Translator Version 2

Upright reason dictates that the recipients of the good, of whatever type and level of beneficence it may be, must show gratitude and blessing to the beneficent person in every way possible, commensurate with the value of the beneficence. And one who has benefited all the people of the world — for example, one who invented a new instrument for the good of the world, or a good book — it is fitting for every discerning person, out of the obligation of love of fellow beings, to at least purchase it, so that the man will profit and his heart will be encouraged thereby to invent yet more good instruments in the world. And similarly, all other wise-hearted people will likewise strive and exert themselves to invent good things and instruments needed for the repair of the world and its perfection.

And therefore, whoever says: "What do I need this new instrument for?" — he does not act well towards the world. For if not for the man who invented it, where would you be? And what would your city do? And more than this, if the man did not exert himself, what would the world do?

— R. Pinchas Eliyahu Hurwitz, *Sefer HaBris HaShalem* (1797)

A note on the work

The *New Almagest* (Bologna, 1651) is the great Jesuit encyclopedia of seventeenth-century astronomy, by Giovanni Battista Riccioli (1598–1671). This second part, Books VIII–X, turns from the individual heavens to the shape of the whole: comets and new stars, the systems of the world, and a book of practical astronomical problems. Its centre is Book IX, where Riccioli lays out 126 arguments for and against the Earth's motion — the fullest case ever made against Copernicus, set out fairly enough that both sides read it. The first part, with the Sun, Moon, stars and planets and the famous Moon-map, is a separate volume.

A note on the translation process

This translation was produced with the translation-pipeline. See the linked repository for details on the process.

A note on the references. A scriptural or bibliographic reference given in brackets or parentheses is, in most cases, an **editorial identification of an allusion rather than a citation printed in the source**. Books of this kind quote and weave scripture constantly without naming it, and the identification is supplied here as a convenience to the reader. Where the source does print a reference of its own, it is given as printed. **An identified allusion is not evidence that the author cited that passage —** look at the original before resting an argument on one.

This text is the product of a highly refined automated translation process. It has undergone only cursory human review and should not be treated as an authoritative or scholarly rendering. It is offered solely as a reference and reading aid — a way to make an otherwise inaccessible work approachable — and any passage of real consequence should be checked against the original source.

Acknowledgements

Translated with the assistance of Claude. The translator thanks the Anthropic team for making this work possible.

Notation and abbreviations

A few conventions have been applied uniformly throughout this translation, so that one quantity is always written one way. They change how a value is *written*, never what it is; where the printed source and this translation differ in notation, the source's own form is recorded in the editorial apparatus.

Numerals are Arabic, even where the source sets Roman ones. Roman numerals are kept only in headings, running headers and signatures, which are transcribed as printed.

Dates are given as year, month, day — *1572 November 11*. Dates are Julian, as the source gives them, and have not been converted to the Gregorian calendar.

Times are written with raised unit letters: $7^{h}\ 36^{m}\ 12^{s}$ for seven hours, thirty-six minutes and twelve seconds. An interval longer than a day carries a raised d — $3^{d}\ 7^{h}$. The degree and minute signs below are never used for time.

Angles are written with the conventional signs — 23° 27′ 30″. Early modern astronomy divides the degree sexagesimally and often runs to places for which modern writing has no common symbol; the orders used in this book are:

sign	order	the source's term
°	degrees	*partes*, *gradus*
′	minutes of arc	*scrupula prima*, *minuta*
″	seconds of arc	*scrupula secunda*
‴	thirds	*scrupula tertia*
⁗	fourths	*scrupula quarta*

A **sign** is 30° — one twelfth of the circle — and is written with a raised s: 5^{s} 3° 57′ is five signs and 3° 57′, that is 153° 57′. The source uses the sign both as a place in the zodiac and as a plain unit of 30° for a motion or a distance, and this translation keeps that distinction by writing the count rather than naming a constellation.

The signs of the zodiac. Longitude is reckoned eastward from the first point of Aries.

	Latin	English	longitude
♈	Aries	the Ram	0°–30°
♉	Taurus	the Bull	30°–60°
♊	Gemini	the Twins	60°–90°
♋	Cancer	the Crab	90°–120°
♌	Leo	the Lion	120°–150°
♍	Virgo	the Virgin	150°–180°
♎	Libra	the Scales	180°–210°
♏	Scorpius	the Scorpion	210°–240°
♐	Sagittarius	the Archer	240°–270°
♑	Capricornus	the Goat	270°–300°
♒	Aquarius	the Water-bearer	300°–330°

	Latin	English	longitude
♓	Pisces	the Fishes	330°–360°

The Sun, Moon and planets.

	Latin	English
☉	Sol	the Sun
☽	Luna	the Moon
☿	Mercurius	Mercury
♀	Venus	Venus
♂	Mars	Mars
♃	Iuppiter	Jupiter
♄	Saturnus	Saturn

Abbreviations used in table headings: **Lat.** latitude; **Decl.** declination; **RA** right ascension; **Alt.** altitude.

Where a table in the source spreads one quantity across separate columns for degrees, minutes and seconds, those columns have been joined into a single column and the value written whole. Where a value runs to thirds and beyond, the columns are kept, since there the columns are the notation.

[Front cover of the binding: mottled brown calf, no text.]

[Front pastedown of the binding; no printed matter. A modern pencil note at the head reads "1529 (Rar)", with a pencil stroke running along or through it — a library mark.]

[Front free endleaf of the binding; no printed matter. A modern pencil note at the head, upper right, reads "Rar 947I:1/2 fol." — the library shelfmark.]

Diagram. Engraved frontispiece filling the page within a ruled border; no letterpress. At top centre a hand issues from drapery at the upper right and points to the left; above it stands a Hebrew word, and its three extended fingers carry one word each. Rays fan downward from the hand across the upper half of the plate. In the upper left, putti fly beside a banderole: one carries a globe with the sign ♂ beside it, another a partly shaded sphere with ♀, a youthful face looks out between them, a rayed Sun with a face shines below, and a lower putto holds a shaded disc above the sign ☿. In the upper right, against a dark star-strewn sky, putti carry a body with handles marked ♄, a banded globe in a ring of small stars marked ♃, and a cratered, half-dark Moon; comets streak below them. A second banderole runs across this group. Two inscriptions run along the rays. In the middle ground, on the left, stands a figure whose body is covered with eyes, holding a telescope and pointing upward; on the right a winged woman in a star-strewn robe, with a zodiac belt on which ♏ is legible, holds up a balance by its beam and carries an armillary sphere on her other arm. The beam carries an inscription. The left pan of the balance, riding higher, holds a disc of orbits with the Sun at its centre. The right pan, hanging lower, holds a disc on which a small globe sits at the centre of one circle, with ☾ on that circle, while a Sun with a face stands on a second circle and is itself ringed by smaller circles bearing ♀ and a further sign, with ♂ to the left. Below, an elderly bearded man in a mantle reclines against a cartouche, with an inscription beside his head and his name on the cartouche; the shield in that cartouche shows a star-marked sphere and a globe. At the centre stands a crowned cartouche with a lozengy shield. At lower right a disc of concentric circles lies on the ground, with a small globe at its centre and the signs ♀, ♃ and ♄ near its rim, ☾ on an inner circle and ♂ at the right. The engraver's signature is at lower left inside the border. Below the plate is an oval library stamp.

- Top centre, above the hand: ידך [Hebrew: yadkha, "your hand"] [?]
- On the three fingers: *Numerus*, *Mensura*, *Pondus* — "Number", "Measure", "Weight"
- Banderole, upper left: *Dies diei eructat uerbum* — "Day pours out speech to day"
- Banderole, upper right: *Et Nox nocti indicat scientiam* — "And night shows knowledge to night"
- Ray descending to the left: *Videbo Cælos tuos, opera digitor tuor* — "I shall see your heavens, the works of your fingers"
- Ray descending to the right: *Non Inclinabitur in Sæculum Sæculi* — "It shall not be tilted for ever and ever"

- Along the beam of the balance: *Ponderibus librata suis* — "Balanced by its own weights"
- Beside the reclining man's head: *Erigor dum Corrigor* — "I am raised up while I am corrected"
- On the cartouche beneath his hand: *Cl. Ptolem.* — Claudius Ptolemy
- Lower left, inside the border: *F. Curtus Bon. Incid.* — "F. Curtus [Francesco Curti] of Bologna engraved it"
- Planetary signs on the plate: ♂, ♀, ☿, ♄, ♃, ☾; the sign on each smaller body of the two balance discs and the ground disc is not resolved body by body [?]
- Library stamp below the plate (blue oval): EIDG. POLYTECH[…] […]HULE / […]BIBLIOTHEK [?]; the central device is not read.

[Manuscript, in pencil, upper left: 1529 (Rar)]

AD MAGNANIMVM PRINCIPEM HONORATVM II.

To the Magnanimous Prince Honoré II

Prince of Monaco, Duke of Valentinois, Peer of France, Marquis of Baux, Count of Carladès, Baron of Buis and of Calvinet, Lord of Saint-Rémy, etc.

ALMAGESTI NOVI PARS POSTERIOR TOMI PRIMI.

The Later Part of the First Tome of the New Almagest.

Diagram. An engraved armorial plate, within a plate-mark, beneath the title. A shield of lozenges (fusily) stands at the centre, surmounted by a crown and above it a crowned helm topped with a fleur-de-lis between a plume and a sprig of foliage; heavy acanthus mantling spreads to either side over an ermine-spotted mantle. Two bearded, long-robed figures stand as supporters, one on each side, each raising a sword in his outer hand. A collar of linked chain with scallop shells hangs around the shield, with a small oval medallion and a pendant cross below it at the foot.

- Band of the crown above the shield: a small capital legend, [DEO IVVANTE?] ("with God's help") [?]

Labels read: none securely. Labels not read: the crown-band legend, offered only as a conjecture.

MAGNANIMO PRINCIPI HONORATO II. MONOECI SVPREMO &c.

To the Magnanimous Prince Honoré II, Sovereign of Monaco, etc.

I imagine you were astonished, Magnanimous Prince, that Claudius Ptolemy, risen to life again from a sepulchral pyramid of Egypt, flew from Alexandria into the harbour of Monaco in an unforeseen landing; that soon, having cast the anchors of the deepest trust, he went ashore by stealth; that he eluded the most watchful eyes of your watchtower; and that, not by a creeping climb but by a sudden leap, he made his way up to the height of the Citadel of Monaco, and so into the Court itself. Nay, that he laid hold of the shield of the Grimaldi arms as though it were some Palladium and sacred *ancile*, grasped in a hand so

strong and so tenacious that the hand would not be thought likely to let go of it even if it were cut off!

"What monstrous thing is this?" you say. "From a man unknown, a foreigner, unarmed, half-alive?" Yet this very appearance of grounds for condemning him supplies the argument for pardoning him. He was unknown, unarmed and half-alive: from where could he sooner and better seize a name, arms, a whole life, or even immortality, than from a Prince of royal, and of old even saintly, nobility, of unconquered virtue, and of learning in every field? Horror of the ancient tomb drove him in flight to this refuge. The fear of misfortune, happily turned into boldness, made him seize without hesitation, by usurping it, what he ought to have obtained by entreaty. Having dared things beyond himself, since he had heard the greatest things of You, he took on great courage, for he was about to run to the Magnanimous.

He cast his eyes, moreover, on the hereditary arms proper to your Principality. From their top both the Palm and the Olive put forth leaves — that is, Victory made peaceful, and triumphant Peace — while at the sides, in place of telamons, stand two men of religion, each with his sword drawn: that is, religious Vigour, and armed Religion and Wisdom. Why, then, should our Ptolemy not join his own shield to the shield of so sure and so noble a protection, and entrust to those arms his own — the arms in which the twin globe of Earth and Heaven signifies the wish and the plan to restore Geography and Astronomy together, and to hand them down safely to posterity?

Nor was it without deliberation that I wished this New Almagest, which embraces astronomy old and new — and of it the second volume, but the principal one — to be dedicated and commended above all to You, PRINCE OF MONACO. For turn over for a moment a page or two, and contemplate the figures that stand at the front of the Work. There Argus, with all his lights — nay, all eye — puts the telescope to his knee [genu] rather than to the eye in his cheek [genæ], so that he may not so much see the chief works of God's fingers, namely the Heavens, as venerate them on bended knee. On this side Astraea, herself also jewelled with the most many-eyed stars, weighs the two more recent Systems of the World, balanced by their own weights. In the mobility of the Earth she recognizes an ingenious levity; in its immobility a judgement that outweighs it; and she finds most true what once sounded in her ears from heaven, that saying of David: "It shall not be moved for ever and ever."

Now it was fitting that the system of the world, and the whole weight of this controversy, should be upheld by the authority of that Prince who holds the place of Hercules by hereditary right. For Hercules, not only on account of the Muses, whom the Platonists believed to preside over the nine orbs of the heavens — on account of their company — was called *Musagetes*[1]; he also so restored and advanced astronomy, which was already tottering, that Atlas is

[1] "leader of the Muses"

said to have unloaded the whole sky and the weight of the cosmic sphere onto his shoulders. And yet that same Hercules, as the polymaths report, when he had routed Geryon and withdrawn into this harbour of yours, drove everyone out and lived alone in that citadel, long and much; and so Hercules came to be called Μόνοικος [Greek: Monoikos, "dwelling alone"], that is, the Solitary. What would he do there alone, the leader of the Muses and the nobler heir of Atlas's sphere? Placed nearer the heavens on that summit, would he not refresh himself after the countless labours and wanderings he had endured on land and sea by contemplating the labours of the stars and the wanderings of the planets? From this, then, your harbour here became, and was called, Herculean; from this the citadel of Monaco became, and was called, Herculean — a fact that Strabo, Ptolemy, Pliny the Elder and Tacitus did not pass over in silence, and that the poets, Silius Italicus and Lucan above all, celebrated in song more than once.

Now it is well established that the Grimaldi who is counted fifth in the direct line of descent from Grimoald — brother of Charles Martel and son of Pepin the Fat — was chosen by the Emperor Otto I as one of the chief commanders of his army, and bore himself as so vigorous a hero, first in the storming of Lyon and other cities, then in the siege of Paris, by which he restored Louis IV, King of the Franks, from captivity to liberty, and finally in freeing Italy from the tyranny of Berengar, that he obtained from that Emperor the citadel of Monaco and many neighbouring places in sovereign lordship. He handed down the rights of the dynasty to his descendants, right down to you at the present day; and from then on, in unbroken succession, when one Prince of Monaco was torn away, another has not been lacking.

Among them, your grandfather HONORATVS [Honoré I] and your father HERCVLES [Ercole Grimaldi] so joined martial courage with wisdom and letters that your grandfather seemed to be the arm of the Emperor Charles V in his various battles and his right eye in council, while he sat first among the councillors and envoys of Charles himself and of Philip II; and, cultivated in every kind of learning, he was called the Maecenas of his age. Your father, for his part, when he was already destined for the higher honours of the ecclesiastical order and was making his way towards them through expertise in both laws, was drawn from letters to arms, and was compelled, by a fortunate and noble necessity, to defend the citadel of Monaco from a surprise attack by the enemy, and to weave the siege crown into his scholar's laurels.

You have done nothing, then, foreign to your ancestors if you, HONORÉ, have made your grandfather HONORÉ live again in yourself; if, as son of HERCULES, a most learned Prince, you have held that the ancient Hercules was to be emulated, both in the other disciplines and in the study of mathematics and of the doctrine of the sphere. To these ornaments of intellect were added outstanding piety towards God; towards your subjects, an admirable blend of justice with clemency; an immense greatness of mind alike in adversity and in prosperity; and finally a charm of manner, without loss of majesty, as great

as was once found in Titus Vespasian, who, as we know, was for that reason called the darling of the human race. And it is plainly for these reasons that you have been wished for as a patron not only by other writers but by me as well: that you may show yourself a HERCULES to this work of mine, such as it is, in protecting it, and an HONORÉ[2] in illustrating it and imparting fame to it by your very name. Farewell.

Bologna, on the Day of the Conception of the Blessed Virgin, in the year 1651[3].

Your Excellency's
most devoted and most obedient
Io. Baptista Ricciolus [Giovanni Battista Riccioli], of the Society of Jesus.

EPITOME GENEALOGIÆ GRIMALDÆ GENTIS.

Epitome of the Genealogy of the Grimaldi Family

PROHEMIVM.

Preface

In the dedications of both parts of this volume — namely in the letters to the Most Eminent Cardinal Girolamo Grimaldi and to the magnanimous HONORÉ II, Prince of Monaco — I said that they are of royal stock, and of stock that was once holy. So that no one, then, out of ignorance or an itch to disparage, may put this down to flattery on my part, which has always been abhorrent to my profession and my long-standing habits, or to frivolity in seizing on conjectural arguments of whatever kind, however obscure — something I resolved long ago should be foreign to the good faith, diligence and rigour I have set myself to keep in all my chronological works — I have decided to indicate briefly the foundation of both my assertions.

CAPVT I. De GRIMOALDI, qui Primus Grimaldæ Genti Cognomen dedit, Stirpe, & Propagine.

Chapter I. On the stock and progeny of Grimoald, who first gave the Grimaldi family its surname

All the historians I have been able to see agree that GRIMOALD, surnamed the Just, the legitimate son of Pepin the Fat, sprang from the royal stock of the Franks — indeed, if you consider the female line as well, from imperial stock and from other kings; although a few dissent from most concerning the manner and the series of descent, or concerning the father of Anselbertus, who was the great-great-great-great-grandfather of Pepin the Fat. For according to most of them — especially François de Rosières, Wassebourg, Abbot Bertels and, more or less, Hunibald and Trithemius, in passages to be cited at the end of the chapter — their genealogy ran as follows.

[2]the Latin *Honoratus* also means "honoured"
[3]the feast falls on 8 December

PHARAMVNDVS [Pharamond], who was crowned King of France in the year of the Lord 420, fathered Chlodio by his wife Argotta, daughter of the King of the Cimbri, and died in 430.

[Margin: Chlodio.]

CLODIO, or Clogio, surnamed the Long-haired [Capillatus], King of France — so called because he ordered the Franks to grow their hair as a sign of liberty, the hair that the Romans had wanted shorn as a mark of servitude — married Basina, daughter of Vuidelphus, petty king of Thuringia, by whom he fathered Phriso, Albericus, Raucherius and Reginaldus. But when Phriso died in a certain battle, Chlodio contracted a fatal illness from grief and died in 447, having first declared Meroveus, or Merovingus, Master of the Horse and guardian of his sons.

[Margin: Albericus.]

ALBERICVS, or Albero as others name him, when he had grown older recovered Alsace, Brabant, the Moselle region and almost all of East Francia — partly by defeating Meroveus, his guardian, who had thought that a good part of the kingdom was justly held by himself, and partly by his yielding. He married Argotta, daughter of Theodemir, King of the Goths, and sister of Theodoric, by whom he fathered Vuabertus, or Vuambertus.

[Margin: Vuabertus.]

VVABERTVS, King of East Francia and Prince of the great Ardennes and of Hainaut, enriched with Aquitaine by inheritance from his mother, married Lucilla, daughter of Zeno the Isaurian, Emperor of Constantinople, by whom he had Vuabertus II, who was to die in 528, and Anselbertus, or by contraction Ansbertus.

[Margin: Anselbertus.]

ANSELBERTVS, since he defended the rights of the Empire, was made a Senator by the Emperor, Marquis of the Holy Empire over the Scheldt, and Lord of the Moselle region — provinces that Chlothar I, King of France, had usurped. The marquisate already mentioned comprised Antwerp, Ghent, Tournai, Dendermonde, Mortagne, Condé, Valenciennes, and all the fortresses on both banks of the Scheldt. Nor did Chlothar dare to resist, for fear of the Emperor and of the King of the Goths, through his connection by marriage to whom Anselbertus was powerful; on the contrary, he gave him in marriage his own Blithild, daughter of Clotilde II (for Clotilde I was the saint who married Clovis I and converted him to the faith of Christ).

[Margin: The opinion of more recent writers on the origin of Anselbertus.]

But Scaevola and Aloysius de Sainte-Marthe [Scévole and Louis de Sainte-Marthe], in the *Genealogical History of the House of France*, say that from Ferreolus I, Praetorian Prefect of Gaul under Honorius about the year 400, a native of Auvergne, and from Papianilla, daughter of the consul Syagrius, was born Tonantius Ferreolus II, Senator and Praetorian Prefect of Gaul; that he, by a daughter of the Emperor Avitus, fathered Tonantius Ferreolus III, Senator; that this man in turn had, by Industria, daughter of Clovis I, Anselbertus, Senator and

Duke of Gallia Narbonensis; and that Anselbertus married Blithild, daughter of Chlothar I. It does not seem to me that the authors already mentioned can be reconciled except by saying that Anselbertus was the natural son of Vuabertus but the adopted son of Ferreolus III, who adopted him for lack of natural children, on account of his connection by marriage with Clovis and the proximity or intermingling of rights in Gallia Narbonensis, which was once comprised under Auvergne or Aquitaine.

[Margin: Saints Ferreolus and Condulphus.]

[Margin: Saint Tarsita.]

However that may be, by the consent of all, Anselbertus fathered by Blithild, daughter of Chlothar I, King of the Franks, five children: namely Arnold-Anchises, or Ansegisus; St Ferreolus, or Ferrioldus, Bishop of Traiectum; St Condulphus, pastor of the Tungri; Modericus, Bishop of Auxerre; and St Tarsita, who by others is also called Tarsicia and Ulsida. Anselbertus died in 567, as Vignerius has it, or rather in 570, as most have it.

[Margin: Arnold-Anchises.]

ARNOLD-ANCHISES, or Ansegisus, or, as others call him, Arnold-Buggisus, Marquis of the Holy Empire over the Scheldt, Lord of the Moselle region, Count Palatine and Duke in Austrasia, married Oda, daughter of Cunzo, or Guizo, Duke of Swabia, by whom he fathered St Arnulf; and he was so well received by Gun- tram, King of Orléans, that Guntram wanted to make him heir and successor to the kingdom. But Arnold-Anchises refused, and withdrew from the cares of the world into solitude, having built the monastery of St Martin at Longamuilla, in which he lived devoutly, died and was buried, in 601.

[Margin: St Arnulf.]

ST ARNVLPHVS [Arnulf], Marquis of the Holy Empire over the Scheldt, Lord of the Moselle region, Count [?] of Namur, and then under Chlothar II Count Palatine, Master of the Horse, Mayor of the Palace in Francia and Austrasia, and tutor of King Dagobert, whom Chlothar II had had by Queen Bertrude — urged by the nobles to propagate his line, and dispensed from his vow of chastity, married Doda, daughter of the Duke of Saxony or of Swabia, or, as others say, of the Count of Boulogne, whom Trithemius and Baronius call a saint.

[Margin: St Doda.]

[Margin: St Clodulphus.]

[Margin: St Vuandregisilus.]

By her he fathered St Clodulphus, Ansegisus II, and Valchisius, Count of Verdun and father of St Vuandregisilus, the abbot who was to die on 789 July 22. When Doda died, Arnulf withdrew from court to the monastery of Lérins, where he gave himself to the contemplation of divine things and to theology; but from there, through the eagerness of the people and of Pepin, Mayor of the Palace, and by the authority and almost the force of Chlothar II, he was called back and made Bishop of Metz, and Chlothar was present with his son

Dagobert at his consecration in 620. Moreover, as before, so afterwards the kings of France undertook nothing without consulting him or Pepin, and that kingdom was therefore at its most flourishing then. One Notto, who slandered St Arnulf because the Queen had repeatedly come to his house at night to seek counsel, God punished with a shameful penalty, and the King himself with the loss of his head.

[Margin: St Gauricus.]

[Margin: St Arnulf's generosity repaid by God.]

At length St Arnulf obtained from Dagobert, who was long unwilling, leave to resign his bishopric to his cousin St Guaricus and withdraw again into solitude. Having already sold off even the sacred vessels for the use of the poor, he asked his sons for leave to sell and distribute to the poor the goods that were coming to them by inheritance. Clodulphus, the eldest, refused for his own share; Ansegisus II consented. St Arnulf then prophesied that his house would come to possess far more goods than he himself could leave to his sons, and he blessed his whole posterity. Not long afterwards, in the 18th year of his episcopate, he withdrew into solitude; there, when he was about to die two years later, he summoned Ansegisus and ordered him to marry St Begga, daughter of Pepin the Elder, and then died a most holy death on 640 July 18, or in 641.

[Margin: St Clodulphus.]

His cousin and successor in the bishopric, St Guaricus, died in 654, and was succeeded at last in the same bishopric by St Clodulphus, son of St Arnulf. Though at first Clodulphus had refused his father consent to the distribution of the goods to the poor, he afterwards emulated his father's holiness with such ardour that St Remaclus, Bishop of the Tungri, called him a man full of faith and of the Holy Spirit, and sent St Trudo to him as to an oracle, as Abbot Theodoric relates in the life of St Trudo; and he died a holy death on June 8. But for our purpose it is necessary to insert a little about Pepin, the father of St Begga.

De Pipino Seniore, S. Beggæ Patre.

On Pepin the Elder, father of St Begga

[Margin: Pepin of Landen.]

[Margin: St Allowin Bavo, Pepin's cousin.]

PIPINVS of Landen [à Lauda], or the Elder, Duke of Neustria and Brabant, was the son of Carloman, paternal cousin of Agilulphus, Count of Hesbaye. This Agilulphus, by Adelthrudis, a woman of outstanding uprightness, fathered St Allowin Bavo, famous for his pilgrimages and his hermit's life — even to the point of shutting himself into a hollow tree, and afterwards into the prison of a very narrow cell. In 631, dying a holy death on October 1 in the monastery of St Peter at Ghent, which he himself had built at the urging of St Amand, Bavo appeared to St Gertrude, asking her to send linen cloths to Ghent to bury his naked body.

When St Arnulf first withdrew to the monastery of Lérins, Pepin was Mayor of the Palace of Francia, and in Austrasia, under Chlothar the Great, Dagobert I and Sigebert II. Remarkable are the things proclaimed of his prudence, faith, justice and piety by Abbot Stephen in the life of St Modualdus, and, in Surius, by the ancient author of the life of St Vuiro, the bishop whom Pepin used to summon to the deliberations of the kingdom and to whom he used to go barefoot for holy confession [exhomologeſis].

[Margin: St Itta.]

But this Pepin was most illustrious for his kinship with saints. For his wife was St Yduberga, called by most St Itta, or Ida. Sought by many nobles for a second marriage on account of the singular elegance of her manners, her nobility and her wealth, she preferred, at the urging of St Amand, Bishop of Traiectum, to build the monastery of Nivelles in Brabant under the protection of St Peter, where, having taken the religious habit, she died a holy death on 658 March 8.

[Margin: St Modualdus.]

The brother of St Itta was St Modualdus, made Bishop of Trier at Pepin's urging and regularly summoned, though unwilling, to the business of the kingdom. Having built on the Moselle the convent of St Symphorian the Martyr, he set over it as abbess his own and Itta's sister, St Severa the Virgin; and after she died on July 20, he too died, on May 12, sighing all the more ardently for heaven.

[Margin: St Severa, Virgin.]

[Margin: St Vuandalinus.]

[Margin: St Begga.]

[Margin: St Gertrude.]

[Margin: Blessed Pepin.]

His brother was St Vuandalinus, a monk, or rather a distinguished hermit, after whom a town in Belgium is named, as Trithemius relates. Pepin, further, by St Itta fathered Grimoald; St Begga, of whom more below; and St Gertrude, the most celebrated virgin, whose life is extant in Surius under March 17, the day on which she died a most holy death in the 33rd year of her age. Pepin died in 646 — the author of the life of Blessed Pepin says more of him — and was succeeded in the office of Mayor of the Palace of Austrasia under Sigebert II by Grimoaldus, or, as Trithemius puts it, Grimaldus. On him see Petavius [Pétau] in the *Rationarium temporum*, book 8, chapter 2; for we must return to our former series.

De S. Arnulphi Succeſſoribus vſque ad Theobaldum.

On the successors of St Arnulf down to Theobald

ANSEGISVS II, son of St Arnulf and brother of St Clodulphus, bishops of Metz, by order of his father married St Begga, daughter of Pepin of Landen, by whom he had, in the town or village of Heristellum, or Heristallum, Pepin the Fat, called from it "of Herstal". But he had brought up a little foundling

called Goduinus, found on the road, and enriched him with wealth, and was killed by him while hunting, in 680, in the hope of seizing the principate.

[Margin: St Begga, widow.]

When his funeral was over, St Begga, a woman of lofty spirit and greater than her sex, gave herself wholly to imitating the holiness of her sister Gertrude and of Saints Arnulf and Allowin. She set out for Rome and, furnished by the Supreme Pontiff Adrian with holy relics and his blessing, returned home and built at Adana on the Meuse [Andenne] the Monastery of the Seven Churches, in honour of the same number of churches at Rome; and in it she died a holy death on 698 December 17. Goduinus, however, by no means gained the principate of Ansegisus; Pepin did.

[Margin: Pepin the Fat.]

PIPINVS of Herstal, surnamed the Fat, or the Younger, Mayor of the Palace of France and Duke of Lotharingia, or Austrasia, ruler of the kingdom and in fact, though not in name, its king, had entered on that dignity as early as 687, but did not hold it in peace until 691, after the death of Ebroin and the defeat of Theodoric. This Pepin married Plectrude, daughter of Grimoald, Duke of Bavaria, or Boiaria, by whom he fathered Drogo, surnamed Bosso, Count of Champagne and Duke of Burgundy, and Grimoald, surnamed the Just, as Ado of Vienne says, who was put in his ageing father's place as Mayor of the Palace of France.

[Margin: St Hugh.]

For Drogo, his first-born, after fathering by Adeltrudis, or Austrudis, daughter of Varato, among others Arnold, Duke of Burgundy, and St Hugh, Bishop of Rouen, died either in 699, as Baronius reports from Sigebert under the year 698, or in 708, as Scaevola and Aloysius de Sainte-Marthe say. Of Grimoald's killing we shall speak shortly.

[Margin: Divine vengeance on concubines.]

Pepin, moreover, took Alpais, or Elpais, as his concubine, and put away his lawful wife Plectrude from court and bed. When St Lambert, Bishop of Tongeren, repeatedly rebuked him for this, Alpais had Lambert killed by her brother Dodo at the estate of Liège [villa Legia] as he prayed at the altar of Saints Cosmas and Damian. But Dodo, vomiting up his rotted entrails through his mouth and unbearable to everyone for the stench, was thrown into the Meuse; and while others flocked to the body of St Lambert the Martyr to venerate it, concubines alone were driven back by some hidden force, so that they could not come near to kiss the sacred relics.

Pepin did indeed grieve at St Lambert's death. Yet when he lay mortally ill at Jupille [Iopiliæ] in 714, Plectrude, who was living at Cologne, begged him, through St Suitbert of Vuerda and Agilulphus of Cologne, both bishops, not to deprive the children of his legitimate sons — namely of Drogo and Grimoald — of their inheritance, to the ruin of his soul and the scandal of the kingdom. He nevertheless heard those bishops on the matter with indignation, and chose to leave as his heirs Charles Martel and Childebrand, whom he had had by Alpais.

[Margin: Plectrude's epitaph.]

When he died, however, on 714 December 16, Plectrude, Duchess of Lotharingia, held Charles Martel in custody and fostered her grandson Theobald, Count Palatine and of Gallia Belgica. But when Charles Martel escaped, and defeated and expelled both her and Theobald, she died at Cologne and was buried in the church of the Blessed Virgin on the Capitol, which she had built together with a monastery; and this epitaph was inscribed for her, in perpetual memory of her lawful marriage:

> *Plectrude, joined to Pepin in lawful wedlock, bore Bosso, and the great duke Grimoald.*

[Margin: Why Charles Martel was so called.]

Charles Martel, or Tudes, was so called because, with incredible speed and impetus, he inflicted defeats on the Saracens and other barbarians and beat them down like a hammer falling on them. He fathered Pepin, surnamed the Short, who was long the administrator of the kingdom and at length, because of the inertia of the kings, was elected King of France by the people and confirmed by Pope Zachary. He transferred the kingdom of the Merovingians to the Carolingians, and was the father of Charlemagne [Carolus Magnus], King of the Franks and Emperor of the Romans.

[Margin: Grimoald the Just.]

GRIMOALDVS [Grimoald] the Just, second son of Pepin the Fat by Plectrude, was Count of Gallia Belgica, Mayor of the Palace of France and of Austrasia, Prefect of the Gallic cavalry, and director of the kingdom under Childebert II. He married Theodosinda, daughter of Ratbodus, or Radbodus, petty king of Frisia, and by her fathered Theobald. But whether through the plotting of Theodosinda, burning with jealousy, or of Radbodus, it is certain that Grimoald — having come to Jupille [Iopiliam] to visit his father Pepin, and having turned aside to Liège — was killed while praying in the basilica of St Lambert the Martyr by Rangarius, an assassin of Radbodus, in the month of April, that is, seven months before Pepin's death, in the year 714. Radbodus, for his part, died a most wretched death in 719.

[Margin: Theobald.]

THEOBALDVS [Theobald], son of Grimoald the Just and of Theodosinda, was Count of Gallia Belgica and Prefect of the Gallic cavalry and of the palace under Childebert II and Dagobert II, Kings of France. But Charles Martel feared him as the lawful successor, passed over in Pepin's will; so, with the help of Ramanfredus, who had been put in Theobald's office, and with his own forces, he drove Theobald out of Gaul. Theobald therefore fled with his mother to Pelagius and Alphonsus, Kings of Spain, in 723. He fought vigorously for them against the Moors and Saracens and recovered Salamanca [Salmanticam], and for that reason was given several towns in that province. Among them is a town or village celebrated for the monastery of St John, founded by Theobald and Theodosinda, on whose walls these inscriptions are read even today:

To the once-fortunate Count of Belgica, I. N. Y., and Imp. C. M. F. R. drove him out in the year 722.

That is, Charles Martel, King of France, drove him out. Theobald also built a town there with a citadel, to which he gave a name taken from his father's name, and he wished his descendants to be named from it, that name being turned, as a patronymic, into the surname of his family. When Charles Martel died in 742, Pepin and Carloman succeeded to the principate. When the Franks, weary of the sloth of King Chilpericus, surnamed the Stupid, had elected Pepin king, Pepin soon recalled Theobald to Gaul, about the year 751, and raised him to high offices. Theobald, for his part, having put the Saracens to flight out of Provence [Gallo-Prouincia] and taken Antibes [Antipolim] by storm, obtained the lordship of Antibes. He married Aliarda Clovisia, daughter of the Duke of Orléans, and by her fathered Hugo, of whom we shall speak in chapter 2, and Rainerus Grimaldus, lord of the town of Grimaldi, of Santiuanez and of other places in Spain, a vigorous commander against the Saracens under Alphonsus, who made him perpetual Governor of Salamanca. From him the Spanish Grimaldi were then propagated, who held the fief of Grimaldi until the year 1370. In that year the male line failed; and the female line surviving in Hurraca Bermudez, wife of Petrus Tressius, lord of the citadel of Almofrague, that lordship passed to the Tressius family, from which came Cardinal Tressius.

Auctores ex quibus hæc collecta ſunt.

