beyond the point where it touches the diurnal or nocturnal arc of the 24 hours, belongs to the hour of the same number from the east, and conversely — 168
- The layout of the Babylonian horizontal sundial — 169
- The layout of the Antique horizontal sundial — 171
- By what method the unequal hours, called planetary — each of which of course corresponds to fifteen degrees of the ecliptic — may be determined — 172
- A horizontal astronomical sundial constructed for any latitude of place whatsoever is a vertical sundial in a region whose latitude is the complement of the former latitude — 179
- What the horizontal line is, and how it is drawn on a vertical sundial, and its use — 180
- The horizontal line on every sundial cuts off the upper portion,
- (...upper portion) which shows the sundial to be placed on the opposite face of the sundial, if the upper part is first made lower; and the part which, after this inversion, is on our right as we turn toward the sundial becomes the left, and conversely — 184
- How the line of the 12th hour from east or from west is drawn on a vertical sundial — 196
- By what method it may be known which of the hour-lines from east or from west, produced beyond the horizontal line, belong to the hours from the east and which to the hours from the west — 197
- What the horizontal line on a meridian sundial is — 199

- How the line of the 12th hour from east or from west is drawn on a meridian sundial — 213
- The layout of the horizontal line on a polar sundial — 217
- By what method the line of the 12th hour from east or from west is drawn on a polar sundial — 227
- In a latitude less than 66 degrees 30 minutes the hour-lines from east or from west cut the tropics; in a latitude of exactly 66 degrees 30 minutes they touch the tropics; in a greater latitude, finally, they do not reach the tropics, even if produced to infinity, but touch other parallels between the tropics, and the equinoctial line, both on the polar sundial and on the meridian one — *ibid.*
- The layout of the horizontal line on an equinoctial sundial — 230
- The drawing of the 12th hour from east or from west on an equinoctial sundial. page — 241
- What regular and irregular sundials are, and to which points of the heaven the regular ones are opposed — 245
- The horizon, vertical, and meridian cut one another at right angles in every climate — 245
- How the hours from noon and from midnight are drawn on a sundial declining from the vertical, by means of the horizontal sundial — 249
- The layout of the horizontal line on a sundial declining from the vertical — 264
- By what method the hours from noon and from midnight are drawn on a sundial declining from the horizon, from the horizontal sundial — 281
- The layout of the horizontal line on a sundial declining from the horizon — 286
- The layout of the horizontal line on a sundial inclined to the horizon — 301
- The layout, from the horizontal sundial, of the hours from noon or from midnight on a sundial at once declining and inclined — 321
- The layout of the horizontal line on a sundial at once declining and inclined — 334

- By what method it may be found at what hour the Sun, standing on the equator, reaches any vertical whatsoever — 337
- By what means it may be determined at what hour the Sun, standing on the equator, reaches a given circle of the celestial house — 342
- By what method sundials may be made on the most oblique sphere, where the arctic pole is raised 90 degrees above the horizon — 358
- By what method sundials may be drawn on the oblique sphere where the antarctic pole is raised above the horizon — 359
- By what method sundials constructed for the northern oblique sphere are to be adapted to the southern oblique sphere — *ibid.*
- What diversity the hours from east and from west have in different latitudes — 360
- Which segments of the hours from east and from west that touch some parallel belong to the hours from the west, and which to the hours from the east — 361
- Given a sundial together with its style and its place, by what method it may be known for what pole-altitude it was made, and what declination it has from the vertical, and its inclination to the horizon (if it is declining or inclined), and also how great the altitude of the pole above the declining or inclined plane itself is; and conversely, given a sundial together with the pole-altitude for which it was constructed, and also its inclination to the horizon (if it is inclined), by what method the length of the style and its place may be sought, together with the declination from the vertical (if the sundial is declining), and the altitude of the pole above the declining or inclined plane itself — 363
- How a given sundial may be reduced to a larger or smaller form for a given length of style — 370
- How it may be known whether a given hour, for which the Sun's altitude is sought, falls on the proposed face of the given plane or on the other face — 375
- By what method the hours falling on a given face of the proposed great circle may be known — 377

- By what method it may be found at what hour the proposed face of the great circle begins or ceases to be lit by the Sun — 378
- Which are the hour-arcs, and by what method they may be investigated on any plane whatsoever — 411
- By what method the hour-arcs of all horizons are also the hour-arcs of all verticals properly so called — *ibid.*
- The construction of all sundials from tables of the latitudes and longitudes of shadows, or from tables of hour-arcs — 412
- The most expeditious layout of the hours from noon and from midnight by means of hour-arcs — 417
- What the movable horizon is according to Ptolemy [Ptolemæum] — 448
- What the hectemerion circle [Greek ἑκτημόριον, "one-sixth part"] is according to Ptolemy — 449
- What the hour-circle is according to Ptolemy — *ibid.*
- What the horizontal circumference is — *ibid.*
- What the hour circumference is — *ibid.*
- What the hectemoria circumference is — *ibid.*
- The horizontal and descensive circumferences are necessary for the construction of the horizontal sundial — 450
- The hour and vertical circumferences are necessary for the construction of the vertical sundial — 450
- The hectemoria and meridian circumferences are necessary for the construction of the meridian sundial — 450
- The composition of the horizontal sundial from the horizontal and descensive circumferences — 470
- By what method the horizontal and descensive circumferences may be found on the vertical, the meridian, the circle of the 6th hour from noon or from midnight, and the equator, as on the horizon — 471

- By what method sundials facing the horizon squarely — such as those painted on walls — may be made from the horizontal sundial, together with all those things which were described concerning it in the second book — 477
- By what method sundials facing the horizon squarely — namely those usually painted on walls — may be composed from the horizontal and descensive circumferences found on the horizon — 481
- By what method sundials may be drawn on any plane whatsoever by means of the instrument constructed for this purpose — 530
- By what method sundials may most easily be drawn on any plane whatsoever from the shadow falling on a horizontal sundial or on any other — 532
- By what method the hours from noon and from midnight, from a certain universal sundial drawn on a plane surface, may be reduced to hours from east and from west — 539
- The construction of the concave hemispherical sundial, as to the hours of every kind and all other matters described concerning sundials in books 2 and 3 — 540
- The construction of the plane sundial in the form of a convex cylinder — 544
- The easiest way of knowing the hours from the altitude of the Sun found by means of some instrument — 545

I

- What a sundial inclined to the horizon is — 4
- What unequal hours are, and why they are so called — 5
- What Italian hours are — 6
- What an Italian sundial is — 6
- The first inventor of sundials was Anaximenes of Miletus [Anaximenes Milesius] — 6
- The various inventors and writers on the several sundials — 7

- The instrument for drawing an ellipse by means of a thread — 30
- By what method the inclination of a proposed plane to the horizon may be investigated, and toward which part the inclination falls — 69
- The instrument for marking the shadow, for finding the meridian line and the declination of a proposed plane — 70
- How the inclination of a proposed plane to the meridian may be determined — 78
- By what artifice the arc of an inclined plane between its own meridian and the meridian of the horizon may be determined — 85
- The finding of the inclination which the proper meridian of an inclined plane has to the meridian of the horizon — 86
- By what means the arc of an inclined plane may be known which lies between the great circle drawn through its poles and through the poles of the horizon, and between both its own meridian and the meridian of the horizon — 87
- Giovanni Battista Benedetti [Ioan. Baptista Benedictus] does not rightly criticize the drawing of the arcs of the signs from the figure of the rays of the Zodiac — 137
- The construction of the Italian horizontal sundial — 163
- The use of the Italian sundial is that it may be known how many hours have passed since the last setting of the Sun, and how many remain until the next setting — 168
- The combined usefulness of the Italian and Babylonian, or the astronomical, sundial for eliciting the length of day and night from the gnomon's shadow: the time of noon and midnight, as to the hours from east and from west; the time of sunrise, as to the hours from midnight and from the west; and finally the time of sunset, as to the hours from noon and from the east — 170
- By what method an inclined or declining sundial drawn on one face of a plane may show another to be drawn on the opposite face — 176
- The composition of the Italian vertical sundial — 194

- The construction of the Italian meridian sundial — 211
- The Italian eastern meridian sundial drawn on the opposite face of a plane, so that line corresponds to line, by what method it gives the Italian western sundial; and the Italian western gives the Babylonian eastern, and conversely — 214
- The layout of the Italian polar sundial — 225
- The construction of the Italian equinoctial sundial — 239
- Giovanni Battista Benedetti does not rightly criticize the drawing of the sundial declining from the vertical — 249
- The layout of the Italian sundial declining from the vertical — 276
- The layout of the astronomical sundial inclined to the horizon — 295
- By what method an astronomical sundial inclined to the horizon is to be constructed on a fixed plane — 298
- The layout of the astronomical sundial inclined to the horizon for a given style and its place — *ibid.*
- A new and most beautiful layout of the astronomical sundial inclined to the horizon, by means of the ellipse — most convenient for drawing the hours which cut the equinoctial line scarcely at all or very far from the meridian line — 299
- The construction of the Italian sundial inclined to the horizon — 307
- The layout of the Babylonian sundial inclined to the horizon — 309
- The layout of the Antique sundial inclined to the horizon — 310
- The layout of the Italian sundial at once declining and inclined — 345
- By what method sundials inclined to the horizon, together with all the things drawn on other sundials on the oblique sphere, may be laid out on the right sphere — 356
- The layout of the astronomical sundial inclined to the horizon on the right sphere, for a given style and its place — 356

- By what method an inclined or declining sundial may be drawn from its own horizontal and descensive circumferences — 475
- The instrument for making sundials on any plane whatsoever, and its use — 530
- How an Italian sundial on a quadrant and a cylinder may also be a Babylonian one — 547

L

- By what method the rising or setting latitude [*latitudo ortiva vel occidua*] may be determined from the analemma — 15
- By what means the rising or setting latitude may be explored by means of a style fixed at right angles on a wall — 82
- By what method the rising or setting latitude may be investigated from the limits [*finis*] — 98
- What the latitudes of shadows are, and how they may be investigated on any plane whatsoever — 408
- The latitudes of shadows computed for the hours above one face of a proposed circle are the same as those for the hours above the opposite face of the same circle, if the hours from noon and from the east are changed into hours from midnight and from the west, and the northern parallels into southern ones, and conversely — 409
- How the scale of the latitudes of regions is constructed for universal sundials — 535

M

- What a meridian sundial, both eastern and western, is — 3
- The finding of the meridian line from the drawing of the astrolabe, from the analemma, and from the limits — 71
- By what art the meridian arc between the horizon and an inclined plane is to be investigated — 78
- By what method the meridian arc between an inclined plane and the arctic pole, or between the vertex of the head [*i.e.* the zenith], may be known — 80
- By what method the meridian altitude of the Sun may be found from the Sun's declination — 102
- What the meridian depression of the Sun is, and by what method it may be found — 103

- The meridian altitude of the Sun above the horizon is twofold, when the complement of the pole's altitude is less than the declination of the northern parallel of the Sun — 103
- The drawing of the meridians on a horizontal sundial — 148
- The use of the meridians drawn on a sundial is that we may understand for which peoples it is noon at any given time, and what the hour is in any place whose longitude is known — *ibid.*
- By what method the culminations of the heaven [*mediationes cœli*], when the beginnings of the signs rise, may be investigated — 154
- The drawing of the meridians on a vertical sundial — 189
- The layout of the astronomical meridian sundial — 199
- The layout of the astronomical meridian sundial on a fixed plane parallel to the meridian — 201
- The layout of the astronomical meridian sundial for a given length of style whose place is also given — *ibid.*
- The drawing of the meridians on a meridian sundial — 207
- The construction of the Italian meridian sundial — 211
- The construction of the Babylonian meridian sundial — 214
- The layout of the Antique meridian sundial — *ibid.*
- The Antique eastern meridian sundial drawn on the opposite face, so that line corresponds to line, gives the Antique western, and conversely — 215
- How the astronomical meridian sundial differs from the polar sundial — 215
- The drawing of the meridians on a polar sundial — 221
- The drawing of the meridians on an equinoctial sundial — 235
- The meridian, horizon, and vertical cut one another at right angles in every climate — 245
- The meridian, the circle of the 6th hour from noon or from midnight, and the equator cut one another at right angles in every climate — *ibid.*
- The drawing of the meridians on a sundial declining from the vertical — 270
- The drawing of the meridians on a sundial declining from the horizon — 290
- The drawing of the meridians on a sundial inclined to the horizon — 303

INDEX (continued)

*Alphabetical subject index to the Gnomonices**; entries continue from the letter M (catchword "Meri-" at the end of the preceding leaf). Each entry is a subject lemma followed by its page reference; entries are given in printed column order (left column, then right). Page references are transcribed as printed (Arabic numerals; "ibid." = same page as the entry above).*

M (*continued*)

- By what means the meridian line and the equinoctial line come to be parallel on a sundial that is at once declining and inclined — 323
- The drawing of the meridians on a sundial at once declining and inclined — 340
- By what method meridian sundials are laid out in the right sphere, together with everything that was set out for sundials in the oblique sphere — 352
- By what means the meridian altitude of the Sun above any great circle whatever may be investigated — 378
- How great the meridian arc is between an inclined plane and the equator above the horizon — 381
- What the meridian line, the equinoctial line, and the gnomon are according to Ptolemy — 448
- What the movable meridian is in Ptolemy — *ibid.*
- Which circumference is the meridian — 449
- The meridian circumferences and the hectemoriae [hectemoria: Greek ἑκτημόριον, "sixth-part," a sixth-part of the ecliptic/signs] that are needed for constructing the meridian sundial — 450
- The construction of the meridian sundial from the meridian circumferences and the hectemoriae — 471
- By what means a meridian sundial may be constructed after the manner of a horizontal sundial, from the horizontal circumferences and the descending points found on the meridian as though on the horizon — 471

N

- Why night and day were each divided by the ancients into 12 hours — 2
- The nocturnal arcs are the complements of the diurnal arcs — 15

O

- The error of Oronce Finé [Orontius Finaeus] in his laying-out of the horizontal and vertical sundial — 133

P

- What the polar sundial is, both the upper and the lower — 3
- In which sundials a parabola is produced while the Sun remains on any parallel whatever — 18
- How a parabola whose diameter in a given cone is given is drawn in a plane — 22
- How the latus rectum of a parabola whose diameter in the cone is given may be found — 25
- By what method a parabola whose latus rectum is given is drawn in a plane — 25
- How any parabola whatever is drawn in a plane without regard to the cone from which it arises — 29
- The greatest of the parallels on the sphere, and two great circles touching any parallel at two opposite points, have one and the same common section — 39
- A plane cutting any number of planes that have the same common section: if that plane is parallel to that common section, it makes the common sections parallel; but if it cuts that common section, it makes the common sections meet at the point where the cutting plane divides their common section — 42
- By what device the altitude of the pole above the horizon may be found by means of the analemma — 81
- How the altitude of the pole above any inclined plane may be ascertained — 83
- By what means the parallels of the signs are drawn on a horizontal sundial — 134
- Whether the parallels of the signs on a horizontal sundial are hyperbolas, parabolas, or ellipses, and how this may be known from the figure of the rays of the Zodiac — 139
- By what means the whole parallel of each sign, together with the parallel of the opposite sign, is drawn from only the portion of the parallel drawn up to the meridian line — *ibid.*