The authors from whom this has been gathered

What has been said so far we have not gathered wholly from each source; rather, some from some and some from others. Passing over the older chronologers and historians — Fredegar [Fridegario], Flodoard, Aimoin, Sigebert, Ado of Vienne and Otto of Freising — the chief authorities here were: Hunnibaldus, and Trithemius following him, in the *Annals on the Origin of the Franks*; François de Rosières, on the lineage of the Dukes of Lorraine and Bar, whose book is a library in itself; Vignerius; Fauchetus [Claude Fauchet]; and the fragments of the annals of France and of the Mayors of the Palace of France, edited by Pithoeus [Pierre Pithou]. Also: Paulus Vuarnefridus [Paul the Deacon], deacon, chancellor of Desiderius, King of the Lombards, and contemporary of Charlemagne, *On the Deeds of the Lombards*, book 6, chapter 5; the Metz manuscript cited by P. Mauritius in the *History of the Bishops of Metz*; the author of the life of Blessed Pepin; Marcellinus the Priest, a contemporary of Pepin of Herstal, in the life of St Suitbert, in Surius under March 1, from chapter 22; Stephen, Abbot of Liège [Leodiensis], in the life of St Modualdus, in Surius under May 12; Theodoric, Abbot of St Trudo, in the life of St Allowin Bavo, in Surius under October 1; likewise four ancient writers in Surius — of the life of St Gertrude, March 17; of St Vuiro, May 8; of St Vuandregisilus, July 22; and of St Trudo, November 23. Vincentius Lirinensis, in the *Speculum*, book 23, chapter 72; Bede, tome 3, in the acts of St Arnulf; Molanus, in the *Feasts of the Saints of Belgium*; Baronius, in the notes to the Martyrology for the

days March 1 and 17, May 8 and 12, July 20 and 22, October 1, November 23 and December 20, and besides in the *Annals*, tome 8, for the years 614, 615, 626, 631, 644, 698 and 714. Io. Bertelius [Jean Bertels], Abbot of Echternach, in the *History of Luxembourg*; Ambrosius Morales [Ambrosio de Morales], chronicler of Philip II, King of Spain, tome 3, book 13, chapter 16; Wolfgang Lazius [Vuolfangus Lazius], *On the Migrations of Peoples*, book 3; Consaluus Argona, *On the Nobility of Andalusia*, book 11, chapter 20; Salazar Mendoza, *On the Origin of the Dignities* [?] of Castile and León, book 1, chapter 7; Io. Serranus [Jean de Serres], in the *Inventory of French History*; Regino, *Annals*, book 1; Dionysius Petauis [Pétau], *Rationarium temporum*, book 8; Petrus Frizon [Pierre Frizon], in the *Gallia Purpurata*; Scévole and Louis de Sainte-Marthe, twin brothers, counsellors and ordinary historiographers of the Most Christian King, in book 6 of the *Genealogical History of the House of France* and in the tables prefixed to book 1; the manuscript of Cardinal Tressius preserved in the archive of Monaco; and Carolus de Venasque Ferriolus, Doctor of Both Laws, who in 1647 published at Paris the *Genealogical and Historical Tree of the Grimaldi Family*. Among other very substantial witnesses, he cites at the end of the work a testimony that could stand for all of them: that of the Most Christian King, Louis XIV, who expressly acknowledges the Grimaldi Princes of Monaco to be of the stock of the Kings of the Franks, through Pepin, father of Grimoald and of Charles Martel, and attests the same in these very words:

[Margin: Testimony of the Most Christian King for the Grimaldi family.]

[French] *Our very dear and well-beloved cousin the Prince of Monaco, Duke of Valentinois, Peer of France, Knight of our Orders, who is today recognized as the stock of the house of Grimaldi, and who has rendered a signal service to the State by placing his person and that of his children, his fortress, his goods and his subjects under our protection, and by renewing the ancient alliance which his ancestors had made with France — from which even the predecessors of the Princes of Monaco, who formerly held the greatest offices of the Crown, took their origin, through one Grimoaldus, Mayor of the Palace, son of Pepin the Younger and brother of Charles Martel; and in order also to show that we wish the nobility and antiquity of this house to see the light, so as not to deprive the public of so curious a work: etc.*

CAPVT II. De Grimoaldi ac Theobaldi ſucceſſoribus Monœcique Principibus vſque ad Honoratum II.

Chapter II. On the successors of Grimoald and Theobald, and on the Princes of Monaco down to Honoré II

[Margin: Hugo Grimaldus.]

HVGO Grimaldus, lord of Antibes and of other cities and places in Provence, first-born of Duke Theobald, aided the Emperor Charlemagne in command of his army, above all when Charlemagne restored Pope Leo III, oppressed by the Roman nobles, to his see in the year 800. Hugo married the sister of the

Archbishop of Milan, and by her fathered Passanus and Theobald — Thaddus for short — Archbishop of Milan, who died renowned for holiness in 876 and was buried in the church of St Ambrose. So say Nicolaus Grimaldus and Carolus de Venasque in the *Genealogy of the Grimaldi*, and Io. Franciscus Besozzius in the *History of the Pontiffs of Milan*, page 109. Antipolis, moreover, is in French Antibes, between Nice and Forum Iulii, or Fréjus [Freiuls].

[Margin: Passanus.]

PASSANVS, lord of Antibes etc. and Grand Master of France, fathered by his lawful wife Grimaldus and Bombellus Artisius. So Nicolaus and Carolus Venasque in the Genealogy already cited.

[Margin: Grimaldus I.]

GRIMALDVS I, lord of Antibes etc., and afterwards created the first sovereign Prince of Monaco by the Emperor Otto I, because he had borne himself vigorously in command of the army when, after Lyon and other cities had been taken, he freed Louis IV, King of the Franks, merely by the sound of arms in besieging Paris [Lutetiam], and then restored peace to Italy. He obtained the perpetual lordship of Monaco for himself and his successors, as appears from the *Register of Imperial Privileges*. He married Crispina, daughter of Rollo, or Robert, first Duke of the Normans. So Nicolaus and Carolus Venasque in the Genealogy cited, and Fa- nus. Campan.; the manuscript *On the Illustrious Families of Italy*, which is extant in the Ambrosian Library at Milan, chapter 14.

[Margin: Giballinus.]

By Crispina, further, Grimaldus fathered Guido, of whom below, and the hero Giballinus. After the Saracens had been driven out of Provence in the year 980, Giballinus was given by William I, Count of Provence, as the reward of a signal victory, the Sambracitan Gulf [Sinu Sambracitano], or Riuus S. Torpetis, with the places adjoining. Because of that victory and that grant, the gulf is called to this day the Gulf of Grimaldi [Sinus Grimaldus], and it extends in length to about 5 leagues, or 15 Italian miles. The authentic deed of this grant is extant in the acts of the church of Fréjus [Foroiuliensis], and in Carolus de Venasque, page 9. This Forum Iulii, moreover, is in Gallia Narbonensis — in French Friuls — between the Gulf of Grimaldi and Antibes.

[Margin: Crispinus, head of Branch 1.]

Grimaldus also fathered Crispinus, surnamed Ansgothus because on his mother's side he was descended from the Goths, from whom came the first Branch of the Grimaldi family, of which we shall speak in chapter 3. So Nicol. Grim. and Carolus de Venasque in this Genealogy, William of Jumièges [Guillelmus Gemeticensis], Orderic Vitalis [Odericus Vitalis], and others to be cited below.

[Margin: Guido.]

GVIDO Grimaldus, first-born of Grimaldus, sovereign of Monaco and lord of Antibes etc., assisted the Emperor Henry the Bavarian in many battles with a great number of ships and galleys of the Republic of Genoa and some of his

own, and withstood Stephen, King of Hungary. He married Rolanda, daughter of the Count of Alençon [Alanconij], by whom he fathered Prince Hugo.

[Margin: Hugo.]

In the year 1070 Hugo ordered the ears and nose of Antinopus, one of the captains of his galleys, to be cut off, because Antinopus had tried to carry the body of St Devota, Virgin and Martyr, away from Monaco to Florence — though in vain, since (wonderful to say) that ship could not by any force get out of the harbour of Monaco. Guido also fathered Grimaldus II, and Alphanius, Bishop of Apta Iulia [Apt] in Provence, who in 1056 took part in the Council of Toulouse with the nuncios of Pope Victor II, and died in 1065. So Nicol. Grim. and Carol. Venasque in the Genealogy already mentioned, and the catalogue of the bishops of Provence.

[Margin: Grimaldus II.]

GRIMALDVS II, when his brother Hugo died without children, succeeded to the sovereign principate of Monaco and the lordship of the Gulf of Grimaldi, on whose shore he built the tower and town of Grimaldi, in which the arms of the Grimaldi are still to be seen. Having formed an alliance with Robert Guiscard, the Norman, Duke of Apulia, he set free Pope Gregory VII, besieged by Henry III in the Castel Sant'Angelo [arce S. Angeli] at Rome. Afterwards he accompanied Hugh, brother of Philip I, King of the Franks, to Syria, and won famous victories over the Saracens with him. He was the first of the Grimaldi to live in Genoa, and in 1084 married Alexia, niece of the Emperor Alexius of Constantinople. By her he fathered Guido II; Theobald, Cardinal of the Holy Roman Church of Saints John and Paul, of the title of St Pammachius, created by Urban II; and Luca, one of the nobles who went to the war of Jerusalem with Godfrey of Bouillon [Gothofredo Bullionio] and was envoy of the Republic of Genoa to the Supreme Pontiff. From Luca came Luca, Cardinal of the Holy Roman Church of Saints John and Paul, of the title of St Pammachius, created by Innocent II; and Balduinus, shield-bearer of the King of Jerusalem and admiral [Hamiralus] at the capture of Almería and Tortosa in 1147 and 1148. Grimaldus II also fathered Hugo, commander of a great many ships and galleys for the Republic of Genoa in the holy war of Jerusalem, from whom came Guido, Cardinal of the Holy Roman Church of the title of St Balbina, created by Paschal II. So Nicol. Grimald. and Carolus de Venasq. in the Genealogy cited; Platina, under Urban II; Laurentius Pignor. [Lorenzo Pignoria], in the notes to Torquato Tasso; Io. Lup Sard., in the *Epitome of the History of Genoa*; and Platina, under Paschal II and Innocent II.

[Margin: Guido II.]

GVIDO II, Prince of Monaco, lord of the Gulf of Grimaldi etc., admiral of the Emperor Henry IV and Governor of Como [Comi], fought fiercely against the Milanese in 1120. He married Arasima of Carretto [à Carrecto], daughter of Boniface, Marquis of Savona and Finale and Vicar of the Holy Empire; and then a daughter of Fulco de Castro, admiral of the Republic of Genoa. By them, among very many children, he fathered Grimaldus III; Vmbertus, Bishop of

Colonia Iulia Pacensis Augusta and Rector of the church of Fréjus in 1183; Boso, Abbot of Lérins in 1151; and Otholinus, who married Ludovica of Lorraine and was prefect of the crossbowmen of Louis, King of the Franks, and Henry, King of the English, in aid of Pope Alexander III against Frederick I. So Nicol. Grimald. and Carol. de Venasq. in this Genealogy, the catalogue of the bishops of Provence, and the Chronicle of Lérins.

[Margin: Grimaldus III.]

GRIMALDVS III, Prince of Monaco, lord of the Gulf of Grimaldi etc., was one of the army commanders with whom the Emperor Lothar II defeated Roger, Duke of Apulia, an enemy of the Holy See, and drove him into Sicily. As Consul of Genoa in the years 1162, 1170 and 1184 he enclosed part of the city with walls; as admiral of the same Republic he defeated the Saracens and the Pisans with many galleys of his own; and he was twice its envoy to the Emperor Frederick Barbarossa [Ænobarbum]. He married Antonia Pia, daughter of the Count of Provence, by whom he fathered, among others, Obertus; and then Petrus, Bishop of Vintium Nerusiorum [Vence] in Provence, who died in 1210; Fridericus, Prefect-General of the Arms of the Holy See and counsellor, chamberlain and grand master of the crossbowmen of the King of England; likewise Rossus, Consul of Genoa in 1173; Raymundus, Bishop of Antibes in 1190; Guido, Consul of Genoa and envoy to the Republic of Venice, who married Francisca, daughter of the Marquis Malaspina; and Passanus, Seneschal of Normandy. So Nicol. Grim. and Carolus Venasq. in this Genealogy, the catalogue of the bishops of Provence, the archive of Vence [Vintij], Iustinianus [Giustiniani] in the *Annals of Genoa*, and Vbertus Folieta [Uberto Foglietta].

[Margin: Obertus.]

OBERTVS, Prince of Monaco, lord of the Gulf of Grimaldi etc., Baron of San Demetrio in Calabria, and lord of Carrosio and Aymerium in Liguria, was grand master of the palace of the Emperor Frederick I, and was sent by him as envoy to Philip of France and Richard of England, Kings, for the pilgrimage and war of Jerusalem in 1188. In the same year, with his father-in-law Obertus, he built the church of St Luke at Genoa for himself and his successors. Then, in 1197, he was Consul of Genoa, admiral, and again envoy to the Kings of France and England. He married Corradina Spinula [Spinola], daughter of Obertus, lord of Savenio, by whom he had first Grimaldus IV; then Ingo, from whom come the Dukes of Eboli [Euboli], the Grimaldi Cavallerones, and the Grimaldi who live in Bologna;

[Margin: Ingo, head of Branch 2.]

[Margin: And Obertus, of Branch 3.]

and Obertus, from whom come the Grimaldi of Castrum Novum [Castri noui] and of Gattières; and Luchineta, who married Iacobus à Iudicibus, nephew of the Emperor Michael of Constantinople, grand chamberlain and Prefect-General of the army against the Saracens; and Guido, lord of the Gulf of Grimaldi, who came to an agreement with the Genoese on fortifying the citadel of Monaco in 1215 and married Iolanda of Savoy; and Carolus Isnardus,

Marquis of Gavi and admiral of the Republic of Genoa; and Nicolaus, one of the Eight Nobles governing Genoa in 1235 and envoy to the Republics of Florence and Lucca against the Pisans in 1255, who married Argentina, daughter of Nicolosinus ab Auria [Doria], and was head of Branch 4;

[Margin: Nicolaus, head of Branch 4.]

and Renatus, Governor of Provence and master of seven galleys, who married Maria, sister of Ludovicus de Claromonte [Louis de Clermont], a prince of the royal stock; and lastly Adelaide, wife of Pyrrhus Ruffus, Count of Sinopoli and of Santa Cristina. So Nicol. Grim. and Carol. Venasq. in this Genealogy, Iustinianus in the *Annals of Genoa*, the archive of Genoa, and Vbertus Folieta.

[Margin: Grimaldus IV.]

GRIMALDVS IV, Prince of Monaco, lord of the Gulf of Grimaldi etc. and Baron of San Demetrio, was Prefect-General of the Genoese fleet at the capture of Damietta in 1219, and one of the Eight Nobles governing Genoa in 1232 and 1244 — the year in which he received in his own house Pope Innocent IV on his way to France. He married Orieta, daughter of Merlus de Castro, and, when she died, a daughter of the Count of Modigliana [Modilianæ]. By them he fathered Franciscus; then Devotus, Bishop of Grasse in 1263; and Luchettus, lord of Petraelata and Stella and co-lord of Clausana, who, after Ventimiglia [Intemelio] had been wrested from the Ghibellines, governed Genoa as one of the Eight Nobles in 1237, was Praetor of Milan in 1242, and, twice admiral of the Republic of Genoa, was victor over the King of Armenia and the Venetians in 1267. Grimaldus IV also fathered Alexia, who married Philippus Medicaeus, Governor of Florence; and Lanfrancus, one of the Eight Nobles governing Genoa in the years 1240, 1246 and 1249, and Prefect-General of Piacenza. He also fathered Gabriel, a vigorous warrior against the Saracens under the Emperor of Constantinople, lieutenant of Charles I, King of Naples, and Grand Master of the Royal Household, by whom he was honoured with a military belt of 250 pounds of gold in 1269. This man had as sons Iacobus, chamberlain of Charles I, King of Naples, and Guigno, one of the three sent to Rome by the whole family to stipulate peace between the Grimaldi and the Fieschi [Fliscos], Guelfs, and the Doria [Auriacos] and the Spinola, Ghibellines. Present were Bertrand, Cardinal Bishop of Sabina, legate *a latere*, Philip, Emperor of Constantinople, and Charles I, King of Naples, as appears from the instrument executed at the Capitol in the chambers of Charles himself on 1276 June 18, and drawn up by Bartholomaeus de Regio, notary. For the rest: Nicol. Grim. and Carolus Venasque in this Genealogy, the Register of Fréjus and the Register of Charles I in the archive of Naples, Iustinian. in the *Annals of Genoa*, and Vbertus Foliet.

[Margin: Franciscus.]

FRANCISCVS, Prince of Monaco, lord of the Gulf of Grimaldi etc. and Baron of San Demetrio, counsellor and chamberlain of the Emperor of Constantinople, vicar of Charles I, King of Naples, in the County of Provence and of Nice, and his admiral, was delegated by the Emperor of Constantinople to negotiate peace between the Kings Charles II of Naples and James of Aragon

and Sicily. In 1272 he was joined to Aurelia of Carretto, sister of the Marquises of Savona and Finale, by whom, above all others, he fathered Raynerus; then Andaro, Baron of Boleum and lord of Vallis Massae, from whom came Branch 6; and Grimaldus

[Margin: Andaro, head of Branch 6.]

Grand Seneschal of Rhodes, master of many galleys and a warrior against the Turks in 1318; and Antonius, commander of the seven galleys that the Grimaldi family sent against the King of Sicily in support of Charles II, King of Naples, and husband of Antonia Spinella. So Nicol. Grim. and Carolus Venasq. in this Genealogy, and the archives of Naples and of Boleum.

[Margin: Raynerus.]

RAYNERVS, Prince of Monaco and Baron of San Demetrio, Grand Master of the palace [Regiæ] of the Emperor of Constantinople, and envoy of the King of the Franks to the King of Jerusalem and Sicily, aided Charles II, King of Naples, with ten galleys of his own against the Sicilians; for this and for his distinguished exploits he received a military belt weighing 260 pounds of gold. He married Speciosa of Carretto, daughter of Iacobus, Marquis of Finale, by whom he fathered Hugo, sovereign of Monaco, who died without children; Raynerius II; then Guigno, commander of 23 galleys for the Grimaldi family in aid of Charles II, King of Naples, against the Ghibellines who were occupying Monaco, whose son Greppus was guardian of Charles the Great, Prince of Monaco, in 1344; Aymo, commander of a great force of crossbowmen from the Grimaldi and the Fieschi in support of the King of Spain against the Saracens, whom he successfully routed; Rogerius, knight of the chamber [cubicularium Equitem] of Boniface VIII, in 1296;

[Margin: Bartholomaeus, head of Branch 7.]

and Bartholomaeus, or Bertonus, commander of the Grimaldi fleet of galleys in aid of Robert, King of Naples, and his viceroy in Calabria, from whom came the seventh branch. At that time Franciscus, son of Guillelmus, Raynerus's brother — called Massa from the strength of his body — recovered the citadel of Monaco, which the Spinola had occupied, in 1317. So Nicol. Grim. and Carolus Venasq. in this Genealogy, Cor. in the *History of Milan*, and the Register of the archive of Naples.

[Margin: Raynerus II.]

RAYNERVS II, Prince of Monaco, lord of Cagnes [Cagniæ], Villeneuve [Villænouæ] etc., and Baron of San Demetrio, joined fifteen galleys of his own to the fleet of the Republic of Genoa against the Venetians. As admiral of France, with many of his own galleys, he defeated in a famous naval battle Guy, Count of Flanders, who was in arms against Philip the Fair, King of France, and brought him back captive, with the greater part of the nobility of Belgica, in 1304. Afterwards he triumphed over the Pisans and did other distinguished things. Having married Margarita Ruffa, of the Counts of Sinopoli, he fathered Carolus and, among others, Vinciguerra, Baron of San Demetrio and lord of Malapeza in Calabria, viceroy of both Calabrias under Robert; and Lucianus,

lord of Villa Franca, chamberlain, counsellor and Prefect-General of the fleet of Joanna I, Queen of Naples, against the King of Hungary, whom he defeated in 1348, and who, as admiral of Provence and Forcalquier [Folcalcarij] in 1361, brought aid with five galleys fitted out at Monaco to Alphonsus, King of Aragon, against the Sardinians;

[Margin: Antonius, head of Branch 8.]

and Antonius, lord of Pratum, Utellae, Vallis Lantuscae and other places in Provence, proprietor of six galleys, counsellor and Vicar in Provence of Joanna, Queen of Naples, and head of Branch 8. For his son Lucas — who, with the consent of Clement VII, received back into his obedience Antibes, which belonged by most ancient right to the Grimaldi family but had been cut off from it in the course of time — fathered Nicolaus, lord of Antibes, Capria etc., counsellor of Joanna, Queen of Naples, and Governor of Marseille [Massiliæ]. Nicolaus's second son, Lambertus, married Claudia, only daughter of Catalanus, Prince of Monaco, and heiress of the principate, of whom more below in her place. Raynerus II died in 13[?]4. From Nicol. Grim. and Carolus Venasq. in this Genealogy; the registers of the Kings of Naples; Io. Villanus [Giovanni Villani], part 1, book 8; Paulus Aemil.; the brothers de Sainte-Marthe and other French historians; Iustinianus in the *Annals of Genoa*; Nostradamus in the *History of Provence*, part 4; and the archives of Monaco and of Antibes.

[Margin: Charles the Great.]

CAROLVS, surnamed the GREAT [MAGNVS], sovereign Prince of Monaco and of Ventimiglia [Intemelij], lord of Cagnes, Villeneuve etc., and lord of many places in the Balearic Islands, bought back with gold the houses that the Spinola still held in Monaco. Having made a treaty with the King of the French, he recovered the Gulf of Grimaldi by the King's favour; he bought Menton [Mentonum], Roquebrune [Roccabrunam] and Castellionum and joined them to his sovereign dominion. He was counsellor of King Robert and, in 1344, Vicar of Queen Joanna in Provence. As admiral of the Guelfs he took part in the peace between the Grimaldi and the Fieschi and the Doria and the Spinola in 1331; then, as perpetual admiral of Genoa, he won many victories, especially over the Catalans [Catalaunis]. In 1338 he brought twenty galleys fitted out at Monaco by the Guelfs against Edward, King of England, in aid of Philip of Valois, King of France. Later, in 1346, as admiral of France, with 30 galleys of his own and ten thousand legionaries armed at Monaco, he hastened to the aid of the same Philip against the same Edward; in that battle, at Crécy [Cresciacum], he was gravely wounded — but most honourably. He married Luchinetta, daughter of Gerardus Spinula, lord of Lucca and Tortona [Dertonæ], and died in 1363. His sons were many, but the chief were Raynerius III; Lancellotus, chamberlain and counsellor of Queen Joanna I in 1348; Franciscus Baptista, Prefect-General of the Guelf fleet in aid of the King of Naples; and Carolus, co-lord of Menton, Governor of Aquila, counsellor of Queen Joanna, and envoy to the King of the Franks.

[Margin: Carolus, and Henricus, head of Branch 9.]

Carolus's son Henricus, chamberlain and counsellor of Martin, King of Sicily and Aragon — by whom, for his distinguished military exploits, he was created Baron of Buzetta and Scitibillinum and Governor of the city of Castrum Ioannis — was head of Branch 9. So from Nicol. Grimald. and Carol. Venasq. in this Genealogy; the registers of the royal archive of Naples and of Monaco; Zurit. in the *Annals of Aragon*; Iustinianus in the *Annals of Genoa*; Vbertus Folieta; Io. Villanus, part 2, book 12; Matth. Villanus [Matteo Villani], *History of Florence*, book 1; the register of the chancery of Palermo; and Fasel. in the *History of Sicily*.

[Margin: Raynerus III.]

RAYNERIVS III, Prince of Monaco, Menton etc., Baron of the city of Vincium, lord of Baussonis, Boissonis, Turreta, Leventium, Esa, Turbia etc., Baron of Lunellum and Servianum, lord of Vallis Baiae in Piedmont, and lord of the islands of Cephalonia, Leucata, Santa Maura and Zacynthus, of Vallis de Compare and of other cities of Greece, was Prefect-General on land and sea for Louis and Joanna, sovereigns of Naples; Seneschal of Piedmont; chamberlain and counsellor of the King of the Franks; admiral of the Mediterranean Sea; Prefect-General of the land armies in Provence, with supreme right of peace and war; and envoy to the King of England for a treaty. Always most ready to aid the Kings of France and of Naples, he earned eternal praise by signal victories. At Menton in 1378 he received Io. Serra, apostolic nuncio, sent to him as legate by Urban VI with a special charge to defend the Holy See against the schismatics; and he handed over to the nuncio the rod of Moses, with sacred relics and the registers of the Apostolic Camera, which had been carried off by the deserting cardinals but wrested from them. Monaco, seized in his absence in 1395, he recovered in 1402; and there, in 1406, he also received Pope Benedict XIII as his guest. He married Isabella Assenaria, of imperial stock, and died in 1407.

[Margin: Ambrosius, Prince of Monaco.]

His chief children were Ambrosius, Prince of Monaco, who, while busy fishing near Menton, was drowned in the sea in 1422, being unmarried; and Ioannes. From Nicol. Grim. and Carolus Venasq. in this Genealogy; the archive of Monaco; Iustinianus in the *Annals of Genoa*; Vbert. Foliet.; Nostradamus in the *History of Provence*; and the registers of the Kings of Naples.

[Margin: Ioannes.]

IOANNES, sovereign of Monaco etc., after many wars and losses inflicted on the Florentines, made peace and a treaty with that Republic in 1424. Then, as Prefect-General of Philip, Duke of Milan, he routed the Venetians near Cremona on the Po, taking eight thousand of them captive, in 1431. He defeated the Catalans many times and was most skilled in naval warfare. Together with his son Catalanus he approved the aggregation of the Ceba and Oliva families to the Grimaldi in 1448. He married Pomelina, daughter of Thomas Fulgosius, Doge of Genoa, in 1433, and died in 1454. His children were Catalanus and Bartholomaea, wife of Petrus Fulgosius, Doge of Genoa. When Petrus had died

and Francesco Sforza [Franciscus Sfortia] was besieging the citadel of Genoa, Bartholomaea governed Genoa and showed herself a heroine, in 1464. From Nicol. Grim. and Carolus Venasq. in this Genealogy; the archive of Monaco; Iustinian. in the *Annals of Genoa*; Vbert. Foliet.; Sabellicus in the *History of Venice*; Tarcagnota; Blondus; and others.

[Margin: Catalanus.]

CATALANVS, sovereign Prince of Monaco etc., inflicted many defeats on the Catalans with his galleys in defence of the rights of the port of Monaco. He married Blanca of Carretto, of the Marquises of Finale, and died in 1457. His sons Io. and Raynerius died in the cradle; but his daughter Claudia, her father's heir, married Lambertus, of whom presently. From Nicol. Grimald., Carol. Venasq., and the archive of Monaco.

[Margin: Claudia, and Lambertus.]

CLAVDIA, only daughter of Catalanus and heiress of the State, married in 1457 Lambertus Grimaldus, son of Nicolaus I, lord of Antibes, her kinsman in the 4th and 5th degree — namely, the great-great-grandson of RAYNERVS II, Prince of Monaco. By virtue of the marriage Lambertus became sovereign of Monaco etc., and in 1463 he gained possession of the County of Ventimiglia. He was helper, with his galleys and soldiers, counsellor, and envoy extraordinary of René, King of Sicily and Jerusalem, to Louis XI, King of France; and, concluding a treaty with that Most Christian King, he was enriched by him with many privileges. He was, besides, Prefect-General of the fleet of Savoy under Duke Amadeus in 1465, and counsellor and chamberlain of Charles III, King of Sicily and Jerusalem, in 1481, who by codicil gave him two galleys. Some years later, from Charles VIII, King of the Franks, he obtained as duke and royal lieutenant the whole western Riviera of Genoa; and he died in 1493. Of Claudia and Lambertus were born, first of all, Ioannes II, sovereign of Monaco etc., who was killed by his brother and left no children; and Lucianus and Augustinus, of whom below. From the archives of Monaco, of Antibes and of Paris, and Car. Venasq.

[Margin: Ioannes II.]

IOANNES II, sovereign of Monaco and Ventimiglia [Intemelij], counsellor, chamberlain [Cambellanus] and pensioner of Charles VIII and Louis XII, Kings of the Franks, and Knight of the Order of Saint Michael, hastened as commander of his own galleys and troops to the aid of Charles VIII in acquiring the Kingdom of Sicily, and of Louis XII in acquiring the Duchy of Milan and the lordship of Genoa; for that reason he was Prefect-General of the whole western Riviera in 1495 and 1500. He built the citadel of Menton and a bulwark of wonderful architecture. He married Antonia, daughter of Philip, Duke of Savoy, but, being without children, he was killed in a quarrel by his brother Lucianus, who was greedy for power, in 1505. From the archive of Monaco; Carolus Venasq. in this Genealogy; Aret. in the *Compendium of the Princes of Europe*, book 3; and Pignor. in the genealogical tree of the Dukes of Savoy.

[Margin: Lucianus.]

LVCIANVS, then, sovereign of Monaco etc., counsellor, chamberlain and pensioner of Louis XII and Francis I, Kings of the Franks, and enriched by them with many privileges, vigorously defended the citadel of Monaco in 1506, when it was besieged and attacked by the Genoese and the Pisans in a long and stubborn war. In 1506 he recovered Menton and Roquebrune [Roccabrunam], which the same enemies had taken by storm. He married Pontevesia [Pōteueſiam], lady of Cabanae [Cabanarum] in Provence, by whom he fathered Franciscus II, Prince of Monaco, to whom the subjects swore the oath of fealty although he was an infant; but he died at four years old. He also fathered Honoratus, of whom below. At last Lucianus was killed by his nephew Bartholomaeus ab Auria [Doria], lord of Dolceacqua [dulcis aquæ], in 1523. From the archive of Monaco; Iustinian. in the *Annals of Genoa*; Carolus Venasq.; Io. de Auton [Jean d'Auton], *On the Deeds of Louis XII*; and others.

[Margin: Augustinus.]

AVGVSTINVS, Bishop of Grasse, Abbot of Lérins, counsellor and almoner of the Most Christian King, entered the citadel of Monaco when his brother Lucianus was barely dead. Taken on as guardian of his young nephews, he exacted from the subjects an oath of fidelity to himself and to his nephews, and declared himself Prince for his lifetime. By force of arms he stripped his brother's murderer of his state of Dolceacqua, compelling its subjects to swear fealty to himself and his nephews; and, having captured the murderer at Castrum Pennae, he later had him executed at Monaco. Then, in 1524, having made a treaty with the Emperor Charles V and taken his side, he rendered him great services with his galleys, soldiers, port and citadel. For these he was elected Archbishop of Oristano and Bishop of Majorca, and was named Cardinal, although he did not reach the promotion: death forestalled him in 1532, after he had received Charles V as his guest at Monaco in 1529. From the archive of Monaco and of Grasse; the Chronicle of Lérins; Iustinianus in the *Annals of Genoa*; and Carolus de Venasq. in this Genealogy.

[Margin: Honoratus.]

HONORATVS I [Honoré I], son of Lucianus, Prince of Monaco, Marquis of Campagna [Campaniæ], Count of Canosa [Canuſij], lord of Dolceacqua [Dulciſquæ], and counsellor of the Emperor Charles V, from whom he obtained Campagna and Canosa because he had stood ready to serve him with his galleys in various battles — above all at Lepanto [Naupacti] under Io. Austriacus [Don Juan of Austria], at the storming of La Goletta [Goletæ], and at Tunis. This Prince was cultivated in every kind of learning and was the Maecenas of his age; and he had such authority with Charles V, and with Philip II, King of Spain, that those who acted as their ambassadors sat beside him. When his guardian Augustinus died while Honoratus was still under age, he had a second guardian, Stephanus Grimaldus of Genoa, whose niece [neptem] Isabella he married in 1545 in return for the guardianship well discharged; and he died in 1581. His children were Carolus, Prince, of whom presently; Franciscus, the second-born, who, sent by his brother Carolus to the Catholic King on business in 1583, died

at court; Hercules, the third-born; and Horatius, the fourth-born, cupbearer of Philip III, King of Spain, who died at Naples in 1620; besides other sons and daughters. From the archive of Monaco and Carolus de Venasqu. in this Genealogy.

[Margin: Carolus.]

CAROLVS, Prince of Monaco, Marquis of Campagna, Count of Canosa and pensioner of Philip, King of Spain, drove back the French when they made a sudden attack on the citadel of Monaco in 1584; and he died unmarried in 1589.

[Margin: Hercules.]

HERCVLES [Ercole], third-born son of Honoratus, Prince of Monaco, Marquis of Campagna and Count of Canosa, had taken degrees in both laws [I. V.] and was destined for higher rank in the ecclesiastical order. He defended the citadel of Monaco in 1596 against a surprise attack by the French and against a conspiracy within, and so joined arms to letters. In 1595 he married Maria, daughter of Claudius Lando [Claudio Landi], Prince of the Holy Roman Empire and of Val di Taro [Vallis Tari], and of Ioanna of Aragon; she was herself a pensioner [Penſionariam] of the Catholic King. Treacherously killed by some of his Monegasque subjects in 1604, he left Honoratus II as his successor. His daughter Ioanna married Theodorus Triuultius [Teodoro Trivulzio], Prince of Mesocco [Miſochij] and of Val Mesolcina [Vallis Miſolcinæ] in the Holy Roman Empire, Count of Meltium and Gorgonzola, lord of Cothoneum and Venzaghelum, Knight of Santiago [S. Iacobi], pensioner of the Catholic King, commander of two troops of horse for the same King, and Imperial Commissary in Italy. After his wife's death in 1620 he was created Cardinal of the Holy Roman Church by Urban VIII in 1629, and he was afterwards Governor of Milan [Mediola-lani] in 1640, Viceroy of Aragon in 1642, and Viceroy of Sicily in 1646. From the archive of Monaco and Carolus Venasqu. in this Genealogy.

[Margin: Honoratus II.]

HONORATVS II, Prince of Monaco, Marquis of Campagna, Count of Canosa and Knight of the Order of the Golden Fleece, was seven years old when his father died. His guardian was his maternal uncle Fridericus Lando [Federico Landi], Prince of the Holy Roman Empire and of Val di Taro, who, having made agreements with the Spaniards and thinking his ward's safety better provided for, brought a Spanish garrison into the citadel in 1605. When the time of his wardship was over, the Prince returned to the citadel from far away and, not recognizing his liberty as free, he published apologetic writings; then, with an armed band of a few subjects and courtiers, he fearlessly expelled the Spanish garrison by night in 1641, admitted the arms of Louis XIII into the citadel, and sent back the Golden Fleece. In compensation for what the Spaniards had taken from him, King Louis therefore created him Duke of Valentinois [Dux Valentinus], Peer of France, Count of Carladès [Carladeſij], Baron of Buis [Buiſſij] and of Calvinet [Caluineti], lord of Saint-Rémy [S. Remigij], perpetual and hereditary Governor of the royal forces in the citadel

of Monaco, and Prefect-General of its fleet; and before Perpignan, amid the camp drawn up in order, the same King decorated him with his own hand, out of the regular order, with the collar of the Royal Orders. He married Hippolyta [Ippolita Trivulzio], daughter of Theodorus Triuultius, Count of Meltium, and of Catharina Gonzaga, and sister of the Cardinal Prince; she died in 1638. By her he had Hercules, formerly Marquis of Campagna, Knight of the Order of Alcántara, commander of Benfaianen, and Prefect of the cuirassiers [Equitum Cataphractorum] in the Kingdom of Naples, but afterwards created by the Most Christian King Marquis of Baux [Baucij], pensioner, captain in France of a hundred men-at-arms, and knight of the Royal Orders with the collar. In 1641 Hercules married Aurelia, daughter and heiress of Lucas Spinula [Luca Spinola], lord of the city of Molfetta, and of his wife Pelina, likewise a Spinola. By her he had Ludouicus [Louis], Count of Carladès, born 1642 July 25, who in 1643 was held at the sacred font of baptism by the Count and Countess of Alais [Aleſijs] in the name of King Louis XIV and of the August Queen Mother, the Regent. From the archive of Monaco and Carolo de Venasque in this Genealogy.

CAPVT III.

Chapter III.

De Ramis Nobiliſſimis Grimaldæ Arboris, ex Monœci Principibus fœcunditate legitima in Galliam, Hiſpaniam, & Italiam dilatatis.