- By what method the parallel on which the Sun stands on any given day is drawn on a sundial — 143
- By what art the parallels of the signs are drawn on a horizontal sundial that has no center — *ibid.*
- The use of the parallels of the signs drawn on a sundial is that we may learn in what part of the Zodiac the Sun is — 144
- How the parallels of the horizon are drawn on a horizontal sundial — 147
- The use of the parallels of the horizon drawn on a sundial is that we may know the altitude of the Sun above the horizon — 148
- The drawing of the parallels of cities — that is, of the circles of latitude — on a horizontal sundial — 149
- The use of the parallels of cities drawn on a sundial is that we may learn which peoples have the Sun at the zenith at noon — 149
- By what means the planetary hours — which are of course unequal, and each answer to fifteen degrees of the ecliptic — may be ascertained — 172
- By what method the parallels of the signs are drawn on a vertical sundial — 179
- The portion of any sundial that lies above the horizontal line is itself a sundial to be placed on the opposite face, if all its parts are inverted — 181
- How it may be known whether the parallels of the signs on a vertical sundial are hyperbolas, parabolas, or ellipses — 183
- How the parallels of the signs are drawn on a vertical sundial where there is no center — 183
- The drawing of the parallels of the horizon on a vertical sundial — 189
- The drawing of the parallels of cities — that is, of the circles of latitude — on a vertical sundial — 190
- By what method the parallels of the signs are drawn on a meridian sundial — 201
- The drawing of the parallels of the horizon on a meridian sundial — 205
- The drawing of the parallels of cities — that is, of the circles of latitude — on a meridian sundial — 207
- How the astronomical polar sundial differs from the meridian sundial — 215
- The drawing of the astronomical polar sundial — *ibid.*
- By what means a polar sundial is drawn on a fixed plane parallel to the circle of the 6th hour from noon or from midnight — 216

- By what method a polar sundial is constructed for a given style whose place is also given — *ibid.*
- By what means the parallels of the signs are drawn on a polar sundial — *ibid.*
- The drawing of the parallels of the horizon on a polar sundial — 218
- The drawing of the parallels of cities on a polar sundial — 221
- The drawing of the Italian polar sundial — 225
- The drawing of the Babylonian polar sundial — 227
- The drawing of the Antique polar sundial — 228
- By what method the parallels of the signs are drawn on an equinoctial sundial — 229
- The drawing of the parallels of the horizon on an equinoctial sundial — 233
- The drawing of the parallels of cities on an equinoctial sundial — 255
- By what means the altitude of the pole above a plane declining from the vertical may be ascertained from the construction of a sundial declining from the vertical — 247
- How the parallels of the signs are drawn on a sundial declining from the vertical — 261
- On a sundial declining from the vertical, which parallels of the signs are hyperbolas, which parabolas, and which ellipses — 263
- By what method the parallels of the signs are drawn on a sundial declining from the vertical that has no center — 267
- The drawing of the parallels of the horizon on a sundial declining from the vertical — 269
- The altitude of the pole above the vertical (properly so called) of any region is equal to the complement of the altitude of the pole above the horizon of that same region — 280
- By what means the altitude of the pole above a plane declining from the horizon may be drawn out from the very construction of a sundial declining from the horizon — 280
- By what method the parallels of the signs are drawn on a sundial declining from the horizon — 285
- The drawing of the parallels of the horizon on a sundial declining from the horizon — 289
- On a sundial declining from the horizon, which parallels of the horizon [printed *Paralleli Horizontis*; the "hyperbola / parabola / ellipse" content

elsewhere attaches to *paralleli signorum*] are hyperbolas, which parabolas, and which ellipses — 289

- The drawing of the parallels of cities on a sundial declining from the horizon — 290
- By what means the altitude of the pole above a plane inclined to the horizon may be found — 296
- By what method the parallels of the signs are drawn on a sundial inclined to the horizon — 299
- The drawing of the parallels of the horizon on a sundial inclined to the horizon — 302
- The drawing of the parallels of cities on a sundial inclined to the horizon — 304
- By what method the altitude of the pole above a plane at once declining and inclined may be drawn out from the construction of a sundial at once declining and inclined — 313
- By what method the parallels of the signs are drawn on a sundial at once declining and inclined — 331
- On a sundial at once declining and inclined, which parallels of the signs are hyperbolas, which parabolas, and which ellipses — 335
- The delineation of the parallels of the horizon on a sundial at once declining and inclined — 338
- The drawing of the parallels of cities on a sundial at once declining and inclined — 341
- The construction of polar sundials in the right sphere, as regards everything that is drawn on sundials in the oblique sphere — 360
- Whether the pole of the world raised above the face of any given great circle is the arctic or the antarctic pole — 378
- How many hours any parallel of the Sun contains above the given face of the proposed great circle — *ibid.*
- Which parallels of the Sun are cut by the vertical proper to each plane — 410
- By what means the parallels of the signs are drawn on sundials from the tables of the latitudes and longitudes of shadows — 415
- By what method the parallels of the signs may be drawn on an astronomical sundial constructed by means of the hour-arcs — 447
- Which circles Ptolemy chiefly considers in the *Analemma*, and what motions he assigns to them — 448

- By what means a polar sundial may be constructed after the manner of a horizontal sundial, from the horizontal circumferences and the descending points found on the circle of the 6th hour from noon or from midnight as though on the horizon — 473

Q

- The construction and use of the quadrant, which has wonderful uses in the laying-out of sundials and in other astronomical matters — 7
- Which are the four quadrants of the upper hemisphere on a sundial — 146
- The construction of the hour-quadrant — 546

R

- What the rays of the signs, or of the Zodiac, are — 10
- By what method the fourth part of the rectangle contained by the transverse diameter of a hyperbola and its latus rectum is applied to the transverse diameter on either side so that it exceeds by a square figure — 26
- By what means the fourth part of the rectangle contained by the transverse diameter of an ellipse and its latus rectum is applied to the transverse diameter on either side so that it falls short by a square figure — 28
- The straight lines on a sundial take their name from the great circles that produce them on the sundial, and whose circles cannot be drawn as lines on the sundial — 35
- What the rays of the diurnal arcs are, and how they are drawn — 91
- What the rays of the rising and setting amplitudes are — 193

S

- What a sciothericum [Greek: σκιοθηρικόν (skiothērikon, "shadow-catcher," i.e. a sundial)], or solar sundial, is, and its various kinds — 3
- The whole sines are proportional to the sines — both right and versed — of similar arcs; and those arcs whose sines, both right and versed, are proportional to the whole sines are similar — 11
- The tip of the style on any sundial is the center of the world — 15
- The Sun, when it stands on the equator, describes by its ray — or by any point of the heaven passing along a straight line through the center of the world — the equinoctial circle; but outside the equator it describes two conical surfaces, the base of one being the parallel described from the center of the Sun (or from the point of the heaven), while the base of the

other is the parallel opposite to this. Of these, one is called the conical surface of light, the other of shadow — 16

- The shadow of the style, and the ray of the Sun, is cast onto the common section of the plane of the sundial and of the great circle on which the Sun stands; and at the equinoxes it describes the equinoctial as a straight line on any sundial — 34
- The shadow of the style, and the ray of the Sun, outside the equinoxes is cast onto a conic section, which is the common section of the plane of the sundial and of the conical surface whose base is the parallel opposite to the Sun's parallel; and it describes that conic section on any sundial — 36
- By what means the semidiurnal arc may be computed — 98
- By what means it may be known whether the Sun, when it is in the northern signs, has reached the vertical or not — 110
- The semidiurnal arcs at the beginnings of the signs, for latitude 42° — 153
- The place of the style on any sundial — when it falls outside the tropics, when exactly on a tropic, when within the tropics, or on the equinoctial line itself — 361
- By what method the style of any sundial is set upright in its proper place on the plane of the sundial, and its tip restored to its proper seat should it ever have shifted from it — 362
- The style is a mean proportional between the straight shadow and the versed shadow — 397
- By what method the lengths of the solstitial and equinoctial shadows may be known, for any latitude, from the table of shadows — 408
- By what means, from a given hour, it may be known whether the Sun stands on the vertical proper to each plane, or short of it, or beyond it — 410
- How the scale of the latitudes of regions for universal sundials is constructed — 535

T

- A table containing the hours from noon or midnight and from sunrise or sunset, intersecting one another on the equinoctial line of each sundial at one and the same point — 43
- The 36 tables containing the hours from noon or midnight and from sunrise or sunset, intersecting one another on the horizontal line (that is, the line of the 24th hour from sunrise or sunset), on the line of the 12th hour from sunrise or sunset, on the line of the 6th hour from noon or

midnight, on the meridian line (that is, the line of the 12th hour from noon or midnight), and finally on the other hour-lines, both from sunrise or sunset and from noon or midnight — 45

- The tables of the diurnal and nocturnal arcs, containing the hours from noon or midnight and from sunrise or sunset, as well as the unequal hours, intersecting one another on those very diurnal and nocturnal arcs at one and the same point, on any sundial — 94
- A table of the hours at which the beginnings of the signs rise above the horizon, for latitude 42° — 152
- A table of the culminations of the heaven and of the angles of the earth, together with the declinations, for when the beginnings of the signs rise, for latitude 42° — 155
- A table of the points of the ecliptic set on the circle of the 6th hour from noon or midnight, together with their declinations, for when the beginnings of the signs rise, for latitude 42° — 155
- The tables of the points of the ecliptic set on the circles of the 11th, 1st, 7th, and 5th hours from noon or midnight, together with their declinations, for when the beginnings of the signs rise, for latitude 42° — 157
- A table of the points of the ecliptic set at the mid-heaven and at the angle of the earth, together with the descending signs, for when the beginnings of the signs rise — 160
- By what means the table of right ascensions is constructed — 162
- By what method the table of oblique ascensions is compiled from the ascensional differences — 163
- The tables of the hours at which the beginnings of the signs rise above the horizon in the right sphere — 349
- The tables of the distances of the Sun from the proper meridians of the various great circles of the sphere — 385
- The tables of the altitudes of the Sun above the various great circles on the sphere, both for the hours from noon or midnight and from sunrise or sunset, and for the unequal hours, for latitude 42° — 387
- A table of the lengths of shadows, both straight and versed, in parts of which the gnomon is 12, computed for each degree and minute of the Sun's altitude — 399
- The tables of the latitudes and longitudes of shadows, and of the hour-arcs, for drawing the various plane sundials, for latitude 42° — 412
- A table of the altitudes of the Sun above the horizon at the beginnings of the signs, for the hours from noon and midnight, for latitude 42° — 542

- A table of the altitudes of the Sun above the horizon, for the hours from sunset, on the tropics and on the parallels whose diurnal arcs comprise 15, 14, 13, 12, 11, 10, and 9 hours, together with the declinations of those parallels, for latitude 42° — 542

V

- What a vertical sundial is, whether facing south or facing north — 3
- The drawing of the vertical circles on a horizontal sundial — 146
- The use of the vertical circles drawn on a sundial is that we may know in which quadrant of the upper hemisphere the Sun is — 146
- The composition of the astronomical vertical sundial — 172
- A very convenient way of drawing the astronomical vertical sundial for tracing those hours which cut the equinoctial line scarcely at all, or very far from the meridian line — 175
- The construction of the astronomical vertical sundial when the altitude of the pole above the horizon is so great that the pole departs but little from the zenith, or when it is very small — 175
- The drawing of the astronomical vertical sundial on a fixed plane parallel to the vertical circle properly so called — 177
- The construction of the astronomical vertical sundial for a given style whose place is also given — 178
- The drawing of the vertical circles on a vertical sundial — 187
- The composition of the Italian vertical sundial — 194
- The construction of the Babylonian vertical sundial — 197
- The drawing of the Antique vertical sundial — 198
- The delineation of the vertical circles on a meridian sundial — 204
- The drawing of the vertical circles on a polar sundial — 218
- The drawing of the vertical circles on an equinoctial sundial — 231
- The vertical, the horizon, and the meridian cut one another at right angles in every clime — 245
- The drawing of the vertical circles on a sundial declining from the vertical — 267
- The delineation of the vertical circles on a sundial declining from the horizon — 288
- The drawing of the vertical circles on a sundial inclined to the horizon — 301

- The drawing of the vertical circles on a sundial at once declining and inclined — 336
- The delineation of vertical sundials in the right sphere, with everything that was set out for sundials in the oblique sphere — 350
- How the shadow [printed *Verba*[?]; evidently *Umbra*, "shadow" — the entry is about the straight and versed shadow], both straight and versed, projected from a given style, may be investigated from the given altitude of the Sun — 397
- The straight shadow of any altitude of the Sun above the horizon is the same as the versed shadow of the complement of that same altitude — 397
- What the movable vertical is in Ptolemy — 449
- Which circumference is the vertical — 449
- The vertical and hour circumferences that are to be employed for constructing the vertical sundial — 450
- The construction of the vertical sundial from the vertical and hour circumferences — 471
- By what means a vertical sundial may be constructed after the manner of a horizontal sundial, from the horizontal circumferences and the descending points found on the vertical circle as though on the horizon — 471
- The construction of the universal equinoctial sundial — 534
- The construction of a universal sundial in the form of a cross — 536
- The drawing of a universal sundial on a plane surface in the form of a parallelogram — 536

Z

- By what means the points of the Zodiac set on the circle of the 6th hour from noon or midnight, and their declinations, for when the beginnings of the signs rise, may be found — 155

FINIS.

(cursive), illegible]

Translation of the title page:

THE CONSTRUCTION AND USE OF THE INSTRUMENT most well-suited to the
laying-out of Sundials [Horologia].

There is added a most exact method of describing the hours from noon and from
midnight, never before brought to light.

By the author Christoph Clavius [Christophorus Clavius] of Bamberg, of the
Society of Jesus.

PRAEFATIO. (Preface)

In past years we published our *Gnomonics* [*Gnomonica*], furnished with almost
countless geometric demonstrations, in which we taught how to describe on any
plane not only the hours of every kind, but also most of the other things that can
be known from the shadow of a gnomon — such as the signs of the Zodiac, the
lengths of the days, the vertical circles, the parallels of the horizon, the meridians
(that is, the circles of longitude), the parallels of cities [civitatum paralleli], the
ascending signs, and so on. And at the end of Book 7 we added the construction
and use of a certain instrument by which, with almost no trouble (provided the
instrument is properly built), sundials can be described on any plane whatever
and for any elevation of the pole.

But although we have seen that this labor of ours was not unwelcome to students
of mathematics, the book nonetheless — because of the multitude of matters it
contains — has grown almost beyond measure, so that on that account it might
seem less convenient to some. We have therefore decided to set out that same
instrument, reduced now to a better form, separately in its own little book
[poprio [recte: proprio] libello], together with a certain new and very easy
method, never before published, of laying out the hours from noon and from

midnight on any plane — whether it be parallel to the horizon, or stands at right angles to it, or finally neither makes right angles with it nor is parallel to it.

The first inventor of this method — which is a most excellent one — is said to be a certain Spaniard named Ioannes Ferrerius [Joan Ferrer], a man especially sharp-witted and very shrewd in matters of invention. This method does not seem to differ much from the one we set forth in the *Gnomonics* by means of a cylinder extended along the world's axis, since the whole thing depends on a certain parallelepiped passed through that same axis, whose opposite bases are squares and are described on the bases of our cylinder. When I had examined this method rather carefully — for I was not able to see a complete treatment of the matter, but only certain fragments pertaining to the describing of hours on horizontal and vertical sundials were sent to me from Spain by a most friendly man of our order — and when I had found the geometric demonstration of the whole description, I was wonderfully delighted with it, since I found that it squares with every plane.

In this place, however, we shall set forth that method for the description only of the astronomical hours — namely those that are reckoned from noon and from midnight — [Illegible: ~1 word struck through in ink] for the sake of students, employing everywhere geometric demonstrations of my own devising, so that anyone may understand that the hours are correctly laid out in this way. We hope this will not be unpleasant to those who take delight in mathematics, and in gnomonics especially. For this method has this advantage, that by it all the hours and the parts of the hours can be laid out most exactly, since in it each single hour has three points through which they are drawn — just as, in the ellipse that arises from that cylinder of ours, three points correspond to each single hour. By what means the others — those we treated in our *Gnomonics* — can be described on sundials by this route, we shall explain at another, more convenient time.

Now, so that this little book may come out more complete, we shall add from our *Gnomonics* that method of describing the hours from sunrise and sunset, which is derived from the diurnal and nocturnal arcs. If anyone is not content with this, other methods must be sought from the *Gnomonics*, where everything is set out and demonstrated fully enough. In presenting these matters we shall follow this plan: we shall make horizontal sundials, vertical ones, and those wholly declining from the vertical, complete and entire, with certain repetitions from our *Gnomonics* that are necessary to the matter. For since these sundials are commonly described, we did not wish to allow anything to be found wanting for their description in this little book; and for that reason, on the horizontal sundial

and on the one declining from the vertical, we shall also draw the arcs of the signs and of the days, together with the hours from sunrise and sunset. On the other sundials, however, since they are not so frequently used, we shall here present only what depends on this new method, and shall omit entirely the rest, which is to be taken from the *Gnomonics*. At some other time, perhaps, when leisure permits, we shall publish a fuller compendium on this subject. Finally, we shall also repeat from the last chapter of Book 7 of the *Gnomonics* that easy and pleasant method by which sundials are drawn on any plane, by means of the shadow of the style of some properly constructed sundial, to a given magnitude of the style. But now let us proceed to the matter itself.

CONSTRVCTIO INSTRVMENTI AD HOROLOGIORVM DESCRIPTIONEM APTISSIMI.

(Construction of the Instrument most fitted to the laying-out
of Sundials)

CAPVT I. (Chapter 1)

Let there be prepared, from copper or brass [orichalcum], or from any other hard material, two flat semicircles, fitted and connected by three oblong screws [cochleolae] at a moderate distance from one another, placed one beneath the other, so that — the lower one remaining fixed — the upper can be raised and lowered by means of the screws, now on this side, now on that, as the matter requires. Of this kind, in the instrument set beside here, are the semicircles ABCD and EF: the former the upper, and this the lower, somewhat smaller and — to be lighter — hollowed out for the most part. The first screw corresponds to the points E and A; another lies under the point D; and the third has its seat under the point C, and near F. [Margin: A certain Horizon of the instrument.] Let the upper semicircle be called the Horizon of the instrument, because in use it must always be parallel to the horizon.

Near the middle of the lower semicircle let there be fixed a certain oblong cylinder, or a smooth round nail [clavus], making right angles with the said semicircle. For by this the whole instrument will have to be set up in a certain hole, as we shall say below, so that the upper semicircle ABCD, by the benefit of the said three screws — raised or lowered now here, now there — may at last be found to be parallel to the horizon. But if anyone should prefer to steady the semicircle ABCD parallel to the horizon in some other way, there will be no need

of that lower semicircle with its three screws; it will be enough if the said nail, or cylinder, is fixed to the semicircle ABCD, and so on.

Next, at G, the midpoint of the diameter AD of the upper semicircle, let there be fixed a certain small column [columella] GH, firm and strong, making right angles with the semicircle, so that around it a quadrant marked with the letters ILK can be turned about, in such a way that its semidiameter IK is always parallel to the said column. The poles of this motion are: one indeed in the piece [frustum] HI, which is fixed projecting from the column, and the other in the Horizon ABCD. [Margin: A certain Meridian of the instrument.] This quadrant, divided into 90 degrees whose beginning is set at the point L, near the Horizon, represents that quadrant of the meridian circle in which the visible pole of the world is contained; for this reason, in use, it must always be so directed toward the visible pole that it lies in the plane of the meridian. Let it, moreover, be hollowed out in the middle, lest it be too heavy.

From the center M of the quadrant also let there proceed the axis of the world MN, revolvable about the center M, having at the center a small screw M by which it may be fastened, and besides a fiducial line [linea fiduciae] accurately corresponding to the center — as is usually done in other mathematical instruments — so that it can indicate the degrees of the pole's elevation. [Margin: A certain Axis of the world in the instrument.] On the same axis let there also be a small screw N, near the circumference, so that it can be fastened at the proposed elevation of the pole. This will best be achieved if, on the other side of the quadrant, a certain piece is bent back toward the center, yet not going beyond the circumference, which, when the axis is moved, always clings to the quadrant: in this piece, indeed, a more convenient place for the small screw N would perhaps be found than in the axis itself.

Let there also be made a circle OPQ, of whatever size, which is to be divided into 360 degrees, and into 24 equal hours, and the single hours into quarters of an hour. Then, the center having been pierced and the circle for the most part hollowed out so that it becomes less heavy, let it be set upon the axis just above the circumference of the quadrant, so that the twelfth hour — both of them (for we divide the said circle into twice twelve hours, after the manner of the Germans, the French, and the Spaniards) — corresponds perpendicularly to the circumference of the quadrant, so that the plane of the quadrant, produced, passes through both twelfth hours. This being so placed, let it be fastened at right angles with the axis by little pegs or screws, so that it cannot change its position. The lower twelfth hour looks toward the south [meridies], and the next toward

the left (the instrument being turned toward us) to 1 after noon, and so on.
[Margin: A certain Equator of the instrument.] Let this circle be called the Equator, because, the axis being set at the proper elevation of the pole, it lies in the plane of the equator.

Moreover, let a rectangular plane be constructed, longer on one side, RS, of such a width that, when a straight line RS is drawn parallel to both longer sides through the point T — which is the center of the circle circumscribed about the rectangle — this straight line RS may represent the radius of the Equator, and the other radii of the signs of the Zodiac may be drawn out on either side of the straight line RS from the same point T. By what method these radii are described, we shall teach in chapter 10; but to which signs the several radii are to be assigned, we shall explain in the following chapter, where we shall reveal the use of the instrument. Let the length of this same rectangular plane be a little greater than the diameter of the Equator OPQ; and let the point T be finely pierced, so that a thin thread can conveniently pass through it. [Margin: A certain Colure of the solstices, or movable Hour-circle, in the instrument.] Let this rectangular plane, which is to be called the Colure of the solstices [Colurus solstitiorum], or the movable Hour-circle — since it performs the office of all the hour-circles passing through the poles of the world, as will be clear from the use of the instrument — be set at right angles to the Equator OPQ, on the axis, by means of a certain hollowed cylinder, through whose axis, which [is fastened] to the center M of the meridian quadrant IKL, to the very [point...]

(Continuation of Caput I, "Construction of the Instrument," from the preceding pages.)

corresponds exactly [ad unguem], the rectangle itself is to be understood as so drawn that the straight line NT — cutting the straight line RS at right angles, and projected out through the middle of the cylinder — reaches precisely to the center M of the meridian quadrant [quadrans Meridiani]; that is, so that the straight line NTM represents exactly the axis of the world [axem mundi].

This rectangular plane RS is turned about the axis of the world — an axis which, for this purpose, must at its end above the Equator be smoothed and made round to match the size of the hollow cylinder fixed to that same rectangular plane. As it is turned, it should always make right angles with the Equator; and its face, on which the radii of the signs of the Zodiac are drawn, should always pass, like a diameter of the Equator, through two opposite hours, so that the radius of Aries (♈) and Libra (♎) — namely the straight line RS — remains perpetually parallel to that same Equator.

This same rectangular plane should also have, next to the circumference of the Equator, certain pieces attached and bent back toward the lower parts, with little screws at α and β , so that the said Colure of the solstices [Colurus solstitiorum] can be halted and fastened at any hour whatever. Finally, the parts of it around the radii of the signs, being superfluous, should be cut away, so that the instrument is made lighter.

Diagram. A large woodcut showing the complete dialling instrument mounted on a wooden wall-bracket. The instrument is drawn in perspective, hanging on a right-angled wooden frame that carries a toothed (ratcheted) vertical strip on the right side, along which a square sliding ring can be moved and clamped. The following labels are legible on the scan:

- Θ (top-left corner of the wooden frame).
- Y (upper-left, on the frame near the mounting): the square ring [annulus quadratus] by which the instrument is hung.
- Z (bold, on the top horizontal beam): the square wall-column ς Z.
- α (upper-left, near the top of the Colure plate): little screw seat α .
- β (lower, where the Colure plate meets the Equator ring): little screw seat β .
- O (far left of the great ring): a labelled point of the Equator circle OPQ.
- The Equator ring [$\mathcal{E}$ quator] OPQ, graduated and bearing Roman hour-numerals around its rim, "twice twelve" (...XII, XI, X ... I, II, III, IIII ... V, VI, VII, VIII ... IX, X, XI, XII...).
- P (center-lower, on the ring/quadrant assembly); a Q is expected on the ring but is not separately legible [?].
- Φ (phi, beside P, center-lower).
- Lower-left cluster on the meridian quadrant / semicircle ABCD: D, G, A, K, E (with E at the foot).
- The triangular Colure / movable hour-circle plate [horarius mobilis], rising to the upper right, bearing a small inner hour-scale (Roman numerals I, II, III, IIII, V, VI).
- R (lower-right corner of the Colure plate).
- ρ (rho, at the far right edge of the Colure plate).
- C and F (lower-right, on the arm below the ring).
- μ (mu): the compass-box [pyxis], a round dial with a magnetic needle / compass-rose, at the lower right.
- Base pedestal (bottom center): a wooden block bearing the label X (the securing screw [cochleola] X), with V nearby (the mounting hole/peg).

- Several small looped corner-marks (rendered ς in the text below) appear along the left post and the joints of the wooden columns.
- A central ornamental cartouche within the ring bears letters that appear to read "HO" (left) and "I" (right) [?] — apparently decorative rather than a construction label.

After this, let two square columns be made of hard wood, like parallelepipeds of equal thickness, joined to one another at a right angle ς [the corner marked with a small looped symbol, here rendered ς]; of these let ςV be the shorter and ςY the longer. In the shorter one, ςV , let there be a round hole near V , into which the whole instrument constructed so far can be set by means of that round peg or cylinder which — as we said — is to be fixed at the outset into the lower semicircle. On the side of the same column ςV , opposite the hole, let a little screw X be set, by which the peg (or cylinder), and hence the whole instrument, can be secured. Moreover, the distance of the hole V from the right angle ς should be somewhat greater than the radius of the upper semicircle $ABCD$ — great enough, that is, for the instrument to turn freely in that hole.

Then, at the end of the longer column ςY , let a square ring Y be fastened with screws or nails, made of brass [orichalcum] or iron, having at its top another screw ϖ . By this screw the instrument — once set into the hole V and secured — together with the whole apparatus, can be carried back and forth along another square column ςZ (five or six palms long and fixed to any wall), and there be halted and fastened by means of that square ring.

Lastly, at the end of the lower radius kL of the meridian quadrant, let a compass-box [pyxis] μ be attached, fitted with a magnetized needle, so that by its help the meridian quadrant — the instrument having first been fixed in the hole V — may be set in its proper position...

in its proper position, namely in the plane of the meridian circle. This compass-box may also be fixed, if that is judged more convenient, to one side of the quadrant, as you see done in the compass-box ϕ on the instrument.

Finally, alongside the radius IK of the quadrant, let a thread ab with a plumb-weight hang from the point a — a plumb that can swing freely in the hole b cut out for it — a straight line ab having first been drawn parallel to the radius of the quadrant (that is, to the small column GH), so that by means of this plumb-line the Horizon of the instrument $ABCD$ can be set parallel to the celestial Horizon. This is done as follows. By means of three little screws, let the Horizon of the instrument be raised or lowered, now on this side, now on that, until the freely

hanging plumb-line agrees exactly with the straight line ab and grazes the edge of the quadrant. For in this way the Horizon of the instrument ABCD will be everywhere parallel to the celestial Horizon.

[Margin: How the Horizon of the instrument is set parallel to the celestial Horizon. (*Quo pacto Horizon instruménti coelesti Horizóti statuatur aequidistans.*)]

So much for the construction of the instrument. Now let us come to its use, from which the directions we have given about its making will become clearer. And I do not doubt that, once its use is rightly understood, anyone may, by his own effort, arrange some parts of the instrument in another way, and perhaps improve them.

Usus praecedentis instrumenti — The Use of the Preceding Instrument, in describing sundials on any plane whatever

Caput II

On the wall or plane on which the sundial is to be described — whether it stands at right angles to the Horizon or not — let that long wooden column ζZ of the instrument described above be fixed a little above the place of the sundial, so that, to the judgment of the senses, it is parallel to the Horizon; and let it be fastened so firmly that it cannot be shifted from its place.