On the most noble branches of the Grimaldi tree, spread by lawful fruitfulness from the Princes of Monaco into France, Spain and Italy.

Hardly had the name of Grimoald the Just begun to be taken up patronymically as the family surname by his son Theobald, when from that stock [ceſpite] there sprang, as it were, a twin trunk. One of the two spread into France through Hugo Grimaldus, Theobald's first-born; the other into Spain through Ramirus Grimaldus, second son of the same Theobald. Granted that, before the year 1280, the Spanish nobles of this line remained unnamed through the negligence of writers, yet Cardinal Tressius, formerly President of Castile, as is recorded in his manuscript preserved at Monaco, asserts that the Grimaldi family held vassals and fortresses in Spain for about 900 years, and that the Grimaldi surname flourished until the year 1370. In that year the male line failed: the family was indeed continued through a woman, Hurraca [Urraca], but the surname passed with the inheritance to the most noble family of the Tressii.

[Margin: The Spanish Grimaldi.]

For, as the same Cardinal testifies, Petrus Sanz Grimaldus, lord of the castle, or fief, of Grimaldi in Spain, fathered Ruy Perez Grimaldus; and when Petrus died he was buried in 1280 at S. Petrus de masculis near Santiuanez. Ruy Perez Grimaldus, lord of Grimaldi, was one of the judges in the city of Plasencia

[Placentia], recently founded, in 1320; and he fathered Bermudus Guttierez Grimaldus and Ruy Perez Grimaldus, Bishop of Plasencia under the last Alfonso [Alphonſo vltimo]. Bermudus, lord of Grimaldi, fathered Consaluus Bermudez Grimaldus, who in 1340 was in attendance on King Alfonso at the battle of the Salado; and Nico- laus Bermudus Grimaldus, Bishop of Plasencia, who was buried in 1350 in the metropolitan church of Plasencia at the altar of the Blessed Virgin, commonly called *Del perdon*, where his Grimaldi arms are to be seen. Lastly, Consaluus, lord of Grimaldi, fathered Hurraca Bermudez Grimalda, lady of Grimaldi, who married Petrus Tressius, lord of the castle and place of Almolfrague; and so the male line of the Grimaldi in Spain came to an end about the year 1370.

Leaving aside, then, this trunk — a trunk of the stock rather than a branch — from the other trunk, that is, from Hugo Grimaldus, there came forth, besides the straight stem of the Princes of Monaco, Nine Branches, by whose flowers and fruits the nobility of this tree and stock has been confirmed. It is therefore worth pointing them out.

PRIMVS RAMVS

The First Branch

Criſpinorum, nunc Vardij, & de la Boſſe Marchionum.

That of the Crispini, now Marquises of Vardes [Vardij] and of la Bosse.

CRISPINVS, surnamed Ansgothus as being descended from the Goths on his mother's side, was the son of Grimaldus I, Prince of Monaco, and of Crispina, daughter of Robert I, Duke of the Normans. For that reason he lived in Normandy, where he held the barony du Bec in the Pays de Caux [Regione de Caux]. He married Heloysa [Heloyſan], daughter of Rodulphus, Count of Guînes [Guiſnenſium] and of Boulogne [Bononienſium], and of Rosella, of the Counts of Saint-Pol [à S. Paulo]; from them the Norman Crispini sprang. So Carolus de Venasque teaches in this Genealogy, from Nicolaus Grim., William of Jumièges, Orderic Vitalis, a report sent from Normandy, letters of Charles VI, King of France [Galliar.], preserved in the archive of Monaco, and the Norman Chronicle. From these, and from very many other historians and authentic documents, the same Carolus wove together the genealogy of this branch, whose direct line, leaving out the collateral lines, is as follows.

Of Crispinus Ansgothus was born Gilbertus, Baron du Bec and lord of the castle of Thilliers in 1041, Constable of Normandy and commander of its forces, who took the surname Crispinus, in place of Grimaldus, from the proper names of his grandmother and his father, and handed it down to his posterity, though the Grimaldi arms were kept. Of him was born Guillelmus Crispinus, Baron du Bec, a vigorous warrior in England in 1059 and 1066; of him, Guillelmus II Crispinus, surnamed the Great, Baron du Bec, the most celebrated hero of his age, who in the pitched battle of Breniuilla [certamine Breniuillano]

struck Henry, King of the English, two blows on the head in 1119; of him, Goscelinus Crispinus, Baron du Bec and lord of Sterpigneium, in 1153; and of him was born Guillelmus III Crispinus, Baron du Bec, lord of Dangutum and Sterpigneium, in 1196. Then came Gullielmus IV Crispinus, Baron du Bec, lord of Dangutum, Sterpigneium and Lisortium; of him, Gullielmus V, Baron du Bec, lord of Varengibeccum, Dangutum and Sterpigneium, hereditary Constable of Normandy and Marshal of France in 1283; and also Hugo, of whom presently.

Of Guillelmus V were born Guillelmus VI, heir to the same estates, father of Ioanna Crispina and Maria Crispina; and Ioannes Crispinus, lord of Dangutum. Of Ioannes came another Ioannes, likewise lord of Dangutum, and Guillelmus Crispinus, whose son Guillelmus Crispinus, lord of Three Towns [trium vrbium], of S. Dionysius in the forest of Lihuntium, etc., recovered the barony du Bec Crespin, which had been alienated by Ludouicus Chalonius, son of Maria Crispina. He fathered Ioannes Crispinus, Baron du Bec Crespin, lord of Maunium, of Three Towns and of Plana; of him came Ioannes Crispinus du Bec Crespin, Baron of Maunium, lord of Plana, of Three Towns, of Aurichier, etc., hereditary Marshal of Normandy and supreme inquisitor of the waters and forests of all Normandy and Picardy; and also Ioanna Crispina du Bec Crespin, Baroness of Maunium, lady of Plana, Malleporium, etc., wife of Petrus de Brezè [Pierre de Brézé], Grand Seneschal of Normandy, from whom a great many princes sprang. In this way the barony du Bec Crespin, etc., passed out of the Crispin family.

Hugo Crispinus, for his part, fathered Ioannes Crispinus, of whom came Michael du Bec Crespin, Cardinal of the Holy Roman Church with the title of S. Stephanus on the Caelian Hill, created by Clement V in 1312; and Guillelmus du Bec Crespin, father of Iordanus, of whom came Gothofredus du Bec Crespin, lord of Boisdilliers, la Mothe Dusseau [?], etc. He fathered Guillelmus du Bec Crespin, lord of la Mothe Dusseau [?], father of Carolus, Bishop of Bayeux [Baiocenſis] and ecclesiastical senator in the Parlement of Paris, and also of Ioannes du Bec Crespin, Viscount of Canium, lord of Bourium and cupbearer of the King of the Franks. Of Ioannes came Carolus du Bec Crespin, lord of Bourium, Vice-Admiral of France and knight of the King's Order with the collar. Of him were born Philippus du Bec Crespin, Bishop of Nantes [Nannetenſis] and of Saint-Malo [Machlouienſis], afterwards Archbishop and Duke of Reims, first Peer of France and admitted to the Royal Orders, who gave a great proof of learning and integrity at the Council of Trent; and Petrus du Bec Crespin, lord of Vardes etc. Of Petrus came Renatus I du Bec Crespin, Marquis of Vardes and of la Bosse, knight of the Royal Orders of France with the collar, Governor of La Capelle [Capellæ] and of the Thiérache [Regionis Tirraſchanæ] etc.; and he fathered Renatus II du Bec Crespin, Marquis of Vardes, etc. So Carolus Venasq. in this Genealogy, from various historical authors, epitaphs and authentic manuscripts; the Norman Chronicle; William

of Jumièges [Guillelm. Gemeticen.]; Orderic Vitalis [Oder. Vital.]; Matthew Paris [Math. Pariſ.]; etc.

SECVNDVS RAMVS

The Second Branch

In quo Duces Euboli, & Cauallerones, & Bononienſes Grimaldi.

In which are the Dukes of Eboli [Euboli], the Cavallerones, and the Grimaldi of Bologna.

[Margin: Ingo.]

INGO, son of Obertus, the sixth of the Princes of Monaco, was lord of Carrosium, Aymerium, Stella and Campastrum, and one of the Eight Nobles governing Genoa in 1225. As commander of the army of the same Republic against the people of Tortona [Dertonenſes] and Alessandria, he took the fortress of Montanaria by storm. Elected to negotiate peace between the Republic of Genoa and the King of Sicily in 1237, he restored to the Archbishop of Genoa a great part of the Most Holy Cross that had been recovered. He married first Theodora ab Auria [Doria], then Faustina, daughter of the Count of Ventimiglia. From Nicol. Grim. and Carolus Venasq. in this Genealogy; Vbertus Folieta; Iustinianus in the *Annals of Genoa*; and the archive of Genoa.

[Margin: Luchinus.]

[Margin: Boarellus, from whom Part 1 of Branch 2.]

By these wives he fathered Lucas, or Luchinus, lord of Carrosium, Aymerium and Stella, one of the 8 Nobles governing Genoa in 1256 and arbiter of the disputes between the Genoese and the Venetians in 1258. He also fathered Boarellus, of whom below in Part 1 of this Branch; and Petrinus, Prefect-General of the Genoese fleet of 25 galleys against the Venetians in aid of the Emperor of Constantinople in 1263. From Nicolaus Grim. and Carolus Venasq. in this Genealogy; the archive of Genoa; Vbertus Folieta; and Iustinianus in the *Annals of Genoa*.

[Margin: Gabriel.]

[Margin: Perciuallus.]

From Luchinus and Maria ab Auria was born Gabriel, lord of Carrosium, Aymerium and Stella, one of the Eight Nobles governing the Republic of Genoa in 1267. He took part in the agreements between the Republic and Michael, Emperor of Constantinople, in 1261, and the King of Sicily in 1269, and was made Baron and castellan of Mons Sacarius [montis Sacarij] by Charles I, King of Naples. His brother Perciuallus was Prefect-General of the Holy See against Manfred, who was occupying the kingdom of Naples, in 1252, and subdued the cities of Troia and Foggia in 1279. From Nicol. Grim. and Carolus Venasq. in this Genealogy; the archives of Genoa and Naples; Thomas Cost. in the *Life of Innocent IV*; and Matth. Spinellus in the *History of Naples*.

[Margin: Gaspar.]

[Margin: Rabella, from whom Part 2 of Branch 2.]

Of Gabriel were born, among others, Gaspar, lord of Stella, who, after the Doria [Auriacis] and the Spinola had been expelled, was rector and Doge of Genoa together with Carolus Fliscus [Fieschi] in 1317. He defended the city when it was long besieged by the Ghibellines of Lombardy and Tuscany, and in 1318 he handed over the government of the city for 10 years to Robert, King of Naples, who was hastening to its aid. He was pensioner of the said King in 1324, and he married Anna Marina. His brother was Rabella, lord of Carrosium, Aymerium and Stella, head of the second part of Branch 2. So Nicol. Grim. and Carolus Venasq. in this Genealogy; the archive of Genoa; Iustinian. in the *Annals of Genoa*; Villanus in the *Chronicle of Florence*; and the Register of King Robert of Naples.

[Margin: Perciuallus.]

[Margin: Gabriel, from whom Part 3 of Branch 2.]

[Margin: Ioannes.]

[Margin: Antonius.]

Of Gaspar was born Perciuallus, lord of the city of Policastro, counsellor and pensioner of King Robert in 1332 and of Queen Joanna I in 1348; and Gabriel, from whom Part 3 of this Branch 2; and Ioannes, viceroy for King Robert in the district of Otranto [tractu Hidruntino]; and Antonius, lord of Policastro, admiral of King Robert in 1329. Antonius was afterwards admiral of the Republic of Genoa with 45 galleys: he put to flight the fleets of the Kings of Aragon and of Majorca and captured five galleys of the Catalans in 1332; he was admiral again, with 60 galleys, against the Venetians and the Catalans; and by grant of Queen Joanna I in 1375 he was made lord of Baux in Provence for a term. So Nicol. Grim. and Carolus Venasq. in this Genealogy; Iustinian. in the *Annals of Genoa*; Vbertus Folieta; and the Registers of King Robert and of Joanna.

[Margin: Aymo.]

[Margin: Perciuallus II.]

[Margin: Lucianus.]

Of Perciuallus came Aymo, lord of Policastro and counsellor and pensioner of Queen Joanna I; of Aymo, Perciuallus II, who aided the King of Naples with his own galleys, and whose marble inscriptions survive in the church of S. Nicolaus de Busqueto near Genoa; of this Perciuallus, Lucianus, who negotiated peace between the Genoese, the Venetians, the Florentines and the Duke of Milan. Lucianus was envoy of the Republic of Genoa to the Kings of France, Aragon and Naples, and in 1448 procurator and commissary for the aggregation of the Ceba and Oliva families to the Grimaldi. In San Giorgio [In Sancto Georgio] he left, in 1474, most ample legacies for members of the Grimaldi family tossed by adverse fortune; and for that reason he deserved a statue and marble inscriptions in the old hall of San Giorgio.

[Margin: Merualdus.]

[Margin: Augustinus.]
[Margin: Nicolaus the Monarch.]

Of Lucianus was born Merualdus, an Elder [Antianus] of Genoa, whose inscriptions survive in the church of S. Maria Cella, S. Petrus de Arena. Of Merualdus came Augustinus, one of the envoys of the Republic of Genoa sent in 1504 to render obedience to Julius II, Supreme Pontiff, and envoy of the same Republic to receive Charles V. Of Augustinus came Nicolaus, Duke of Eboli, Prince of Salerno, Marquis of Teano [Theani], Count of Pola, and Baron of other places in the Kingdom of Naples, and lord of Tapazium and Rudaranum in Spain, who was called "the Monarch" for the abundance of his riches. He built from its foundations a most splendid palace in the Via Nuova of Genoa [in via noua Genuæ], and in 1570 he married Iulia Cibo, great-granddaughter of Innocent VIII. Of him came Augustinus II, Duke of Eboli etc.; and of Augustinus, Nicolaus II, Duke of Eboli etc., Knight of the Order of Alcántara, who died at Genoa unmarried and without offspring in 1639, and with him this distinguished line became extinct. So Nicol. Grimaldus and Carolus Venasq. in this Genealogy; the archive of Genoa; and the Registers of the Kings of Naples.

SECVNDI RAMI

Of the Second Branch

Pars 1. Nempe Grimaldorum de Caſtro.

Part 1: namely, that of the Grimaldi de Castro.

[Margin: Boarellus.]
[Margin: Conradus.]
[Margin: Boarellus II.]
[Margin: Conradus II.]
[Margin: Boarellus III.]
[Margin: Ingo.]

BOARELLVS, son of Ingo and brother of Luchinus, was one of the Eight Nobles governing the Republic of Genoa in 1262, and envoy of the same Republic to Clement IV, Supreme Pontiff, in 1266, and to Charles I, King of Naples, in 1272. His son Conradus, knight of Charles I, King of Naples, was governor of Barcarium and Camerana in 1272 and Praetor of Bologna in 1306; a prudent and vigorous commander, he took many enemy places by storm. His son Boarellus II aided Robert, King of Naples, with four galleys of his own and was his counsellor; he married a daughter of the Marquis Malaspina. Of them came Conradus II, lord of Stella in 1332; of him, Boarellus III, lord of Stella, a fief that he sold to the Republic of Genoa in 1390. His son Ingo discharged 24 embassies for the Republic of Genoa to various and greater princes of Europe; a Doctor of both laws [I. V. Doctor] and a knight of remarkable eloquence and learning, he earned for these a solemn funeral at public expense.

[Margin: Baptina.]

[Margin: Raphael.]

Ingo's daughter Baptina married Franciscus de Castro, son of Iulianus, who by virtue of the marriage was aggregated to the Grimaldi family. Of them came Raphael, Commissary-General in Corsica for the Republic of Genoa, who took Lecca by storm and laid waste Ginerca, after Paulus à Lecca, governor and rebel, had been driven from the island, in 1487. He was likewise Treasurer of the Holy See, governor of Terni [Interamnij] and Rieti [Reates] in 1496, and Prefect-General of the fleet of the Emperor Maximilian I against the French and the Florentines. He carried the Emperor and the imperial standards in his own ship, and for his distinguished deeds the Emperor created him at Sarzana, before the princes of the court, knight and Count Palatine, with the privilege, extending also to his descendants, of placing the Imperial Eagle on a gilded field in the upper part of the Grimaldi arms, in 1497. He served the King of the Franks at the storming of Mytilene [Mettelini].

[Margin: Franciscus.]

[Margin: Raphael II and Lucas.]

[Margin: Franciscus II.]

His son Franciscus, counsellor of Charles V, was made by him a gilded knight [Eques aureatus] and Count Palatine in 1531, and was envoy of the Republic of Genoa to the same Charles in 1547. He married Caecilia, daughter of Lucas Spinula, by whom were born to him Raphael II, created Count Palatine by Charles V, and Lucas, Doge of Genoa in 1605, who in 1597 married Nicoleta, daughter of Baptista Grimaldus, Duke of Terranova [Terrę nouę]. Of her was born Franciscus II, who married Nicoleta, daughter of Io. Baptista ab Auria, of the lords of Sassello [Saffelli]. So Nicol. Grimald. and Carolus Venasq. in this Genealogy; Iustinian. in the *Annals of Genoa*; the archive of Genoa; the Registers of the Kings of Naples; Marcus Anton. Cecald. [Marcantonio Ceccaldi] in the *History of Corsica*; and Sigonius in the *Life of Andrea Doria* [Andreæ ab Auria].

SECVNDI RAMI

Of the Second Branch

Pars 2: In qua Grimaldi Cauallerones.

Part 2: in which are the Grimaldi Cavallerones.

[Margin: Rabella.]

RABELLA, son of Gabriel and grandson of Ingo, lord of Carrosium, Aymerium and Stella, was the chief author of the expulsion of Opicinus Spinula, who had usurped the lordship of Genoa in 1310. He was Prefect-General of the Guelfs against the Ghibellines in 1317 and Elder of Genoa, 1333; he worked for the solemn peace between the Grimaldi and the Spinola.

[Margin: Rabellinus.]

[Margin: Dorinus.]
[Margin: Rabella II.]

He married Eleonora, sister of Raphael ab Auria. Of her were born Rabellinus, governor [Preſes] of Vallis Grata and Terra Iordana, and viceroy for King Robert in the Principato Citra [Principatu citra]; and Dorinus. Of Dorinus came Rabella II, Elder of Genoa in 1394 and envoy of the Republic of Genoa to the Emperor Sigismund in 1398, who married a daughter of Georgius Adornus [Giorgio Adorno], Doge of Genoa.

[Margin: Dorinus II.]
[Margin: Angelus.]
[Margin: Georgius.]
[Margin: Io. Bapt.]
[Margin: Nicolaus and Stephanus.]

From them was born Dorinus II, Elder of Genoa in 1421, and in 1448 procurator and commissary of the whole family for the aggregation of the Ceba and Oliva families to the Grimaldi. He brought aid to the King of Naples against the King of Aragon in 1443, and was envoy of the Republic of Genoa once to the Pontiff and three times to the Duke of Milan. Of him came Angelus, who flourished in 1448; of Angelus, Georgius, Elder of Genoa in 1471, who dedicated a sumptuous chapel in the church of S. Maria de Consolatione near Genoa in 1497; of Georgius was born Io. Baptista, lord of Montaldeo [Montaldei], created Count Palatine and gilded knight by the Emperor Charles V, together with his brothers Stephanus and Nicolaus, in 1525. The title was transmitted to their descendants, and on account of it they are commonly called the Cavallerones. Nicolaus was most generous to the poor. Stephanus was guardian of Honoratus I, Prince of Monaco, and an excellent administrator of the principality: he restored the church of S. Nicolaus and fortified the citadel with great bulwarks and with artillery. He was a man endowed with every kind of learning, shrewd and prudent, and he was buried in the tomb of the Princes of Monaco in 1561.

[Margin: Augustinus I.]
[Margin: Franciscus.]
[Margin: Georgius.]
[Margin: Thomas.]
[Margin: Dominicus.]

Io. Bapt., moreover, married Magdalena Pallauicina [Pallavicini], and of them were born many illustrious children: namely, Augustinus I, Baron of the city of Mons Pelusius [Montis Peluſij], senator of Genoa in 1581; Franciscus, who served Philip II, King of Spain, as commander of horse in acquiring the kingdom of Portugal, and also with his own galleys; Georgius, who with his own galleys served the same Philip II, King of Spain, in the naval battle of Lepanto [Naupacti] in 1571; and Dominicus, Commissary-General of the galleys of the Holy See under Pope Pius V in the naval battle of Lepanto in 1571. Dominicus was first Bishop of Savona, then of Cavaillon [Cabellicenſis], and finally Archbishop and Vice-legate of Avignon and governor of the armed forces of

the whole State in 1585; together with his brother Thomas, commander of horse, he drove the heretics out of the Comtat Venaissin [Comitatu Venayſſino], took Minerba by storm, and died in 1592. There was also Io. Iacobus, Baron of S. Foelix in the Kingdom of Naples and senator of Genoa in 1606, who married Hieronyma, daughter of Augustinus de Mari, by whom he fathered many sons; among them Hieronymus, Cardinal of the Holy Roman Church, stands out, of whom presently.

[Margin: Nicolaus.]

[Margin: Augustinus II.]

[Margin: Father Iulius.]

Augustinus married Maria, sister of Ambrosius ab Auria, Doge of Genoa, and died in 1592. Of her was born Nicolaus, Baron of Mons Pelusius, who married Paula Maria, daughter of Iulius Spinula, in 1609, and died at Mons Pelusius in 1636. His sons were many, but above all Augustinus II, Baron of Mons Pelusius; Father Iulius Grimaldus of the Society of Jesus; and Fathers Ioseph, Raynerius and Ioannes, Theatines.

[Margin: HIERONYMVS, Cardinal.]

Of Io. Iacobus, brother of Augustinus I, were born Io. Bapt., Baron of S. Foelix, Commissary-General of arms of the Republic of Genoa against the Savoyards in 1625 and Commissary-General of the army of the Holy See under Pope Urban VIII in 1630, who married Magdalena, daughter of Andreas Spinula, in 1613, and died in 1645. Of the same Io. Iacobus was born HIERONYMVS, whom we have tried, after a fashion, to sketch in the dedicatory letter of the first part of this first Tome.

HIERONYMVS, then, was Referendary of both Signatures under Gregory XV, Pontiff, in 1621; Pro-legate of the Province of the Patrimony in 1625; Governor of Rome in 1628; Nuncio extraordinary to the Emperor Ferdinand II in 1632; Governor of Perugia in 1634; Vice-legate of the Duchy of Urbino in 1636; Archbishop of Seleucia and Nuncio to Louis XIII, King of France, in 1641; and finally he was created Cardinal of the Holy Roman Church, with the title of S. Eusebius, by Urban VIII in 1643. The chief management of French affairs was conferred on him for his outstanding skill in civil and ecclesiastical matters and his consummate prudence and sagacity joined to integrity. So Nicol. Grim. and Carolus Venasq. in this Genealogy; Iustinian. in the *Annals*; Vmb. folieta; and the archives of Genoa and Monaco.

RAMI SECVNDI

Of the Second Branch

Pars 3. In Qua Grimaldi Bononiæ Incolæ.

Part 3: in which are the Grimaldi living at Bologna.

[Margin: Gabriel.]

GABRIEL, son of Gaspar, lord of Stella, and great-great-grandson of Ingo (from whom comes the Second Branch), of the lords of Policastro, obtained in 1324, through the liberality of Robert, King of Naples, the freedom of his son Raphael, who had been captured by the enemy. He was Regent of the Vicaria of Naples in 1326, Viceroy of the Abruzzi [Aprutij] in 1328, and envoy of the same King to the Supreme Pontiff; then pensioner of Queen Joanna I in 1343.

[Margin: Raphael.]

[Margin: Gaspar.]

[Margin: Franciscus.]

[Margin: Stephanus.]

His son Raphael, of the lords of Policastro, served Robert, King of Naples, with his own galleys in 1328, and was afterwards pensioner of the sovereigns [Reg.] Louis and Joanna I in 1348. He fathered Gaspar, who flourished in 1381; Gaspar fathered Franciscus, who flourished in 1411; and Franciscus fathered Stephanus, who because of private quarrels, left Genoa and lived at Reggio in Emilia [Regium Æmiliæ] in 1478. He married Catharina Fesseta, a noblewoman of Reggio, by whom was born Grimaldus. In 1525 Grimaldus married Ludovica Anzina, a noblewoman of Reggio, and from them sprang Franciscus II, who in 1556 married Ursina Rampionesia, a noblewoman of Reggio. By her he fathered Paris [Paridem], who lived at Bologna in 1589 and married Anna Catanea, a noblewoman of Bologna; and by her he fathered five children of outstanding character. They are Father Vincentius Maria and Father Franciscus Maria Grimaldi [Francesco Maria Grimaldi] of the Society of Jesus; Iosephus Maria, who married Sulpitia, daughter of Alexius Orsus [Alexij Orſi], Senator of Bologna and Count of San Quintino [S. Quintini], by whom he had Vespasianus; Antonius Maria, who died young; and Paris Maria Grimaldus. So from Nicolaus Grim. and Carolus de Venasque in this Genealogy, the Registers of the Kings of Naples, the archive of Naples, and various instruments of Reggio and Bologna drawn up by public notaries [publica manu rogatis].

[Margin: Grimaldus]

[Margin: Franciscus II.]

[Margin: Paris.]

[Margin: Fathers Vincentius Maria and Franciscus Maria.]

[Margin: Iosephus Maria and Paris Maria.]

De Reliquis Ramis.

On the Remaining Branches.

[Margin: Branch 3.]

The Third Branch [RAMVS Tertius], comprising the lords of Castrum Novum [Caſtri Noui] and of Gattières [de Gattieres] in the County of Nice, originated from Obertus, brother of Ingo and son of Obertus, Prince of Monaco; on it see Nicolaus Grimaldus and Carolus Venasq. in this Genealogy, from p. 124. The male line of this branch died out in Anna Francisca, co-lady of

Turreta [Turretæ Condomina], who married Michael Angelus Lassaris, of the senatorial order of Nice.

[Margin: Branch 4.]

The Fourth Branch originated from Nicolaus, likewise a brother of Ingo and son of Obertus, Prince of Monaco. From him come the Grimaldi living at Carignano [Carignani] in Piedmont, on whom see Nicolaus Grim., Iustinianus in the *Annals of Genoa*, and Carolus de Venasque in this Genealogy, from p. 132.

[Margin: Branch 5.]

The Fifth Branch, in which are the Marquises of Petra [Petræ], the lords of Bellifortis and of Cuneo [Cunei] in Piedmont, and those living at Seville [Hiſpalis] in Spain, originated from Luchetus, lord of Petra Alta [Petræ altæ] and of Stella, and son of Grimaldus IV, Prince of Monaco. On this branch see Iustinianus in the *Annals of Genoa*, Vbertus Folieta, Nicolaus Grimald., and Carolus de Venasque in this Genealogy, from page 140.

[Margin: Branch 6.]

The Sixth Branch, in which are the Counts of Bolci, of the Holy Roman Empire [Sacrocæſarienſes], and of Marantium [Marantij], the Marquises of Bovesium [Boueſij] and Peveranium [Peueranij], and the lords of Leventium [Leuentij]. Their head, Andaro, son of Franciscus, Prince of Monaco, was lord of Bolei and of Vallis Massae [Vallis Maſſæ]. On this branch consult Carolus de Venasque in this Genealogy, from p. 158.

[Margin: Branch 7.]

The Seventh Branch, in which are the Grimaldi living at Seminara [Seminaræ] and lords of Missimerium [Miſſimerij] in the Kingdom of Naples, whose head was Bartholomæus, son of Raynerius, Prince of Monaco. On this branch see Nicolaus Grim. and Carolus Venasq. in this Genealogy, from p. 172.

[Margin: Branch 8.]

The Eighth Branch, in which are the lords of Antibes [Antipolis] and the Marquises of Corbonium [Corbonij], whose head was Antonius, son of Raynerius, Prince of Monaco. On this branch see Nicolaus Grim., the archives of Monaco and Antibes, the Register of the Kings of Naples, and Carolus Venasq. in this Genealogy, from p. 180.

[Margin: Branch 9.]

The Ninth Branch, in which are the Princes of Sancta Catharina [Sanctæ Catharinæ] and the Barons of Busetta, Pasquasia, Canuti, Favara [Fauaræ], Galisium [Galiſij] and Carropipium [Carropipij] in Sicily. Their head was Henricus, on whom see Nicolaus Grim. and Carolus de Venasque in this Genealogy, from p. 188.

Facultas R.P. Vincentij Carrafæ SOC. IESV Præpoſiti Generalis.

Licence of the Reverend Father Vincentius Carrafa [Vincenzo Carafa], Superior General of the Society of Jesus.

Since three theologians of our Society have examined the First Volume of the *Almagestum Novum* of Father Ioannes Baptista Riccioli [Giovanni Battista Riccioli], a priest of our Society, and have approved it as fit to be published, we grant permission for it to be printed, if those whom it concerns see fit. In testimony of this we have given this letter, signed by our hand and secured with our seal, at Rome on 1647 March 12.

Vincentius Carrafa.

Place of the seal.

Facultas R.P. Alexandri Boſelli SOC. IESV Prouincialis in Prouincia Veneta.

Licence of the Reverend Father Alexander Bosellus, Provincial of the Society of Jesus in the Venetian Province.

Since three theologians of the same Society have examined the additions made to the First Volume of the *Almagestum Novum*, divided into two parts, by Father Io. Bapt. Riccioli, a priest of our Society, and have approved them as fit to be published, we too, having received the authority from our Reverend Father Gosuinus Nickel [Goswin Nickel], Vicar General of the Society of Jesus, grant that they be printed, if those whom it concerns see fit. In testimony of this we have given this letter, signed by our hand and secured with our seal, at Bologna on 1651 August 17.

Alexander Bosellus.

Place of the seal.

Examined by Father Bonaventura Cavalerius [Bonaventura Cavalieri], and afterwards by Father Franciscus Maria Grimaldus, professors of mathematics, on behalf of the Most Eminent and Most Reverend Cardinal Archbishop.

Don Andreas Cuttica, Clerk Regular of St Paul and Penitentiary Rector [Pœnitent. Rect.], on behalf of the Most Eminent and Most Reverend Cardinal Archbishop.

IMPRIMATVR

Let it be printed.

Brother Vincentius Pratus à Serravalle, Inquisitor General of the Holy Office at Bologna.

INDEX LIBRORVM ET CAPITVM SECVNDÆ PARTIS TOMI I.

Index of the Books and Chapters of the Second Part of Volume I.

LIBER VIII.

Book VIII.

DE COMETIS, ET STELLIS NOVIS.

On Comets and New Stars.

SECTIO I.

Section I.

De Cometis.

On Comets.

Chapters

- I. Proem [Prohemium], treating the principal authors who have written on comets, p. 1
- II. The names, kinds and species of comets. 2
- III. A chronological history of 154 comets, with the events that others, rather than we, have been accustomed to attribute to comets as their causes or signs. 3
    - History of the comets before Christ. 3
    - History of the comets after Christ, with their observations and ephemerides, from p. 5 to 23
- IV. On the properties, or accidents, of comets, gathered into one from the preceding history. 23
    - The number of comets, p. 23
    - Comets appearing together at the same time [Concurſus]. 23
    - Comets divided into several, or coalescing from several. 23
    - The season of the year in which comets have appeared. 23
    - The duration of comets. 24
    - The apparent size of the head of comets. 24
    - The apparent size of the tail, or beard, of comets. 24
    - The true size of the head or tail of comets. 25
    - The position of the tail. 26
    - The region of the sky in which comets arose or were extinguished, or into which they were carried. 26
    - The motion of comets in consequence, or in precedence, or with the first mover [primi Mobilis]. 27

- The arc, or path, of comets: its magnitude, and the distance from the Sun. 28
- The speed of comets. 28
- The place of comets, or their distance from the Earth. 28
- The shape, colour, smell and transparency [Diaphaneitas] of comets. 29
- Two scholia. 29

- V. On the prognostics and the final cause of comets. 29
  - The views of poets, historians, astrologers, meteorologists and astronomers on these prognostics, from p. 30 to 34
  - A chronicle of comets that were fortunate or unfortunate for particular people. 34
- VI. The opinions on the matter, place and efficient cause of comets are set out in summary, gathered with the greatest fidelity and diligence. 35
- VII. That a comet is not a mere appearance of reflected or refracted light, nor the joint appearance of several known stars. 40
  - Two scholia. 42
- VIII. Whether comets are extraordinary planets, yet perpetual, appearing to us after long intervals of time. 42
- IX. Whether comets are an aggregate of many small stars, existing from the beginning of the world but separately unknown and invisible. 44
- X. Whether comets are formed from an abundance of elementary exhalations, compressed and ignited in the highest region of the air, or remaining below the Moon. 45
- XI. Twelve arguments against the Aristotelian opinion on comets, with some kind of solution of each. 47
  - Argument 1, from the turning of the tail away from the Sun. 47
  - Argument 2, from the diurnal motion of the comet, imitating the motion of the first mover. 48
  - Argument 3, from the motion of the comet above the horizon. 48
  - Argument 4, from its proper motion, slower than the Moon's. 49
  - Argument 5, from the ordered and regular motion of the comet along the same great circle. 50
  - Argument 6, from the size of comets. 52
  - Argument 7, from the duration of comets, p. 54
  - Argument 8, from the transparency of the tail. 55
  - Argument 9, from the apparent size of a comet viewed through the telescope. 55
  - Argument 10, from the height of comets required for them to be seen at the same time by many observers far apart. 56
  - Argument 11, from the height of a comet required for it to be visible outside the Earth's shadow. 56
  - Argument 12, from parallax. 56
  - Scholium. 56

- XII. Whether a comet is made of elementary matter, not ignited but illuminated by the Sun, and raised above the air or the Moon. 57
- XIII. Whether comets, if they are celestial in origin and place, are produced by condensation or by mere alteration of parts of the heaven, or by generation from matter flowing out of the Sun and the other planets. 57
- XIV. On the height of the regions of the air: seven problems. 58
- XV. On the height of comets visible from one or from different places on the Earth, to be investigated independently of parallax: nine problems. 63
- XVI. Whether the argument taken from parallax has any force, and how much, for determining the distance of any phenomenon from the Earth, and on its use or abuse; on which occasion the authority of Tycho, and of Claramontius [Scipione Chiaramonti], in this matter is discussed. 70
- XVII. Definitions and axioms needed for understanding parallaxes and their properties. 74
- XVIII. Whether the comet of 1577 was demonstrated to be above the Moon or below it — that is, whether it was shown to have a smaller or a larger parallax than the Moon has — the arguments of Tycho and others being examined. 77
- XIX. On the parallax and height of the remaining comets from 1577 to 1590. 90
    - On the comet of 1582, p. 91
    - On the comet of 1585, p. 91 and 93
- XX. On the parallax and height of comets from 1590 to 1600. 95
- XXI. On the comet of 1607, p. 96
- XXII. On the comets of 1618. Ten arguments are examined, from p. 100 to 117
- XXIII. The opinions of others being collected into one synopsis, it is established, in five conclusions, what should be held on the place, parallaxes and distances of comets from the Earth. 117
- XXIV. On the true size of the head and tail of comets, to be determined from observations. 120
- XXV. On the position of the tail of comets, and its physical and optical causes. 121
    - Two scholia. 12S[4]
- XXVI. On the rectilinear and curvilinear motion of comets. 128

SECTIO II.

Section II.

[4]so printed — the third sort is a roman capital S, presumably a wrong sort for 5 (page 125); not checked against the page the entry points to.

De Nouis Stellis.

On New Stars.