[Margin: How the instrument is to be positioned for describing sundials. (*Quo modo instrumentum in descriptione horologiorum locandum sit.*)]

Onto this column, by means of the square ring Y, let the whole instrument be set, in such a way that the point T stands off from the wall by roughly the length you want the style [stylus] to have. Then, having fastened the ring by the screw ϖ, and the instrument by the screw X, let the fiducial line of the axis [linea fiduciae axis] be set at the degree of the pole's elevation for the place where the sundial is being built, and let it be fixed with the screw N, so that it cannot be pulled away from that degree.

Lastly, let the Horizon of the instrument ABCD be set parallel to the celestial Horizon by means of the screws and the plumb-line ab, as was taught at the end of the preceding chapter. And let the meridian quadrant be moved this way and that until it lies in the plane of the meridian circle and the axis MN looks toward the visible pole of the world. This will happen only when the magnetized needle lies directly over the meridian line at the bottom of the compass-box — or at least (which I myself prefer, since a needle of this kind almost never points exactly to

the pole, but deflects from the true meridian line now more, now less, so that I judge it not much to be trusted; at Rome I have more than once found the point of such a needle deflecting from the meridian line toward the east by about 6 degrees) — when the meridian quadrant is parallel to the meridian line found on the Horizon of the instrument, as we taught in the scholium to Proposition 23 of Book 1 of the *Gnomonics*.

Once the instrument has been set in this position, the Equator of the instrument OPQ will lie in the plane of the celestial Equator; the Colure of the solstices — that is, the movable hour-circle RS — carried to each successive hour, will take the position of each of the hour-circles that pass through the poles of the world; and finally the radii of the signs of the Zodiac will correspond exactly to the diameters of the Ecliptic (insofar as these are the common sections of the Ecliptic and the Meridian), when the beginnings of the signs are placed under the Meridian.

Therefore the plane of the meridian quadrant, if it is then imagined as extended all the way to the wall, will produce on the wall the meridian line — that is, the common section of the Meridian with the wall. So too the plane of the Colure of the solstices, or of the movable hour-circle, set at any hour, if it is understood to run out to the wall, will make on the wall the hour-line of that hour — that is, the common section of that hour-circle with the wall. Finally the radii of the signs, if extended to the wall, will mark on the wall the points onto which the shadow of the gnomon (or style) — of whose placing we shall treat shortly — is cast, when the Sun is on that hour-circle and at the beginnings of the signs. In this way the whole sundial will have been constructed, if the movable hour-circle is understood to be carried to each hour, and so on.

But since these planes cannot actually be extended, we shall find their common sections with the wall — and the points through which the arcs of the signs of the Zodiac are to be drawn — with the help of a thread, in this way. First of all, let the movable hour-circle be set to the 12th hour of the Equator, and fixed in that position. Then from the point T let a very fine thread be sent out all the way to the wall, grazing freely the plane of the hour-circle itself, so that the extended plane does not depart from the thread but always lies along it. For if that thread is applied to each of the radii, and the points are marked on the wall, a meridian line is to be drawn through those points, indicating the 12th hour from noon or from midnight.

[Margin: The description of the hours from noon and from midnight. The meridian line. (*Descriptio horarum à mer. & med. noct. Linea meridiana.*)]

The highest point will correspond to the sign Capricorn (♑); the next to Aquarius (♒) and Sagittarius (♐); the one after that to Pisces (♓) and Scorpio (♏); the next to this to Aries (♈) and Libra (♎); another following to Taurus (♉) and Virgo (♍); the next to Gemini (♊) and Leo (♌); and the lowest to Cancer (♋).

Then, moving the movable hour-circle and carrying it to the 1st hour — which follows the 12th hour on the left, at the lowest part of the Equator, that is, toward the east — and fixing it there, we shall find (with the same thread grazing the plane of the hour-circle freely and lying along each radius) the points of those same signs on the wall, through which the line of the 1st hour from noon is to be drawn. And the same method applies to all the other hours that can fall on the wall — that is, those whose points can be marked on the wall by that thread grazing the plane of the hour-circle.

And if the corresponding points of the signs are suitably joined by curved lines, there will also be described the arcs of the signs which the tip of the shadow traverses when the Sun is at the beginnings of the signs. Yet all the points of Aries (♈) and Libra (♎) must — if no error has been made in the work — fall on a straight line, namely on the common section of the Equator with the plane of the sundial, as we demonstrated in the *Gnomonics*. Moreover, we shall find the points of these same arcs of the signs, and so shall trace the arcs themselves, without any regard to the hours.

[Margin: How the arcs of the signs are drawn, without regard to the hours. (*Quo pacto arcus signorum ducantur, nulla habita ratione horarum.*)]

For if we carry the movable hour-circle around to various places on the Equator only slightly apart from one another, and in each position mark on the wall with the thread the points for the several signs, the points of all the signs will be found, even though no account has been taken of any hour. And the more numerous the intervals on the Equator at which the movable hour-circle is halted, the more numerous the points that will be found on the wall...

that will be found on the wall for each sign, and the less they will be apart from one another; and consequently the arc of the signs itself will be drawn more precisely.

[Margin: The horizontal line. (*Horizontalis linea.*)]

The horizontal line is drawn as follows. Let the thread be stretched to the wall, and raised and lowered until it is parallel to the Horizon — which you will achieve by means of a level [libella], a plumb-line, and a ruler applied to the

thread itself. For when the thread holds this position, if a point is marked on the wall, the straight line drawn through that point parallel to the Horizon will be the horizontal line; and on walls that stand at right angles to the Horizon, this line will be perpendicular to the meridian line.

We shall draw it more surely in this way. With the movable hour-circle set at the hour at which the Sun, being at the beginning of Capricorn (♋), rises or sets, let the thread be applied to the radius of Capricorn (♋), and let the point be marked on the wall. For a straight line drawn through this point parallel to the Horizon will give the horizontal line. You will obtain that hour of rising or setting if you count the semidiurnal arc of Capricorn (♋) — in the *Sphere* we set out the semidiurnal arcs for various elevations of the pole — from the lower 12th hour of the Equator toward each side. For the count ended on the western side will give the hour of rising, and on the eastern side the hour of setting. If, then, both hours can be marked on the wall with the thread, you will have two points through which the horizontal line is to be drawn; if only one of the two, a single point.

Diagram. The same dialling-instrument woodcut as (fig-p580-1), printed again from the identical block. The same labels are legible — Θ , Y, Z, α , β , O, the graduated Equator ring OPQ with its twice-twelve Roman hour-numerals, P, Φ , the meridian quadrant labels D, G, A, K, E, the triangular Colure plate with its inner scale (I, II, III, IIII, V, VI) and corner labels R and ρ , C, F, the compass-box μ , and the base block with X and V. See fig-p580-1 for the full description.

Once the horizontal line has been drawn, let all the lines lying above it be erased, as superfluous, since in that part of the sundial the shadow of the gnomon can never fall, because the earth lies between.

[Margin: How the style is to be placed. (*Stylus quo pacto locandus.*)]

We shall place the style, or gnomon, the indicator of the hours, in this way. From the point T of the movable hour-circle, let three points be marked on the wall with the thread, keeping always the same length of thread. For if the center of these three points is found by the method of the scholium to Proposition 5 of Book 4 of Euclid, the style is to be fixed at right angles in that center; and its length will be given by the length of thread intercepted between that center and the point T, which represents the center of the world.

Or we shall proceed in this way. From a high place let a plumb-line be let down, ending in a freely hanging point, until its extreme point touches the point T. For then, with the instrument removed, if a style of any size is fixed at any place on the wall in such a way that its tip coincides with the extreme point of the said

plumb-line, the tip of this style's shadow will indicate the hours just as well, even though it is not perpendicular to the wall.

Now, in order that the hours of sunrise and sunset may be laid out, the hours themselves must first be marked in ink — or by some other means — upon the Equator, in the following way. From the lower 12th hour let the semidiurnal arc of Capricorn (♑), taken from our *Sphere* or from some other source, be counted off in both directions along the Equator. For the end of the count toward the west, that is, to the right, will give the 24th hour reckoned from sunrise; and to the left, that is, toward the east, the same count gives the 24th hour reckoned from sunset. If, then, starting from the earlier point — the one we assigned to sunrise — you transfer along the circumference of the Equator the hour-spaces taken with the compass upon that same Equator, advancing toward the lower 12th hour, you will obtain the hours 1, 2, 3, 4, 5, and so on, reckoned from sunrise. But if you transfer those same hour-spaces from the later point — the one we ascribed to sunset — toward the same lower 12th hour, up to the hour of rising, you will obtain the hours 23, 22, 21, 20, 19, and so on, reckoned from sunset. You may also mark out these hours without a compass, if from the said points of rising and setting you count off 15 degrees for each single hour toward the lower 12th hour.

Once the hours from rising and setting have been marked on the Equator in this way, then, if we bring the movable hour-circle to each of them in turn, we shall find by means of the thread the points of those same hours upon the wall for the tropic of Capricorn (♑) — the points through which the tropic of Capricorn is to be drawn. In just the same way you will find the points of those same hours for the other parallels upon the wall, provided you have first marked out their hours on the Equator by means of the semidiurnal arcs, as we described for the tropic of Capricorn. It will be enough to determine the points of the hours for Aries (♈) and Libra (♎), and for the two tropics, Capricorn (♑) and Cancer (♋). For the straight lines connecting the three corresponding points of any given hour in Capricorn, Aries, and Cancer will be the hour-lines from rising and setting. But when in the tropic of Cancer (♋) the points of some hours are lacking, then the two corresponding points in the parallel of Capricorn (♑) and of Aries (♈), or of Libra (♎), must be connected. And if the points of certain hours are not present even in the parallel of Aries (♈) or Libra (♎), their points must be sought in the parallel of Capricorn (♑) or of Aquarius (♒). The line of the 24th hour will here give the horizontal line. As for the arcs of all the signs, if you should want them, they are to be drawn here just as we described in the sundial of the hours from noon and from midnight.

[Margin: The laying-out of the hours from rising and setting.]

Finally, the unequal [seasonal] hours are drawn by the same method, if you have first impressed some mark for them on the Equator. You will do this if you divide into six equal parts the semidiurnal arc of each parallel (though it is enough to take the three parallels: Capricorn (♋); Aries (♈) or Libra (♎); and Cancer (♋) — except when the point of some hour in Aries or Libra does not fall on the wall, for then that hour must be taken in the parallel of Capricorn or of Aquarius).

[Margin: The laying-out of the unequal hours.]

A horizontal sundial can be laid out with the same instrument in no other way, provided it is to be a large one. For small ones cannot be described by the instrument; since, once the instrument is fixed (so that its horizon ABCD is parallel to the celestial horizon), the style must be as large as the distance of the point T — where the rays of the signs meet on the movable hour-circle — from the plane of the horizontal sundial.

[Margin: The laying-out of a large horizontal sundial by the same instrument.]

CONSTRVCTIO FVNDAMENTI HOROLOGIORVM, ID EST, FIGVRAE

(The Construction of the Foundation of Sundials — that is, of a General Figure, most convenient for laying out the hours from noon and from midnight on any plane and for any elevation of the pole.)

CAPVT III.

Let there be made a rectangle longer on one side, ABCD, of any size; and from the longer side BC let a straight line BE be cut off equal to the shorter side AB. Then from E, at any interval, let an arc of a circle FG be described toward BA; and with the compass unchanged let the arc FG be marked off, which will be a sixth part of the circle, as is established from the corollary to Proposition 15 of Book IV of Euclid. Next, from center E, let a straight line be drawn to A, cutting the arc FG at H; the arc FH will be an eighth part of the circle, that is, half a quadrant. For since the angle HEF at the center is equal to the angle BAE [Margin: a. *Elements* I.5] — because the straight lines BE, BA are equal — each of them will be a half-right angle, and therefore an eighth part of four right angles. Of whatever parts, then, the whole circumference of the circle is 24, of such parts the arc FG is 4, the arc FH is 3, and the arc GH takes up 1. Therefore, if from the arc FH three arcs HI, Ik, kF are cut off equal to the arc GH, the arc FH will be divided into three equal

hours. Now, drawing from center E through the points I, k [Margin: b. *Elements* I.33] hidden straight lines cutting the side AB at L and M, let there be taken on the opposite side CD the straight lines CO, CN equal to BM, BL; and let the straight lines LN, MO be drawn, which will be parallel to the sides AD, CB. The straight line BC, then, will be assigned to the 6th and 12th hours from noon or from midnight; the straight line MO to the 1st and 11th, and also the 5th and 7th; the straight line LN to the 2nd and 10th, and also the 4th and 8th; and finally the line AD to the 3rd and 9th — in such a way that BC is the 12th hour from midnight, that is, the hour of noon; MO is 1 from noon; LN, 2; AD, 3; then again LN, 4; MO, 5; BC, 6; and again MO, 7; LN, 8; AD, 9; and once more LN, 10; MO, 11; and BC, 12, namely the hour of midnight, as we shall presently demonstrate. For half-hours, quarter-hours, and other subdivisions, the arcs HI, Ik, kF are to be divided into two and into four equal parts, and so on. In the figure the said arcs are divided in two, and parallels are drawn for the half-hours.

With this figure, then, we shall draw with the greatest accuracy the hour-lines from noon and from midnight on any plane and for any given elevation of the pole, as will be clear from what follows — so much so that it would be worth the effort, with the utmost care, to construct in some hard material two or three such rectangular figures, so that we might use them in laying out sundials as general instruments: larger ones for larger sundials, smaller ones for smaller. For large sundials are more easily drawn from a larger figure, and small ones more conveniently from a smaller. And we may not unfittingly call this figure the Foundation of sundials.

[Margin: The composition of the Foundation of sundials.]

[Margin: The Foundation of sundials.]

But let us demonstrate the origin of this figure, and why the hours are assigned to those parallels in the stated order. Let there be understood, then, a rectangular parallelepiped whose opposite bases are squares and whose sides are equal to twice AB, set about the axis of the world in such a way that its axis (I call the axis the straight line joining the centers of the opposite squares) coincides with the axis of the world; and let two of its opposite rectangular planes — one upper and the other lower — be parallel to the circle of the 6th hour from noon and from midnight, while the other two — one eastern and one western —

[Margin: The demonstration of the Foundation of sundials.]

occidental — are each equidistant from the meridian circle. Such a parallelepiped, inscribed in a cylinder extended along the axis of the world, by

means of which we constructed the sundials in our *Gnomonics*, is described once the squares have first been described in the bases of the cylinder. The common section of this parallelepiped and of the Equator will be a square, that is, a figure equal and similar to the [bounding] planes, or opposite bases, from the corollary to Proposition 25 of Book XI of Euclid, since the Equator is equidistant from the bases. Let this square be RADS, having half of the side AR — namely the straight line AB — equal to the straight line AB in the figure of the Foundation of sundials; and through its center E let the axis of the world pass, standing at right angles upon it. Let the straight line PQ be the common section of that same square, or of the Equator, and of the meridian circle; and let BC be the common section of that same [square], or of the Equator, and of the circle of the 6th hour, and also of the Horizon and of the prime Vertical circle. For these four circles have one and the same common section, namely the axis of the meridian, to which they are perpendicular, since they all pass through the poles of the meridian circle, as is evident. Now PQ and BC will cut one another at the center E at right angles. [Margin: a. *Elements* XI.19] For since both the Equator and the circle of the 6th hour are perpendicular to the meridian, their common section BC will also be perpendicular to it, and therefore, by Definition 3 of Book XI of Euclid, also to the straight line PQ lying in the meridian. [Margin: b. *Elements* XI.16] And to these two straight lines PQ, BC the sides of the square will be parallel. For RS, BC, AD are the common sections of parallel planes (namely, of the circle of the 6th hour drawn through BC; of the upper rectangular plane in the parallelepiped drawn through RS; and finally of the lower plane in the same parallelepiped passing through AD),

Diagram. The upper figure: a rectangle developed (unrolled) from the parallelepiped, carrying the hour-lines and diagonal projection-lines of the Foundation figure, with an hour-number ladder appended along its right edge.