Chapters

- I. A chronological catalogue of the new stars observed in the heavens, in former times and most recently. 130
    - Three scholia. 132
- II. History of the general observations of the new star of 1572 seen in Cassiopeia, and of the opinions on its place and origin. 133
- III. History of the particular observations of the same star, as regards numbers and measurements. 137
- IV. Whether it has been demonstrated, by arguments not involving parallax, that the star of 1572 was above or below the Moon. 140
- V. By what reasoning Tycho tried to demonstrate, from the lack of sensible parallax, that the star of 1572 was above the Moon, the Sun and Saturn. 142
    - Three scholia. 145
- VI. Tycho's arguments drawn from parallax are answered, and it is shown that he did not demonstrate that the new star of 1572 was above the Moon, let alone in the eighth sphere; the most subtle fallacies lurking in the depths of parallaxes are exposed. 146
    - Scholium. 150
- VII. Whether Tycho, from other observations made at one place on the Earth and adduced in volume 1 of the *Progymnasmata*, chapters 8 and 9, or the authors he reports, or Santutius, demonstrated that the star of 1572 was above the Moon. 150
- VIII. Whether Galileo, from observations made at different places, demonstrated that the new star of 1572 was above the Moon, or even among the fixed stars. 155
- IX. Whether any of the authors whom Tycho adduces against himself in volume 1 of the *Progymnasmata*, chapter 10, demonstrated that the new star of 1572 was below the Moon. 159
- X. Whether Scipio Claramontius demonstrated, absolutely or from some definite hypothesis, that the new stars of 1572 and 1573 were sublunary. 160
    - Two scholia. 164
- XI. The opinions of authors on the place of the new star of 1572 and its distance from the Earth being collected, it is established what may be maintained about its distance — if not with certainty, then at least probably — or what is more probably to be asserted. 164
    - Eight conclusions. 165
- XII. History of the new star seen from 1600 onward in the breast of the Swan, and whether it was truly new, and how long it lasted. 166

- XIII. On other observations concerning the new star of 1600, and whether, or with what certainty, it may be inferred that it was above the Moon. 167
- XIV. History of the new star of 1604 and 1605 seen in Serpentarius. 168
- XV. On the parallax of the new star of 1604, and its distance from the Earth. 172
- XVI. A synopsis of the opinions on the distance and size of the three new stars that appeared in 1572 in Cassiopeia, in 1600 in Cygnus, and in 1604 in Serpentarius. 173
- XVII. On the matter, nature and generation of new stars. 174
- XVIII. On the efficient and final cause of new stars. 177
- XIX. On the wonderful star that foreshowed to the three holy Magi the birth and cradle of Christ the Lord. What astronomers, and what the holy Fathers and Doctors of the Church, thought of it. 179
- XX. The errors of some concerning the star of the Magi are reported and refuted, but chiefly those of the genethliacs [Genethliacorum]; where something is also said of the nativity figure of Christ, erected by some with little piety, and of the great conjunction that preceded this star. 186

LIBER IX.

Book IX.

DE MVNDI SYSTEMATE.

On the System of the World.

SECTIO I.

Section I.

De Subſtantia, & Accidentibus Prȩcipuis Cæleſtium Corporum.

On the Substance and the Principal Accidents of the Celestial Bodies.

Chapters

- I. On the work of the first day, that is, on the creation of the heaven and the Earth, and of light and time, from Holy Genesis and according to the mind of the Fathers and theologians. 193
  - Question 1. Whether by the words "In the beginning God created the heaven and the earth, and the earth was without form and void" the creation of any determinate body on the first day is signified. 193
  - Question 2. On the notion of the names "heaven" and "firmament" among the Latins and the Hebrews. 194

- Question 3. What Moses meant by the name of heaven and earth created by God in the first instant of the world. 194
- Question 4. How many and which elements the ancients, and chiefly the Fathers, recognised from Moses. 200
- Question 5. What chaos was according to the poets, philosophers and theologians. 201
- Question 6. Whether there is an empyrean heaven, when it was made, and of what kind it is. 204
- Question 7. What the light was that God made on the first day of the world. 209
- Question 8. On the distinction of the first three days, from the words "and he divided the light from the darkness, and called the light day, and the darkness night, and there was evening and morning, one day." 211
- Question 9. Whether day preceded night, or night day. 213

- II. On the work of the second day: that is, what the firmament made on that day was and is, from what matter, and what and of what kind are the waters above the heavens. 216
  - Question 1. Whether some heaven was made on the second day of the world from water condensed and solidified in the manner of ice or crystal. 216
  - Question 2. Whether some starry heaven, made or left on the second day, is fluid, in which the planets move of themselves. 218
  - Question 3. Whether there are waters above the starry heavens, and which, for what end or use, and of what bulk. 220
  - Question 4. Whether the upper waters are holy angels. 223
  - Question 5. Whether the upper waters are clouds or vapours of the air. 223
- III. How many heavens, and which, were established by God on the first day of the world. 224
- IV. On the work of the fourth day, that is, on the luminaries and the other stars, established and placed in the heaven by God. 225
  - Question 1. Why the production of the stars was deferred to the fourth day. 225
  - Question 2. Whether the Sun, with the other stars, was produced on the fourth day as to its substance, or not. 226
  - Question 3. By what kind of action the luminaries etc. were produced: by creation or by generation. 228
  - Question 4. From what matter the luminaries and the other stars were made. 229
  - Question 5. Why the Moon and the Sun are called the great luminaries. 231

- Question 6. Whether the Sun on the fourth day was placed at a solstitial point or at an equinoctial one, and at which equinox; and the Moon at new moon or at full moon. 232
- V. Whether the heaven is a simple body, or composed of form and of matter different from the elementary, or of the same nature as the elementary, and of which element. 232
  - Question 1. On the simplicity and composition of the heaven. 232
  - Question 2. On the matter of which the heaven consists. 233
  - Question 3. Of which element, or elements, the heaven consists. 235
- VI. Whether the heaven is generable and corruptible. 237
- VII. Whether the heavens are solid or fluid, all of them or some. 239
  - The arguments for the solidity of the heavens are examined, with their solutions. 240
  - The arguments for the fluidity of the heavens are examined, with the replies to them. 242
- VIII. Whether the heavens and the stars are animate. 242
- IX. Whether the heaven is infinite, and whether its figure is spherical. 246

SECTIO II.

Section II.

De Motoribus, & Motibus Cælorum.

On the Movers and the Motions of the Heavens.

Chapters

- I. Whether the heavens or the stars are moved by Intelligences, or by an intrinsic form or nature of their own. 247
- II. On the instruments of the celestial motions: whether they are solid orbs, or mere circles that can be traced in a fluid aether, or mere concentrics. p. 251
- III. Whether there is a motion of the primum mobile distinct from the motion of the fixed stars and of the planets, and in what subject; whether the motion of the secondary mobiles is contrary to it; and by what reasons these two motions can be reconciled. p. 254
  - Three scholia. 261
- IV. Whether the proper motion of the stars is, of itself and by the primary intention of nature — or rather of God — uniform or non-uniform, yet ordered and regularly non-uniform, etc. 262
- V. Whether the moving Intelligences of the stars intend of themselves the description of some geometrical figure, or depend on it as on a rule; or whether they complete the numbers of the motions by the force of

logistic alone; and whether people should attempt the same in setting out these motions. 268
- VI. Whether the proportions of the celestial motions can be known by us in this life, and expressed; whether they are all rational, or some irrational; where their revolution, all of them together, into the same state is treated. 269
- VII. On the sound and concord, that is, on the harmony, of the celestial motions. 270

SECTIO III.

Section III.

De Syſtematibus Mundi Terram Immobilem Ponentibus.

On the Systems of the World That Make the Earth Immovable.

Chapters

- The principal authors who treat of the systems of the world. 271
- I. On the number of the total heavens. 271
  - Table of the opinions on the number of the heavens, p. 275
- II. What the system of the world is and how many kinds there are; and on the most ancient systems, chiefly the Pythagorean, the Archimedean, the Plinian and the Ptolemaic, which prevailed down to Clavius [Christoph Clavius]. 276
- III. On the system of Plato, of the Platonists, of Geber [Jābir ibn Aflaḥ] and of Theon; on which occasion Cicero's system is discussed. 280
- IV. On the system of the Egyptians, that is, of Vitruvius, Martianus Capella, Macrobius, Bede and Argolus [Andrea Argoli]. 283
- V. On the system of Eudoxus, Callippus and Aristotle. 283
- VI. On the system of Averroes, Alpetragius [al-Biṭrūjī], Delphinus [Federico Delfino] and Io. Bapt. Amicus [Giovanni Battista Amico]. 285
- VII. On the system of Io. Bapt. Turrianus [Giovanni Battista della Torre] and Hieronymus Fracastorius [Girolamo Fracastoro]. 286
- VIII. On the system of Tycho, Longomontanus, Blancanus [Giuseppe Biancani] and many followers of Tycho. 287
- IX. On our own system. 288

CECTIO IV.

Cectio [?] IV.

De Syſtemate Terræ Motæ.

On the System of the Moving Earth.

Chapters

- I. On the dignity and necessity of this treatment, and on the authors who have undertaken to defend or to attack this system. 290
    - Authors for the hypothesis of Copernicus. 290
    - Authors against the hypothesis of Copernicus. 291
- II. On the authors who have attributed to the Earth a diurnal turning about its own centre. 291
- III. On the authors who, besides the diurnal turning, have also ascribed an annual translation to the Earth; where Vesta is discussed in passing — whether she was the Earth or fire. 293
    - Six scholia, on certain other motions attributed to the Earth. 295
- IV. The three or four motions attributed to the Earth by Copernicus and his followers are explained distinctly, together with their properties and wonderful conditions. 296
    - The diurnal revolution of the Earth is explained. 296
    - The second motion of the Earth is explained. 299
    - The third motion of the Earth is explained. 304
    - The fourth motion of the Earth is explained. 308
    - Eight scholia, on the figure arising from the motions already mentioned, and on their other properties. 309
- V. Ten arguments for the diurnal revolution of the Earth, taken from the conditions of the Earth compared with the conditions of the highest sphere, are proposed and resolved. 311
    - Argument 1, from the figure of the Earth; where the figure of the heaven is treated in passing. 311
    - Argument 2, from the mobility of the Earth, capable of being carried along [raptilis] by the motion of the primum mobile. 312
    - Argument 3, from circular motion as befitting the elements of themselves, and so the Earth too, rather than straight motion. 313
    - Argument 4, from the enormous size of the eighth sphere, and from the proportion of the whole compared with the smallness of the Earth, a tiny particle of the universe. 314
    - Argument 5, from the ease of motion arising from the size of the moving body. 315
    - Argument 6, from the infinity of the world and of the heaven supreme; where something is also said in passing on the infinity of the world. 316
    - Argument 7, drawn from the nature of place and of the container. 318
    - Argument 8, taken from the incorruptibility of the heaven. 318
    - Argument 9, from the fluidity of the heaven and the constant distance of the fixed stars from one another. 318
    - Argument 10, from the neediness of the Earth and the independence of the stars from the Earth, which does not seem to be the end to which the stars are ordered. 319

- VI. Seven arguments, drawn from the conditions of the diurnal motion itself, for a diurnal motion of the Earth rather than of the heaven, are proposed and resolved. 320
    - Argument 1, from the incredible speed of the diurnal motion if it is attributed to the heaven. 320
    - Argument 2, from the proportion of the motions, the intervals and the moving bodies [Mobilium]. 322
    - Argument 3, from the incompatibility of a proper motion with the motion of the primum mobile in the same subject. 323
    - Argument 4, from the simplicity of motions. 324
    - Argument 5, from the unequal participation in the diurnal motion, that is, the unequal speed of the things said to be moved by the diurnal motion. 325
    - Argument 6, from the inconstant declination and speed of the fixed stars. 325
    - Argument 7, from the inequality of the natural days, arising from the inequality of the diurnal motion. 326
- VII. The three remaining arguments for the diurnal motion of the Earth are proposed and resolved. 326
    - Argument 1, from comets. 326
    - Argument 2, from the perpetual blowing of the air westward within the tropics. 327
    - Argument 3, from the likeness of a chemical earth and of a magnetic terrella; where in passing certain notable magnetic experiments made with a terrella are given. 328
- VIII. Ten arguments for placing the Earth outside the centre of the world by an annual motion are proposed and resolved, taken from various conditions of the Earth and the planets that do not involve motion. 330
    - Argument 1, from the nobility of the Sun, greater than that of the Earth. 330
    - Argument 2, from the centre of the planetary system. 331
    - Argument 3, from the source of light and heat. 332
    - Argument 4, from the source of motion. 332
    - Argument 5, from the bulk of the Sun and of the Earth. 333
    - Argument 6, from need and from the end of motion. 333
    - Argument 7, from the analogy of the microcosm, p. 334
    - Argument 8, from the fitting thickness of the heavens. 334
    - Argument 9, from the distinction of the heavens. 334
    - Argument 10, from the intervals and the number of the planets, derived from the dimensions of the five regular bodies, that is, from Kepler's *Mysterium Cosmographicum*. 335
- IX. Five arguments for the annual motion of the Earth, taken from the motions of the planets and the instruments of those motions, are proposed and resolved. 339

- Argument 1, from the superfluity of the motions of the three superior planets on epicycles, and of the two inferior ones on their own eccentrics, removed by the single, simple annual motion of the Earth. 339
- Argument 2, from the imperfection of the celestial motions, if they are in reality such as they appear, removed by the annual motion of the Earth. 341
- Argument 3, from the cause of certain other phenomena, which is given a priori by the annual motion of the Earth alone. 343
- Argument 4, from the latitude and inclination of the planets to the ecliptic. 343
- Argument 5, from the equant circle, removed by the annual motion of the Earth. 345

- X. Five arguments for the annual motion of the Earth, taken from certain celestial motions and variations, are proposed and resolved. 345
  - Argument 1, from the diameter, motion and distance of the fixed stars, apparently varied. 345
  - Argument 2, from the satellites of Jupiter. 345
  - Argument 3, from the variation and libration of the Moon. 346
  - Argument 4, from the new stars. 346
  - Argument 5, from the passage of comets, p. 346
- XI. Two arguments for the annual motion of the Earth, from the change of the meridian line and of the altitude of the pole, are proposed and resolved. 347
  - Argument 1, from the change of the meridian line. 347
  - Argument 2, from the change of the altitudes of the pole. 348
- XII. The argument for the annual motion of the Earth drawn from the motion of the sunspots is proposed and resolved; and on that occasion the doctrine on these spots handed down by Galileo and Scheiner [Christoph Scheiner] is reduced to an epitome, so that this argument and its solution may be set out more clearly. 351
  - Scheiner's doctrine on the sunspots, taken from *Apelles post tabulam*. 354
  - Scheiner's doctrine on the sunspots, from the *Rosa Ursina*. 355
- XIII. Five lighter arguments for the annual or diurnal motion of the Earth, taken from the motion of many things toward the east, are resolved. 360
- XIV. For a fuller understanding and resolution of the argument for the diurnal and annual motion of the Earth together, derived from the tide of the sea, both the history of the sea tide and of the other motions of the sea, and the celebrated opinions on the cause of the tide, are treated carefully. 360
  - Galileo's argument is proposed. 360
  - History of the motions of the sea from various writers. 363
  - The first motion, from north to south. 363

- The second motion, from east to west, and another arising from these. 364 and 365
- The third motion, the flux and reflux. 365
- The diurnal, monthly and annual period and variation of the tide. 367 to 369
- Nautical rules for finding the hour of high water [Aquæ Viuę], that is, of the highest tide, on any given day of the Moon in a given port of Europe. 370
- Table 1. Of the hours of high water on the day of new and of full moon, from a Cantabrian ship's master [Nauclero Cantabro] and from Crescentius. 370
- Table 2. Of the hours of high water for any day of the Moon, from Father Georgius Furnerius [Georges Fournier] of the Society of Jesus. 371 and 372
- Opinions on the cause of the tide. 373
- Refutation of the cause of the daily tide adduced by Galileo. 377
- Refutation of the cause of the monthly and annual variation of the sea tide devised by Galileo. 380

- XV. The system of Don Io. Bapt. Balianus [Giovanni Battista Baliani] is indicated, for explaining the cause of the sea tide by the motion of the Earth better than Galileo achieved — not, however, asserted by him, but devised as a mere hypothesis, p. 381
- XVI. For a better understanding and solution of the argument for the diurnal and annual motion of the Earth together, from the increase of the velocity of heavy bodies, selected theorems and problems are proposed on the velocity of heavy and light bodies and on the increase of velocity, drawn from our own experiments in air as well as in water. 381
    - First class of experiments, for lightness as distinct from heaviness. 383
    - Second class of experiments, for the unequal motion of heavy bodies descending ever faster through the air. 384
    - Third class of experiments, for the proportion of the increase of velocity of heavy bodies descending through the air. 386
    - Fourth class of experiments, for the unequal descent through the air of two heavy bodies of different weight from the same height. 387
    - Fifth class of experiments, for the unequal descent of heavy bodies through water. 389
    - Sixth class of experiments, for the increase of velocity of heavy bodies descending through water. 389
    - Seventh class of experiments, for the unequal descent through water of two heavy bodies of different weight. 390
    - Eighth class of experiments, for the unequal ascent through water of light bodies taken separately. 391

- Ninth class of experiments, for the increase of velocity of light bodies ascending through water. 392
- Tenth class of experiments, for the unequal ascent through water of two light bodies of different lightness. 392
- Eleventh class of experiments, for the fall of different balls along a plane inclined to the horizon, at different degrees of inclination. 392
- Twelfth class of experiments, for the raising of a greater weight by a heavy body descending naturally from a greater and greater height. 393
- Thirteenth class of experiments, for the penetration of water made by a heavy body descending from a greater and greater height. 394
- Thirteen theorems selected from the experiments set out above. 394
- Six problems selected from what has been said. 396

- XVII. Whether, and how, the diurnal and annual motion of the Earth together give the only, or a better, account of the increase of velocity of heavy and light bodies, and whether such motion is therefore strongly confirmed by this. On which occasion the figure that heavy and light bodies describe by their natural motion on the hypothesis of the moving Earth is discussed, and Galileo's argument for the motion of the Earth taken from it is resolved. 397
  - The opinion and arguments of Bullialdus [Ismaël Boulliau] are answered, p. 398
  - Galileo's arguments, and objections against his asserted demonstrations. 399 to 406
- XVIII. Whether, and how, on the hypothesis of the resting Earth, an a priori account is given of the continuous increase of velocity of heavy and light bodies naturally descending or ascending. 407

Hactenus de Argumentis pro Motu Terræ Excogitatis. Sequuntur Argumenta pro Terræ Immobilitate.

So far, the arguments devised for the motion of the Earth. There follow the arguments for the immobility of the Earth.

Chapters

- XIX. Five arguments from the increase of velocity of heavy and light bodies are proposed against the diurnal, or also the annual, motion of the Earth. 408
  - Argument 1, from the real increase of velocity of heavy bodies, against the diurnal motion of the Earth. 409
  - Argument 2, against the diurnal and annual motion of the Earth together, likewise drawn from the real increase of velocity of heavy bodies. 413
  - Argument 3, against the diurnal motion of the Earth. 416

    - Arguments 4 and 5, against the same motion. 417
- XX. Six arguments from the rectilinear and perpendicular motion of heavy and light bodies are proposed against the diurnal and annual motion of the Earth together. Many of them, once the replies of the Copernicans have been weighed, stand firm in their physical evidence. 417
    - Argument 1, p. 418
    - Argument 2. 421
    - Argument 3. 421
    - Argument 4. 422
    - Argument 5. 422
    - Argument 6. 423
- XXI. Fourteen arguments are proposed, from the motion of elementary bodies toward the four cardinal points, or quarters, of the world, against the diurnal motion of the Earth, and much more against the motion compounded of the diurnal and the annual; five of them are physically evident. 423
    - Argument 1. 423
    - Arguments 2, 3, 4 and 5. 424
    - Argument 6, from cannon [Bombardis]. 425
    - Arguments 7 and 8, from cannon. 426
    - Argument 9, from cannon or other things. 427
    - Arguments 10, 11 and 12. 428
    - Arguments 13, 14. 429
- XXII. Five arguments are proposed — but invalid ones — from the impetus and excessive speed of the Earth and of kindred bodies, if they were moved with a diurnal or even an annual motion. 429
    - Seven tables for the speed of the Copernican Earth. 430 and 431
    - Arguments 1 and 2. 431
    - Arguments 3 and 4. 532 [?]
    - Argument 5. 433
- XXIII. Four arguments against the motion of the Earth are proposed and resolved, taken from the risings and settings of stars seen either in the open or from a well, or from the solstitial shadow of the Sun, or from the eclipse at the death of Christ. 434
    - Arguments 1 and 2, containing four problems. 434
    - Arguments 3 and 4. 436
- XXIV. Four arguments against the diurnal and annual motion of the Earth, taken from the principle and the simplicity of motion, are proposed and resolved. 437
    - Arguments 1, 2, 3, 4. 437
    - Scheiner's various questions and smaller queries are answered. 438
- XXV. Eleven arguments against the annual motion of the Earth alone are proposed and answered — first those that Aristotle and his followers

took from the place owed to the Earth in the world — and the selected texts bearing on this are collected and, where needed, explained. 439
    - Text from Book 2 of *De caelo*. 439 [?]
    - Text from Book 4 of *De caelo*. 441 [?]
    - Argument 1. 442 [?]
    - Arguments 2, 3 and 4. 444 [?]
    - Arguments 5, 6, 7 and 8. 445 [?]
    - Arguments 9, 10 and 11. 446 [?]
- XXVI. Five lighter arguments against the annual motion of the Earth and its position outside the centre of the universe are proposed and resolved. 447
- XXVII. Nine arguments against the annual motion of the Earth, taken from the celestial phenomena, and chiefly from eclipses and the evident motion of the Sun [euidentia motus Solis], are proposed and resolved. 448
    - Arguments 1 and 2. 448 [?]
    - Arguments 3, 4, 5, 6 and 7. 449 [?]
    - Arguments 8 and 9. 450 [?]
- XXVIII. Three more subtle arguments against the annual motion of the Earth, taken from the parallax of the annual orb, are proposed and resolved. 450 [?]
    - Argument 1. 450 [?]
    - Argument 2. 452 [?]
    - Argument 3. 453 [?]
- XXIX. Three arguments against the annual motion of the Earth, taken from the excessive distance of the fixed stars and the insane size of the eighth sphere, are proposed; where the opinions on the distance of the fixed stars drawn from the various hypotheses of the Copernicans are reviewed, together with their foundations. 454
    - Opinions of the Copernicans on the distance of the fixed stars. 454
    - Opinions on the distance of the fixed stars of those who are not Copernicans but who differ [?] from the Copernican hypothesis. 455
    - Argument 1, from the immensity of the eighth sphere. 457
    - Argument 2, from the immense interval, empty of stars, between Saturn and the fixed stars, p. 458
    - Argument 3, from the smallness of the Sun, too weak to illuminate fixed stars so remote. 459
- XXX. The argument from the enormous bulk of the fixed stars against the annual motion of the Earth is proposed. On which occasion it is debated whether this bulk in motionless fixed stars is more incredible than the speed that befits them on the hypothesis of the resting Earth. 460

    - Table of the sizes of the fixed stars according to the hypothesis of the Copernicans. 461
- XXXI. Six subtle arguments against the annual motion of the Earth, taken from refraction, are proposed. 463
    - Arguments 1, 2 and 3. 463
    - Argument 4. 464
    - Arguments 5 and 6. 465
- XXXII. An argument against Copernicus from the excessive licence of devising different systems. 465
- XXXIII. The arguments made so far for the diurnal and annual motion of the Earth, and the solutions of those arguments, are reduced to an epitome. 465
    - Twenty arguments for the diurnal motion of the Earth. 466
    - Twenty-nine arguments for the annual motion of the Earth. 469
- XXXIV. The arguments made so far for the immobility of the Earth, with the solutions of many arguments, are reduced to an epitome. 472
    - Thirty-eight arguments against the diurnal and annual motion of the Earth together. 472
    - Thirty-nine arguments against the annual motion of the Earth. 475
- XXXV. From reasons alone, setting aside all authority, it is finally concluded which of the hypotheses is to be asserted absolutely: the one that supposes the motion of the Earth, or the one that supposes its immobility, that is, its rest. 478
- XXXVI. The authorities of Holy Scripture for the motion of the Sun and the immobility of the Earth are brought forward. 479
- XXXVII. How the Fathers and the sacred interpreters understood the passages of Holy Scripture already mentioned; where the miracles performed in the motion of the Sun are treated carefully. 481
- XXXVIII. The replies of the Copernicans to the sacred authorities on the motion of the Sun and the rest of the Earth are brought forward and refuted, as not only insufficiently solid but also dangerous. 487
    - Question 1. Whether expertise in physics and astronomy is necessary for ecclesiastical persons in order to pass a valid and binding censure on physical and astronomical matters according to the rules of the faith and of the sacred canons. 487
    - Question 2. Whether Holy Scripture teaches physical or astronomical matters. 490
    - Question 3. Whether the assertions on the motion of the Sun and the stability of the Earth contained in the Holy Scriptures belong to questions of faith and religion. 490
- XXXIX. Question 4. Whether the assertions of Holy Scripture on the motion of the Sun and the stability of the Earth are to be taken in the literal sense, or figuratively, or according to the sense of the common

people, that is, as to appearance. Where ecclesiastical rules on the use of the literal sense are given. 491
- XL. What censure the assertors of the motion of the Earth and the immobility of the Sun deserve, and have received, from learned men, but chiefly from the Sacred Congregation of Cardinals deputed by the Supreme Pontiff to the Office of the Inquisition. 495
    - Extract of the decree of the Sacred Congregation concerning the assertions of Copernicus. 496
    - The sentence against Galileo, the abjuration, etc. 497
    - Conclusion of the section, on the opinion to be chosen in this controversy. 500

SECTIO V.

Section V.

De Syſtemate Mundi Harmonico.

On the Harmonic System of the World.

Chapters

- I. On the necessity of this section, and on the authors who have treated of harmonic proportions. 501
- II. On the concord of the heavens in general. 501
    - Whether the celestial bodies produce a real sound by their motion. 504
- III. On proportions, chiefly the harmonic. 506
- IV. On the discoverers, discovery, number and nomenclature of the consonances and of the dissonant intervals; and on the simple division of the monochord. 507
    - Definitions and harmonic axioms. 508
    - Table 1. Of the consonances with their proportions, etc. 509
    - Table 2. Of the dissonant intervals. 510
    - Question 1. Which consonances different authors accepted. 510
    - Question 2. Why consonances arise from proportions of greater rather than of lesser inequality. 510
    - Question 3. Whether the tone is divisible into two equal semitones. 510
    - Question 4. Why the diapason contains, or bounds, within itself the whole diversity of the consonances, and is the queen of the consonances. 511
    - Question 5. By what art all the consonances can be distinguished by hearing itself, and how the division of the monochord is to be made, p. 511
    - Two scholia. 513

- V. On the various divisions and genera of music, of melodies and of songs. 515
  - Table of the tetrachords. 515
- VI. On strings, voices and musical notes, their nomenclature, and their distribution in the harmonic system, that is, in the musical scale. 516
  - The greatest diatonic system [Syſtema Maximum Diatonicum]. 518
  - The chromatic system. 519
  - The enharmonic system. 519
  - The Keplerian system. 520
- VII. In what order the voices of the Muses and the sounds of the strings should be fitted to the celestial spheres. 521
- VIII. Whether, and on what principle, the intervals of the harmonic system should be fitted to the distances of the stars. 525
- IX. Whether the size and density of the celestial bodies were determined from harmonic proportions. 531
- X. Whether, and on what principle, the motions of the planets were determined by God from harmonic proportions. 531
- XI. Whether the aspects of the stars have their force and determination from harmonic configurations. 533

LIBER X.

Book X.

SECTIO I.

Section I.

De Triangulorum Analyſi.

On the Analysis of Triangles.

Chapters

- I. Proem, in which certain definitions and general precepts for the use of logarithms are given, p. 536
- II. In which are 13 rules for plane, that is rectilinear, right-angled triangles, with examples. 538
- III. In which are 9 rules for plane oblique-angled triangles, with examples, p. 540
- IV. In which are 16 rules for spherical right-angled triangles, with examples, p. 541
  - Scholium. 544
- V. In which are 14 rules for spherical oblique-angled triangles, with examples, p. 545
  - Index of the preceding rules. 549

SECTIO II.

Section II.

Problemata Generalia primi Mobilis.

General Problems of the Primum Mobile.

Order of the problems

- Proem. 550
    - Authors, the source of some of what follows.
- 1. To find the meridian line and the altitude of the pole. 551
- 2. To find the greatest declination of the Sun, or the obliquity of the ecliptic. 551
- 3 and 4. To derive the declination of a star from its meridian altitude, or the latter from the former. 551
- 5 to 7. To find the place of the Sun in three ways, p. 551
- 8 to 10. To find the right ascension of the Sun or of a point of the ecliptic in three ways, without trigonometry. 551
- 11 to 13. To find the obliquity of the ecliptic in three ways. 552
- 14. To determine the angle of the ecliptic and the meridian. 552
- 15. To seek the declination of the Sun or of a point of the ecliptic trigonometrically, and to construct a table of declinations. 553
    - Authors of the table of declinations. 535 [?]
- 16. To find the right ascension of the Sun or of a point of the ecliptic trigonometrically, and to compile tables. 553
    - Authors of these tables. 553
- 17 to 23. To observe the right ascension of a star in seven ways, which give as many problems. 553
- 24. To determine the increments or decrements of right ascension and declination, p. 553
- 25 to 28. To observe in four ways the declination of a star placed outside the meridian. 553
- 29 to 33. To investigate in five ways the angle of the vertical circle and the circle of declination at the centre of a star. 554
- 34 to 37. To investigate the azimuth of a star by four different problems. 554
- 38, 39. To deduce the azimuth of a star by observing, in two ways. 554
- 40 to 43. To seek the altitude of any star by four different problems. 555
- 44 to 46. To seek in three ways the altitude of the Sun or of any star on the prime vertical. 555
- 47. To find the distance of the Sun or of any star from the prime vertical. 556
- 48 to 51. To find the longitude of a star by four different problems. 556
- 52 to 55. To seek the latitude of a star by four different problems. 557

- 56 to 59. To seek the right ascension of a star by four different problems. 557
- 60. To construct a table of right ascensions for planets, or for stars having latitude. 557
- 61 to 64. To seek the declination of a star by four different problems. 557
- 65. To construct a table of declinations for planets, or for stars having latitude. 558
- 66 to 75. To trace, by ten distinct problems, the angle made at the centre of a star by the circle of declination and the circle of latitude. 558
- 76 to 83. To investigate by eight different problems the angle of the circle of declination with the ecliptic. 558
- 84 to 87. To seek in four different ways the angle of the circle of latitude and the equator. 559
- 88. To seek the angle of the ecliptic and the vertical made at the centre of a star having latitude. 559
- 89 to 98. To investigate, by ten distinct problems, the angle of the ecliptic and the vertical made at the centre of the Sun, or of a star lacking latitude. 559
- 99. To find the difference of right ascension. 559
- 100. To seek the right ascension of a star by its distance from another star. 560
- 101. To investigate the declination of a star by its distance from another star. 560
- 102. To seek the difference of longitude between two stars by their distance from each other, p. 560
- 103. To find the longitude of a star by its distance from another star. 560
- 104. To deduce the latitude of a star from its distance from another star. 560
- 105. To deduce the distance between two stars from their longitude and latitude, or from their right ascension and declination. 560
- 106. To deduce the longitude and latitude of a star from its distance from two stars, p. 560
- 107. To deduce the right ascension and declination of a star from its distance from two stars. 560
- 108 to 113. To trace in six ways the right ascension of the midheaven, or the culminating point of the equator. 561
- 114 and 115. To determine the ascensional difference and its table, and the rising and setting amplitude. 561
- 116 to 121. To find in six ways the angle made by the horizon and the circle of declination at the centre of a star, or at a point of the ecliptic, when rising or setting. 561
- 122. To determine the semidiurnal and seminocturnal arc, and its table. 562

- 123. To determine the oblique ascension and descension of a point of the ecliptic or of a star, and to construct a table of oblique ascensions. 562
- 124. To find the point of the ecliptic corresponding to an oblique ascension or descension at a given altitude of the pole. 562
- 125. To find the point of the ecliptic with which a star rises or sets. 563
- 126. To find in another way the point of the ecliptic with which a star rises or sets. 563
- 127 to 130. To investigate in four ways the point of the ecliptic with which a star passes through the midheaven. 563
- 131. To find the longitude and latitude of a star, or its right ascension and declination, by means of two stars set in the same straight line, p. 563
- 132. To find the longitude and latitude of a star, or its right ascension and declination, by means of two stars set on either side of it in the same straight line. 564
- 133 to 136. To find in four ways the culminating point of the ecliptic and its meridian altitude. 564
- 137. To find the point of the ecliptic occupying the lowest part of the sky [imum Cæli], and its depression. 565
- 138. To find in another way the meridian altitude of the culminating point of the ecliptic. 565
- 139 to 143. To find in five ways the rising or setting point of the ecliptic. 565
- 144 and 145. To find in two ways the rising and setting point of the equator. 565
- 146. To find the oblique ascension of the ascendant [Horoſcopi], p. 566
- 147 to 154. To investigate in eight ways the angle of the ecliptic and the horizon. 566
- 155. To find in seven ways the distance of the nonagesimal from the zenith, and its altitude. 566
- 156 to 161. To investigate in six ways the angle of the meridian and of the vertical drawn through the nonagesimal. 567
- 162 to 173. To find in twelve ways the arc of the ecliptic between the meridian and the nonagesimal, and between the meridian and the horizon. 567
- 174 to 180. To find in seven ways the rising amplitude of the ascendant, or the setting amplitude of the setting point of the ecliptic. 568
- 181. To find the nonagesimal degree of the ecliptic. 568
- 182 to 186. To find in five ways the position of the nonagesimal with respect to the east or the west, p. 568
- 187. To find the arc of the meridian between a culminating star and the culminating point of the ecliptic, p. 569

- 188 to 193. To find in six ways the angle of the horizon and of the circle of declination drawn through a star, or a point of the ecliptic, placed outside the horizon. 569
- 194 to 198. To seek in five ways the distance of a star, or of a point of the ecliptic, from the meridian. 569
- 199. To find the angle made at the centre of a rising or setting star by the circle of latitude and the horizon. 570
- 200. To find the angle made at the pole of the equator by the solstitial colure and the circle of declination. 570
- 201. To find the angle made at the pole of the ecliptic by the solstitial colure and the circle of latitude. 570
- 202. To find the angle made at the pole of the world by the equinoctial colure and the circle of declination. 570
- 203. To find the angle made at the pole of the ecliptic by the equinoctial colure and the circle of latitude. 570
- 204. To investigate the angle made at the pole of the world by the meridian and the solstitial colure when they do not coincide. 570
- 205. To find the angle made at the pole of the world by the meridian and the equinoctial colure. 570
- 206 and 207. To investigate in two ways the distance of the pole of the ecliptic from the zenith. 570
- 208 to 215. To find in eight ways the angle made at the centre of a culminating star by the meridian and the circle of latitude. 571
- 216. To investigate the point of the ecliptic that culminates with a given star, and the arc of the meridian intercepted between them. 571
- 217. To determine the arc of the ecliptic that is always visible. 571
- 218. To determine the position of a star or of a point of the ecliptic with respect to the eastern or the western hemisphere. 572
- 219. To determine the position of a star or of a point of the ecliptic with respect to the hemisphere above or below the horizon. 572
- 220 to 223. To seek in four ways the altitude or the depth of the Sun or of a star, p. 573
- 224. To investigate the angle of the hour circle and the ecliptic. 573
- 225. To investigate the arc of the horizon cut off by an hour circle. 573
- 226. To find the arc of a vertical circle cut off by an hour circle. 573
- 227 and 228. To find the hour arc, that is, the arc of the horizon intercepted between an hour circle and the point of the Sun's true rising and setting. 573
- 229. To find the arc of position. 574
- 230. By how many temporal hours a star, or a given point, is distant from the meridian. 574
- 231. To find the horary ascension or descension of a star, or of a point of the ecliptic. 574

SECTIO III.

Section III.

In qua Problemata Temporis.

In which are the Problems of Time.

Order of the problems

- 1. To distinguish the day of the primum mobile from the sidereal and the solar day, and their hours, and to convert them into parts of the equator and back again, and to construct tables for both, p. 575
- 2. To distinguish the use of the time of the primum mobile and of the solar day. 576
- 3. To convert fractions of a day into hours etc. and parts of the equator, and back again, and to compile tables for these. 576
- 4. To convert equal time into apparent, or the reverse. 576
- 5. To convert into one another the astronomical, Babylonian, Italian and European hours, and equal hours into temporal hours. 576
- 6. To determine the hours during which the Moon shines, p. 576
- 7 to 10. To find in four ways the true semidiurnal and seminocturnal time of the Sun, or of any star. 576
- 11. To determine the true semidiurnal time of the Sun even when it consists of several days, that is, where its parallel does not cut the horizon. 577
- 12. To find the apparent semidiurnal and seminocturnal time of the Sun, or of any star. 577
- 13. To find the apparent semidiurnal time of the Sun where its parallel does not cut the horizon. 577
- 14. To investigate the horizontal refraction of the Sun required for its parallel not to cut the horizon at a given altitude, p. 578
- 15 to 20. To seek in six ways the moment of time from an observation of the Sun. 578
    - 3 scholia on observing the altitude of the Sun. 579
- 21 to 24. To deduce in four ways the moment of time from an observation of the fixed stars, without trigonometry. 580
- 25 to 31. To do the same by trigonometry in seven ways. 580
- 32. To trace the time of the true or apparent rising and setting of the Sun. 581
- 33. To define the apparent time of the rising or setting of the limbs of the Sun. 581
- 34. To find the time at which the whole disc of the Sun rises. 581
- 35. To investigate how much earlier a star rises for someone living on the summit than at the foot of a mountain of known height. 582
- 36. To seek the size of the apparent twilight. 582

- 37 and 38. To find in two ways the time at which the Sun or any star comes to a given vertical. 582
- 39. To find the time at which a star will come to a given altitude on a vertical. 582
- 40 and 41. To seek the time at which the Sun or any star will reach the nonagesimal. 583
- 42 and 43. To find the time at which a given arc of the ecliptic passes through a given vertical. 583
- 44. To determine the time between the transits of two stars, or of two points of the ecliptic, through the midheaven. 583
- 45. To find the moment of time at which a given star or point passes through the midheaven. 583
- 46. To find the day on which a star culminates together with the Sun. 584
- 47 to 49. To seek in three ways the moment of time at which a star or a given point rises or sets absolutely on a given day. 584
- 50. To find the time between the absolute risings or settings of two stars. 584
- 51. To find the day of the rising or setting of some star — respective, but true — whether morning or evening. 584
- 52. To find the time at which some star once truly rose or set. 584
- 53. To determine the arc of vision, or of shining [Fulfionis], and the interval of the ecliptic for the heliacal rising and setting. 584
- 54. To determine the day of the heliacal rising and setting of any star. 584
- 55. To find the time at which a star fitted for it will reach the equator or a tropic, or will cross it. 584
- 56. To find the time at which a star capable of passing through the zenith of a given place will pass through it. 584
- 57. To find the time at which a star that rises and sets will pass into the number of the always visible, or the always hidden, stars, and will remain so, p. 584
- 58. To seek the time at which a star capable of reaching the pole of the world will arrive there, or has already arrived. 584
- 59. To trace the time at which a suitable star will reach the polar circle, whether inside it or outside. 584
- 60. To investigate the time at which the right ascension of a star fitted for it will increase and when it will decrease, or has already increased or decreased, while its longitude still always increases. 585

SECTIO IV.

Section IV.

In qua Problemata Geographica.

In which are the Geographical Problems.

Order of the problems

- 1. To find the ratio of a parallel to a great circle of the sphere, and to construct its table. 585
- 2. To investigate the size of the Earth's diameter by the method of Maurolycus [Francesco Maurolico]. 585
- 3. To seek the same by the method of Father Christophorus Griembergerus [Christoph Grienberger]. 586
- 4. To trace the diameter of the Earth by the method of Father Marius Bettinus [Mario Bettini], although it is fallacious. 587
- 5, 6, 7. To investigate the diameter of the Earth by the threefold method of Father Christophorus Clavius [Christoph Clavius]. 587
- 8. To find the diameter of the Earth by the method of Father Paulus Casatus [Paolo Casati]. 587
- 9. To seek the diameter of the Earth by the method of Kepler. 588
- 10. To seek the diameter of the Earth by the method of Father Nicolaus Cabaeus [Niccolò Cabeo] and of Dom Alphonsus Isaeus [?]. 588
- 11. To investigate the circumference of the Earth in the manner of Eratosthenes, and to correct his errors. 588
- 12. To seek the circumference of the Earth in the manner of Posidonius, and to correct his errors. 589
- 13. To measure the circumference of the Earth by the device of Marinus of Tyre and of Ptolemy. 589
- 14. To hunt out the circumference of the Earth in the manner of Almaeon [al-Maʾmūn] and of many Arabs and cosmographers. 589
- 15. To seek the circumference of the Earth by the device of Ioannes Fernelius [Jean Fernel]. 589
- 16. To conclude the circumference of the Earth by the ingenuity of Petrus Nonius [Pedro Nunes] and Iacobus Mazzonius [Jacopo Mazzoni]. 590
- 17. To investigate the circumference of the Earth by the geometry [Geometriſmo] of Villebrordus Snellius [Snel]. 590
- 18. To investigate the circumference of the Earth by our method and that of Father Franciscus Maria Grimaldus [Francesco Maria Grimaldi], p. 591
- 19. To attempt the circumference of the Earth by another method of ours. 591
- 20. To determine the circumference of the Earth from a distance, by another method. 591
- 21 to 26. To measure the height of a tower by altimetry in six principal ways. 592

- 27. To measure the distance of an island, or of any place visible from a shore or a riverbank. 593
- 28, 39 [?], 30. To measure the height of mountains by a threefold method, with an example in the mountains Etna, the Pico and the Caucasus. 593
- 31. To measure the heights of mountains in the manner of the older geometers, which is however doubly fallacious. 594
- 32. To correct the method of the older geometers in measuring the height of mountains. 594
- 33, 34, 35. To measure the height of a mountain by another, threefold, method. 595
  - On that occasion, to define the height of Mount Athos. 596
- 36. To seek the height of a mountain by another method, and on that occasion on the wonderful height of the Caucasus and Mount Casius. 596
- 37. Given the height of a mountain or tower, to investigate the height of another mountain, etc., p. 597
- 38. Given the Earth's semidiameter and the distance between two mountains, the summit of one being visible from the other, to find the height of each, or the least height of the one supposed the greater. 598
- 39. Given the Earth's semidiameter and the height of the eye raised above the convex surface common to land and sea, to find the terrestrial arc visible from the eye, that is, the distance of sight. 598
- 40. Given the height of a mountain, tower, etc., and the Earth's semidiameter, to define the distance from which it can be seen by an eye raised not at all above land or sea. 599
- 41. Given the height both of the object and of the eye, and the Earth's semidiameter, to find the greatest distance from which such an object is visible. 599
- 42. Given the distance of a spring from the sea, to find the height of the level, that is of the spring, required for a river to be able to descend to the sea by the same straight course. 599
- 43, 44. Given the distance between two places and the altitude of the pole, to find the difference of geographical longitude, the angles of position, and the azimuths of the common vertical. 599
- 45, 46. Given the polar altitude of two places and the difference of longitude, to find the distance between them and the azimuths of the common vertical. 599
- 47, 48. Given the altitude of the pole of one place, and its distance from another place, with the difference of longitude, to find the altitude of the pole of the other place, the angles of position, and the azimuths of the common vertical. 599
- 49. To find the meridian line by two direct shadows. 599

- 50 to 54. Either to correct a meridian line already found, or to find one, in five ways, p. 600
- 55 to 59. To find the meridian line in five other ways. 601
- 60 to 66. To attempt the meridian line in seven other ways. 602
- 67 to 70. To seek the altitude of the pole in four ways without trigonometry. 602
- 71 to 74. To investigate the altitude of the pole in four other ways. 603
- 75 to 78. To seek the altitude of the Sun from the shadow of a gnomon, or the shadow from the altitude, and to construct a gnomonic table, and to correct the errors of some geometers. 603
- 79, 80, 81. Given the Sun's shadow, to find the altitude of the pole, and to correct in this the errors of certain cosmographers. 604
- 82 to 85. To obtain the altitude of the pole in four other ways. 605
- 86, 87. To find the altitude of the pole in two other ways. 606
- 88. Given the altitude of the pole, to determine the clime and the parallel of the clime. 606
- 89 to 95. To investigate the altitude of the pole in seven other ways. 606
- 96 to 101. To hunt out the altitude of the pole in six other ways. 607
- 102. Given the altitude of the pole of two places, and either angle of position, to find the difference of longitude and the distance between the places. 608
- 103. Given the distance between two places and the difference of longitude, with either angle of position, to find the altitude of the pole of each. 608
- 104. Given the distance between two places and the altitude of the pole of one, with the angle of position, to find the altitude of the pole of the other and the difference of longitude. 608
- 105. Given the distance between two places and the angle of position of each, to find the altitude of the pole of each and the difference of longitude. 608
  - Note on the remaining ways of investigating the altitude of the pole. 608
- 106, 107, 108. To investigate in three ways the difference of longitude, that is the distance between the meridians, by eclipses of the luminaries; and which eclipses are better for the purpose. 608
- 109. To investigate the distance [?] between the meridians by clocks inspected at the beginning and the end of a journey. 609
- 110. To investigate the distance between the meridians by eclipses of the satellites of Jupiter. 609
- 111 and 112. To find the distance between the meridians by eclipses or illuminations of the lunar spots. 610
- 113 and 114. To find the distance between the meridians by the place of the Moon, by the methods of Orontius [Oronce Finé], Vernerus [Johannes

Werner], Gemma Frisius, Apianus [Peter Apian] and Santbechius [Daniel Santbech] — which are, however, fallacious. 610

- 115. To attempt the distance between the meridians by the method of Hieronymus Ruscellus [Girolamo Ruscelli]. 610
- 116. To investigate the distance between the meridians by the method of Longomontanus and Kepler, which however needs correcting. 611
- 117. To correct the preceding method of Longomontanus. 611
- 118 and 119. To seek the distance between the meridians by the method of Io. Bapt. Morinus [Jean-Baptiste Morin], although it is fallacious. 612
- 120. To seek the distance between the meridians by the method of Herigonius [Pierre Hérigone], and on that occasion to find the declination of the Moon. 612
  - Note on the remaining ways of seeking the distance between the meridians. 612
- 121 to 125. Given a moment of time, to define where it is then noon and where midnight; where it is day and where night, at least within the temperate zones and the torrid zone; for which places the Sun is then rising and for which it is setting; and what hour of any kind it is at any given place; and conversely, at what place on Earth there are such and so many hours and minutes of hours. 612

SECTIO V.

Section V.

De Parallaxibus.

On Parallaxes.

CAPVT I.

Chapter I.

De Parallaxi Altitudinis, vel Diſtantiæ à Vertice in communi.

On the Parallax of Altitude, or of Distance from the Zenith, in General. 613

CAPVT II.

Chapter II.

In quo Problemata ad Parallaxim Altitudinis ſpectantia.

In which are the Problems Concerning the Parallax of Altitude.

Order of the problems

- 1. Given the horizontal parallax, to find the distance of a star from the centre of the Earth. 613
- 2. To find the horizontal parallax of a star, given its distance from the centre of the Earth, p. 613
- 3 and 4. To find the parallax corresponding to a given true or apparent altitude, given the distance of the star from the centre of the Earth; where the construction, use and authors of tables for these are treated. 614
- 5 and 6. To seek the distance of a star, given its true or apparent altitude, together with the parallax of altitude. 614
- 7 and 8. Given the horizontal parallax, to find the parallax of any apparent altitude, and the reverse, etc. 614
- 9. Given the parallax of some apparent altitude, to find the parallax corresponding to another given apparent altitude. 614
- 10. Given two parallaxes of two apparent altitudes, to seek the horizontal parallax. 614
- 11. Given the difference of two parallaxes, with the ratio their sines have, to make each parallax known separately. 615
- 12. Given the difference of two unknown parallaxes of altitude, and the two altitudes at which it was observed, to recover separately each parallax due to each apparent altitude. 615
- 13. Given the sum of two parallaxes separately unknown, and the two apparent altitudes at which that sum was observed, to recover each parallax of altitude separately. 615
- 14. To find the parallax of altitude of the Moon from the Sun. 615
- 15. To investigate the parallax of altitude of a phenomenon, given its latitude and longitude observed at the same moment in two places on Earth of which the altitude of the pole and the distance between the meridians are known; given in addition the moment of time, the culminating point of the ecliptic on each meridian, and the obliquity of the ecliptic. 615
- 16. To investigate the parallax of altitude, given the apparent distances of a phenomenon from the same fixed star at the same moment of time from two places on Earth of which the altitude of the pole and the distance between the meridians are known, and the moment of time, with the declination and right ascension of the fixed star, p. 615
  - Note on the remaining matters concerning the parallax of altitude. 615

CAPVT III.

Chapter III.

De Parallaxi Profunditatis.

On the Parallax of Depression.

- 17. To find the greatest parallax of depression of a star standing on the astronomical horizon. 615
- 18. To find the greatest parallax of depression of a star standing below the astronomical horizon. 616
- 19 and 20. To find in two ways the height of the eye necessary for it to be able to see a star, by unrefracted rays, when the star is first on the rational horizon. 616
- 21. To find both the true and the apparent depression of a star first visible by unrefracted rays, given the height of the eye, etc. 616

CAPVT IV.

Chapter IV.

De Parallaxi Orbis Annui.

On the Parallax of the Annual Orb. 616

CAPVT V.

Chapter V.

De Parallaxi Diſtantiæ inter duo Phænomena.

On the Parallax of the Distance between Two Phenomena.

- 22, 23, 24. From the parallax of altitude or of depression and the true distance of two phenomena, to deduce their apparent distance, in three cases. 617
- 25, 26, 27. From the parallax of altitude or of depression and the apparent distance of two phenomena, to deduce their true distance, in three cases. 617

CAPVT VI.

Chapter VI.

De Parallaxi Declinationis & Aſcenſionis Rectæ.

On the Parallax of Declination and of Right Ascension.

Order of the problems

- 28, 29, 30. To convert in three ways the parallax of the true declination and right ascension into the apparent. 618
- 31, 32, 33. To convert in three ways the parallax of the true [?] declination and right ascension into the true. 618

• 34, 35. To investigate in two ways, by another route, the parallax of declination and right ascension, both apparent and true. 618

CAPVT VII.

Chapter VII.

De Parallaxi Longitudinis ac Latitudinis.

On the Parallax of Longitude and Latitude.

CAPVT VIII.

Chapter VIII.

De Parallaxi Motus.

On the Parallax of Motion.

• 36. To find how great the height above the Earth must be of a phenomenon appearing above the horizon and moved beneath the equator with the motion of the primum mobile. 620
• 37. To find the time for which a phenomenon moved beneath the equator by the motion of the primum mobile can stay above the horizon. 620
• 38. To find the difference in the stay of a phenomenon above the physical and the astronomical horizon. 620
• 39. To investigate the distance of a phenomenon from the centre of the Earth from its stay above the horizon, etc. 620

CAPVT IX.

Chapter IX.

De Differentia Parallaxium Altitudinis, Locorumque viſorum.

On the Difference of the Parallaxes of Altitude and of the Apparent Places.

• 40. On a vertical circle common to two places on Earth, to determine the position of a phenomenon at which the difference of the apparent places coincides with the difference of the parallaxes, or is equal to it, or consists of the sum of the parallaxes. 620
• 41, 42, 43. To investigate separately the parallaxes of altitude of a phenomenon on the same vertical, seen simultaneously from two places on Earth, in three cases. 621
• 44 to 47. To investigate the difference of the apparent places of a phenomenon on the same vertical, seen simultaneously from two places on Earth, in four cases. 621

- 48, 49. To find in two ways the difference of the parallaxes, or their sum, on a circle of altitude. 622
  - A twofold note, and a theorem drawn from what has been said above. 622

CAPVT X.

Chapter X.

De modis Obſeruandi an, & quantam Parallaxim Altitudinis habeat Phænomenon, per obſeruationes in eodem Terræ loco factas ſecluſa Refractione.

On Ways of Observing Whether a Phenomenon Has a Parallax of Altitude, and How Great, by Observations Made at the Same Place on Earth, Refraction Excluded.

- 50 to 62. To discern the parallax of altitude, excluding refraction if there is any, and its size, by thirteen very ingenious problems. 623

CAPVT XI.

Chapter XI.

De modis Obſeruandi an & quantam Parallaxim Altitudinis habeat Phænomenon per obſeruationes in diuerſis Terræ locis factas, ſecluſa Refractione.

On Ways of Observing Whether a Phenomenon Has a Parallax of Altitude, and How Great, by Observations Made at Different Places on Earth, Refraction Excluded.

- 63 to 72. To discern the parallax of altitude, excluding refraction if there is any, and its size, by ten problems, through the observations already mentioned. 628
- 73, 74, 75. How great a maximum parallax and minimum distance from the centre of the Earth can be supposed, and the horizontal refraction, in the Moon, the Sun, Saturn and the fixed stars. 634

C A P V T XII.

Chapter XII.

Theoremata Viginti recondita de Diſcrimine Parallaxeos Veræ ac per ſe ſenſibilis à Falſa vel inſenſibili.

Twenty recondite theorems on the distinction between a true parallax, sensible in itself, and a false or insensible one.

SECTIO VI.

Section VI.

Problemata Refractionum Siderearum in Aere.

Problems of the Refractions of the Stars in the Air.

CAPVT I.

Chapter I.

In quo Quæſtiones 15. de Refractionibus in communi.

In which are 15 questions on refractions in general. 642

CAPVT II.

Chapter II.

In quo Definitiones, & Axiomata Refractionum in communi.

In which are the definitions and axioms of refractions in general. 645

CAPVT III.

Chapter III.

In quo Theoremata ſelecta de Quantitate Refractionum experimentis aut rationibus per alios demonſtrata.

In which are selected theorems on the quantity of refractions, demonstrated by others through experiments or reasonings. 647

CAPVT IV.

Chapter IV.

In quo Problemata ad Refractiones ſpectantia.

In which are the problems pertaining to refractions.

Order of the problems

- 1 to 6. To measure in six ways the refractions that occur from air into water or another liquid. 648
- 7 to 11. To measure in five ways the refractions of rays from air into glass or crystal. 649
- 12 to 19. To estimate, from the inclinations, the simple or compound refractions, and from the refractions the inclinations; and from this, or from their weight, the density of the media. 650

- 20 to 23. To find in four ways the refraction of altitude in a star free of sensible parallax. 652
- 24, 25. To investigate the horizontal refraction of a star whose parallax is smaller than its refraction, and to correct a fourfold fault of Tycho's in the refraction of the Sun. 653
- 26. To find the refraction of a star appearing above the horizon, and the limit of altitude at which sensible refractions cease. 654
- 27. To separate the simple refraction on a circle of altitude from the whole refraction observed. 654
- 28. To find the horizontal refraction of a star whose refraction is smaller than its parallax. 655
- 29, 30. To investigate in two ways the refraction of a star through observation of its altitude and its declination. 655
- 31. From the parallax and the other requisites, to determine whether a star is on the true horizon, below it, or above it. 656
- 32. To deduce the horizontal refraction of the Sun from its apparent rising or setting. 656
- 33 to 35. To attempt in three ways the horizontal refraction of the luminaries through horizontal eclipses. 656
- 36. To convert the apparent altitude of a star into the true, or the true into the apparent, given the refraction and the parallax. 656
- 37, 38. To convert the apparent distance of two stars from each other into the true, or the true into the apparent, given the refraction, the parallax, etc. 656
- 39, 40. To convert the true declination or right ascension of a star into the apparent, or the apparent into the true. 657
- 41, 42. To convert the true latitude and longitude of a star into the apparent, or the apparent into the true. 657
- 43, 44. To investigate in two ways the height of the refractive air. 657
- 45, 46. To inquire in two ways into the inclination of a ray above the curvature of the refractive air. 658
- 47. To find the length of a refracted ray and the thickness of the refractive air. 658
- 48. To deduce the refraction of a star from the inclination of its ray above the air, and from the other data. 658
- 49. To inquire into the height of the refractive air by Kepler's method. 658
- 50. To correct the height of the Caucasus and of certain other mountains, which is uncorrected through neglect of refractions. 660
- 51. From the corrected height of the Caucasus and from other arguments, to elicit a more probable height of the refractive air around the Caucasus, above the Euxine, the Caspian, etc. 661

- 52, 53. To correct the height of the twilight exhalations by means of the Sun's rays, reflected and triply refracted, and to find the thickness of the air between the exhalations already mentioned and our eyes. 662
- 54. To find how much smaller the arc of the sphere of refractive air illuminated by the Sun is than the arc of the Earth illuminated by the Sun through unrefracted rays. 662
- 55. To find how much greater the arc of the Earth illuminated by the Sun's refracted rays is than that illuminated by the unrefracted. 662
- 56. To determine whether, from the horizontal refraction of the fixed stars alone, the Earth's semidiameter and the height of the refractive air, the inclination of the ray of the fixed stars, and their distance and parallax, can be demonstrated. 663
- 57. To determine whether the height of the refractive air, or the inclination of a stellar ray, can be demonstrated exactly from these data only: the horizontal refraction and parallax of a star, and its distance from the vertex or from the centre of the Earth. 663

There follow the anaclastic tables, or tables of refractions. 664

LIBER OCTAVVS DE COMETIS ET STELLIS NOVIS

Book Eight: On Comets and New Stars

SECTIO PRIMA DE COMETIS.

Section One: On Comets.

C A P V T I.

Chapter I.

Prohemiale, In quò & de Auctoribus qui de Cometis ſcripta ediderunt.

Introductory, in which also of the authors who have published writings on comets.

I. Having surveyed, in the first part of this work, the accustomed splendours of the wandering and the non-wandering stars, and having weighed their properties as far as the slenderness of our wit and judgement allowed, we are raised up and roused once more to look up at, and at the same time to discern, the unaccustomed spectacles of the sky. Nor are we merely invited: we are compelled by the laws and command of astronomy, so that it may at last be decided whether, among those eternal, or rather ancient, splendours with which the stage of the heavens has flashed since the beginning of the world, there are to be received, as stars coeval with them or at least temporary, those curly-haired globes of light, or the long-bearded faces of contracted lightnings, or the fires advancing through the tracts of the aether with the long trailing robe of a shining tail, which we call comets; and what place in the system of

this world is to be assigned to them, whether as citizens or as guests. These new portents turn the eyes and minds of mortals to themselves no less than eclipses of the Sun and Moon do. "And so this assembly of stars, by which the beauty of the immense body is set off, does not summon the people. But when something has changed from its custom, everyone's face is turned to the sky. The Sun has no spectator unless it is in eclipse. No one watches the Moon unless she is labouring. Then cities cry out, then each person trembles for himself in vain superstition." So Seneca, who soon adds: "If something is disturbed, or has flashed out contrary to custom, we gaze, we ask, we point it out: so natural is it to wonder at new things rather than at great ones. The same happens with comets. If a fire of rare and unaccustomed shape has appeared, there is no one who does not wish to know what it is; forgetting the rest, he asks about the newcomer, not knowing whether he ought to admire it or to fear it."

[Margin: Seneca's words, bk 7 *Natural Questions*, ch. 1.]

II. Although this controversy about comets holds, for the most part, more uncertainty and trouble than fruit, we must nevertheless proceed by a middle way, so as to handle these matters with a mind neither too timid nor too confident. For well known is that saying of Aristotle in book 2 of *De caelo*, ch. 7, text 34, where, dealing with celestial phenomena, he professes his modesty: "Perhaps," he says, "to attempt to declare something about some things, and about everything, and to pass over nothing, will certainly seem a sign either of great folly or of great readiness. Yet it is not just to rebuke everyone alike; one must see what the reason for speaking is, and moreover how they stand in believing, whether in a human way or more firmly. Therefore when anyone has attained more certain and necessary reasons, then we ought to be grateful to those who find them; but for now, what seems so must be said." And in book 1 of the *Meteorologica*, ch. 4, about to speak of the causes of comets, he says: "Since, concerning things not manifest to sense, we think it sufficient to bring forward reasons that contain nothing impossible."

[Margin: Aristotle's modesty.]

Seneca sprinkles on us a taste of the same sobriety when he says, in book 7 of the *Natural Questions*, ch. 29: "These are the things concerning comets that move others, or me. Whether they are true, the gods know, who have knowledge of the truth. To us it is allowed only to search these things out and to conjecture in the dark, neither with confidence of finding nor without hope." Twin to these is that saying of Cicero in *Tusculans* 1: "Which of these opinions is true, some god will see; which is most probable is a great question." But I cannot yet tear myself away from Seneca, who in that same book 7, ch. 30, pursues the matter in these words: "Aristotle says excellently that we ought never to be more reverent than when the gods are in question. If we enter temples composed, if when about to approach a sacrifice we lower our face, draw in our toga, and put on every sign of modesty, how much more ought we to do this when we dispute about the heavenly bodies, about the stars, about

the nature of the gods, lest we affirm anything rashly, anything impudently, or ignorantly, or lie knowingly? Nor let us wonder that things lying so deep are dug out so slowly." And a little after: "How many things besides these" — comets, that is — "move in secret, never rising to human eyes? For God has not made all things known to human eyes. How small a part of so great a work is entrusted to our eyes?" Yet the same writer is to be rebuked when, in ch. 31, speaking of God, he says: "What this is, without which nothing is, we cannot know. And do we wonder that we know little of some little fires, when the greatest part of the world, God, lies hidden?" For God is not, properly speaking, a part of the world.

[Margin: Seneca's moderation in the inquiry into comets.]

Now therefore, if in any matter at all the opinions of many, or of better, men are to be gathered, and we must learn from many what cannot be sufficiently acquired from one man or from the men of one sect, I judge that this must be done above all in the present controversy, and that we must obey the admonition of Symmachus, who says in book 10, letter 61: "It is fair that whatever all worship should be thought one. We look on the same stars; the sky is common to us; the same world envelops us. What does it matter by what wisdom each seeks the truth? One cannot reach so great a secret by a single road." I shall therefore review the principal authors who have written on comets, and then undertake to hand on to posterity, in order, each of the choicer points drawn from them.

[Margin: Symmachus's excellent maxim.]

Auctores Præcipui, qui de Cometis Scripſerunt.

The Principal Authors Who Have Written on Comets.

III. Those who have written on comets are, first of all, Charimander, as Seneca reports in book 7 of the *Natural Questions*, ch. 3; Aristotle, book 1 of the *Meteorologica*, chs. 6 and 7, and his interpreters; Seneca himself in the whole of book 7 of the *Natural Questions*; Pliny the Elder, book 2, ch. 25, and his interpreters on that place, especially Valla [?] and Milichius [Jacob Milich]; then Plutarch, book 3 of *De placitis philosophorum*, ch. 2; Ptolemy in the *Centiloquium*, aphorism 100, and Pontanus [Giovanni Pontano] on that place; and in the *Quadripartitum*, or *On the Judgements of the Stars*, book 2, and Cardanus [Girolamo Cardano] on that place, commentaries 53 and 54; and again Cardano, book 4 of *De subtilitate*, and against him Iulius Cæsar Scaliger [Julius Caesar Scaliger], exercise 79; Albumasar [Abū Maʿshar], book 8 of *De magnis coniunctionibus*; Haly [ʿAlī ibn Riḍwān] on book 2 of the *Quadripartitum*; Angelus Cato [Angelo Cato], a short work on the comet of the year 1472; Regiomontanus on the comet of the year 1475, and in sixteen problems on comets; Ioannes Vogelinus [Johannes Vögelin] on the occasion of the comets of the years 1527 and 1532; Petrus Apianus [Peter Apian] at the end of the Caesarean work[5], who then was flourishing, and who besides those two described three other comets; Daniel

[5]the *Astronomicum Caesareum*

Santbech, *De observatione phaenomenωn*, proposition 19; Fracastorius [Girolamo Fracastoro] in the *Homocentrica*, section 3, ch. 23; Kechermanus [Bartholomäus Keckermann], book 6 of the *Systema physicum*; Ludouicus Lauaterus [Ludwig Lavater] and Eberus [Paul Eber] in the *Catalogue of Comets*; Antonius Mizaldus [Antoine Mizauld] in the *Cometographia*; Grisaldus [?] in the *Cometologia*; Bodinus [Jean Bodin], book 2 of the *Theatrum*; Leopoldus [Leopold of Austria], tract 5, *De annorum revolutionibus*; Franciscus Iunctinus [Francesco Giuntini] at the end of the *Speculum astrologiae*; Simon Maiolus [Simone Maioli] in the *Dies caniculares*, colloquy 1, from p. 11; Thomas Garzonius [Tommaso Garzoni] in the *Theatro*, pp. 72 and 200; Maginus [Giovanni Antonio Magini] in the *Primum mobile*, book 12 of the problems. To these must be added a great many natural philosophers and writers on meteorology: first of all Nyphus [Agostino Nifo] on book 1 of the *Meteorologica*; Libertus Fromondus [Libert Froidmont], book 3 of the *Meteorologica*; the Coimbra commentators [Conimbricenſes], tract 3 of the *Meteorologica*; Ioannes Cottunius [Giovanni Cottunio] on the *Meteorologica*, from lecture 30 to 33; Bartholomæus Mastrius [Bartolomeo Mastri] and Bonaventura Bellutus [Bonaventura Belluto], disputation 4, *De caelo ac meteoris*, question 2, article 4; Franciscus Resta [?], book 1 of the *Meteorologia*, tract 1; Raphaël Aversa [Raffaele Aversa], tome 2 of his *Philosophia*, questions 32 and 33; Nicolaus Cabæus [Niccolò Cabeo] on book 1 of the *Meteorologica*, text 37, from question 1 to 9; Bartholomæus Amicus [Bartolomeo Amico], *De caelo*, tract 4, question 5, d. 2, article 4, and tract 5, question 1, d. 1, article 7, and question 5, last dubium, a. 5; Libavius [Andreas Libavius] and Telesius [Bernardino Telesio], treatises on comets; Ludouicus Columbus [Lodovico delle Colombe] and Cornelius Frangipanius [?], treatises on comets; Arriaga [Rodrigo de Arriaga], the single disputation *De caelo*, section 3, subsection 2; Ouiedus [Francisco de Oviedo], the single controversy *De caelo*, point 3, paragraph 3; Balthassar Tellez [Baltasar Teles] in the *Physica*, disputation 4, section 1, and disputation 47, section 2; Blancanus [Giuseppe Biancani] in the *Loca mathematica Aristotelis*, marginal number 136, and the *Sphaera*, book 16; Ioannes Camillus Gloriosus [Giovanni Camillo Glorioso] in the astronomico-physical dissertation on comets; Fortunius Licetus [Fortunio Liceti] in the book *De cometis ac novis astris*, and in the disputation on the regular motion and minimal parallax of celestial comets; Adamus Tannerus [Adam Tanner], *De caelo*, question 7, paragraph 4; Descartes, part 3 of the new *Philosophia*, no. 41 and from no. 126 to 139.

[Margin: Writers on the comet of the year 1577.]

Besides these, on the occasion of the comet that appeared in the year 1577, there wrote: Tycho, in the whole of tome 2 of the *Progymnasmata*; Cornelius Gemma; Michaël Mæstlinus [Michael Mästlin]; Gulielmus, Landgrave of Hesse [Wilhelm IV of Hesse-Kassel]; Helisæus Rœslinus [Helisaeus Röslin]; Thaddæus Hagecius [Tadeáš Hájek]; Bartholomæus Scultetus; Andreas Nolthius; Nicolaus Vuincklerus [Nikolaus Winckler]; Io. Prætorius [Johannes Praetorius]; Cunradus Dasypodius [Conrad Dasypodius]; Valentius Steinmetz [?];

Nicolaus Bazelius [?]; Georgius Henischius [Georg Henisch]; Io. Huernius [?]; Theodorus Graminaus [?]; Antonius Paduanus [?]; Antonius Santutius [Antonio Santucci]; in Italian, Marcellus Squarcialupus [Marcello Squarcialupi]; Thomas Erastus; Petrus Surdus [?]; Io. Maria Fiornouellus [Giovanni Maria Fiornovelli]. Again, on the occasion of the comets that shone in the years 1580, 1585 and 1590, Tycho wrote in his letters to the Landgrave of Hesse, or to Rothmann [Christoph Rothmann], which begin at pages 13, 36, 121, 137, 170, 173 and 176. And once more, on the occasion of the comet of the year 1607, Longomontanus and Kepler published writings.

[Margin: Writers on the comet of the year 1618.]

But many more wrote on the comets of the year 1618, namely: the same Longomontanus, in the treatise *De novis phaenomenis*; Kepler, in three books (see him also in the *Optical Part of Astronomy*, pp. 264 and 335, and the *Epitome of Astronomy*, pp. 12, 57, 440 and 442, and in the *Hyperaspistes*, of which more shortly); Ambrosius Rhodius; Io. Remus Quietanus [Johannes Remus Quietanus]; Antonius Santutius; Io. Baptista Cysatus [Johann Baptist Cysat]; Thomas Fienus [Thomas Fyens]; Erycius Puteanus; Villelmus Schicchardus [Wilhelm Schickard]; Antonius Lucianus [?], in Spanish; Villebrordus Snellius [Snel]; Alphonsus Zobolus [?]; Io. Baptista Venantius [?]; Philippus Millerus [?]; Isaac Habrechtus [Isaac Habrecht]; Beniamin Vrsinus [Benjamin Ursinus]; Carolus Piso [?], in the *Speculum* of this comet; the author of the disputation held in the Roman College of the Society of Jesus, on the three comets of the year 1618; and another author, of a little work entitled in Italian *L'Asemblea di Parnaso*; Marius Guiducius [Mario Guiducci], setting out Galileo's opinions; Lotharius Sarsus [Lotario Sarsi] in the *Libra astronomica*, in which he weighed the statements of Mario Guiducci and Galileo, speaking in the person of Father Horatius Grassius [Orazio Grassi] of the Society of Jesus, his master; to which Galileo paid back his own weighing, or consideration, and examination in a little Italian work entitled *Trutinator*, *Il Saggiatore*; Gotardus Arthus Dantiscanus [Gotthard Arthus of Danzig].

Further, after the many listed so far who wrote on the comets of the years 1577, 1580, 1585, 1590, 1607 and 1618, Scipio Claramontius [Scipione Chiaramonti] wrote against many, but above all against Tycho, in his *Antitycho*; and in his defence of himself against the attacks of Liceti; and in the book *De sede sublunari cometarum*. But Kepler, in his *Hyperaspistes*, took up Tycho's defence, and, not content with the shield of protection, attacked Chiaramonti's *Antitycho* in words whether very sharp or very bitter; to which Chiaramonti at once replied with a second *Apologia*. And so these comets, but especially those of the years 1577 and 1618, might seem ominous and threatening on this account alone, that they stirred up so many and such sharp quarrels and contentions: between Kepler and Chiaramonti; between Liceti and the same Chiaramonti; between Galileo and Grassi; between Galileo and Chiaramonti; between Squarcialupi and Erastus; besides those with which the University of Padua resounded in Italian pamphlets.