- Top edge, left → right: B, F, E, α [?] (a small script letter, possibly italic *a*), v [?], T, d [?]
- Left edge, top → bottom: B, M, L, A
- Interior (left region): K, I, H, with a curved arc descending to G; dotted radiating lines from M, L, K, I toward H and G
- Interior (center-right region): X, X (two, stacked), R, Y; a small *f* near the top; a further label near the lower right, Γ/ρ [?]
- Bottom edge, left → right: A, Z, P, C, Q, D
- Right edge (appended number-ladder), edge letters top → bottom: O, O, N, D

- Number-ladder pairs (left column | right column), top → bottom: 12 | 6, 6 | 12, 1 | 7 [?], 5 [?] | 11, 2 | 8, 4 | 10, 3 | 9, 3 | 9 [?]

Diagram. The lower figure: a square with an inscribed circle (the Equator) divided into 24 equal hours, with straight lines radiating from the circle to the sides of the square (the hour-circles' common sections). Center E; the two diameters PQ (vertical) and BC (horizontal) cross at E.

- Corners: R (top-left), S (top-right), A (bottom-left), D (bottom-right)
- Top edge, center: P
- Bottom edge, center: Q
- Left edge, top → bottom: B, M, L
- Right edge, top → bottom: C, O, N
- Center: E
- Letters set on the circle's left arc, top → bottom: F (at hour 6), K (at 7), I (at 8), H (at 9), G (near 10–11)
- Hour-numerals around the circle: two sequences 1...12; upper arc reads 1, 12, 11, 10, 9, 8; right arc descending 7, 6, 5, 4, 3, 2; lower 1, 12; left arc ascending 3, 4, 5, 6, 7, 8, 9, 10, 11 [several small numerals uncertain]

made from the plane of the Equator; while RA, PQ, SD are the common sections of parallel planes (namely, of the meridian circle passing through PQ, and of both the left-hand and the right-hand rectangular planes in the parallelepiped, of which the former, the western, is drawn through RA, and the latter, the eastern, through SD — and we have supposed both to be equidistant from the meridian circle), made from that same Equator. From which it follows [Margin: c. *Elements* I.29] that the angles at P, B, Q, C are likewise right angles.

Now, an Equator-circle of any size having been described from center E in the plane of the Equator, and divided into 24 equal hours, beginning from PQ, the common section of the meridian and the Equator, and straight lines having been drawn from E through the points of division as far as the sides of the square, these will be the common sections of the Equator (that is, of the said circle) and of the hour-circles through the poles of the world and through the axis, and therefore also through the center

E — of the [lines] drawn — for the reason that the Equator and the aforesaid circle, described from the same center E, are cut into similar parts by the said hour-circles, as we demonstrated in the *Sphere* at the end of Chapter 1. Now the lines of the 3rd and 9th hours will fall upon the corners of the square, on account of the half-right angles REP, AEB, DEQ, SEC at the center E, which the semi-

quadrants of the circle subtend, each of which takes up three hours. Moreover, these same hour-circles will make, in the rectangular planes of the parallelepiped, common sections parallel both to one another and to the axis of the world, as is clear from what was demonstrated in Propositions 18 and 22 of Book I of our *Gnomonics*; and all of these will pass through the points of the square at which the common sections of the hour-circles and of the Equator fall.

Since, then, the eight lines of the square — RB, BA, AQ, QD, DC, CS, SP, PR — are cut in like manner by the hour-circles, it comes about that any one of them stands for all. In this way the figure of the Foundation of sundials contains the straight line AB, divided at the points L, M just as the line AB is divided in the square, as is manifest from the description. For both the arc FG in the figure and the arc FG in the square, each comprising four hours, is a sixth part of the circle; and FH, an eighth part, comprises three hours. And the parallels AD, LN, MO, BC express those common sections which we said were made in the rectangular planes of the parallelepiped by the hour-circles. Therefore, if the straight line AB is set upon the straight line RP, with the point A placed at R and the point B at P, the said parallels will represent the hours 12, 1, 2, 3. But upon the straight line RB, with the point A placed at R and the point B at B, [they will represent] the hours 3, 4, 5, 6. Upon the straight line BA, with the point B placed at B and the point A at A, the hours 6, 7, 8, 9. And upon the straight line AQ, with the point A placed at A and B at Q, the hours 9, 10, 11, 12 — all of which hours are reckoned from noon. Then, upon the other four straight lines QD, DC, CS, SP, the same straight line AB, placed in the aforesaid order, will represent by the same parallels the same hours reckoned from midnight: so that the rectangle ABCD, with its parallels, reproduces half of each rectangular plane in the parallelepiped, together with the sections made by the hour-circles — yet in this order, that the straight line BC always coincides with the straight line drawn through the middle of the rectangular plane, and the straight line AD with the outermost side of that same rectangular plane. This is the origin and source of the figure that we have chosen to call the Foundation of sundials.

HOROLOGIA HORIZONTALIA, ATQVE VERTICALIA HORARVM à meridie, & media nocte.

(Horizontal and Vertical Sundials of the Hours from noon and from midnight.)

CAPVT IIII.

In the figure of the Foundation of sundials, from any point of the side AD or BC — say, from the point P of the side AD — let an arc of a circle QRS be described at any interval, on which, the altitude of the pole QR being marked out for the horizontal sundial and its complement QS for the vertical, let the straight lines PRT, PSV be drawn, cutting the parallels MO, LN at the points X, Y. In the figure the altitude of the pole QR takes up 42 degrees, about what it is at Rome, and its complement QS, 48 degrees. But if at any time the straight line PT or PV does not cut the opposite side BC, then the side BC must be produced together with the parallels MO, LN, etc., until it can be cut — which is likewise to be understood whenever other lines, which we shall use in what follows, are to be transferred to the Foundation of sundials but do not cut the opposite side. The straight line AB is the common section of the plane of the horizontal and vertical sundial and of the circle of the 6th hour, which is the upper and lower plane the parallelepiped represents. PT is the common section of the plane of the horizontal sundial and of the eastern or western plane of the parallelepiped. Finally PV is the common section of the vertical sundial and of that same eastern or western plane of the parallelepiped — all of which will be demonstrated below.

[Margin: The finding of the sections of the plane of the horizontal and vertical sundial, and of the parallelepiped extended along the axis of the world.]

Next, in the plane of the sundial let there be given the place of the style, A, and its length AB. Through A let a straight line CD be drawn in any direction for the meridian line — though, when the plane of the sundial is fixed and the meridian line has been found in it, a line CD parallel to that must be drawn through A for the meridian line, which in the vertical sundial is perpendicular to the horizon. Let AB, equal to the style, be drawn perpendicular to it, and at B, upward, let there be set up — for the horizontal sundial — the angle ABC equal to the angle QPS, the complement of the pole's altitude in the Foundation of sundials; and downward, the angle ABD equal to the angle QPR, the altitude of the pole. But for the vertical sundial let the angle ABC upward be [equal to] the altitude of the pole, and the angle ABD downward [equal to] the complement of the pole's altitude. In each sundial let the straight lines BC, BD cut the meridian line at the points C, D. C will be the center of the sundial, and CB the axis of the world; and, drawing perpendiculars ECE, FDG through C, D to CD, the former will be the line of the 6th hour and the latter the equinoctial line — all of which we demonstrated in the scholia to Propositions 1 and 13 of Book II of our *Gnomonics*.

[Margin: The construction of the horizontal and vertical sundial.]

After this, from the line ECE of the 6th hour, in each sundial, let there be cut off on both sides a straight line CE equal to the straight line AB, or CD, of the Foundation of sundials. Likewise, from the meridian line of the horizontal sundial equal to the straight line PT of that same Foundation, and from the meridian line of the vertical sundial equal to the straight line PV of the same Foundation, let there be cut off, both upward and downward, a straight line CH equal [to them]. Then, in each sundial, from the points E, upward and downward, let two small arcs be described at the interval of the straight line CH cut off from the meridian; and from the points H, on both sides, [let arcs be described] at the interval of the straight line CE cut off from the line of the 6th hour, which cut the former at I. Let two straight lines IEI and two IHI be joined, which will pass entirely through the points E, H, and will form a rectangular parallelogram, as is evident and can easily be proved. For the four quadrilaterals EH, since by construction they have their opposite sides equal, are parallelograms, from the scholium to Proposition 34 of Book I of Euclid; and therefore, since the four angles at C are right, [Margin: a. *Elements* I.34] the four opposite ones at I will also be right, and so on.

[Margin: The laying-out of the hours from the Foundation of sundials.]

Finally, let the intervals of the straight line AB of the Foundation of sundials, intercepted between the point B and the parallels MO, LN, etc., be transferred in each sundial from the points H, on both sides, onto the straight lines HI; and in the horizontal sundial, from the points I toward the points E, onto the straight lines IE, let there be transferred the intervals of the straight line PT of the Foundation of sundials, intercepted between the point P and the parallels MO, LN, etc.; while in the vertical sundial

and in the vertical sundial let the same be done with the intervals of the straight line PV intercepted between P and the said parallels. For the straight lines drawn through the center C of the sundial and through the points on the sides of the parallelogram IEIHIEIH — each of which will pass through three points — will give the hours from noon and from midnight, in the following order. In each sundial the lower CH looks to the 12th hour from noon, and the upper to the 12th hour of midnight. In the horizontal sundial the line next after the lower CH, toward the left, shows the 1st hour from noon, and the one following it the 2nd hour from noon, and so on in sequence. In the vertical sundial, by contrast, the line following the lower line CH, toward the right, answers to the 1st hour from noon, and the next after it to the 2nd hour from noon, and so on — as appears in

the figures, and as the intervals transferred from the Foundation of sundials indicate.

It would indeed be enough, for laying out either sundial, to draw only the lower, or upper, or left, or right half of the rectangle IEIHIEIH — namely either of the two rectangles EIHIECE, or either of the two HIEIHCH. But then the individual hours would be drawn through only two points each; yet, when produced beyond the center C, they would complete the whole sundial.

The half-hours and the quarter-hours are drawn in the same way, if the spaces cut off in the Foundation from the parallels of the half- and quarter-hours are transferred onto the sides of the parallelogram IEIHIEIH in the sundial, and so on.

Diagram. A rectangular sundial figure in which the hour-lines radiate from a central point C. Through C run the meridian line H–C–H (vertical) and the line of the 6th hour E–C–E (horizontal); the equinoctial line F–D–G runs across just below C. Near the center is the style, shown as the small triangle with points A and B (with an arrow between A and B) and D just below. The rectangular rim is inscribed with the parallelogram IEIHIEIH, whose four corners are marked I, with H at the top and bottom mid-points, E and F on the left side, and E and G on the right side. The hours are labelled around the rim as follows:

- Top edge (left → right): 9, 10, 11, 12, 1, 2, 3
- Right edge (top → bottom): 4, 5, 6 (at point E), 7 (at point G), 8
- Bottom edge (left → right): 3, 2, 1, 12, 11, 10, 9
- Left edge (top → bottom): 9, 8, 7, 6 (at point E), 5, 4 (point F lies on the left side just below the 6-line E)
- Interior letter-points: C (center); A, B, D (the style); E, E (ends of the 6th-hour line E–C–E); F, G (ends of the equinoctial line F–D–G); H, H (ends of the meridian line H–C–H); I (the four corners of the parallelogram IEIHIEIH)

[Margin: Demonstration of the preceding description.] [Margin: a. *Elements* XI.16]
[Margin: b. *Elements* XI.19] [Margin: c. *Elements* I.28]

Demonstration. The demonstration of this construction depends on the parallelepiped that we described in Chapter 3. For since the sections made in the plane of the sundial — of both the horizontal and the vertical — by the opposite and parallel rectangular faces of the parallelepiped are [a] parallel [to one another], the common section of the plane of either sundial and of the parallelepiped will be a parallelogram; and this I say is IEIHIEIH. For since the

plane of either sundial, and likewise the rectangle of the parallelepiped — both the upper and the lower — stand at right angles to the meridian, the common section of the plane of either sundial and of either said rectangle will also [b] be at right angles to the same meridian, and therefore also perpendicular to the meridian line HCH lying in the meridian; and hence [c] parallel to the straight line AB of the Foundation of sundials, and consequently double it. For AB alone reaches only to the middle of the said rectangle in the parallelepiped, as we said in Chapter 3; so that AB may rightly be called the common section of either sundial and of the circle of the 6th hour, which the plane of the Foundation — that is, the upper or lower plane of the parallelepiped — represents. Therefore, in the horizontal sundial the straight line IHI, inclining toward the south, and...

the straight line AB, double [the line] of the Foundation of sundials — such as is the line that cuts the line of the 12th hour of midnight. In the vertical sundial, on the other hand, the upper straight line IHI, double that same AB of the Foundation of sundials, will be the common section of the plane of the sundial and of the upper rectangle in the parallelepiped. And for this reason the two straight lines IEI, equidistant from the meridian itself, will be the common sections of the plane of either sundial with the rectangle of the parallelepiped, both eastern and western. For the common sections of the meridian and of the rectangle — both eastern and western — of that parallelepiped, made by the plane of the sundial (since these three planes are parallel), are [a] parallel to one another.

I now assert that these common sections IEI ought, in the horizontal sundial, to be double the straight line PT of the Foundation of sundials, and in the vertical double the straight line PV — just as they were taken in each sundial. For since the horizon makes with the axis of the world, and hence with any straight line of the parallelepiped parallel to the axis, the angle of the pole's altitude, while the vertical circle makes the angle of the complement of the pole's altitude, the straight line PT — making with AD (which in the parallelepiped is parallel to the axis) in the Foundation of sundials the angle of the pole's altitude TPD, namely equal to the one the horizon makes with the same AD — will be parallel and equal to the common section of the half of the eastern or western rectangle of the parallelepiped...

[Margin: a. *Elements* XI.16]

Diagram. The same rectangular sundial construction as on the facing page, reprinted here (the figure appears on both facing pages 10 and 11). The hour-lines again radiate from the central point C, with the meridian line H–C–H vertical, the

6th-hour line E–C–E horizontal, and the equinoctial line F–D–G just below C; the style is the small triangle A–B (arrow between A and B) with D below. The rim carries the parallelogram IEIHIEIH (corners I; H at top and bottom mid-points; E, F on the left; E, G on the right). Rim hour-labels, matching the facing figure:

- Top edge (left → right): 2, 1, 12, 11, 10, 9 [the labels visible across the top run ...2, 1, 12, 11, 10, 9]
- Right edge (top → bottom): 8, 7, 6 (at point E), 5 (at point G), 4
- Bottom edge (left → right): 9, 10, 11, 12, 1, 2, 3
- Left edge (top → bottom): 3, 4, 5, 6 (at point E), 7, 8, 9
- Interior letter-points: C (center); A, B, D (style); E, E (6th-hour line); F, G (equinoctial); H, H (meridian); I (four corners of the parallelogram)

piped, and of the plane of the horizontal sundial — that is, if the rectangle AC of the Foundation is conceived in the parallelepiped as being the eastern, or western, one joined to the upper by the straight line AD, but with the point D inclining toward the north, and with the straight line AD set parallel to the axis: so that PT may rightly be called the common section of the horizontal sundial and of the eastern or western plane of the parallelepiped. Therefore each IEI, being double PT, will in the horizontal sundial be equal to that whole section; and accordingly the lower IHI will be the common section of the same plane of the sundial and of the lower rectangle of the parallelepiped.

We shall show in just the same way that, in the vertical sundial, each straight line IEI is equal to the whole section of the plane of the sundial and of the eastern or western rectangle of the parallelepiped, while the lower straight line IHI is the common section of the same plane of the sundial and of the lower rectangle of the parallelepiped — that is, if the rectangle AC of the Foundation is understood in the parallelepiped to be the eastern or western one joined to the upper by the straight line AD, but with the point D inclining toward the south, and with the straight line AD set parallel to the axis: so that PV may rightly be called the common section of the vertical sundial and of the eastern or western plane of the parallelepiped. Since, therefore, the straight lines IHI, IEI, in the sundials...

are cut just as the straight lines AB, PT, or PV are in the Foundation of sundials, that is, in the parallelepiped, the hour-circles will pass through the points where the straight lines IHI, IEI are cut, in the same way as we taught them to pass through the points where the straight lines AB, PT, and PV are cut, namely through the parallels of the Foundation. And so, since they also pass through C, the center of the sundial, as we showed in the *Gnomonics*, the hour-lines have

rightly been drawn by us in each sundial through C and through the points where the straight lines IHI, IEI are cut.

[Margin: Another construction of the horizontal and vertical sundial.]

Furthermore, we shall construct both sundials by one and the same operation, even if the Foundation of sundials has not been separately built up, in this way. Draw two straight lines AB, CD cutting each other at E at right angles; at any point A — whether to the left or to the right — set up the angle of the pole's altitude EAC. From E, perpendicular to AC, draw EF; on the straight line AC, whether upward or downward, cut off FG equal to it, and join the straight line EG. Then, having described from G an arc of a circle of any size and radius, divide the portion of it lying between the straight lines GE, GC into three equal parts HL, LM, MI — a division that is very easy. For if, with the same opening of the compasses by which the arc of the circle was described, the arc IK is cut off, then the arc HK, beyond the straight line GF, will be a third part of the arc HI. For since the arc IK is a sixth part of the circle — by the corollary to [a] Proposition 15 of Book IV of Euclid — and the arc IH an eighth part, because the angle G at the center is half a right angle (for since the angle F is right, and the angles FGE, FEG are equal on account of the equal straight lines FE, FG, the angle G will be half a right angle), the arc IK will contain four parts, and IH three, and therefore HK one, of the kind of which the whole circumference of the circle contains 24.

Moreover, drawing from the center G, through the points of division L, M, hidden straight lines cutting EF at N, O, let there be drawn through N, O lines parallel to AC, cutting AE, CE at R, S, T, V; these parallels will be drawn without much labor as follows. At the interval of the straight line EF, or FG, describe from E and G two arcs intersecting each other at Z; the straight line GZ drawn [to it] will be parallel to EF, because, once the straight line EZ is drawn, FZ becomes a parallelogram — by the scholium to Proposition 34 of Book I of Euclid — since its opposite sides are equal. Onto this parallel GZ transfer the spaces FO, FN to the points Q, P. For the straight lines OQ, NP drawn [there] will be [b] parallel to FG, since they join the equal straight lines FO, GQ, and ON, QP, or FN, GP.

[Margin: a. *Elements* I.5] [Margin: b. *Elements* I.33]

Diagram. A combined construction figure for both sundials at once, labelled HORIZONTALE (upper right region) and VERTICALE (lower left region, the word set vertically). Two straight lines AB and CD cross at right angles at the central point E; the pole's-altitude angle is set at A. The construction shows the trisected arc and the parallels described in the text. Readable labels, with position:

- HORIZONTALE (heading, upper right); VERTICALE (label, set vertically on the left)
- A (top center); X (upper right corner); G (upper left); C (left, on the horizontal axis); E (center, intersection); D (right); 6 (left, below C, on the vertical line CE)
- Interior/construction points read on the tiles: F, I, M, L (a row on the left-center); N, O (between E and the left); Q, P (small parallelogram near top, with R); S, R, H, K (near center); Z (right of center); T, V (lower-left region); Y (bottom-left corner); B, E (bottom center/right)
- Rim hour-numerals read near the top-right: 12, 1, 2 (with a small point-mark, possibly σ , near A) [?]
- A second, smaller construction is drawn at the lower right, with its own points A, B, C, D, F, G and hour-marks 12, 1, 2

[?] Several interior labels in the crowded upper-center cluster (around Q, P, R, K, S, H) and the small mark beside A could not be resolved with certainty at this resolution; the second small figure at lower right partly overlaps the main one. (more than two labels flagged [?]).

[Margin: Demonstration of the immediately preceding construction.]

Now if on the straight line EF equal segments ED, EB are cut off, and into these the intervals EN, EO are transferred from E; likewise, if from D an arc is described at the interval AE, which is cut at X by another arc described from A at the interval ED; and also from B an arc is described at the interval CE, which is cut at Y by another arc described from C at the interval EB; and if through X, Y straight lines are drawn through the points of the straight lines [recte: rectarum] AE, ED; CE, EB — then we shall have the hours from noon or from midnight. Between the 12th hour, which both the straight line XD and YB give us, and the 6th hour, which both the straight line XA and YC present to us, [the hour-lines are laid out]: these are hours from noon if the straight line AC is drawn to the left of AB, but from midnight if to the right. The horizontal sundial will be AEDX, at the angle of the pole's altitude EAC; the vertical, however, will be CEBY, at the angle ECA of the complement of the pole's altitude.

Demonstration. The demonstration of this construction does not differ from the one above. For the parallels AC, RV, ST make up a portion of the Foundation of sundials, whose breadth is EF, and whose length is extended along the straight line AC — since the parallels drawn here [correspond], as the parallels BC, MO, LN did in the upper Foundation, because the straight line FG here is equal to the

breadth FE, just as there the straight line BE [was equal] to BA, and the arc IK is divided here just as the arc FG was there, as is plain: for the straight line GE here answers to EA there, and so on. Next, the rectangle AD of the horizontal sundial here laid out (for AD is a parallelogram, by the scholium to Proposition 34 of Book I of Euclid, since its opposite sides are equal; and consequently a rectangle, on account of the right angle E) represents the lower rectangle EH, to the left of the meridian line of the horizontal sundial constructed from the Foundation. For ED here is equal to the breadth EF, just as there IH [was equal] to the breadth AB; and here AE, set between the parallels, makes the angle of the pole's altitude CAE, just as there EI is equal to the straight line PT in the Foundation, which sets up the angle of the pole's altitude TPD.

The rectangle CB of the vertical sundial here constructed, on the other hand, expresses the lower rectangle EH, to the right of the meridian line of the vertical sundial drawn from the Foundation. For EB here is equal to the breadth EF, just as there IH [was equal] to the breadth AB; and CE, set between the parallels, here sets up the angle ECA of the complement of the pole's altitude, just as there EI is equal to the straight line PV in the Foundation, which makes the angle VPD of the complement of the pole's altitude. Finally, the straight lines ED, EA, and likewise EB, EC, are divided here just as there IH, IE were cut, in each sundial, and so on. Rightly, therefore, the hour-lines have here too been drawn. And if the straight lines ED, EB are doubled by being produced, and other rectangles are made equal to the rectangles AD, CB, onto whose sides the points of the straight lines ED, EA and EB, EC are transferred, and lines are produced from X, Y through the said points, the whole sundials will be complete.

The half-hours and the quarter-hours are drawn by the same technique, if the arcs HL, LM, MI are bisected and [divided] into four equal parts, and from G, through the points of division, hidden straight lines are sent out cutting EF at points through which other parallels are drawn. For these will cut the straight lines AE, CE at points through which the straight lines are to be drawn from the points X and Y for the half-hours and quarter-hours of the same, and so on.

Now, given the length of the style, we shall find its place in each sundial just laid out by the following method...

method. Let the right angle BAC be constructed, and at A let the angle CAD of the pole's altitude be set up; produce DA toward E, and at A raise to it the perpendicular AG. Now, taking — for the horizontal dial — the line AB equal to the given style, and drawing through B the perpendicular EF to AB, the style AB in the horizontal dial must stand off, along the meridian line XD, from the dial's

center X by as much as the line EB; and the equinoctial line must lie away from that same center X by as much as the line EF. This is because the triangle AEF, together with the perpendicular AB, is entirely similar to the triangle CBD, together with the perpendicular BA, in the horizontal dial constructed by the earlier method — since the angle AEF [Euclid I.29] equals the angle DAC of the pole's altitude, the interior to the exterior, because the lines EF and AC [Euclid I.28] are parallel, and so on.

Likewise for the vertical dial: taking the line AC equal to the given style, and drawing DG through C perpendicular to AC, the style AC in the vertical dial must stand off from the dial's center Y, along the meridian line YB, by as much as the line DC; and the equinoctial line must recede from that same center Y by as much as the line DG. For the triangle ADG, together with the perpendicular AC, is exactly similar to the triangle CBD, together with the perpendicular BA, in the vertical dial laid out by the earlier method — on account of the angle ADG, which is the complement of the angle DAC of the pole's altitude, and so on.

Once a vertical dial facing south has been drawn in this way, we may derive from it another one facing north, as we set out in the scholium to Proposition 13 of Book II of the *Gnomonics*. We simply invert all its parts, so that what was the upper part becomes the lower, and whatever, after this inversion (with us now turned to face the dial), had been placed on the right is shifted to the left, and vice versa — the hour-numbers themselves, however, remaining exactly the same. But then that portion of the meridian line which runs from the dial's center toward the equinoctial line, and which on the southern dial marks the 12th hour of noon, will on this northern dial signify the 12th hour of midnight; and what on the former belongs to the 12th hour of midnight will on this one point to the 12th hour of noon. Accordingly, the hours reckoned there from noon must here be counted from midnight, and those there from midnight, here from noon. All of this we demonstrated in the aforesaid scholium to Proposition 13 of Book II of the *Gnomonics*.

For the rest: horizontal dials, when the pole's altitude is less than 20 degrees, and vertical dials, when the same altitude exceeds 70 degrees, are awkwardly drawn by the earlier method — that is, from the foundation of the dials — unless the parallels of the dials' foundation are very narrow, as is plain. The reason is that in horizontal dials the line PT, which makes with AD the angle of the pole's altitude above the horizon, and in vertical dials the line PV, which makes with the same AD the angle of the complement of the pole's altitude above the horizon, then cut the parallels BC, MO, LN very obliquely, and so meet the line BC too far off, unless

the line AB is extremely small, so that the foundation of the dials becomes very narrow. By the later method, however, with which we constructed both dials — the horizontal and the vertical — at one and the same operation, this drawback is avoided, since the construction itself presents the parallels to us spaced a moderate distance apart, as is clearly evident from the next figure.

The first example of this chapter is a horizontal dial, and the second a vertical dial, both constructed for the latitude of the city of Rome, 42 degrees.

DIALS DECLINING FROM THE VERTICAL.

CHAPTER 5.

We call "declining from the vertical" those dials that stand upright to the horizon but are inclined to the vertical circle properly so called — and hence also to the meridian; the kind commonly drawn on the walls of buildings. Let there be proposed, then, a wall upright to the horizon but declining from the vertical, from south toward the east, by 30 degrees. Draw the line AB equal to the line AB in the foundation of the dials, and at B set up the angle of declination ABC; and to the line AB, from A, draw the perpendicular AC, cutting BC at C. Then, having set up at A, together with AC, the angle CAD of the pole's altitude, draw from C, perpendicular to AC, the line CD, cutting AD at D. Also produce AC to E so that AE is equal to AD, and draw the line EB; and finally at C erect, perpendicular to BC, the line CF equal to CD, and join the line BF.

[Margin: The finding of the common section of the plane declining from the vertical, and of the parallelepiped extended through the axis of the world.]

The angle BFC will be equal to the angle which the common section of the 6-o'clock-hour circle and the declining plane makes, in the declining plane, with the common section of the meridian and the declining plane. And the angle AEB will be equal to the angle which the common section of the 6-o'clock-hour circle and the declining plane makes with the common section of the meridian and the 6-o'clock-hour circle, in the plane of the 6-o'clock-hour circle — that is, in the upper or lower rectangular face of the parallelepiped, that is, in the plane of the dials' foundation — with the line AD or BC. In this business we take both the upper and the lower face of the parallelepiped for the 6-o'clock-hour circle, since each is equidistant from that circle; and we take both the eastern and the western face of the same parallelepiped for the meridian circle, since each is parallel to that circle.

[Margin: Demonstration of the aforesaid finding.]