IV. So much for the astronomers or natural philosophers. But orators too are to be counted in addition: Carolus Malapercius [Charles Malapert], in an oration delivered at the beginning of the school year, and Vincentius Guinisius [Vincenzo Guinigi], *De felicitate Cometis*. And poets too: Pontanus in the *Meteora*, and the interpreters on that passage of Virgil, *Georgics* 2:

> Non aliàs cælo ceciderunt plura ſereno Fulgura, nec diri toties arſere Cometæ.
> *At no other time did more lightnings fall from a clear sky, nor did dire comets so often blaze.*

CAPVT II.

Chapter II.

Nomina, Genera, & Species Cometarum.

The Names, Genera and Species of Comets.

I. *Cometa*, or *Cometes*, in Greek Κομήτης [Greek: Κομήτης (komētēs, "long-haired")], is so called from *coma*, "hair". Although, when it is taken in a narrower and stricter sense, it signifies one particular species of phenomenon — namely a hairy star, or one tressed with a mane of rays, or, to speak with Cicero, a curled star — in a wider sense it is nevertheless the common name. For Seneca rightly says, in book 7 of the *Natural Questions*, ch. 11: "They do not have one form. For although the Greeks have made distinctions among those whose fire is indeed diffused, but tending towards a peak, yet all of these are of the same mark and are rightly called comets." And soon after: "At the very time they appear, the spectators do not agree about their aspect; according as each has sharper or duller sight, so he says that it is brighter, or redder, and that its hair is either drawn forward or divided to the sides. But whether there are some differences among them or not, comets must come about in the same way." In the same way the Latins embraced all forms of such portents under the name of hairy stars. Thus Pliny, book 2, ch. 25, begins: "The Greeks call them comets, we call them *crinitae*, bristling with blood-red hair, and shaggy at the top like a head of hair." In that place he reviews twelve names, or species — granted that Albertus Magnus, tract 3 on book 1 of the *Meteorologica*, ch. 10, makes five differences of comets. Cornelius Gemma, for his part, in book 1 of *De divinis naturae characteribus*, ch. 8, expressed Pliny's forms in pictures, and Leopold confirmed them in tract 5 of *De annorum revolutionibus*. It is worth enumerating them, with the Greek names substituted.

[Margin: Comet, the generic name.]

[Margin: Pliny's division of comets.]

II. Let the first, then, be the κομήτης [Greek: κομήτης (komētēs)], that is, a comet in the strict sense of the name, or a star hairy all round, also called the Rose.

[Margin: 1. The comet.]

The second is the πωγονίας [recte: πωγωνίας] [Greek: πωγονίας (pōgō-nias, "bearded")], that is, a bearded star or bearded comet; for ὁ πὼγον [recte: πώγων] [Greek: ὁ πὼγον (ho pōgōn, "beard")] is "beard", which is also why Constantine, Emperor of the East, was called Pogoniates, that is, Long-beard or Beard-long. It is commonly not distinguished from the tailed comet, because, as Fromondus notes in book 3, ch. 4, only its relation to the Sun makes this difference. For if, by the motion of the primum mobile, it precedes the Sun in the morning, it appears bearded, its hairs running forward towards the west — such was the comet of the year 1618. But if it survives in the evening, after the Sun has set, it is seen as tailed, and marked out behind with a very long trailing robe towards the east — such was the comet of the year 1577.

[Margin: 2. The bearded, or tailed.]

The third is the Ακοντίας [Greek: Ακοντίας (akontias, "javelin-comet")], because it is darted with a long appendage of rays in the manner of a javelin; for in Greek ἀκοντίζω [Greek: ἀκοντίζω (akontizō, "I hurl a javelin")] is *iaculor*, "I hurl a javelin", and τὸ ἀκόντιον [Greek: τὸ ἀκόντιον (to akontion, "the javelin")] is "javelin". Such was the one seen in the year 1533, in the month of July, on the testimony of Milichius; and the one about which Titus Caesar, in his fifth consulship, wrote in a splendid poem, on the testimony of Pliny.

[Margin: 3. The javelin.]

The fourth is the ξιφίας [Greek: ξιφίας (xiphias, "sword-comet")], namely the Sword, or rather the sword-shaped, whose head indeed shows the hilt of a sword, while its mane tapers, shorter, to a point, so that it imitates a dagger rather than a longer sword. Pliny adds that this is the palest of all, with a certain gleam as of a sword, and without any rays — understand: distinct rays. In Greek, τὸ Ξίφος [Greek: τὸ Ξίφος (to xiphos, "the sword")] is "sword",

[Margin: 4. The sword, or dagger.]

and ξιφίδιον [Greek: ξιφίδιον (xiphidion, "little sword")] means a small sword or dagger. Piso, however (chapter 15 of the *Speculum*), thinks that this may be the same as the one the historians called the Goal-post or Pyramid. Such, it is said, was the comet that appeared in the year 1532.

[Margin: 5. The discus.]

The fifth is the Δίσκευς [Greek: Δίσκευς (diskeus, "discus")], or rather δισκοειδὴς [Greek: δισκοειδὴς (diskoeidēs, "disc-shaped")], that is, the disc-shaped, which, shining with a broad roundness, spreads a few rays at its rim and is the colour of electrum, says Pliny.

[Margin: 6. The pithetes, or jar-shaped, and the Tenaculum.]

The sixth is the πιθίτης [Greek: πιθίτης (pithitēs, "jar-like")], because it appears in the shape of a jar, as if hiding a smoky light and dark rays within a hollow in its middle; for in Greek ὁ πίθος [Greek: ὁ πίθος (ho pithos, "the jar")] means a jar. To this is referred the Tenaculum, lurid with a smoke like that of embers under ash.

[Margin: 7. The ceratias, or horn.]

The seventh is the Κερατίας [Greek: Κερατίας (keratias, "horned")], or κερατοειδὴς [Greek: κερατοειδὴς (keratoeidēs, "horn-shaped")], that is, the horned or horn-shaped, whose flame is twisted round in a curve like a horn, an augur's crook, or a Persian scimitar. Such, it is reported, was the comet that sounded from heaven like a war-trumpet as Xerxes was crossing into Greece, and also the last comet of the year 1618. For to the Greeks τὸ κέρας, ατος [Greek: τὸ κέρας, -ατος (to keras, "the horn," with its genitive ending)] is "horn."

[Margin: 8. The lamp.]

The eighth is the Λαμπὰδιας [Greek: Λαμπὰδιας (lampadias, "torch-like")], or Lamp, a comet that imitates a burning torch.

[Margin: 9. The horse star.]

The ninth is the ἱππὲυς [Greek: ἱππὲυς (hippeus, "horseman")], or Horse star, representing a horse's mane, which Piso says more recent writers call the Rose; and it is of very swift motion. In Greek ἵππος [Greek: ἵππος (hippos, "horse")] is "horse."

[Margin: 10. The silver-haired.]

The tenth is the Αργυροκόμης [Greek: Αργυροκόμης (argyrokomēs, "silver-haired")], the Argyrocomus — "silver-maned," as you might say, or "silver-haired" — of which Pliny speaks thus: *A white comet also occurs, gleaming with silver hair so brightly that one can scarcely look at it, and showing within itself the likeness of God in human form.* Fromondus (bk 3, ch. 4) suspects that these words refer to the Star of the Magi, perhaps because of the report, well established, that under Augustus a comet was seen in the East and in Judaea in which the image of a little boy was expressed, signifying God made man. In Greek ὁ ἄργυρος [Greek: ὁ ἄργυρος (ho argyros, "silver")] is "silver."

[Margin: 11. The goat.]

The eleventh is the Goat, a comet surrounded by the look of shaggy hair and a sort of mane, bristling, that is, with very fine fibres of rays; in Greek it would be called τραγοειδὴς [Greek: τραγοειδὴς (tragoeidēs, "goat-like")], since τράγος [Greek: τράγος (tragos, "he-goat")] is "goat."

[Margin: 12. The spear, or spit, or pole.]

The twelfth is the Λογχίτης [Greek: Λογχίτης (lonchitēs, "spear-like")], that is, the one having the form of a spear, which more recent writers have called the Spit or the Pole. Of this one Pliny says: *Once only so far has the likeness of a mane been changed into a spear, in the one hundred and eighth Olympiad, in the three hundred and ninety-eighth year of the City.* In book 2, chapter 25, Pliny adds other species, invented rather than actually seen: as when he says that if they have the likeness of flutes they portend something for musicians, if they are triangular, for men of talent, and so on.

[Margin: Aristotle's division of comets.]

III. If, then, we look to the accidents of colour and shape that Pliny lists, there are twelve species of comets. Aristotle, however (*Meteorologica* bk 1, ch. 8), reduces them to two species, namely the Haired and the Bearded. The first

is of those that spread their hair all round, and to it can be reduced the Disc, the Jar, the Horse, the Silver-haired and the Goat. The second is of those that stretch out a mane, straight or bent, toward one side only, and to it are reduced the Javelin, the Sword, the Horned, the Lamp and the Spear. Albertus Magnus, however, as I said, sets up five classes. Others prefer three kinds, namely the Haired, the Bearded and the Tailed.

[Margin: The astrological division of comets.]

Another division of comets is taken from their matter or place, inasmuch as some are elementary and others celestial; or from the efficient cause, as the astrologers count seven simple species of comet, arising from the seven planets, and assign them different colours and effects. Thus they ascribe leaden comets to Saturn, silver to Jupiter, red to Mars, golden to the Sun, yellow to Venus and blue to Mercury; and the Saracens call the Mercurial comet *Dominus Asconae* [Dominum Aſconæ]. Of these more below, from Iunctinus [Francesco Giuntini], when we deal with the prognostics of comets.

[Margin: The division of Epigenes.]

Lastly, Epigenes establishes two kinds by their motion and substance; of him Seneca writes thus (*Natural Questions* bk 7, ch. 6): *There are, says Epigenes, two kinds of comets: some pour out their fire on every side and do not change their place; others stretch out a wandering fire toward one side in the manner of hair, and pass through the stars.* This does not mean that the first kind lacks the motion of the primum mobile, but that, in the manner of the fixed stars, it does not stray on a roving course and has no proper motion of its own. This division seems to me very apt: since these phenomena, if they are not stars, are nevertheless certain imitations of stars, they may thus be divided into fixed and wandering comets.

[Margin: The waking rod and the seething pot of Jeremiah were not comets.]

But if anyone should try to drag the waking rod and the seething pot divinely shown to Jeremiah into portents of comets, he would surely act incongruously, says Johannes Praetorius at the beginning of his account of comets; and this is confirmed by the common opinion of the sacred interpreters on those passages of Jeremiah.

[Margin: Years before Christ.]

CAPVT III.

Chapter III.

Hiſtoria Cometarum 154. Chronologica & Aſtronomica. Cum euentibus, qui Cometis tanquam cauſis aut ſignis attribui conſueuere ab alijs, potiùs quàm à nobis.

A chronological and astronomical history of 154 comets, with the events that others, rather than we, have usually attributed to comets as their causes or signs.

I. Seneca, before his whole inquiry into comets (*Natural Questions* bk 7, ch. 2), rightly said: *It is necessary, moreover, to have the past appearances of comets*

collected; for because of their rarity their courses cannot yet be grasped, nor can it be explored whether they keep their turns and whether a fixed order brings them forth on their own day.

[Margin: The number of comets observed.]

Lavater (from Keckermann) [Lauatterus ex Kechermanno; Ludwig Lavater, Bartholomäus Keckermann] collects no more than 117 comets from Augustus to the year 1556. Yet Io. Camillus Gloriosus [Giovanni Camillo Glorioso] (bk 1, ch. 1) prudently judges that there were many others, either unobserved in the northern hemisphere and belonging to more southern climes, or inconspicuous for some other cause, or omitted by the historians. Nor indeed can any probable reason be adduced why so many comets should have blazed in the preceding century, and not, in other centuries, if not as many, at least far more than those recorded in the writers.

[Margin: On the ancient observers of comets.]

Nor is it surprising that the ancient astronomers were rather negligent in these matters, since much was still uncertain even about the regular planets. Whether, however, the observation of comets was neglected by the Chaldaeans may be doubted, from Seneca's words (*Natural Questions* bk 7, ch. 3): *Democritus,* he says, *the most subtle of all the ancients, says he suspects that there are more stars that move; but he set down neither their number nor their names, the courses of the five planets not yet being understood. Eudoxus first brought these motions from Egypt into Greece; yet he says nothing about comets. From this it appears that not even among the Egyptians, who took greater care of the heavens, was this part worked out. Conon later, himself a diligent investigator, collected the eclipses of the Sun observed by the Egyptians, but made no mention of comets — and he would not have passed over it had he found anything explored among them.*

[Margin: The contradictory assertions of Epigenes and Apollonius on comets observed in Chaldaea.]

Two men, certainly, who say they studied among the Chaldaeans, Epigenes and Apollonius of Myndus — the latter most skilled in the inspection of natural things — disagree with each other. Apollonius says that comets are placed by the Chaldaeans among the wandering stars and that their courses are known. Epigenes, on the contrary, says that the Chaldaeans have nothing grasped about comets, but that comets seem to be kindled by a certain whirl of air stirred up and twisted. I would reconcile them thus: Epigenes does not deny the Chaldaeans' efforts in observing and expounding comets, but only the certainty and evidence of their causes and matter. Let us come to the history.

[Margin: Year 480.]

[Margin: Ceratias.]

In the first year of the 75th Olympiad, or 480 before Christ, when Xerxes had crossed into Greece, a comet appeared — a Ceratias — shortly before Greece fought it out against him at Salamis, as Pliny reports (bk 2, ch. 25). Xerxes was defeated by Themistocles in a naval battle and returned to Asia, having lost a great part of his land army.

[Margin: The birth of Democritus.]

[Margin: Year 450, approximately.]

In the year 469 before Christ, or the third year of the 77th Olympiad, Democritus was born; he lived 105 years, as Diogenes reports from Thrasyllus. In his time certain comets appeared, and Democritus himself related that on their dissolution certain stars appeared, as Aristotle has it (*Meteorologica* bk 1, ch. 3). In the same century flourished Hippocrates of Chios and Aeschylus, in whose time a comet shone, as Aristotle relates in the same place.

[Margin: Year 431.]

In the year 431 before Christ, or the 2nd year of the 87th Olympiad, a huge comet was seen after sunset for 75 or 60 days, according to Thucydides and to Plutarch in his *Lysander*. With it came a great eclipse of the Sun; the Peloponnesian War began at once; and in the following year a pestilential catarrh ravaged Athens.

[Margin: Year 410.]

In the year 410 there was the comet of which Aristotle writes (*Meteorologica* bk 1, ch. 6): *When Eucles son of Molon was archon at Athens, a comet appeared, the Sun being near the winter tropic, in the month of January.*

[Margin: Years before Christ.]

[Margin: Year 400, approximately.]

In the year 412 before Christ Archelaus, king of the Macedonians, began his reign, and he reigned 14 years; in his time a comet shone, as Praetorius reports from Seneca.

[Margin: The birth and death of Aristotle; the birth [?] and the beginning of the reign of Alexander.]

In the year 384 before Christ, namely the first year of the 99th Olympiad, Aristotle was born, as Diogenes Laërtius reports from Apollodorus; he lived 63 years and died in the 3rd year of the 114th Olympiad, the year in which Diogenes also died, that is, in the year 321 before Christ. Alexander the Great was born in 356 before Christ, or the 106th Olympiad, and began to reign in the 20th year of his age, when Pythodorus was archon, that is, in the year 336 before Christ, the 111th Olympiad, as we have it from Diodorus Siculus, Plutarch, Arrian and others.

[Margin: Year 373 or 372.]

[Margin: A huge comet when Aristotle was a young man.]

Within these years several comets blazed. Notable among them was the one in the 4th year of the 101st Olympiad, that is, 373 or 372 before Christ, in which, as Cottunius [Ioannis Kottounios] says (*Meteorologica* bk 1, lecture 30), Aristotle was completing his eleventh year. Of this comet Aristotle writes thus (*Meteorologica* bk 1, ch. 3): *For that great comet occurred around the time of the earthquake in Achaea and the rising of the waves; it rose from the equinoctial west.* That this is the same comet as the one Seneca speaks of (*Natural Questions* bk 7, ch. 5) is gathered from these words: *Charimander too, in the book he composed on comets, says that Anaxagoras saw a great and unusual light in the sky, the size of a*

broad beam, and that it shone for many days. Callisthenes reports that a fire of a long shape of this kind appeared before the sea covered Buris and Helice. Aristotle says that it was not a beam but a comet; but that because of its excessive heat the scattered fire did not appear, and that as time went on, when it was now blazing less, the comet's own appearance was restored. In this fire there were many things worth noting, but nothing more so than that, as soon as it shone in the sky, the sea was over Buris and Helice.

Ephorus, however, added certain things about the same comet, but of doubtful credit, in Seneca, in the same place, chapter 16. For Seneca says: *But Ephorus, a writer of by no means the most scrupulous good faith, is often deceived and often deceives. So with this comet, which was watched by the eyes of all mortals because it drew after it the outcome of an enormous event, when at its rising it sank Helice and Buris: he says that it divided into two stars, which no one but he reports. For who could observe the moment in which the comet was dissolved and reduced to two parts? And how is it, if there is anyone who saw a comet split into two, that no one has seen one made out of two? And why did he not add into which stars it was divided, since it must have been one of the five stars?* But neither of these conclusions necessarily follows. The beginning of the comet could have gone unobserved, while its end was observed, or its breaking up into two — not into two of the five known planets, but into lesser comets, or unknown planets. Seneca, however, out of Stoic disdain and a swollen wit, is inclined to carp at the Greeks whom the Romans had conquered.

[Margin: A comet occupying a third of the hemisphere.]

Again, in book 1, chapter 7 of the *Meteorologica*, Aristotle adds that a great comet occurred, in these words: *Moreover, all those seen in our time vanished without setting, in a place above the horizon, gradually consumed, so that the body of no single star was left behind, nor of several. And the great star, of which we made mention earlier, appeared in winter, in frost and clear weather, in the evening, when Aristaeus was archon. On the first day it did not appear, as if setting ahead of the Sun, but on the next day it appeared, as far as was possible, for it lagged behind the Sun by the least amount, and it soon set. Its light, however, stretched out as far as a third part of the sky, like a leap; for this reason it was also called the PATH. It climbed as far as the belt of Orion, and there it was dissolved.*

[Margin: Year 373.]

Since, then, he says that this was the great comet of which he had spoken earlier, it certainly seems to be the one that appeared in 373 before Christ, around the time of the earthquake in Achaea. The catalogue of the Athenian archons also supports this, for in that year Astius is listed, perhaps a contracted or corrupted form of the name Aristaeus. That comet was therefore famous on many counts and, as Seneca said, *watched by the eyes of all mortals*. Diodorus Siculus makes this comet a rival of the Moon; and Aristotle must be understood of the same comet in that book 1, chapter 7, when he says: *When the stone fell from the air at the river Aegos, raised up by a wind, it fell by day; and then too a comet had appeared in the evening. At the time of the great comet it was winter, and a*

northerly one, and the flood was produced by the opposition of the winds: for within the gulf Boreas prevailed, while outside a great south wind was blowing. Here he seems to be speaking a third time of that great comet which was followed by the submersion of Buris and Helice: understand this from the words *And at the time of the great*, etc.

[Margin: Years before Christ.]

[Margin: Year 341.]

Again, in the year 341 before Christ, in which, according to the catalogue of archons, Nichomachus presided at Athens, a comet shone out, of which Aristotle writes (*Meteorologica* bk 1, ch. 7): *Further, when Nichomachus was presiding over the Athenians, a comet occurred for a few days near the equinoctial circle, rising in the evening; in its time that wind about Corinth occurred.* It seems probable to me that those three comets were known to Aristotle by sight: one shone out when Aristaeus, another when Eucles son of Molon, and the third when Nichomachus presided at Athens. Nor, perhaps, did the three others escape him of which we shall speak in the following paragraph.

[Margin: Years 356 and 336.]

For both in the year in which Alexander the Great was born, namely 356 before Christ, and in the year in which he began his reign, which was 336, as we said above, comets appeared, two in all, each of which was visible for 70 days, as Justin the historian relates. So, although the first of these comets was unlucky for the Illyrians, since they were defeated by Parmenio, the general of Philip, who stormed Potidaea, it was nevertheless lucky for Philip. The other comet even then began to be unlucky for the Persians: for in that same year 336 Darius Codomannus, who was to be the last king of the Persians, inaugurated his reign, and against him Alexander was elected commander by the common votes of all Greece, if you except the Lacedaemonians. First, however, Alexander took up arms against the Thebans, who had revolted from him, and razed Thebes to its foundations; ninety thousand Thebans were slain and thirty thousand captured — namely in the 2nd year of the 111th Olympiad, that is, the first of his reign.

[Margin: Pindar's house alone was left intact.]

[Margin: Year 348.]

Between the two preceding comets, however, there was the one that appeared in 348 before Christ, of which Pliny says (bk 2, ch. 25): *Once only so far has the likeness of a mane been changed into a spear, in the one hundred and eighth Olympiad, in the three hundred and ninety-eighth year of the City.*

[Margin: Year 146.]

[Margin: A comet no smaller than the Sun.]

After it, at a long interval, came the one Seneca narrates thus (*Natural Questions* bk 7, ch. 15): *After the death of Demetrius, king of Syria, whose children were Demetrius and Antiochus, a little before the Achaean war, a comet shone out no smaller than the Sun. At first it was a fiery and reddish orb, giving out a bright light, enough to overcome the night; then gradually its size contracted and its brightness faded, and at last it vanished altogether. How many stars, then, must come together*

to make so great a body? Though you gather a thousand into one, they will never equal this extent of the Sun. The Achaean war began in the year 146 before Christ; about that year, then, this great comet blazed out, which was unlucky for Corinth and Carthage, both destroyed.

Seneca continues: *In the reign of Attalus a comet appeared, modest at first; then it raised itself and spread out, and came as far as the equinoctial circle, so that, stretched out immensely, it equalled that region of the sky which is called the Milky Way. How many wandering stars, then, must have come together to occupy so long a tract of the sky with continuous fire?* It is credible that he is speaking of the Attalus who flourished after the Achaean war and was so great a friend of the Romans that he made the Romans heirs of his kingdom; he began to reign in the year 137 before Christ and died in 133. Within these years, then, this portent was seen.

[Margin: Year 135, approximately.]

[Margin: 130.]

Not much later Mithridates was born, namely in the year 130 or 129 before Christ. For it is established that he was killed in the consulship of Iulius Silanus and Licinius Murena, that is, in the year 62 before Christ, and that he lived 68 or 69 years and reigned 57, according to Appian.

[Margin: 119.]

A comet seen at each time foretold the beginning both of his life and of his reign, as Justin records (bk 37) in these words: *Celestial portents too had foretold his future greatness. For both in the year in which he was born and in the year in which he first began to reign, a comet shone throughout each period for seventy days so brightly that the whole sky seemed to be on fire. For in size it had filled a fourth part of the sky, and in brilliance it had surpassed the splendour of the Sun; and in rising and setting it took up a space of four hours.* For together with its tail it occupied 45°, which are a quarter of the hemispherical circle; so it is no wonder if, by oblique ascension and descension, it did not wholly rise or set except over a space of 4 hours. Eutropius, however, says that Mithridates reigned 60 years and lived 72.

[Margin: And 60, approximately.]

About the year 60 another comet was observed by Posidonius, as Seneca indicates (bk 7, ch. 20), saying: *We do not see many comets because they are obscured by the rays of the Sun; Posidonius reports that during an eclipse of the Sun a certain comet appeared which the nearby Sun had concealed.* Before

[Margin: Years before Christ.]

[Margin: Year 47, 46 or 45.]

the murder of Julius Caesar, who was killed in the Senate in the year 44 before Christ, not one comet but several appeared, as Virgil sings in *Georgics* 2:

> *Never at other times did more lightning fall from a clear sky, nor did*
> *dread comets blaze so often. So Philippi saw Roman battle lines clash*
> *once more with matching weapons.*

But I believe he is also speaking of the comet or comets that shone out before the civil war when Caesar had crossed the Rubicon, of which Lucan writes in book 1:

> *Dark nights saw unknown stars, the pole ablaze with flames, and torches flying slantwise through the void of heaven, and the hair of the dreaded star, the comet that changes kingdoms on earth.*

[Margin: The comet after Caesar's murder.]

Of these Pliny says (bk 2, ch. 25): *The comet, a star terrifying* magna ex partes [?] *and not lightly expiated, as in the civil disturbance in the consulship of Octavius, and again in the war of Pompey and Caesar.*

[Margin: Year 44.]

After Caesar was killed, a hairy star appeared, of which Suetonius writes thus (*Julius Caesar*, ch. 88): *He died in the fifty-sixth year of his age and was numbered among the gods, not only by the mouths of those who decreed it but also by the conviction of the common people. For at the games which his heir Augustus was giving, the first held in his honour, a hairy star shone for seven successive days, rising about the eleventh hour, and it was believed to be the soul of Caesar received into heaven; and for this reason a star is added to the top of his statue.* Plutarch asserts the same in his *Caesar*, adding that it was a huge hairy star which, after Caesar's death, blazed with remarkable brilliance until the seventh night. But Pliny is fuller on this (bk 2, ch. 25), where he narrates thus: *In only one place in the whole world is a comet worshipped, in a temple at Rome; it was judged very auspicious by the deified Augustus himself, because it appeared at his own beginnings, at the games he was holding for Venus Genetrix not long after the death of his father Caesar, in the college he had founded.*

[Margin: Augustus's words on the good omen of the comet.]

For he expressed his joy in these words: "On the very days of my games a hairy star was seen for seven days in the region of the sky that lies under the Septentriones. It rose about the eleventh hour of the day, and was bright and visible from all lands. By that star the common people believed it was signified that Caesar's soul had been received among the divine powers of the immortal gods; on which account that emblem was added to the bust of his head which we shortly afterwards dedicated in the forum." This he said in public; with a more inward joy he interpreted it as born for himself, and himself as born in it; and, if we confess the truth, it was salutary for the world.

Nor is it unfitting that this comet was seen while the Sun was still above the horizon, since Venus has been seen in the daytime more than once by us and often by others. Some take the following words of Q. Curtius (bk 10) to refer to this very comet: *Rightly and deservedly, therefore, the Roman people professes that it owes its safety to its Prince, who shone out as a new star in the night that we had held to be almost our last. It was his rising, by Hercules, not the Sun's, that gave light back to a darkened world. How many torches did he then put out! How many swords did he sheathe! How great a storm did he scatter with sudden calm!*

[Margin: Year 13.]

[Margin: A comet divided into several.]

In the year 13 before Christ, the year before the death of Agrippa, Dio (bk 54) relates that there was a comet which appeared for many days hanging over the City and was then dissolved into many torches. Perhaps this is the one of which Seneca speaks (bk 7, ch. 17) in the words *the one we saw under Augustus*.

Of the wonderful Star, however, which divinely foretold the birth of CHRIST to the Magi, this is not the place to treat, but below, in Section 2, where we deal with new stars.

[Margin: Years of Christ.]

Hiſtoria Cometarum qui Annis poſt CHRISTI Ortum apparuerunt.

A history of the comets that appeared in the years after the birth of CHRIST.

[Margin: 14.]

[Margin: 54.]

II. The first comet after the birth of CHRIST recorded in history is the one seen in the year 14 of Christ, near the death of Augustus, as Fiornouellus [?] reports; or at any rate the one that appeared a little before the death of the emperor Claudius, in the consulship of Q. Asinius Marcellus and M. Acilius Aviola. Of it Suetonius says (*Claudius*, ch. 46): *The chief omens of his death were the rising of a hairy star, which they call a comet, the striking of his father Drusus's monument by lightning, and the fact that in the same year most of the magistrates of every kind had died.* This comet, according to Seneca (bk 7, ch. 21), rose in the north and went on into the east, ever dimmer. Claudius, moreover, died of poison; and so Pliny (bk 2, ch. 25), having said that a comet is a star terrifying for the most part and therefore not lightly expiated, added: *In our own age, about the time of the poisoning by which Claudius Caesar left the empire to Domitius Nero* — understand: the comet was not lightly expiated.

[Margin: Years of Christ.]

[Margin: Year 60.]

Under Nero, however, who succeeded him, a double comet was seen. One was in the year of Christ 60, in the consulship of Nero for the fourth time and Cossus Cornelius Lentulus, as we have it from Tacitus, *Annals* 14, who says: *Amid these events a star also shone out, of which the common opinion is that it portends a change of kingdoms.*

[Margin: Year 64.]

The other was in the consulship of C. Lecanius Bassus and M. Licinius Crassus, namely the year of Christ 64 and the tenth of Nero's reign; of it the same Tacitus writes in *Annals* 15 in this way: *At the end of the year prodigies were reported: lightning more frequent than ever before, and a comet, a star always expiated by Nero with noble blood.* Pliny (bk 2, ch. 25) says that this star was almost continuous and savage during Nero's principate. For Kepler, in *De Cometis*, p. 111, wrongly makes this one distinct from that one and draws the

earlier back to the year 60 of the common era, not attending to the consuls under whom Tacitus places it.

[Margin: A comet of 6 months.]

Seneca, it is true, says (*Natural Questions* bk 7, ch. 17): *There is no reason for us to think that the comet seen under Claudius was the same one we saw under Augustus; nor that this one, which appeared under Nero Caesar and took away the ill repute of comets, was like the one that emerged after the murder of the deified Julius, at the games of Venus Genetrix, about the eleventh hour of the day.* And in chapter 21: *For six months this comet, which we saw in the most happy principate of Nero, offered itself to view, turning round in the opposite direction to that Claudian one. For that one, rising from the north toward the zenith, made for the east, ever dimmer; this one began from the same quarter, but, tending westward, bent toward the south and there withdrew from sight.* But the grim events that followed, and the deaths of senators and of Seneca himself, showed how happy Nero's principate was.

In the same book, chapter 29, Seneca mentions another comet, saying: *The comet that appeared in the consulship of Paterculus and Vopiscus brought about what Aristotle and Theophrastus had foretold: for there were very great and continuous storms everywhere, and in Achaea and Macedonia cities were overthrown by earthquakes.* I would think, however, that these were suffect or honorary consuls, for I do not find them in the catalogue of the ordinary consuls.

[Margin: Year 70.]

In the year 70 of Christ, in the consulship of Flavius Vespasian (for the 1st time) and Titus his son, Jerusalem was laid waste, a comet — a Xiphias — having preceded it and shone for almost a whole year, hanging over the city of Jerusalem itself, as Josephus reports (*Jewish War* bk 7), and Zonaras (vol. 1). So that it might be plain that those who had not believed the star and the Magi announcing Christ deserved to be deprived of kingdom and priesthood, a comet foretold that disaster.

[Margin: Year 76.]

Later, in the year 76 of Christ, another comet blazed out with a very long mane in the shape of a javelin. On seeing it Vespasian, as Aurelius Victor relates, remarked wittily that it concerned the king of the Persians — or, as Dio has it, of the Parthians — whose hair was more flowing. Of this comet is Pliny's remark (bk 2, ch. 25): *The Acontiae quiver like a javelin, with a very swift significance. This was the one about which Titus Imperator Caesar wrote in a famous poem in his fifth consulship, the last seen to this day.* Dio, however, adds that a memorable drought followed, and fiery prodigies around Vesuvius, and vast images of men which the people called aerial Giants; and that ashes were blown not only as far as Rome, so that the Sun was darkened, but even into Africa and Egypt. But a little before Vespasian's death another comet, pertaining more closely to him, was seen — unless perhaps Dio is to be understood of the earlier one.

[Margin: Year 130.]

After these, in the year 130, a comet was seen that was most auspicious for Viuardus [?], king of England, who, having subdued the tyrant Carduela [?], joined many provinces to himself and to God.

[Margin: 340.]

In the year of Christ 340, in which Constantine, son of Constantine the Great, was killed, a huge comet shone for several months, as Praetorius reports.

[Margin: 383.]

[Margin: 386.]

[Margin: 390.]

Praetorius adds that in the year 383, under Theodosius, a comet like the one over Jerusalem shone; and also that in the year 386 the comet was seen of which Claudian speaks in his Panegyric of Honorius; and, about the year 390, the one that Proclus saw above Jupiter, as Peucerus [Caspar Peucer] has it, cited in Tycho (vol. 1, pp. 619 and 625), and Cysatus [Johann Baptist Cysat] (p. 56).

[Margin: Year 392.]

By far the most celebrated is the one that appeared a little before the strangling of Valentinian, which took place on the Ides of May in the year of Christ 392. For of it Nicephorus (*Ecclesiastical History* bk 12, ch. 37), after recounting the unusual floods of the Nile, says: *Then indeed unusual portents too were seen, which*

[Margin: Years of Christ.]

were to forebode evils for the world. *For first an unexpected and unusual star, shining in the sky about midnight near Lucifer, appeared about the zodiac; because of its flashing rays it was large and bright, and scarcely yielded to Lucifer. Little by little a great multitude of other stars also gathered to it. Had you seen this spectacle, you would have likened it to a swarm of bees flying about their leader. The light flashing out from them by their mutual concourse became a single flame and, shining with a certain terror, bore the appearance of a great and dreadful sword, two-edged throughout. For because the remaining stars fell into the same aspect and seemed to be a single star with the one that had been seen first — which was, as it were, the root or hilt — its flame was carried aloft just like a burning wick from a lamp. Its motion, moreover, differed entirely from the course of all the stars. At first, beginning to move from the place we have mentioned, it rose and set together with Lucifer. Then, gradually withdrawing from it, it made at a slow pace towards the Bears, and moved by an oblique path to the left of those watching. Its circuit, indeed, it completed in common with the other stars it had joined; but by its own motion, which was prolonged to the fortieth day, it at last barely reached the Great Bear, and vanished in the middle part of that constellation, where it had last shone. At that time it appeared sword-shaped.*

[Margin: The age of Nicephorus.]

Where Nicephorus drew this from, I do not know; for he cannot have been an eyewitness, since he is scarcely older than the year of Christ 1300, as is gathered from the dedicatory epistle of his *History*. See what I shall say in ch. 6, Scholium 3.

[Margin: Year 396.]

[Margin: Year 400.]

[Margin: A comet reaching right down to the earth.]

But the fire that appeared, sulphurous, over Constantinople in the year 396 — of which St Augustine speaks in his book *On the Destruction of the City* in these words: *At nightfall, when the world was already growing dark, a fiery cloud was seen from the east, small at first; then gradually, as it approached over the city, it grew, until it hung hugely and terribly over the whole city. A dreadful flame seemed to hang there, nor was the smell of sulphur lacking: all fled to the church,* etc. — that fire, I say, does not seem to have been a comet, although Baronius, at the year of Christ 400, designates another, very similar portent over Constantinople by the name of comet. Gainas [Gaynas] was raging at that time and before [?], and so to this time belongs the comet of which Socrates speaks thus (*Ecclesiastical History* bk 6, ch. 6): *Through the tyranny of Gainas so grave a danger hung over the city of Constantinople that a very great comet, reaching from heaven right down to the earth (such as no one had ever seen before), portended that very thing.* Very similar are Sozomen's words about it (bk 8, ch. 4): *At which time a comet too portended such plots of Gainas; it appeared very great over Constantinople, reaching almost to the earth itself, and is said to have been such as never was before.* And those of Nicephorus Callistus (*Ecclesiastical History* bk 13, ch. 6): *Which plots of Gainas that star portended, bearing the appearance of a sword; it was splendid beyond measure, such as the record of letters relates never to have appeared before: shining above the city itself, and reaching from almost the top of heaven to the earth itself.*

[Margin: Year 405.]

In the year 405, in which Stilicho [?] defeated the Getae, there appeared a comet described by Claudian in his poem *On the Gothic War*, in the verses we shall quote in ch. 4, no. 8.

[Margin: 454.]

[Margin: 538.]