For let AB be conceived as the common section of the foundation of the dials and of the vertical circle — namely, the same as the line AB itself in the foundation; and let the triangle ABC be turned about AB, upward, until it coincides with the horizon and is upright to the vertical. With this done, BC will be the common section of the horizon and the declining plane, on account of the angle of declination ABC; while AC will be the common section of the plane equidistant from the meridian — that is, of the western face in the parallelepiped — and of the horizon. For AB, the common section of the horizon and the upper face of the parallelepiped, is perpendicular [Euclid XI.19] to the western face (to which both of them are upright), and hence also to any line whatever drawn through A in the said western plane, by Definition 3 of Book XI of Euclid. Since, then, AC is drawn in the plane of the horizon perpendicular to AB, AC will be the common section of the horizon and the said western plane. For if there were another line in the horizon that was the common section of it and the said plane, then to it AB would be

drawn from A two perpendiculars to AB — and thus a part would be equal to the whole, which is absurd. If, then, the triangle ACD is understood to be turned about AC until it is equidistant from the meridian, the line AD will coincide with the line AD in the foundation, on account of the angle CAD of the pole's altitude which the plane of the foundation — that is, the upper face of the parallelepiped — makes with the horizon along the drawn line AC; and CD will be the common section of the declining plane and of the plane equidistant from the meridian, since both of these planes then pass along the line CD — namely, along their common section, which is perpendicular [Euclid XI.19] to the horizon (to which both planes are upright), and hence also perpendicular to the line AC, which lies in the plane equidistant from the meridian, by Definition 3 of Book XI of Euclid — such as CD is. Therefore, once the line BD is drawn, it will be the common section of the declining plane and of the 6-o'clock-hour circle (that is, of the foundation of the dials), since both these planes, in that position, pass through the points B and D lying in the plane of the foundation. And hence the angle BDC will be the one that BD — the common section of the declining plane and the 6-o'clock-hour circle (which the plane of the foundation, drawn along the line AD set in its proper position, represents) — makes with CD, the common section of the same declining plane and of the plane equidistant from the meridian; that is, the angle that the 6-o'clock line makes with the meridian line in the plane of the dial. The angle BDA, on the other hand, will be the one that the said BD — the common section of the declining plane and the 6-o'clock-hour circle — makes with AD, the

common section of the same 6-o'clock-hour circle and the plane equidistant from the meridian; that is, the angle that the common section of the foundation of the dials and the declining plane makes with the line AD, or BC, of the foundation.

Diagram. A large rectangular figure occupying most of the page: the construction and completed face of a vertical dial declining 30° (from south toward the east) for the latitude of Rome (42°). In the upper-left corner sits a small auxiliary "foundation" triangle; the main body of the frame is the dial face, with all hour-lines radiating from a single center and hour-numbers ranged around the border.

- A (top-left area of frame): apex/corner of the small auxiliary triangle
- B (top of frame, right of A): apex of the auxiliary triangle; a dotted (hidden) line runs from B down-left toward D
- F (upper-left, below A): vertex of the auxiliary triangle
- D (left, below F): vertex of the auxiliary triangle
- c (center of auxiliary triangle, lowercase): interior point
- E (below c): vertex of the auxiliary triangle
- C (center of the dial face): the common point from which all hour-lines radiate
- K (immediately left of C): construction point
- M (below-left of C, on the horizontal line): foot of KM
- L (below C): foot of KL
- N (below C, right of L): construction point on the meridian
- A, B (small labels near C): points of the style-line / axis construction (CA, CB)
- D (near center, below the ray-fan): equinoctial-line construction point
- H (upper-center, near the top hour-marks; and a second H at bottom-center): the two ends of the meridian line HCH
- I (several, at the vertices of the parallelogram IEIHIEIH around the fan): parallelogram vertices
- E (mid-right edge; also near center): points of the 6-o'clock line ECE
- Rim hour-numbers (border of the dial): Arabic numerals are legible along the right and lower edges — reading down the right edge: 8, 7, 6, 5, 4, 3, 2; along the top and lower-left edges further numerals appear (9, 10, and Roman-form marks read as "II" and "III", with a "12" set as "I2") but most of these small border numerals are worn/too small to resolve individually and are left [?]
- P (lower-left, on the dashed baseline): construction point
- O (center of the dashed baseline at the foot): construction point

- A small circle mark ("o") floats just above the top edge of the frame
[unclear — possibly a figure/registration mark] [?]

[The hour-number ring is only partially legible; the individual border numerals]

the declining plane and the 6-o'clock-hour circle with AD, the common section of the same 6-o'clock-hour circle and the plane equidistant from the meridian; that is, the angle that the common section of the foundation of the dials and the declining plane makes with the line AD, or BC, of the foundation.

Furthermore, the line BD is equal to each of BF and BE; and the angle BDC equals the angle BFC, and the angle BDA equals the angle BEA. For since the two sides BC, CD of triangle BCD are equal to the two sides BC, CF of triangle BCF, and contain right angles (since CD, in its proper position, is perpendicular to the horizon, as we showed above, and hence also to the line BC lying in the horizon), the bases BD, BF and the angles BDC, BFC will also be equal to one another [Euclid I.4]. Likewise, since the two sides BA, AD are equal to the two sides BA, AE, and contain right angles (since BA, the common section of the horizon and the 6-o'clock-hour circle, is perpendicular [Euclid XI.19] to the triangle ACD, which is parallel to the meridian, and hence also to the line AD), the bases BD, BE and the angles BDA, BEA will also be equal [Euclid I.4].

And therefore, if the interval BE or BF (since BE and BF, having been shown equal to BD, are equal to each other) is carried by compass from z, in the foundation of the dials, out to a, then the drawn line z-a will be the common section of the declining plane and the 6-o'clock-hour circle — that is, of the foundation of the dials — inasmuch as it makes in the foundation the angle a-z-D, or z-a-B, equal to the angle BEA of this figure. For, when z-b is drawn perpendicular to BC — which will be equal to AB [Euclid I.34] — since the triangles a-b-z and E-A-B have the angles b and A equal, namely right angles, and the sides about the angles z and B proportional (since those sides are equal to these), and since the remaining angles b-a-z and BEA are each less than a right angle [Euclid I.17], the angles b-a-z and BEA will be equal [Euclid I.7], and so on.

[Margin: Construction of the dial declining from the vertical.]

Now, in the plane of the dial, having fixed the place of the style at A and its length AK, draw through A the line MN — in any position — to serve as the horizontal line (on a wall it must be drawn parallel to the horizon with the help of a plumb-line), to which the style AK is erected at right angles. Then, having set up to the right of the style the angle AKL of the declination of the proposed plane, and to the left the angle AKM of the complement of the declination, so that the angle

LKM is a right angle — (when, however, the plane declines from south toward the west, the former angle must be set to the left and the latter to the right) — and having the lines KL, KM cut the horizontal line at L and M, the line HLH, making right angles at L with MN, will be the meridian line; and through M must be drawn both the 6-o'clock-hour line and the equinoctial line. Moreover, having cut off the line LN equal to LK, set up at N the angle LNC of the pole's altitude, and let the line NC cut the meridian line at C. C will be the center of the dial; and the line drawn CM will give the 6th hour — all of which we demonstrated in the scholium to Proposition 1 of Book III of our *Gnomonics*. And the line CM will make with the meridian line the angle MCL equal to the angle BFC, which we showed above to be formed by the common section of the declining plane and the 6-o'clock-hour circle together with the common section of the same declining plane and the plane equidistant from the meridian — that is, by the 6-o'clock line and the meridian line in the plane of the dial. And the line drawn CA will be the style-line, as we demonstrated in the same scholium to Proposition 1 of Book III of our *Gnomonics*.

But so that, because of the closeness of the points C and A, no error is made in drawing the style-line CA (for it can easily be deflected one way or the other unless the greatest care is used), we shall use this device. On the line CH, downward, mark off with the compass any number of parts equal to CL (here five are taken), as far as O. Then, drawing OP perpendicular to CO, mark off on it as many parts equal to LA, up to P, as there are parts equal to CL contained in CO. For the line CA, when extended, must pass through the point P, as is clear from the scholium to Proposition 4 of Book VI of Euclid, since CL is to CO in the same proportion as LA is to OP. And so the style-line will be drawn more accurately through the three points C, A, P [the printed sort reads "B"; P is required — the line is named CP just below] than through the two points C, A alone. To the style-line CP as well, once the perpendicular AB (equal to the style AK) is drawn on either side, the line CB, when drawn, will be the axis of the world. If from B a perpendicular BD is drawn to this axis, cutting the style-line CB at D, then the line projected through M and D will give the equinoctial line, which will be exactly perpendicular to CP, provided no error has been made in the operation. And the angle DCB will be the angle of the pole's altitude above the proposed declining plane, as we showed in the same scholium to Proposition 1 of Book III of the *Gnomonics*. But if from N a perpendicular NR is erected to CN, this too will cut the meridian line at the point R, through which the equinoctial line must be drawn — as we also showed in the same place.

After this, from the 6-o'clock line ECE cut off on each side the line CE equal to the line a–z of the foundation of the dials; and from the meridian line HCH cut off, both upward and downward, the line CH equal to the line PV of the same foundation. From the points E, upward and downward, describe with radius CH four arcs, which are cut at I by another four described from the points H with radius CE; and join the two lines IEI and the two lines IHI, which will pass through the points E and H. And if the intervals of the line a–z in the foundation, intercepted between the point a and the parallels MO, LN, are transferred in the dial from the points H, on either side, onto the lines HI; and the intervals of the line PV in the same foundation, set between P and the parallels, are transferred in the dial from the points I onto the lines IE — then the lines drawn out through the center C of the dial and the points on the sides of the parallelogram IEIHIEIH, each passing through three points, will give the hours from noon and from midnight, whose order is the same as in the vertical dial, since the dial faces south. But if the dial faces north, the order of the hours will be the same as in the horizontal dial.

[Margin: Demonstration of the above construction.]

The demonstration of this construction is as follows. The common section of the plane of the dial and of the parallelepiped is a parallelogram, because the sections made by the plane of the dial in the opposite and parallel faces of the parallelepiped are parallel [Euclid XI.16]. Two of its sides — in the upper and the lower face of the parallelepiped — are the two lines IHI in the dial, since they are double the line a–z in the foundation, or BF, that is, of BD in this chapter's figure — namely, the common section of the plane of the dial and of the upper or lower face of the parallelepiped. And they make with the meridian line angles equal to the angle MCL, which the 6-o'clock line makes with the meridian line in the dial, and which we said is equal to the angle BFC — that is, to BDC — which BD, the common section of the foundation of the dial and of the upper or lower face of the parallelepiped, forms with CD, the common section of the same plane of the dial and of the meridian. It is clear from the construction that the line a–z of the foundation is equal to the line BD, or BF, of the figure constructed at the beginning of this chapter; and this BD is half of the whole common section of the upper (or lower) face of the parallelepiped and the plane of the dial. The other two sides, in the eastern and the western face of the parallelepiped, are the two lines IEI, since they are double the line PV of the foundation and are equidistant from the meridian line, just as in a vertical dial. For all vertical circles, to one of which the plane of the dial is equidistant, cut the parallelepiped in the same way in the eastern and the western face, since they are upright to the horizon; that is,

all vertical circles declining from the prime vertical make, in the eastern or western face of the parallelepiped, sections equal and parallel to the line PV of the foundation, by Proposition 18 of Book I of our *Gnomonics* — and this PV is half of the whole section generated in the entire eastern or western face. Since, then, I say, the section made in the parallelepiped by the plane of the dial is the parallelogram IEIHIEIH, the hour-lines will pass through the points on the sides of the said parallelogram, because those sides are divided just as the lines a–z and PV in the foundation of the dials, and so on.

For the rest: when the wall's declination exceeds 70 degrees, this method of laying out the hours is inconvenient, because the meridian line then lies too far from the place of the style, and the dial's center too far from the horizontal line — even though the meridian bisects the parallelogram formed in the parallelepiped, and the center C lies at its middle: just as the same thing happens, as we noted in Chapter 4, in horizontal dials, when

the elevation of the pole is less than 20 degrees; and in vertical dials, when the elevation of the pole is greater than 70 degrees — because the center of the dial then lies too far from the equinoctial line, as we taught in the scholium to Propositions 1 and 13 of Book II, and in the scholium to Proposition 1 of Book III of the *Gnomonics*. Even so, the layout will come out somewhat more conveniently in that case if the parallels in the foundation of the dials are made narrower — that is, if the side AB is made very small.

But suppose that the space in which the dial is to be constructed is not large enough for the whole parallelogram IEIHIEIH to be drawn in it. Then it will be enough to draw either its lower or upper half, EIHIEC, or else its left or right half, IEIHCH. For the lines drawn out through the points on the sides of that half, and through the center C, will yield the complete dial, even though the individual hour-lines are each drawn through only two points. This is to be understood of the other dials as well.

Diagram. A large declining sundial (the completed dial for the worked example of the preceding chapter, at the latitude of Rome, 42°). It is a rectangular plate enclosed by a heavy border. From the dial's center, C, a full fan of hour-lines radiates out to hour-points marked around the rim; along the bottom edge runs a divided scale (the equinoctial / style scale) drawn as a dashed line ruled with cross-tick divisions and terminating at the corner points P (bottom left) and O (bottom right). In the upper-left region of the plate sits the small style-and-foundation figure. The hour-numbers 1 through 12 appear around the perimeter

in two sets (morning and afternoon); several of these small rim numerals are worn and cannot all be read with confidence.

Readable labels:

- A (upper interior, apex of the small foundation triangle, left): label A
- B (upper interior, apex of the small foundation triangle, right): label B
- F (below and left of A): label F
- D (left, on the small triangle): label D
- C (center of the small foundation triangle, small type "c"): label C
- E (below the small triangle's center): label E
- I (below E): label I
- C (center of the whole dial, from which the hour-lines radiate): label C
- K (just left of the dial center): label K
- L (just right of and below the dial center): label L
- M (lower-left of the dial center, on a horizontal line): label M
- N (right of L): label N
- A (below L): label A
- D (below that A): label D
- E (on the lower-left, and again on the right rim): label E
- H (lower interior, twice): label H
- P (bottom-left corner of the base scale): label P
- O (bottom-right corner of the base scale): label O
- Rim hour-numbers legible in places: on the upper/right side "10", "9", "11", "8", "7", "6", "5", "4", "3", "2"; along the bottom and lower-left "1", "12", "11", "10", "9", "8" [several rim numerals worn — not fully resolved; not pattern-filled]

[The many small radiating hour-lines and rim numerals of this dial-face are marked as a; more than two rim labels could not be resolved with confidence.]

By what further method a dial facing north is derived from one facing south (toward the meridian), we have taught in the scholium to Proposition 1 of Book III of the *Gnomonics*.

Dials Declining from the Horizon

CAPVT VI.

The dials we have described up to now are in more frequent use than those that follow — namely those Declining from the Horizon, those Inclined to the Horizon, and those Declining from the Vertical while at the same time

inclined to the Horizon. For this reason we shall not describe these last fully, but shall only investigate their sections with the parallelepiped, or foundation, of the dials, so that in their planes we may set up parallelograms like the parallelogram IEIHIEIH of the dials treated above, and so on.