[Margin: 557.]

[Margin: 570.]

[Margin: 587.]

[Margin: 594.]

[Margin: 603.]

[Margin: A comet of 6 months.]

[Margin: 632.]

In the year of Christ 454, the 26th of the Emperor Valentinian, Trithemius reports, besides a comet, other prodigies in the sky, which seemed to foretell the death of Theodosius and the invasions of Attila. In the year 538 a comet was followed by so great a famine that men devoured their own flesh, as Idatius [Hydatius] testifies. Likewise, in the year of the saving Birth 557, a hairy star in the shape of a lance appeared at Constantinople, as Johannes Praetorius relates. And again in the year 570 a comet was seen, and the Lombards, with the eunuch Narses as their leader, occupied Italy; but Alboin is killed in the year 571. And after 17 years, namely in the year 587, which was the fourth of the reign of Maurice, a comet appeared at Byzantium, as Zonaras testifies; and

in his eleventh year, namely the year of Salvation 594, a comet appeared for a whole month, and famine and drought followed it. Then in his last year, which was the year of Christ 603, the comet Xiphias was seen, in the year in which Maurice was killed with his three daughters. Under this emperor, moreover, Mahomet was born, at which time, Johannes Praetorius reports, a hairy star appeared for 6 months — and perhaps it was one of those already mentioned. But before Persia was occupied by the Saracens, another comet was seen in the year 632, bearing the form of a fiery sword, as Petrus Surdus [?] and Spondanus [Henri de Sponde] relate from Theophanes.

[Margin: 676.]

[Margin: Year 684.]

In the year of Christ 676 — or, as others relate, 678 — a terrible comet was watched at Rome for three months. Orosius adds that great rains and frequent thunder followed, but Bede says drought and plague, and that in the following year locusts flew in great swarms through Syria and Mesopotamia. And it is said that after 8 years a great star appeared in the east, though it is uncertain whether it was a comet; after it, in the year 685, Vesuvius vomited out fire, as Sabellicus [Marcantonio Sabellico] relates (*Enneads* 8, bk 6).

[Margin: Year 729.]

[Margin: Two comets.]

[Margin: Or 726.]

[Margin: Or 725.]

In the year of restored Salvation 729, Bede and Palmerius [Matteo Palmieri] in his chronicle affirm that two comets appeared in the month of January for 15 days, one of which went before the Sun like Lucifer, while the other followed it like Hesperus. Yet it could have happened that, because of its great declination towards the pole, the same comet was visible and was seen both morning and evening. To this year Johannes Praetorius and Giovanni Camillo Glorioso refer these comets; although Cardano, in bk 2 of *On the Judgements of the Stars*, text 53, refers them to the year 726, and says they were seen within 14 days in the month of January, with their tails turned towards the north. Vincentius Guinisius of the Society of Jesus, however, in his oration *On the Felicity of a Comet*, sets them back to the year 725, in which there was indeed foul weather throughout the whole world, but Charles Martel triumphed over the Saracens.

[Margin: Year 745.]

[Margin: 761.]

[Margin: 763.]

In the year of Christ 745, after a comet seen in Syria at the end of the year, there followed a plague lasting three years, which ravaged first Sicily, then the islands of the Mediterranean and all Greece, and finally Constantinople, as Johannes Praetorius relates. Then in the year 761 a comet shone in the east for ten days, and another in the west for 21 days — perhaps one and the same, although Functius [Johann Funck] in his *Chronicle* reports them as different. Again, in the year 763 a comet was seen in the east, followed by a great drought

and unbearable cold; the Turks, meanwhile, extended their power with great success.

[Margin: 800.]
[Margin: 814.]
[Margin: 829.]
[Margin: A hailstone from the sky.]
[Margin: 837.]
[Margin: 839.]
[Margin: 842.]
[Margin: 843.]
[Margin: Year 844.]

In the year 800 Johannes Praetorius assigns a comet, the year in which the Roman Empire was transferred to Charlemagne; then in the year 814 a terrible comet appeared a little before the death of that same Charles — from the *Annals of the Franks*. And in the year 829, as Fiornouellus relates, there were seen shooting stars rather than comets, which killed cattle and some men; and in the same year a hailstone four feet long fell from the sky. And in the year 837 Pepin died, a comet having gone before — granted that others carry this forward to Louis the Pious, who died in the year 840, and say that in the year 839 a comet shone out in the sign of Aries, at the sight of which, especially with an eclipse added, he began to prepare himself for death. Then in the year 842, which was the second of Lothar, a comet again shone in the sign of Aquarius; and in the following year several comets are said to have foretold the deadly war that Lothar waged with his brothers. Cardano says there were three comets (on Ptolemy, bk 2 of *On the Judgements of the Stars*, text 54), the first of them in Libra, the second in Aries, the third in Aquarius. In the year 844, too, Abū Maʿshar observed a comet above Venus, as Cardano relates in bk 4 of *De subtilitate*, and from him Tycho (vol. 1, p. 783) and Cysatus (*On Comets*, p. 56).

[Margin: Year 876.]
[Margin: 882.]
[Margin: 906.]
[Margin: 945.]
[Margin: 983.]

In the year 786 [?], on the eighth day before the Ides of October, a comet was seen, and floods and plague followed from it. In the year 882, in which Louis, King of the Bavarians, died, a hairy star appeared on the 15th day before the Kalends of February. In the year 906 great rains followed a comet that was unusually red; and in the year 945 a comet of wonderful size was seen in Italy, followed by famine there and in Gaul. In the year 983, too, in which the Emperor Otto II died of grief, a comet was seen, with famine and plague as its attendants. So Johannes Praetorius tells of these five comets in his *Catalogue of Comets*. Earlier, however, in the year 982, Vesuvius had poured out fire, according to Sigonius [Carlo Sigonio] (*On the Kingdom of Italy* bk 7) — or in this same year 983, as Baronius has it (vol. 10).

[Margin: Year 1005.]
[Margin: 1009.]
[Margin: 1027.]
[Margin: 1066.]

In the year 1005 a comet of horrible aspect was seen for thirteen nights about the Easter feast, as Johannes Praetorius has it. And in the year in which John XVIII died — or, as others say, XIX — namely the year 1009, a terrible comet appeared towards the south, followed by great famine and plague, as Cardano affirms (text 54 on bk 2 of *On the Judgements of the Stars*). And in the year 1027, after the blazing of a comet, there was so dire a plague that the living were not enough to bury the dead, says Petrus Surdus.

In the year 1066 a comet, before the death of St Edward, king

[Margin: Years of Christ.]
[Margin: 1067.]
[Margin: 1071.]
[Margin: 1098.]
[Margin: 1099.]
[Margin: 1106.]
[Margin: 1141.]

of England appeared, as Henricus Spondanus [Henri de Sponde] relates in his *Epitome of the Annals*; and in the year 1067 there was another, according to Fiornouellus, in the year in which the supreme pontiff Alexander was harassed by Cadalus, bishop of Parma. Again, in the year 1071, after a new star seen towards the south and west, a comet with long and flaming hair appeared for 25 days. Like it was the flaming comet of the year 1097 or 1098, which appeared in the west, as Keckermann records; and another in the year 1099, in the east, which changed its place by leaps. A very great comet also appeared in the year 1106, in the season of Lent, in which Henry IV died, according to Johannes Praetorius; and in the year 1141 as well.

[Margin: 1169.]

In the year 1169 a comet appeared in Scotland with two very long rays, burning and huge, and Malcolm IV, King of Scots, surnamed the Maiden, died; so Cardano reports (on the *Quadripartitum*, bk 2, text 54).

[Margin: Year 1200.]

In the year 1200 Haly Ben Rodoan [ʿAlī ibn Riḍwān] the Arab, while applying himself to astronomy as a young man, saw a comet whose solid part appeared three times larger than Venus, and of round shape, and its light, he says, was as great as if a quarter of the Moon were shining. Its place was at 15° Scorpio, and it moved with the motion of the primum mobile from east to west, in such a way that it was carried more swiftly against the order of the signs, until it reached 15° Virgo. So he himself says in bk 2 of the *Quadripartitum*, ch. 9; and Cardano in the same place, text 54, describes many astrological circumstances of this comet from Haly. A rebellion in Africa followed, of which he speaks in the same place. The empire of the Tartars then made its beginnings.

[Margin: Year 1211.]

In the year of restored Salvation 1211, in the month of May, a comet was seen with its tail stretched out over Russia, and it lasted 18 days; from it came the flood of the Tartars into Muscovy and Assyria, as Spondanus relates in his *Epitome of the Annals*, as does Johannes Praetorius.

[Margin: Year 1214.]

[Margin: Twin comets.]

[Margin: Year 1240.]

[Margin: A comet of 6 months.]

But in the year 1214 two comets appeared together in Scotland, one going before the Sun in the morning, the other following it in the evening; in that year King William, a man of outstanding prudence and holiness, died at Stirling aged 74, as Hector Boëtius [Hector Boece] has it (*History of the Scots* bk 13). Again, in the year 1240 a comet appeared in the east, with its hair stretched out right to the middle of the sky, and it reached right to the pole, as Albertus Magnus affirms as an eyewitness (*Meteorologica* bk 1, tr. 3, ch. 5); and it was extinguished scarcely within six months, as Daniel Santbech testifies (book *On Observations*, prop. 19). In that year Tamerlane burst into Asia, as Pontanus [Giovanni Pontano] has it. But Cardano, in bk 2 of *On the Judgements of the Stars*, text 54, puts this comet in the year 1260, saying that Pope Urban died in that year, which is false. One or the other, then, must have erred in the numerals, writing MCCXL for MCCLX, or the reverse.

[Margin: Year 1254.]

[Margin: 1264.]

In the year 1254 a comet was visible in Germany for several months, followed by a violent abundance of winds. And in the year 1264 a huge comet appeared in the east about the beginning of August, and shone for 40 days. At first it rose two hours before sunrise, large and bright, spreading out a long and broad tail, which day by day grew fainter, and it joined the Sun: so the *Annals of Colmar* have it. In this year, moreover, it is established that Urban IV died, about the beginning of October; his death the comet already mentioned seemed to have foretold, and it was seen at Ptolemais, in Italy and in France, as Bzovius [Abraham Bzowski] says in his *Annals*. Pontanus too speaks of the same comet in his commentary on Ptolemy's *Centiloquium*, at the last aphorism, saying: *In the year one thousand two hundred and sixty-four from the day of Christ's birth, in the month of August, a hairy star was seen in the eastern part of the sky, which spread its hair from its very rising to the middle of the sky, and it shone for about three months, nor did it cease to be seen before Pope Urban, Pontifex Maximus, died. Then Charles moved with an army out of France and, having overcome Manfred, occupied the kingdom of Naples.* Since, however, Urban's successor Clement IV was not elected until February of the year 1265, Johannes Praetorius perhaps for that reason draws this comet to the year 1265; but Functius and Camerarius agree with the *Annals of Colmar*. Accordingly Cardano has confused this comet with

the other, and Pontanus, who designated the year in words, not in figures, is rather to be believed.

[Margin: Year 1267.]

[Margin: 1268.]

The *Annals of Colmar* add that three years later, namely in the year 1267, a beautiful and great star rose at sunrise near the Moon, on July 18; advancing with great impetus from the Moon towards the east as far as the middle of the hemisphere, it left behind it a tail, or a white and fiery cloud, and the two ceased to be together. And in the year 1268 a comet of wonderful size was seen for several days in Scotland, towards the south (a great marvel of a portent indeed), as Cardano relates in bk 2 of *On the Judgements of the Stars*, text 54, who attributes to it great disasters in Scotland arising from winds.

[Margin: Year 1283.]

In the year 1283 too, Johannes Praetorius relates, a comet was seen in summer, at the time when the Emperor Adolf was defeated in battle by Albert.

[Margin: 1298.]

[Margin: 1301.]

[Margin: 1303.]

[Margin: 1305.]

[Margin: 1312.]

[Margin: 1313.]

[Margin: 1314.]

In the year 1298, as Spondanus and Bzovius relate in their annals, so great an earthquake suddenly occurred in various regions of the world that it surpassed all memory; it happened on the feast of St Andrew, and at the end of November a comet appeared. Then in the year 1301, before the deaths of Charles Martel and of Andrew, King of Hungary, another comet was watched, according to the same Spondanus. And in the year 1303 there was a comet like a fiery column descending and soon ascending again, as Keckermann relates (*Systema physicum* bk 6, p. 694). And soon after, in the year 1305, at the Easter feast, a comet was the herald of a plague that was to rage through the whole world, says Johannes Praetorius. He adds that in the year 1312 a comet showed itself for 14 days, and another in the following year, which ran from north towards south following the motion of Mars; and finally that in the year 1314 a comet appeared at the end of Virgo for three weeks and directed its flame towards the north; and that there was then a very great famine in Lithuania and the adjacent regions, rains through the whole summer, and from them plague, by which a third part of the living were carried off. Philip the Fair, King of France, dies on November 29, thrown from his horse while hunting.

[Margin: Year 1337.]

[Margin: Twin comets.]

[Margin: Year 1341.]

[Margin: 1347.]

In the year 1337 a dire comet lasted in the sign of Taurus for 4 months and more, and another joined it, which shone together with it in the months of June, July and August. There were many disasters of war, a host of locusts, and plague at Nuremberg. Johannes Praetorius, in his *Catalogue of Comets*, adds that three years later another appeared in the sign of Virgo in the month of March, and that 400 buildings at Nuremberg were consumed by fire; the Emperor Andronicus, moreover, died. And he, together with Fiornouellus, reports that in the year of Christ 1347, in the month of August, there was seen in the sign of Taurus, towards the north, something huge — either a comet or a fiery vapour — as if falling from the sky, to the great terror of those watching; the one, however, was seen for a few days, the other for two months. Throughout Europe, but especially in Italy, a severe famine followed, and in the following year a plague from Asia right to Britain, which lasted three years, carried off the greatest part of mortals, and surpassed all pestilences and diseases within human memory.

[Margin: Year 1352.]

[Margin: 1353.]

[Margin: 1363.]

[Margin: A comet of three months.]

[Margin: 1375.]

Then the years 1352 and 1353 also had their comets; and in the year 1363 a huge comet appeared[6] from the east for three whole months, casting its rays, in a dire burning of the air, towards the west up to the middle of the sky, as Johannes Praetorius says. In the year 1375 the death of Charles IV followed a hairy star; and in the year 1391, too, a comet was seen having the shape of a spit, which astrologers, the same Praetorius says, reckon the worst.

[Margin: 1401.]

[Margin: Year 1402.]

In the year 1400 a huge comet appeared at the eastern cardinal point of the sky, which moved towards the west, and this a few months before Tamerlane, dynast of the Tartars, burst into Asia against Bayezid — who had grown proud with many successes — with very great slaughter of the Turks. The *Turkish Annals* record this slaughter in the year of the Hegira 804, which began in the year of Christ 1401, and they call Tamerlane Temir, as Chalcondylas [Laonikos Chalkokondyles] also does. Pontanus, however, who reports on the comet already mentioned at aphorism 100 of the *Centiloquium*, and Cardano, who does so in bk 2 of *On the Judgements of the Stars*, text 54, call him Tamyris or Tamorlanus. He died in the year 1403, likewise with a comet going before, as Johannes Praetorius relates; but Fiornouellus assigns this comet to the year 1402, saying that it too had the shape of a spit and shone for a month, and that shortly afterwards there died not only Tamerlane but also Galeazzo [Galeatius], Duke of Milan. Perhaps there were two different comets.

[6]printed *appatuit*, for *apparuit*

[Margin: 1407.]
[Margin: 1433.]
[Margin: 1434.]
[Margin: 1439.]
[Margin: 1444.]

Johannes Praetorius assigns, moreover, a comet of its own to the year 1407, in which the Prussians are said to have been defeated by the Poles with great slaughter; a comet of three months to the year 1433; and their comets to the years 1434, in which Trapezuntius [Georgios Trapezountios] flourished, and 1439, in which Turkish power grew and the strength of the Christians was weakened; and besides these, in the year 1444, a huge comet at the time of the solstice, which terrified mortals.

[Margin: Year 1450.]
[Margin: A comet eclipsing the Moon.]

In the year 1450 that comet was seen of which Georgius Phranza [Georgios Sphrantzes] tells thus in bk 5, ch. 21, of his *History*: *In the summer of the year of Christ 1450 a comet above the horizon*

[Margin: Years of Christ.]

began to appear every evening immediately after sunset, in the likeness of a broadsword. Passing beneath the full disc of the Moon, it brought about an eclipse, according to the usual order and motion in the circuit of the heavenly lights. Some, seeing that this comet expressed the appearance of a sword, that it moved from west to east and approached the Moon, and seeing the darkness of the Moon's eclipse, interpreted the matter thus: that the Christian princes, having formed a league, would come against the Turks and would vanquish them. The Turks too fell into no slight fear at that portent. So evident was it that that comet was below the Moon. Our Tannerus [Adam Tanner] also reports this author's words (*De Caelo*, question 7, §4). In that year, moreover, Amurath [Murad II], emperor of the Turks, died of drunkenness.

[Margin: Year 1456.]
[Margin: Year 1457.]
[Margin: A comet occupying 60 degrees and more.]

In the year 1456, as Johannes Praetorius relates, a comet appeared with various prodigies for a whole month in Poland and elsewhere; it was believed to have foretold the death of Ladislaus, King of Bohemia, who was carried off by poison. In the following year, that is 1457, says the same author, there shone the comet of which Pontanus speaks thus in his commentary on Ptolemy's *Centiloquium*, aphorism 100: *When we were young men, a remarkable comet also shone for many days towards the east, in the regions of Cancer and Leo, of such length that with the trail of its hair it occupied more than two signs of the sky. It was followed by the death of King Alfonso, which entangled Emilia, Sabina, Campania and the whole kingdom of Naples in a long and grievous war; a pestilence, somewhat longer-lasting, followed as well.* Alfonso died, moreover, in the year 1458, on the Kalends of July, aged 66.

But Kepler, in his *Physiology of Comets*, p. 130, affirms that Pontanus is to be understood of the comet of the year 1456, when Mehmed [Mahometes] the Turk besieged Belgrade, formerly called Taurunum or Alba, after he had stormed Constantinople in the year 1453, on May 29. But in this year 1456 he was driven from the siege, with great slaughter and disgrace of the Turks, by Johannes Corvinus Huniades [János Hunyadi], guardian of Ladislaus, King of Hungary, then still a boy, on the day sacred to St Magdalene. The chief author of this battle was a most holy man of the Order of Friars Minor, Ioannes Capistranus [Giovanni da Capestrano]: at his urging 40,000 men took up the badge of the cross and arms against the Turks. Johannes Huniades, however, who was voivode, that is, prince of Transylvania, died a happy death in the same year.

[Margin: A comet occupying 50 degrees, of wonderful swiftness and motion.]

[Margin: Year 1471.]

But Pontanus continues, in the place already cited, saying: *In these preceding years another comet was seen, at first with a slender head and very short hair. Soon, grown to wonderful size, it began to turn aside from the east towards the north, now with quickened, now with slackened motion; and because Mars and Saturn were both going back, it was itself carried turned away, with its hair going in front, until it reached the Bears themselves. From there, as soon as Saturn and Mars began to proceed in direct course, it bent its path towards the west with such speed that in one day it traversed about thirty degrees; and when it reached Aries and Taurus, it ceased to be seen. This comet both shone for very many days and, though it looked short at the beginning, grew so much that it occupied fifty degrees and more. Not long afterwards Ussonus Cassanus [Uzun Hasan], king of Parthia and Armenia, having set out for the Euphrates with the design of invading Asia, joined battle with Mahomet, king of the Turks, and fought in such a way that he both inflicted and suffered a huge defeat; for two most powerful armies, two very great commanders, clashed twice within a few days.* And a little after: *We learned that in the same period all Spain was shaken by war, and that King Henry died.*

[Margin: Year 1460.]

[Margin: 1470.]

[Margin: 1471.]

[Margin: or]

[Margin: 1472.]

But this comet was not the one that was seen in the year 1460, from which Ioannes a Capistrano is said to have prophesied the evils of the age, as Johannes Praetorius says; nor the one that ran down with very long hair on the Ides of January in the year 1470, if you believe Bodin (*Theatre*, bk 2). The one Pontanus speaks of is referred, rather, to the year 1471, in which Alfonso, King of Portugal, stormed Tangier and Arzila. But Kepler, in his *Physiology of Comets*, p. 129, says that that defeat of the Turks and Tartars was in the year 1473, and the comet in the year 1472, of which presently.

[Margin: A comet observed by Regiomontanus.]

In the year 1472 two comets appeared, as the Polish history has it. One of them, as Petrus Surdus relates (*On Comets*, part 1), was seen in the month of March having the form of a javelin, and so great a drought followed it that springs were long without water. The other was observed by Regiomontanus on January 20; it lingered in Libra and was followed by a drought of three years, as Johannes Praetorius relates in his *Catalogue of Comets*, and Cardano in bk 2 of the *Quadripartitum*, text 54, where he says that this comet is assigned by Antonius Mizaldus [Antoine Mizauld] now to the year 1472, now to the year 1475. Kepler, in *Tycho's Hyperaspistes*, bk 3, ch. 2, 17 and 18, teaches how this arose: Mizauld admits that he took the account of this observation from Ziegler's *Conceptiones in Genesim* [Jakob Ziegler], and Ziegler easily erred, taking the obsolete figure for two as a five. Fracastoro (*Homocentrica* bk 3, ch. 23) says that it was seen in February 1472, that it was a pogonias [bearded comet], and that from southern it became northern. The words of Regiomontanus, as given in Ziegler and Cardano, are these: *On the Ides of January in the year of the Lord 1475* (read 1472) *a comet was seen by us under Libra, with a star of Virgo. Its head was of slow motion until it was near Spica; then it advanced through the legs of Bootes towards his left, and, departing from there, in one natural day it described a portion of a great circle of 40°. When it was in the middle of Cancer, it stood at its greatest distance from the circle of the signs, 67°, and was then passing between the two poles, of the zodiac and of the equinoctial, as far as the space between the feet of Cepheus; then through the breast of Cassiopeia, over the belly of Andromeda. Afterwards, proceeding along the length of the Northern Fish, where its motion slackened greatly, it approached the zodiac, crossing it near the middle of Aries, until its heliacal setting with the stars of Cetus hid it from us in the last days of February. By this proper motion of its own it described a portion of a great circle, along which it was carried northwards, against the succession of the signs, from Libra into Aries. At the end and at the beginning it moved slowly; in the middle very swiftly, in one day through four signs, from the end of Virgo right to the beginning of Gemini. Its tail, however, being less mobile, by continually facing the stars of Gemini, went round them, never deviating from them through the whole time of the apparition. Therefore at its first emergence it stretched the tail towards the west, because the stars of Gemini were there; but at the end, the comet being placed under Aries, it appeared only in the west because of the nearness of the Sun, with its tail stretched towards the east, because in this situation the stars of Gemini lay there. In the middle of the apparition it turned its tail to the south: the stars of Gemini were then there; and it happened in one and the same night that immediately after sunset the tail faced east; as midnight approached it faced south; after midnight, west; before sunrise it pointed to the region of the north. This variation of the tail in position arose from the diurnal motion, which is always from east to west. By its proper motion, however, the extremity of the tail — though more slowly than the head of the comet — also always moved westward, against the succession of the signs, describing a parallel from the beginning of Libra right to the middle of Taurus: passing beneath the feet of the Howler [Ululans], through the Great Bear,*

approaching Perseus, through whom it went around the Pleiades to the tail of Aries, at about the middle of Taurus. From this it is evident that both the head and the tail of the comet were directed towards the west, and never towards the east, not only by the diurnal motion but also by the proper motion.

[Margin: The size of this comet.]

Kepler, moreover, confirms in the places cited that this is the same comet of which Pontanus spoke above: from the motion Pontanus indicated; from the station and retrogradation of Mars and Saturn, which fall at the end of the year 1471 and the beginning of 1472; from the authority of Eber, who says expressly that it is the one which Pontanus too described, both in the *Centiloquium* and in an elegant poem in his *Meteora*, and which the mathematician of Gurk measured and affirmed to have been more than 4000 German miles long, and 26 miles broad at the head and 81 at the tail; and from Matthias Palmerius [Mattia Palmieri], who called this comet the Pole [Pertica]. We therefore subscribe to these rather than to Fromondus [Libert Froidmont], who (*Meteorologica* bk 3, ch. 4, art. 4) assigns this comet of Regiomontanus to the year 1475. Finally Peter Apian, in part 2 of the *Astronomicum Caesareum*, says that the comet of the year 1472 let its tail down right to the earth, that in his own time old men were living who remembered it, and that it was called the peacock's tail. A great drought followed, and the campaign of Ussumcassanus [Uzun Hasan].

[Margin: Year 1477.]

[Margin: 1491.]

In the year 1477 a blackish comet is noted by Eber in his *Catalogue*, after which followed the slaughter of Charles of Burgundy. Finally, towards the end of that century, that is, in the year 1491, there occurred an eclipse of the Sun and a comet about the beginning of Aries, with southern latitude; Vualtherus [Bernhard Walther] notes nothing else about it in his observations. At the beginning of the following year Ferdinand, having taken Granada, expels 800,000 Moors.

[Margin: 1500.]

In the year 1500 a comet appeared in the north, in the longitude of Capricorn, in the month of April, shortly before the

[Margin: Years of Christ.]

Tartars laid waste Poland and the Muscovites Lithuania. Ludovicus Sfortia [Ludovico Sforza] was captured besides; Vesuvius erupted; and the Christians, alas, were defeated by the Turks — so Io. Praetorius and others.

[Margin: Year 1506.]

And in the year 1506 a hairy star appeared within the Bear [inter Arcton] on April 11 [3. Idus Aprilis]. It lasted 25 days and was seen as foretelling the death of the King of Poland and of Philip, father of Charles V, as Praetorius has it. Cardano, however, in book 2 of the *Quadripartitum*, text 53, reports from Augustinus Niphus [Agostino Nifo] that this comet referred to the great conjunction made in Cancer in the year 1504;

[Margin: A drought of 10 months.]

and he adds that the comet's companion in Insubria was a drought so great that from January to November there was no rain.

[Margin: Year 1512.]

[Margin: 1513.]

The comet seen in the year 1512, in March and April, was blood-coloured, and it was followed by the killing of Bayezid [Baiazetis] and, the following year, by the death of Pope Julius II and a great force of wars, as Petrus Surdus relates. He appends another comet, of the year 1513, seen from the end of December until February 19 of the following year, with various colours and an elongated tail, which ran from the end of Cancer to the end of Virgo; it was visible all night. So King Francis of France came into Italy, and various wars followed.

[Margin: Year 1521.]

[Margin: 1526.]

[Margin: 1527.]

[Margin: 1528.]

In the year 1521 a conspicuous comet appeared in the month of April at the end of Cancer, with short hair, bright, and like the Moon at dichotomy; wars against the Roman Pontiff followed, and the death of Leo X. But the one seen in the year 1526, from August 23 to September 7, was like a fiery sword, on the testimony of Petrus Surdus, part 2. Then in the year 1527 another comet is recorded, observed by Io. Vögelin [Io. Vogelino]; the astronomer Petrus Creuster [?] says that it lasted 1¼ hours. Cornelius Gemma, however, in book 1 of *On the Characters of Nature* [de naturæ charact.], ch. 8, says that it was seen in the Palatinate in the form of a sword. And in the year 1528 another comet appeared in Pisces from January 18, in opposition with Saturn: King Francis came into Italy again, and Rome was taken by Bourbon [à Borbonio].

[Margin: Year 1529.]

[Margin: 4 comets.]

[Margin: Year 1530.]

In the year 1529 four comets are recorded, standing opposite one another and spreading their hair towards the four sides of the world; Vienna was besieged by the Turks; there was a severe famine at Nuremberg. Here Io. Praetorius wishes for a more accurate description of them. In the year 1530 — according to the same Praetorius, to Cardano (text 54 on book 2 of the *Quadripartitum*) and to Petrus Surdus — a comet began to be seen from August 6 and lasted until September 3 or 13. It was seen in the morning before sunrise, and then, after some days, in the evening after sunset; and in that time it passed through Cancer and Leo, Virgo and Libra, in which sign it vanished. At that time many towns in Holland, Zeeland and Brabant were submerged; there were Swiss disturbances and the rustic war of the German peasants; and in the following year an earthquake in February shook Lusitania, so that at Lisbon 1050 houses collapsed, and 600 tottered and came close to ruin. Some, however, ascribe these calamities to the comet of the year 1531.

[Margin: Year 1531.]

In the year 1531 there appeared a comet, a Pogonias or bearded comet, as Milich attests on book 2 of Pliny, ch. 25. Apian described it in part 2 of the *Astronomicum Caesareum*, ch. 1, and observed it at Ingolstadt from August 6 to 23. He affirms that its tail ran out towards the side turned away from the Sun, and therefore, once the Sun had set, rose upwards; that at first it was seen in the morning, but on August 15 set heliacally, and afterwards emerged and was seen in the evening; and that from this it came about that the ignorant common people thought there had been two comets. When it approached the horizon its flame seemed to be extinguished — which is how he understands the words of Pliny, book 2, ch. 25, saying that comets are never in the western part of the sky, that is, that because of their weak light they never appear there; for otherwise, on the 13th, it set at 9^{h} 55^{m} after noon. Further, on August 14 the place of the comet's head was ♌ 23° 39′, with northern latitude 23° 2′; that of the end of the tail ♌ 19° 18′, with latitude 39° 45′. But on the 23rd the place of the head was ♎ 2° 51′, with latitude 14° 31′. The northern node of the comet's orbit with the ecliptic was at Scorpio 14°. The motion of the comet in its own path was gathered from the difference of the longitudes and the complements of the latitudes, as you see in the following small table, from the 13th, the day on which the observations were resumed and treated more accurately: it was, namely, swifter in the middle. This comet was followed by disturbances in Switzerland, in Saxony and on the Baltic Sea; a flooding of the sea into the Low Countries [Belgium], and the towns of Zeeland submerged; the Turkish incursion into Austria; and the imprisonment of King Christian of Denmark [Chriſtierni Regis Daniæ].

Motion of the comet in its own course

From day	To day	Daily motion	Distance of the comet's head from the Sun
13	14	4° 3′	23° 40′
14	15	4° 0′	23° 31′
15	16	6° 0′	22° 15′
16	17	5° 24′	22° 12′
17	18	5° 0′	23° 2′
22	23	3° 40′	28° 16′

[Margin: Years of Christ.]

[Margin: Another comet of the year 1531, and Apian's error.]

It is uncertain, however, whether this comet is the same as the one which Fracastoro, in book 3 of the *Homocentrica*, ch. 23, says he saw in this year 1531 on September 8 and 9, in the morning and much further north than the summer tropic; but that about the 13th it became an evening comet and emerged about the summer tropic; and that on the following days, its longitude little changed, it was driven in latitude beyond the equinoctial and was seen not far from Jupiter, which was then at Scorpio 13°, and about the 18th was gradually consumed. Its motion was therefore from west to east, obliquely — that is, from Magister or

Caurus towards Notapeliotes[7]. But since Apian says that his comet began to disappear on August 23, and did not emerge as an evening comet until after August 15, and always places it on this side of the ecliptic and the equator, who does not see that these were different comets? And the report of two comets was not founded on their having been seen first in the morning and then in the evening, but on the fact that the days and months in which they were seen in the morning and those in which they were seen in the evening were different. But the shorter life of this one, of 10 days, and the slow report of it, or cloudy weather at Ingolstadt, perhaps begrudged Apian the observation.

[Margin: Year 1532.]

In the year 1532 there was the comet called Xiphias by Milich on book 2 of Pliny, ch. 25. It was at first southern, then turned towards the north, and began to be seen by Apian on September 25; it was seen until November 20, while he was staying at Dresden, a town of Meissen, under a pole height of 51°. On October 2 the place of the comet was observed by him in ♏ 8° 24′, with southern latitude 13° 44′; and the comet set before the Sun and was seen only in the morning. But on October 31, at 5^h after midnight, its place was seen in ♎ 21° 30′, with northern latitude 13° 15′; and on the preceding evening it had begun to appear in the evening shortly after sunset, its tail inclining day by day more towards the south, until it became perpendicular with respect to the zenith. Then on November 8, at 5^h 12^m after midnight, the place of the comet was Scorpio 3° 35′, with northern latitude 19° 36′, and the tail bent towards the north; it was also visible in the evening. The northern node of this comet's orbit was at the beginning of Libra. This and more is from Apian. Cardano, however, in book 3 of *De subtilitate*, and Fracastoro, in book 3 of the *Homocentrica*, ch. 23, say that it rose on September 22 and set on December 3, and that in those 71 days it advanced no more than 63°, namely from ♏ 5° to Scorpio 8°; and from this he concludes that it was above the Moon. Fracastoro adds that its head was three times larger than Jupiter and its tail two cubits long, that its motion was from south to north, and that on September 22 it was at Virgo 5° with southern latitude 15°, but on December 3, when it vanished, much further east.

[Margin: Parallax of 6° in this comet.]

Vögelin, a pupil of Regiomontanus, is said to have observed in this comet a parallax of 6°, and to have deduced its diameter as one and a quarter German miles. To this comet is attributed Barbarossa's movement against Io. Auria [Doria].

[Margin: Year 1533.]

In the year 1533 the comet Acontias, or spear-shaped, shone out, on the testimony of Milich on book 2 of Pliny, ch. 25. Fiornouellus says that it was of a blackish colour, turned its tail towards Africa, was seen for 30 days in the northern parts, and shone in advance of the death of Clement VII and of

[7]the north-west and the south-east winds

Alfonso III [?], Duke of Ferrara, who died the following year. Cardano, in book 2 of the *Quadripartitum*, text 54, says that its motion was against the order of the signs, from Gemini through Taurus into Aries. Petrus Surdus, in part 2 of *On Comets*, asserts that it was yellow in colour and was seen from the end of June to August 4; and that there followed the English schism in the year 1534, in which Henry VIII of England declared himself head of the Church; the furies of the Anabaptists; the incursions of Aenobarbus [Barbarossa]; the death of Clement VII; and that of the Duke

[Margin: Years of Christ.]

of Milan. Fracastoro, in book 3 of the *Homocentrica*, ch. 23, says that it was seen by some on July 1 between the Pleiades and the horns of Aries, but by himself only on the 7th, about hour 2 of the night; that it was a little larger than Jupiter, with a tail equal in the sky to the length of a militatis [?] spear; that on the 21st, at hour 8 of the night, it was near the sword of Perseus, and on the 27th near the star of the Chair of Antiope [cathedræ Antiopes]; and that all three comets, of the years 1531, 1532 and 1533, had their tails turned away from the Sun. But it is better to hear Peter Apian, its diligent observer. In part 2 of the *Astronomicum Caesareum* he relates that on June 18 he observed the comet in ♊ 3° 40′, at a distance of 66° from the Sun, with northern latitude 32°, near the star Algenib; that on the 21st the tail was 15° long; and that on the 25th it was in ♉ 15°, with latitude 43°, at a distance of 88° from the Sun. It never set, because of its nearness to the north pole, and after June 24 it was visible from about midnight until sunrise, always between Boreas and Subsolanus, since, when the Sun was about to rise, it had nearly ascended to the meridian.

[Margin: A comet above the Moon.]

He adds that, had it been as near the Earth as the Peripatetics think, it would have been hidden within the Earth's shadow; and that some, from its regular motion against the order of the signs, suspected that it was a star which had come down and afterwards turned back upwards. On this comet, however, Gemma Frisius the elder says in the *Radius Astronomicus*: *We saw a comet in the year 1533, in July, moved from the star of the He-goat [Hirci ſidere] along the course of the Milky Way through the constellation of Cassiopeia — that is, at once against the order of the signs and far into the north.* There followed the devastation of Westphalia by the heretics; the open outbreak of the English schism; the movement of the Turks against the Persian; and that of Barbarossa against Muleasses.