By "dials declining from the horizon" we mean those that stand upright to the prime vertical, but are inclined to the horizon — and therefore also to the meridian.

[Margin: Finding the sections of the plane declining from the horizon, and of the parallelepiped passed through by the meridian [?] axis. — Latin *per meridianum axem traiectionis*; the parallel note on the facing page reads *per axem mundi extensi*, "through the axis of the world."]

Let there then be a plane declining from the horizon by 30 degrees, whether it face east or west. Draw the line AB, which is to be equal to the line AB in the foundation of the dials; at A construct the angle of declination from the horizon, BAC, and from B erect BC perpendicular to AB, cutting AC in C. Then at B, with BC, construct the angle CBD equal to the complement of the pole's altitude, and from C draw CD perpendicular to BC, cutting BD in D. Extend BC also to E, so that BE is equal to BD, and draw the line AE. Finally, at C erect CF perpendicular to AC and equal to CD, and join the line AF.

The angle AFC will be equal to the angle that the common section of the hour-6 circle [the 6-o'clock circle] and of the plane declining from the horizon makes with the common section of the meridian and of that same declining plane — that is, the angle that the hour-6 line makes with the meridian line in the plane of the dial, or in the declining plane. And the angle AEB will be equal to the angle that the common section of the hour-6 circle and of the plane declining from the horizon makes with the common section of the meridian and of the hour-6 circle, in the plane of the hour-6 circle — that is, in the plane of the foundation of the dials — with the line AD, or BC.

Diagram. The plane construction described in the text. A is the upper-left apex, B the upper-right apex; the line AB runs across the top. From A the lines AC, AE, and AF descend; a dotted line runs from A toward D. C lies at the center, D on the right (with the segment CD, and BD reaching down to D), E is below C, and F is at the bottom, joined to A and C. All six labels — A, B, C, D, E, F — are legibly printed.

[Margin: Demonstration of the preceding construction.]

For conceive AB, the common section of the foundation of the dials and of the horizon — which is one and the same as the AB in the foundation — and let the triangle ABC be turned about AB, downward, until it coincides with the vertical plane and lies flat upon the horizon. This done, AC will be the common section of the vertical and of the declining plane, the one that faces east; while BC will be the common section of the plane parallel to the meridian — that is, of the eastern plane in the parallelepiped — and of the vertical.

If, then, the triangle BCD is understood to be turned about BC, toward us, until BD is parallel to the meridian, BD will coincide with BC in the foundation, on account of the angle CBD, the complement of the pole's altitude, which the plane of the foundation — that is, the upper plane of the parallelepiped — makes with the vertical drawn through BC. And CD will be the common section of the declining plane and of the plane parallel to the meridian, since both of these planes then run along the line CD — namely along their common section, which stands perpendicular to the vertical (to which both planes are upright) (Euclid XI.19), and therefore also to the line BC lying in the plane parallel to the meridian, by definition 3 of Book XI of Euclid — such as CD is, by the construction.

Draw, then, the line AD: it will be the common section of the declining plane and of the hour-6 circle (that is, of the foundation of the dials), since both these planes, in that position, pass through the points A and D lying in the plane of the foundation. And therefore the angle ADC will be the one that AD — the common section of the declining plane and of the hour-6 circle (which the plane of the foundation, drawn through BD, represents) — makes with CD, the common section of that same declining plane and of the plane parallel to the meridian; that is, the angle that the hour-6 line makes with the meridian line in the dial. And the angle ADB will be the one that the said AD, the common section of the declining plane and of the hour-6 circle, makes with BD, the common section of that same hour-6 circle and of the plane parallel to the meridian — that is, with the side of the foundation BC, or AD.

Now the line AD is equal to each of AF and AE, and the angle ADC equal to the angle AFC, and the angle ADB equal to the angle AEB. For since the two sides AC, CD of the triangle ACD are equal to the two sides AC, CF of the triangle ACF, and contain right angles (since CD, in its proper position, is perpendicular to the vertical, as we showed above, and therefore also to the line AC lying in the vertical), the bases AD, AF and the angles ADC, AFC will also be equal to one another (Euclid I.4). Likewise, since the two sides AB, BD are equal to the two

sides AB, BE, and contain right angles (since AB, the common section of the vertical and of the hour-6 circle, is perpendicular to the triangle BCD, which is parallel to the meridian, and therefore also to the line BD) (Euclid XI.19), the bases AD, AE and the angles ADB, AEB will also be equal to one another (Euclid I.4).

Therefore, if the interval AE, or AF (since AE and AF have been shown equal to AD and so are equal to one another) be carried by the compass from c, in the foundation of the dials, as far as d, the line cd, once drawn, will be the common section of the declining plane and of the hour-6 circle. This will be proved just as it was shown in the preceding chapter that the line a–z is the common section of the plane declining from the vertical and of the hour-6 circle.

[Margin: The drawing of a dial declining from the horizon.]

Now, in the plane of the dial, with the place of the style given and its length, if — following what we wrote in the scholium to Proposition 13 of Book III of the *Gnomonics* — the meridian line, the equinoctial line, and the hour-6 line be drawn: then let there be cut off from the hour-6 line, on either side of the dial's center, a segment equal to the cd of the foundation of the dials; and from the meridian line, both upward and downward, let there be cut off a segment equal to the PT of that same foundation; and let the parallelogram IEIHIEIH be completed, as in the preceding chapter. Onto the sides of this parallelogram let the segments parallel to the hour-6 line be transferred — beginning from the meridian line, on either side the intervals of the line dc of the foundation, starting from the point d [recte: the print reads *puncto*] — and onto the sides parallel to the meridian line, beginning at the angles I, let the intervals of the line PT of the foundation be transferred, starting from P. The hour-lines will then be drawn, each through its three points, as in the preceding dials.

For a plane declining from the horizon produces, in the eastern or western plane of the parallelepiped, a section parallel to the one that the horizon produces in that same plane — namely a section parallel to the meridian line and making with the line AD the angle of the pole's altitude, such as is the angle TPD; just as

a plane declining from the vertical produces, in the same plane of the parallelepiped, a section parallel to the one that the vertical produces in it, as we said in the preceding chapter — namely a section making with the line AD the angle of the complement of the pole's altitude, such as is the angle VPD, and so on.

Dials Inclined to the Horizon

CAPVT VII.

[Margin: The drawing of a dial inclined to the horizon.]

To lay out a dial inclined to the horizon, one must first find the elevation of the pole above the plane of the dial, as we taught in Proposition 25 of Book III of the *Gnomonics*. Then, for that elevation, a horizontal dial is to be drawn, as we prescribed in Chapter 4; for this plane is like a horizon of a sort. The ordering of the hours is to be taken from the precepts of Proposition 25 of Book III of the *Gnomonics*, where we have written out fully everything necessary for this matter — which there is no need to repeat here.

Dials Declining from the Vertical, and at the Same Time Inclined to the Horizon

CAPVT VIII.

So that this whole matter may be explained more clearly, we shall take all six of those planes that decline from the vertical and are at the same time inclined to the horizon, for which we described dials in Proposition 37 of Book III of the *Gnomonics*. In these the whole range of variety seems to be contained.

- The **first** declines from south toward east by 40 degrees, and is inclined to the horizon on the north side by 20 degrees.
- The **second** has a declination of 20 degrees from south toward west, and an inclination to the horizon on the north (boreal) side of 70 degrees.
- The **third** has a declination of 45 degrees from south toward east, and an inclination to the horizon on the north side of 51 degrees 51 minutes.
- The **fourth** deflects from north toward west by 20 degrees, and its inclination to the horizon on the south side comprehends 30 degrees.
- The **fifth** declines by 60 degrees from north toward east, and has an inclination to the horizon of 80 degrees on the south (austral) side.
- The **sixth**, finally, has a declination from north toward east of 30 degrees, and an inclination to the horizon on the south (austral) side of 52 degrees 3 minutes.

So that the same letters may be kept in all the figures, we shall assume that in the first three the declination is always from south toward east, and in the last three from north toward west. For the parallelepiped is cut in the same way by two planes having the same inclination to the horizon, one of which declines from

south toward east by as many degrees as the other deflects from south toward west. You will say the same of two planes that have the same inclination to the horizon but decline toward different sides from the north — as is evident, and as can be plainly gathered from what we shall demonstrate here.

Diagram, first figure ("I. fig."). The construction of the section for a plane declining from the vertical and inclined to the horizon (case for a plane inclined toward the north). A network of solid and dotted lines meeting at the interior point A. Labels read: K at the top, with H and I descending below it; G at the left (dotted); E near the center; F at the left; A at the center; B at the far right; D lower center; C at the bottom vertex. All labels legible.

Diagram, second figure ("2. fig."). The corresponding construction for the second case (plane inclined toward the horizon on the south side), drawn largely with dotted lines. Labels read: K at the top; G at the upper left (dotted) and again G at the lower right (dotted); F at the left (dotted); A at the center; E at the upper right; B at the right; C and D just below and right of A; H at the bottom; and a lowest label near the foot that could not be resolved with confidence [?].

Draw, then, the line AB — which is to be equal to the line AB in the foundation of the dials (only in the fifth figure is it taken smaller, so as to fit it into a narrower space) — and at B construct the angle of declination ABC; from A draw AC perpendicular to AB, cutting BC in C. Then, having again drawn from A the perpendicular AD to BC, construct at D the angle of inclination to the horizon, ADE, and from A erect AE perpendicular to AD, cutting DE in E; from this, on BA produced, cut off AF equal to it, and join the line CF.

Next, in the first three figures — in which the plane is taken to be inclined toward the north — let the angle FAG, the complement of the pole's altitude, be made upward; but in the last three figures — in which the plane is taken to be inclined to the horizon toward the south — let the same angle FAG, the complement of the pole's altitude, be made downward. And if the line CF, produced beyond F, meets AG, as in the first figure, cut off from CA toward A a segment AH equal to AG produced; but if CF, produced below C, meets AG, as in the second figure, or if the line CF cuts the line AG, as in the three later figures, then cut off from AC toward C — produced if need be — the line AH equal to AG, and join the line BH.

Finally, on AC take AI equal to AF (or to AE), join the line BI, and from B, with radius BH, describe an arc of a circle; let another arc, described from I with radius FG, cut it in K; and join the lines BK, IK. The angle BKI will be equal to the angle that the common section of the hour-6 circle and of the declining-and-

inclined plane makes with the common section of the meridian and of that same declining-and-inclined plane — that is, the angle that the hour-6 line makes with the meridian line in the plane of the dial, or in the declining-and-inclined plane.

The angle BHA, in turn, will be equal to the angle that the common section of the hour-6 circle and the declining-and-inclined plane makes — in the plane of the hour-6 circle, that is, in the upper or lower plane of the parallelepiped, that is, in the plane of the foundation of the dials — with the common section of the meridian and the hour-6 circle, namely with the line AD or BC. And finally the angle ACF will be equal to the angle that the common section of the meridian circle and the declining-and-inclined plane makes — in the plane of the meridian circle, that is, in the eastern or western plane of the parallelepiped, that is, in the plane of the foundation of the dials — with the common section of the meridian and the hour-6 circle, namely with the line AD or BC.

But whenever the lines CF and AG do not meet — even when produced to infinity — yet are parallel, as happens in the third figure, then the declining-and-inclined plane is parallel to the axis of the world. Consequently it will make, in the planes of the parallelepiped, or in the foundation of the dials, sections parallel to the lines AD, BC and the other parallels. In that case the dial is more conveniently constructed by the method we set out in the third figure of the scholium to Proposition 37 of Book 3 of the *Gnomonics*.

[Margin: Demonstratio praecedentis inuentionis — Demonstration of the preceding construction.]

For let AB be understood as the common section of the foundation of the dials and of the horizon (or of the vertical) — namely the same AB as in the foundation — except that for the fifth figure one must conceive the foundation to have been constructed of a smaller width, precisely as great as the line AB of that figure. And let the triangle ABC, together with the line AD, be imagined to be revolved about AB, upward, until it coincides with the horizon. Then let the triangle ADE be conceived to be revolved about AD — in the first three figures, that is, in the planes inclined toward the north, upward; but in the last three figures, that is, in the planes inclined toward the south, downward — until it stands perpendicular to the horizon, that is, to the triangle ABC. Consequently EA too will be perpendicular to the horizon, by Definition 4 of Book 11 of Euclid, since it is perpendicular to AD, the common section of the horizon and of the triangle ADE.

Likewise let the triangle ACF, together with the line AG, be understood to be revolved about AC, toward the same side to which ADE was moved, until it stands

perpendicular to the horizon. Consequently FA too will be perpendicular to the horizon, by Definition 4 of Book 11 of Euclid, since it is perpendicular to AC, the common section of the horizon and of the triangle ACF. And therefore the line FA will coincide with the line EA, and the point F with the point E, because of the equality of the lines AE and AF. Likewise the line AG will coincide with the side AD in the foundation, because of the angle FAG — the complement of the pole's altitude — which the line FA (perpendicular to the horizon in that position, and through which the vertical is drawn) forms with the said side. And therefore the point G will fall on the point H, because the lines AG and AH are equal.

For this reason, since in that position the proposed plane passes through the line BC — lying in the horizon because of the angle of declination ABC — and through the line DE, because of the angle of inclination ADE, that is, through the points B and C (of which the former lies in the horizon and in the foundation, the latter only in the horizon), and through the point E, or F (for we showed that the points E and F coincide), the same plane will pass through the line CF, and therefore will meet the side AD in the foundation at the point G, or H, since we have shown that these two points coincide.

The proposed plane, then, cuts the foundation of the dials along the line BH; and so the angle BHA — formed by the common section of the proposed plane and the hour-6 circle, which is BH, and by the common section of the meridian and the hour-6 circle, which is AD in the foundation — is produced in the very plane of the foundation. Again, since in the same position the proposed plane runs along the line CF, which lies in the eastern or western plane of the parallelepiped, and meets the side AD in the foundation at the point G or H, the common section of the proposed plane and of the eastern or western plane of the parallelepiped will form, with the side AD of the foundation, an angle equal to the angle AGF: namely the angle vertical to AGF, in the planes inclined toward the north, as in the first and second figures; but in the other planes, inclined toward the south, the very angle AGF itself, as in the last three figures.

Finally, since in the same position still the line GF is the common section of the proposed plane and of the meridian (or of the eastern or western plane in the parallelepiped), and since the point G coincides with the point H, as we said, the lines BH and GF will then contain the angle that, in the plane of the dial, the hour-6 line — namely BH — makes with the meridian line, to which GF is parallel in that position.

That the angle BKI is equal to this angle we shall demonstrate as follows. Consider the triangle contained by the three lines BH, GF (the point G being placed at H in