[Margin: Year 1538.]

In the year 1538 a comet shone from January 17 to the 21st, observed by Peter Apian. He says that it had its tail erect towards the zenith, 30° long, and that its place was in ♓ 5°, with northern latitude 17°, on the very neck of Pegasus; on the 17th the comet's head stood 32° 30′ from the Sun. Petrus Surdus says that it was in opposition to Saturn, and that it was followed by the Florentine uprisings against Cosimo the Great [Coſmum Magnum], Duke of Etruria; the arrival of Francis, King of the French, in Italy with a great army; the conference

of the Pontiff with him and with Charles V; and the unhappy league of the Christians against the Turks, when Io. Auria, who was commander of the Spanish, Venetian and papal fleet, was defeated by Barbarossa.

[Margin: Year 1539.]

In the year 1539 the same Apian observed a comet from May 6 to the 17th. He says that on the 17th, at hour 10 of the night, it was in ♌ 17°, with southern latitude 3°, with a short and dim tail, and that it stood 72° from the Sun; and finally that its motion was against the order of the signs, and swifter towards the west than the motion of the primum mobile. To this comet are referred the slaughters and disturbances of Meissen, Thuringia, Brandenburg and Brunswick.

[Margin: Year 1543.]

In the year 1543, as Froidmont relates from Senertus [Daniel Sennert] (*Meteorologica* bk 3, ch. 1, art. 6), the tail of a comet, having fallen down as far as a certain stream, drained it dry. For this reason Scaliger too (*Exercitationes* 79) says that a comet of his own time was seen to fall; and Vicomercatus [Francesco Vimercati] thinks that the fable of Phaethon arose from a similar comet, but Tertullian thinks it arose from the burning above Sodom.

[Margin: Year 1556.]

In the year 1556, on the testimony of Cardano (*De varietate* bk 14, ch. 69), a comet was seen *about the beginning of March, almost equal to half the Moon, with hair not long and not steady, but flickering red as in fires, as in torches while the wind blows; it was dusky, and reddish and turbid.* Cardano adds that in 4 days the comet moved 75° from east to west and 30° from south to north.

[Margin: Homelius's observation.]

Io. Homelius [Johannes Homelius], who also observed it, relates that on March 5 it stood above Spica, beside the left wing of Virgo; on the 8th below the knee of Bootes; on the 9th beside Arcturus — so that it moved, as it were, along the circumference of a great circle straight towards the north pole of the ecliptic, and at that time completed more than 15° of that circle in one day. Then it ascended towards the pole of the equator with great speed, and from there, as if descending from a summit, made for Saturn, which was then in Aries. And just as it had earlier advanced in longitude from Libra against the order of the signs, so afterwards it imitated the motion of Saturn and advanced in the order of the signs through Andromeda to the sign of Pisces, where it was extinguished.

[Margin: Whether the tail is always turned away from the Sun.]

He adds that the rays, which in the evening were turned towards the south, were turned at midnight towards the west; and that its hair was not turned away from the Sun until it had moved less than a quadrant of a circle away from the Sun. Since, moreover, it was far from the Sun and from the ecliptic, it could be seen both morning and evening, and at times did not descend below the horizon.

[Margin: Charles V feared the comet for himself.]

Kepler, in the *Physiologia Cometarum*, p. 113, says that Charles V feared it for himself in vain, since he survived it a long while; that it portended rather the disturbances between the Spanish and French kings, and in Livonia by the Teutons [per Teutonicos]; and on p. 129 he also ascribes to it the hidden quarrels between the brothers Charles and Ferdinand.

[Margin: Year 1557.]

[Margin: 1558.]

In the year 1557 a similar portent was seen in the western region in the month of October, in the sign of Sagittarius; and in the year 1558, Io. Praetorius and Fiornouellus relate, a comet having the form of a spit [Veru] was seen in August for many weeks in Scorpio, with its tail turned towards Rome. Froidmont (*Meteorologica* bk 3, ch. 3) thinks that it foretold the death of Charles V, which occurred this year on September 21. Others say that it had its tail turned towards Spain and was beneath Coma Berenices; and so this is rather the one for which Charles V feared for himself, and from which came that pentameter he composed about it:

By these signs, then, do my fates summon me?

[Margin: Year 1559.]

[Margin: A comet unlucky for many princes.]

Mary, Queen of England, also died on November 17, and on the same day Reginaldus Polus [Reginald Pole]; the queens of Poland and of Hungary died too. Again, in the year 1559 another comet appeared in the east from the end of May until June 22; Henry II, King of France, died, and shortly afterwards Paul IV and 15 cardinals, Hercules [Ercole], Duke of Ferrara, the King of England, the King of Portugal, the King of Denmark, the Doge of the Venetians, and many other princes; and the treachery of the Huguenots broke out more openly.

[Margin: Year 1569.]

In the year 1569 a comet is recorded, shining in the month of November in Ophiuchus [Serpentario] and corresponding in its longitude to Sagittarius and Capricorn; Selim was then intent on seizing Cyprus, which he obtained the following year. The comet advanced from Cancer and, towards the end, abandoning its direct course, turned aside towards Virgo 4°, where it became stationary. So Kepler, in the *Physiologia Cometarum*, pp. 114 and 129. The following year an earthquake shook Ferrara, and the sea flooded the Low Countries [Belgium].

[Margin: Year 1577.]

De Cometa Anni 1577. Compendium ſelectarum Obſeruationum Tychonis.

On the Comet of the Year 1577. A Summary of Selected Observations of Tycho.

[Margin: Tycho's observation.]

In the year of restored salvation 1577, sailors on the Norwegian Ocean, enjoying calmer weather, began to see this comet on November 10, as Tycho

acknowledges in the preface to volume 2 of his works; Tycho himself, however, began to see it on November 13, shortly before sunset, when the tail was not yet visible for the brightness of the Sun. After sunset the tail appeared very long and stretched out towards the east. On that day, about one hour after sunset, the comet was seen just above the head of the constellation Sagittarius [Sagittarij ſtellati], not far from Saturn, which it stood a little higher than, and it threw its tail towards the horns of Capricorn. From there, on other nights, it went with a swifter course towards Antinous, and passing his left hand and going past the tail of Delphinus, it was seen to traverse the nostrils of Equuleus, leaving the head of Pegasus to the south. From there it was carried straight towards Scheat of Pegasus with a slower motion than before, and at last disappeared on January 26 of the year 1578, between Scheat and the two very small stars that are in the breast of Pegasus. It never crossed the meridian by night, but always inclined from it towards the west; and for this reason, and because of the inequality of its proper motion, Tycho acknowledges that the investigation of its parallax set very intricate labyrinths before him.

After these preliminaries Tycho reports, in chapter 1 of that volume 2, the observations of this comet: of the distances of the head and of the end of the tail from the fixed stars, taken with the radius and the sextant; of the azimuths and altitudes, taken with the quadrant, at definite moments of time; and of the apparent size of the head. From these I have chosen those set down below, passing over those which Tycho acknowledges were not exact, and the days on which, for want of clear weather, it was not observed.

[Margin: November observations.]

On November 13 the apparent diameter of the comet's head was seen to be 7′; the length of the tail, though not yet fully visible, 22°. At $5\frac{1}{2}^{h}$ the head was 18½° from the new ☾; but at 6^{h} it was 26° 48′ from the bright star of the Flying Vulture, and 21° 19′ from the lower horn of Capricorn. The tail was

[Margin: Years of Christ.]

curved in an arc, wider at the end than in the middle, and its upper part almost touched the lower of the two stars in the horn of Capricorn.

On the 14th, at 6^{h}, it was 23° 25′ from the bright star of the Vulture, 18° 20′ from the lower horn of ♑, and 10° 12′ from Saturn; the tip of the end of the curved tail was already touching the uppermost star of the horn of ♑. On the 15th, at 6^{h}, it was 20° 25′ from the bright star of the Vulture and 16° 14′ from the lower horn of ♑. The tail, more contracted, was as far from the northern horn of ♑ at its lower end as the two stars of that horn are from each other. The colour of the head was pale and a leaden white; the tail, the farther from the head, the darker and more livid. The clouds and storms that followed interrupted the observation.

On the 20th, at 6^{h} in the evening, it was 11° 7′ from the bright star of the Vulture and 27° 35′ from the mouth of Pegasus. On the 21st, shortly after 6^{h}, it was 10° 40′ from the bright star of the Vulture and 25° 19′ from the mouth

of Pegasus; the tail stretched towards the end of the wing of Pegasus. On the 23rd, on a very clear night, at 6^h, it was 11° 1′ from the bright star of the Vulture and 21° 5′ from the star of the mouth of Pegasus. The colour of the head was not as bright as in the fixed stars; the tail was a dusky red near the head, like a flame struggling out through dense smoke. The tail was seen to end at the upper star in the forehead of Equuleus [Equiculi], and was more curved than usual, raising its convex part towards the zenith.

On the 25th, at $5\frac{3}{4}^h$, it was 17° 21′ from the mouth of Pegasus, and at 6^h 12° 38′ from the bright star of the Vulture; the tail inclined towards the gape [rictum] of Pegasus. On the 29th, at 6^h 15^m, it was 11° 33′ from the mouth of Pegasus and 16° 49′ from the bright star of the Vulture, or Eagle; the end of the curved tail ended exactly at the mouth of Pegasus, and its convexity almost touched the little star which is in the mouth of Equuleus. On the 30th, at 6^h, it was 10° 25′ from the mouth of Pegasus and 17° 45′ from the Eagle; the end of the tail still reached the mouth of Pegasus, while its convexity precisely grazed the little stars of the nostrils of Equuleus.

[Margin: December observations.]

On December 1, at $5\frac{1}{2}^h$, the comet was 18° 47′ from the Eagle and 9° 20′ from the mouth of Pegasus; the tail inclined towards the place between Markab [Marchab] and the pair in the middle of the neck of Pegasus. On the 10th, at $5\frac{1}{2}^h$, it was 4° 43′ from the mouth of Pegasus and 24° 33′ from Scheat of Pegasus; the end of the tail was about 4° from the brighter star of the neck of Pegasus.

On the 12th, at 6^h, it stood 5° 8′ from the mouth of Pegasus and 23° 7′ from Scheat; the tail inclined towards the middle of the quadrilateral of Pegasus. On the 14th, at 6^h, it was 21° 42′ from Scheat and 5° 50′ from the mouth of Pegasus. On the 17th, 19° 35′ from Scheat and 7° 20′ from the mouth of Pegasus. On the 24th the comet was so faint that it could scarcely be observed with instruments; yet with the radius it was seen to be about 16° from Scheat. On the 30th it appeared to be 12° 35′ from Scheat and 11° 56′ from the first star of the neck of Pegasus; the tail inclined towards the more southern of the two stars of Triangulum that adjoin the feet of Pegasus. On the 31st, at 6^h, it was 12° 0′ from Scheat and 14° 0′ from the mouth of Pegasus.

[Margin: Year 1578.]

[Margin: January observations.]

On January 1, at 6^h, the comet was 11° 35′ from Scheat and 14° 25′ from the mouth of Pegasus; it was very faint, and threw its rays towards the lower of the two stars of the neck of Pegasus, where they seemed to end. On the 9th, at $6\frac{1}{5}^h$, it was 8° 15′ from Scheat and 7° 40′ from the brighter star of Triangulum at the feet of Pegasus. On the 13th, at 6^h, the comet was so slight that its distances could not be taken; on the following days it could not be observed, because of either clouds or the presence of the Moon. On the 26th, at $7\frac{1}{2}^h$, scarcely a trace of the comet could be observed, and only by those with sharp sight, between

Scheat of Pegasus and the nearer of the two small stars at the breast of Pegasus; and this was its last appearance.

Concluſiones per Tychonem deductæ ex prædictis obſeruationibus.

Conclusions drawn by Tycho from the observations already mentioned.

First, in chapter 2 of volume 2, Tycho deduces the declination, right ascension, longitude and latitude from the altitudes and azimuths of the fixed stars from which the comet was distant, by the usual problems (which we shall treat in Book 10), and then corrects them by observations of the fixed stars made afterwards with larger and more exact instruments. Second, in chapter 3 he derives the comet's longitude and latitude, and in ch. 4 its right ascension and declination, from its distance from fixed stars already known, likewise by the common problems of the primum mobile and the analysis of triangles. But at the end of chapter 4 he acknowledges that he had used an obliquity of the ecliptic of 23° 27′, which he afterwards found to be 23° 31′ 30″; and he adds:

[Margin: Tycho's candid admission.]

But since the difference from the value first assumed is very small, those few minutes altering the truth of the matter under inquiry insensibly, I was unwilling to repeat the whole calculation, with labour more tedious than useful.

After this, third, he passes to chapter 5, in which he investigates the path of the comet and its situation with respect to the ecliptic and the equator, again by common problems — a path which can also very easily be marked out on a globe once the comet's places are known as to longitude, latitude, right ascension and declination. From these he finally deduces the intersection of the cometary orbit with the equator, or northern node, at 299° 50′, counting from the beginning of ♈ in the order of the signs, and the angle of inclination of the comet's path to the equator, 33° 45′. He appends, moreover, an ephemeris of the places and motion of this comet for each day; but we have put together an epitome of it in the following small table, as a specimen and as sufficient knowledge of what is to be said.

Specimen of the Ephemeris of the Comet of the Year 1577, adapted to hour 6 after noon at Uraniborg [Vraniburgi], from Tycho's volume 2, p. 86. The daily motion is to be understood as running from hour 6 of the preceding day, although that day is not named, to hour 6 of the day given.

Month	Day (Old Style)	Daily proper motion	Longitude of the comet	Northern latitude	Right ascension	Declination
November	9	0° 0′	♐ 20° 55′	0° 0′	260° 8′	23° 9′ A
	10	6° 2′	24° 29′	1° 59′	264° 7′	21° 21′ A

8

It began, then, in the ecliptic itself, and on November 22, about midnight, it crossed the equator; and from the beginning to the end of its visibility it completed a quadrant of a circle in its orbit, that is 90°, as Tycho has it. There follows Tycho's chapter 6, in which he contends that this comet was above the Moon and had a parallax smaller than the Moon's. He infers this, first, from its constant progress along the same great circle of the sphere, having completed precisely a quadrant; next, from the comet's distances from the fixed stars, taken on one and the same night, which were the same, or very nearly the same, at different altitudes of the comet; and finally from the comet's distances from the fixed stars as observed by others at other places on the Earth. Then in chapter 7 he shows that the comet's tail was not directed exactly to the part opposite the Sun, but rather to the part opposite Venus, and that its curvature was not real but apparent and optical, because the end of the tail was much nearer to us than the head. In chapters 8 and 9, further, he shows that the comet described a circle about the Sun, larger than the circle of Venus but higher than the Moon. He sets the semidiameter of this epicycle at 8405 parts, of which the radius of the solar orb, or the mean distance of the Sun from the Earth, is 10,000. From this, for November 13, when the apparent diameter of the comet was seen by him as 7′, he infers the comet's distance from the Earth as 210 semidiameters of the Earth; its true diameter as 368 German miles, or in ratio to the Earth's diameter as 3 to 14; and that the body of the comet was smaller than the terrestrial globe 100⅔ times. And finally he infers the length of the tail as 96 semidiameters of the Earth. All of this will have to be examined

[8] A and B after the declinations mark southern (austral) and northern (boreal) declination.

below, together with Chiaramonti's objections against Tycho and Kepler's replies on Tycho's behalf. Meanwhile, reader, enjoy part of another of Tycho's tables, from volume 2, p. 206, in which the comet's motion in its epicycle, or its distance from the Earth, and its horizontal parallax are set out — although afterwards, on p. 268, Tycho seems to retract this motion by an epicycle, as Longomontanus also noted; just as in volume 1 of the *Progymnasmata*, which was published after volume 2, he acknowledged that the tail comes not from the rays of Venus but from those of the Sun.

Table from Tycho's volume 2, p. 206, for the comet of the year 1577, abridged by us to the days written below.

Month	Day of the comet	Motion in the epicycle from the perigee	Distance of the comet from the line of the Sun's mean motion	Distance of the comet from the centre of the Earth (semidiameters of the Earth)	Horizontal parallax of the comet
November	9	6° 2′	25° 4′	173	19′ 52″
	10	6° 45′	28° 31′	179	19′ 12″
	13	9° 32′	39° 22′	211	16′ 18″
	15	11° 23′	44° 38′	235	14′ 39″
	20	16° 9′	53° 10′	308	11′ 10″
	25	21° 49′	57° 51′	423	8′ 7″
	30	28° 31′	59° 44′	515	6′ 40″
December	5	35° 36′	59° 42′	636	5′ 25″
	10	42° 53′	58° 28′	761	4′ 31″
	15	50° 14′	56° 31′	883	3′ 54″
	20	57° 39′	54° 11′	1003	3′ 25″
	25	65° 9′	51° 30′	1144	3′ 4″
	30	72° 39′	48° 37′	1235	2′ 49″
January	5	81° 33′	45° 2′	1362	2′ 32″
	10	88° 55′	41° 58′	1462	2′ 20″
	15	96° 14′	38° 51′	1554	2′ 12″
	20	103° 29′	35° 42′	1640	2′ 6″
	25	110° 37′	32° 33′	1718	2′ 0″
	26	112° 2′	31° 56′	1733	2′ 0″

Ioannis Prætorij Norimbergenſis Mathematici Obſeruatio.

The Observation of Johannes Praetorius, Mathematician of Nuremberg.

Io. Prætorius [Johannes Praetorius], in his account of comets, places this one last among the comets. It was first seen by him on November 12 at Nuremberg, although he admits that it had been seen earlier at Venice on the 8th and at Lyon [Lugduni] on the 9th. "Its colour," he says, "was rather pale; the coma, spreading from a knot of no great size, was diffused widely and lengthwise, and it was always turned away from the Sun, except that in its middle it was seen to be slightly curved, which I think happened from an optical cause. The length

of the coma extended beyond 25 degrees of a circle of the heavens, while in breadth, where it was greatest, it seemed to occupy not fully two degrees."

[Margin: Size of the tail, and its turning away from the Sun.]

That at the beginning it was seen in some places as ruddier and more horrible in appearance, he ascribes to the intervening of vapours or of a thinner cloudlet. Then he goes on thus: "The comet, as to longitude, was seen on November 13 in the middle of Capricorn, with a northern latitude of 15 degrees. Its motion, apart from the diurnal motion it had, was not direct. For although it first appeared below the equinoctial, on the southern side, near the Milky Way, afterwards — not by a straight path — it crossed the equinoctial about November 19 (in the part where 294 of ascension is usually assigned), and, leaving the bright star of Aquila about 4 degrees off, it approached the tail of Delphinus, and about the 29th of the same month it mingled with those last stars of the tail of Delphinus. At that time, too, it seemed swifter in its course, and advanced about one degree, or a little more, in one day. Departing from the said stars, by December 5 it had passed a little beyond the two little stars that are in the mouth of Equuleus [præciſionis Equi], and again it was heading for the star of the third magnitude that is in the gape of the winged horse. But leaving that star too a little below it, it moved between east and north, and on January 1 [Calendis Ianuarij] it formed an equilateral triangle with the two leading bright stars of Pegasus belonging to that quadrangular figure. Afterwards, when its size began to diminish too much, it approached with a slower motion the two little stars that are in the breast of Pegasus, and vanished there, so that after January 10 of the present year 1578 not even a shadow of it remained. From all this its motion can be understood on a celestial globe, and from that it will become plain that it went round with a wandering motion. But if it had proceeded by a straight path to the place where it vanished, then in the said space of time it would have completed about 60 degrees."

[Margin: Apparent motion of the comet.]

Yet he candidly adds: "We could not accurately observe either the true places or the parallax, because we were not furnished with suitable instruments. But at the first time of its appearance it seemed much nearer to the Earth than afterwards, so that I judge that it too was carried upward; about this, however, I have nothing beyond conjecture." He adds that it could be made out through the holes of the sights [dioptrarum foramina] only with the greatest difficulty, because of its dull and weak light, and that it usually disappeared before it reached the horizon. From this he confirms Apian's Plinian interpretation, that comets never stand in the setting part of the sky [in occaſuri cæli parte], and that the comet consisted of terrestrial vapours, not set on fire but illuminated by the Sun, because the tail was turned away from the Sun and its light was more like mere illumination than burning; in this he subscribes to Apian.

[Margin: Praetorius's opinion on the substance of the comet.]

Tycho, however, in volume 2, p. 449, opposes him: because he made this comet elementary; because he gave it a wandering motion, which Tycho asserts

was perpetually constant and regular; because for November 13 he increased its longitude by nearly 8 degrees more than was right and diminished its latitude by 6 degrees; because he assigned the crossing of the equator, which took place between November 22 and 23 at the 300th degree, to November 19 at the 294th degree; and because he set it only 4 degrees from Aquila, when it was never less than 10 degrees from it. So great is the difference between observations made with accurate instruments and observations undertaken roughly with the naked eye or with unsuitable apparatus. That Praetorius did not see this comet beyond January 10, when others saw it until the 26th, must be put down to the keenness of those others' sight and to the weakness of Praetorius's eyes. From this, too — from a false beginning and end — it came about that he gave it a motion of only 60°, which Tycho puts at 91° 46′ from November 9; whereas, since it was seen at Venice on the 8th and on its first day completed not less than 6°, its motion was at least 98 or 100 degrees.

[Margin: Tycho's criticism and disagreement.]

[Margin: Amount of the motion.]

De Obſeruationibus Gulielmi Landtgrauij Haſſiæ & Aliorum circa Cometam Anni 1577.

On the Observations of Wilhelm, Landgrave of Hesse [Wilhelm IV, Landgrave of Hesse-Kassel], and of Others concerning the Comet of the Year 1577.

[Margin: Of the Landgrave of Hesse.]

Tycho reports these in volume 2, from p. 212, and prefers them to the others, as being from larger instruments of solid metal

[Margin: Years of Christ.]

that display azimuths and altitudes. From them he derives the comet's longitudes and latitudes and its apparent diurnal motion; and because he found this retarded by a few minutes, he concludes that the comet had a parallax smaller than the Moon's. In those observations, moreover, the length of the tail on November 16 is noted as 17° and its greatest breadth as 4½°; but on December 30 the length of the tail is given as 4° 10′.

[Margin: Mästlin's observations.]

Michaël Mœſtlinus [Michael Mästlin] covered his observations of this comet in ten chapters. In them he grants that other comets were below the Moon, but says that this one was above the Moon, and that it did not cast its tail exactly towards the part opposite the Sun; he says the tail was at first 30° long. On November 20, he says, the comet was 326 semidiameters of the Earth distant from the Earth, with a horizontal parallax of 10′ 30″. He puts its first appearance on November 12 and its last on January 10. Tycho, however, compares the places of the fixed stars that Mästlin derived from the Prutenic Tables with his own, and shows that they sometimes differ from the truth by a whole degree; having therefore corrected them, he derives truer places of the comet from

Mästlin's observations, and on that occasion he relates that the comet was first seen at Constantinople on November 10.

[Margin: Tail 30°.]

[Margin: Observation of Cornelius Gemma.]

Cornelius Gemma the younger set out his proof [Apodixim] concerning this star in three chapters. In them he asserts that the tail stretched out towards the opposite part of the sky, and that the comet always had a parallax smaller than the Moon's, and therefore shone above the Moon, in the orb of Mercury according to the Ptolemaic system; and that its greatest parallax was 40′ on November 20, but 15′ on the 27th.

[Margin: Parallax 40′.]

[Margin: Roeslin's consideration.]

Heliſæus Rœſlinus [Helisaeus Röslin], using the rather crude observations of Cornelius Gemma and trying to bring the proportions of the comet's motion back to geometric and musical laws, ascribes stations and retrogradations to it, against Tycho's findings [experimenta Tychonica]; although afterwards he thought otherwise and subscribed to Mästlin. But when he affirms that Cornelius's parallax of 40′ on November 20 agrees with Mästlin's, he falls into a serious error: for on that day Mästlin gives the comet a distance from the Earth of 326 semidiameters of the Earth, to which a horizontal parallax of only 10′ 30″ corresponds. He concludes, however, that it was above the Moon — from the regularity of its motion, from the property of its light, from its duration, and above all from its small parallax.

[Margin: Parallax 10′ 30″.]

[Margin: Authors who place this comet below the ☾.]

[Margin: Hagecius.]

The others whom Tycho reports make this comet sublunary. Among them, however, is Thaddæus Hagecius [Tadeáš Hájek], who in his *Dialexis* on this comet gives it a parallax of 5° and some minutes at an altitude of 38°, and sets its tail always turned away from the Sun; afterwards, in his second animadversions on this comet and on the comet of the year 1580, he candidly retracted, and confessed that it was above the Moon.

[Margin: Scultetus.]

Bartholomæus Scultetus [Bartholomäus Scultetus], by contrast, gives this comet a parallax of 5° 22′ at an altitude of 29°. His observations, however, are brought under suspicion of error by many arguments, and this is plain even from the fact that, using the radius, he puts the distance between the seventh little star of Andromeda in the old catalogue and the bright star of the head of Aries at 17° 45′, when it is only 16° 59½′.

[Margin: Nolthius.]

Andreas Nolthius, for his part, attributes to this comet a parallax of 5° 32′ at an altitude of 33°, and a distance from the Earth of 8⅔ semidiameters of the Earth, or 7700 German miles — far above the vapours and exhalations of the atmosphere; all of which Tycho refutes in many ways.

But Nicolaus Vuincklerus [Nicolaus Winckler] infers from his own observations a parallax of this comet of 6° 50′, even when it was 46° high above the horizon, and a distance from the Earth of 8 semidiameters of the Earth. Tycho likewise refutes him, together with others who concluded from their own or others' observations that this comet was sublunary; these I shall review more fittingly below, in their places. Besides these, who were known to Tycho, Petrus Surdus [?] and Ioannes Paduanus [?] and others wrote of it; they say that it began to be seen from November 7 or 9, and ceased about January 10. Kepler, *De Cometis*, p. 129, says that King Sebastian was spurred by this comet to cross into Africa; but Fromondus [Libert Froidmont] laughs at him in book 3 of the *Meteorologica*, chapter 3. In the following year, moreover, Mustapha the Turk was beaten in battle with the loss of 70000 men; and Sebastian, King of Portugal, was slain at Alcazar [Alcazerium] together with the flower of his nobility — though Abd al-Malik [Abdemelecho], his enemy, died of apoplexy; Juan de Austria [Io. Auſtriacus] dies in the camp in the Low Countries; and the English rage against the Catholics.

Sequitur Hiſtoria aliorum Cometarum.

There follows the history of other comets.

[Margin: Years of Christ.]

[Margin: Year 1580. 1582.]

In the year of Christ 1580 a comet appeared, observed by Mästlin, which Fromondus mentions in book 3 of the *Meteorologica*, chapter 1, article 1. And in the year 1582 there was another, on which see Antonius Santutius [Antonio Santucci] and Io. Camillus Gloriosus [Giovanni Camillo Glorioso], book 1, p. 8: from the beginning of March it was a morning star, afterwards an evening star, and it ceased about the middle of April, its tail always turned away from the Sun — so Santucci. But Kepler, in the physiology of comets, p. 120, says that it was retrograde, and that when it became stationary at the beginning of Sagittarius it came nearer to the ecliptic.

[Margin: 1585.]

And in the year 1585 there was a comet observed by Rothmann [Christoph Rothmann] from October 8, Old Style, equal to a star of the fourth magnitude, but, with its coma all round, a little larger than Venus. It was observed by Tycho from October 18, Old Style, to November 15 — on which see Tycho himself in his letters [Epiſtolis] to the Landgrave of Hesse, from p. 4 to 20 and p. 37, where he also indicates that the Landgrave's, or Rothmann's, observations agree with his own. At the beginning this comet was seen nearly equal to Jupiter, but endowed with a thin and nebulous light, near the cord of the more southern Fish, haired all round with rays, without any beard or tail, except on the 20th and 22nd, when it threw out a ray a span long towards the east. It then diminished by degrees, yet remained similar in colour and form to the nebulous ring they call the Manger of Cancer [præſepe Cancri], though smaller than

that in size, whereas at the beginning it had been larger; at last, having become smaller still, it vanished entirely about the middle of November. On the first night on which Tycho observed it, it had passed five degrees or a little more to the east of Saturn, which was retrograde near the cord of the Fishes. On other nights it passed through the whole asterism of Aries, and, leaving the back of Taurus to the south, it turned northwards and was extinguished not far from the asterism of the Pleiades, having attained a greater latitude than they, but a smaller longitude. From selected observations on 9 days (for on other nights either clouds or the glare of the Moon prevented it), he infers that by its own proper path this comet described an arc of a great circle, which nevertheless had a variable angle of inclination to the equator and to the ecliptic; and that it was swifter at first and slower afterwards, yet with a proportional decrease.

[Margin: Parallax of this comet.]

Finally, having examined the comet's apparent places, he affirms that it was subject to scarcely any sensible parallax; and yet, if it had been in the concave of the heaven of the ☾, it would have had to have a large parallax, sensible not only by instruments but even to the naked eye, by mere inspection against the neighbouring fixed stars. And lest anyone should suspect that refraction was the reason this comet kept its motion so conformable to the true and diurnal course, with so great a proportion of advance, Tycho affirms that he chose above all the situation in which the comet was raised so high above the horizon that no sensible refraction could weaken the certainty of the matter under inquiry. For example, on October 18, at $10^h\ 15^m$ after noon, he found the comet's right ascension to be 19° 19′ and its northern declination 4° 25′, the comet's altitude then being 37° 30′. Then at $13^h\ 30^m$ its ascension was found to be 19° 32′ and its northern declination 4° 36½′, and its altitude was then 31° 10′. From these, and from the diurnal motion of the nearest days, Tycho infers that the comet ought to have advanced in its own proper path by 17½′ from $10^h\ 15^m$ to $13^h\ 30^m$, and yet that it had advanced 18⅔′; and therefore that the parallax was no more than 1′ 20″. But if the comet had been in the concave of the Moon, at a distance of 52 17′ semidiameters of the Earth, its parallax at the said altitude ought to have been 27′; and refraction at that altitude is so slight that it could in no way have extinguished so great a parallax, had there been one. In the same way, on November 5 at $7^h\ 50^m$ the comet's altitude was 39° 45′, and at $13^h\ 30^m$ it was 48° 20′; and on the 6th at $6^h\ 5^m$ the comet's altitude was 26°, and at $14^h\ 55^m$ it was 38°. At these altitudes refraction is almost nil. Now a table of the daily motion, drawn up by analogy with the observed motions, is to be taken from Tycho; and it should be known that in the following year Asia Minor, Austria and Hungary were infested by plague, Italy and the Low Countries by famine, and Constantinople by locusts.

[Margin: Years of Christ.]

Daily motion of the comet of the year 1585, for midnight. From Tycho's Letters, p. 19.

Month	Day (Old Style)	Motion in its proper arc	Inclination to the equator	Inclination to the ecliptic	Right ascension	Northern declination	Longitude	Latitude
October	18	6° 24′	45° 28′	23° 17′	19° 25′	4° 33′	♈ 19° 38′	3° 25′ A
	19	8° 42′	45° 26′	23° 7′	21° 3′	6° 11′	21° 45′	2° 30′

9

Rothmann, however, as Tycho testifies in his Letters, p. 118, and in volume 2, p. 442, observed that at its beginning this comet moved three degrees each day by its proper motion; and yet he found so small a parallax in it that he placed it above Jupiter, in the heaven of Saturn.

[Margin: Year 1590.]

In the year 1590 there appeared the comet on which see Tycho in his Letters, from p. 173 to 182. It was seen from February 23, Old Style, to March 6. At the

[9] A and B after the latitudes mark southern (austral) and northern (boreal) latitude; each is printed once, where the latitude changes side.

beginning it appeared larger, though scarcely of 3 minutes, near the head of the northern Fish, in the western quarter of the sky, with a tail about 10 degrees long, directed exactly towards the point opposite the Sun, towards the zenith. Its motion was in the order of the signs, and so rapid that from the first day of observation to the second it completed nearly 8 degrees; afterwards it was slower, and at the end it covered a degree and a half. By Tycho's reasoning it described exactly an arc of a great circle and had no sensible parallax, and was therefore above the Moon — if we believe Tycho. But here, for you, is its daily motion, with the rest deduced by Tycho.

Ephemeris of the comet of the year 1590, adapted to hour 9 after noon at Uraniborg [Vraniburgi], from Tycho's Letters, p. 181.

Month	Day	Motion in its proper path	Daily proper motion	Declination, always northern	Right ascension	Longitude from the beginning of ♈	Latitude, always northern
Febru-ary	23	37° 32′		24° 1′	9° 29′	♈ 18° 27′	18° 14′
	24	45° 6′	7° 34′	28° 16′	16° 26′	♉ 26° 21′	19° 33′
	25	51° 40′	6° 34′	31° 40′	22° 58′	3° 17′	20° 24′
	26	57° 16′	5° 36′	34° 15′	28° 52′	9° 11′	20° 55′
	27	61° 59′	4° 43′	36° 12′	34° 9′	14° 16′	21° 12′
	28	65° 51′	3° 52′	37° 38′	38° 39′	18° 25′	21° 15′
March	1	69° 8′	3° 17′	38° 41′	42° 36′	21° 57′	21° 15′
	2	71° 56′	2° 48′	39° 27′	46° 2′	24° 56′	21° 12′
	3	74° 21′	2° 25′	40° 6′	49° 1′	27° 29′	21° 7′
	4	76° 24′	2° 3′	40° 32′	51° 43′	29° 44′	20° 58′
	5	78° 8′	1° 44′	40° 53′	53° 58′	♊ 1° 34′	20° 52′
	6	79° 42′	1° 34′	41° 10′	56° 0′	3° 15′	20° 46′

The motion in its proper path is counted from its intersection with the equator, or from the node, which would have been at 339° 45′ of the equator; that path, moreover, was inclined to the equator at a constant angle of 42°. The sum of the daily motions makes an arc of 42° 10′.

[Margin: Years of Christ.]

[Margin: 1593.]

The comet of the year 1593 is mentioned by Froidmont [Fromondus] in book 3 of his *Meteora*, chapter 1, article 1; he likewise places it above the Moon on Tycho's authority — but from where he got this I do not know.

[Margin: 1596. Two comets.]

In 1596 Giuseppe Bonfiglio [Ioſephus Bonfilius], in his *Sicilian History*, part 2, book 10, says that two comets were seen beneath Ursa Major, in the sign ♏, and that they were followed by a drought and an earthquake in Asia. Kepler, however, in his *Physiologia Cometarum*, p. 120, says that a comet advanced from Cancer in this year and at the end, from direct, became stationary in longitude, its path bending towards 4° of Virgo. The English fleet burned the

Spanish fleet at Cádiz [Gades]; Matthias of Austria was defeated by Mehmed [Mahomete].

[Margin: Year 1597.]

Finally, in the year 1597 too a comet was seen — on which see Antonio Santucci [Antonius Santutius] — in the month of July, before the 16th; and it lasted until August 9.

[Margin: 1607.]

In 1607 there shone a comet observed by Kepler and Longomontanus, as can be seen from their treatises on it.

[Margin: Kepler's observation.]

Thus Kepler, from p. 25, says that he first saw the comet on September 26 at Prague, at hour 8½ after noon: larger than the fixed stars if viewed through a telescope, and to him without a tail, though to others of sharper sight it had one. The comet stood here near the following knee of Ursa Major, towards the preceding one. The next morning, at hour 3 after midnight, a tail appeared plainly, quite long and turned upwards, while the head, carried by a swift motion in the order of the signs, had moved about 2° 50′ within those 6 hours. But see, in the following table, the core of Kepler's observations — which, however, he admits on p. 30 were not the most precise.

[Margin: The comet here above the ☾.]

Even so, he concludes from them that if the comet had been on the borders of the Moon, the difference of parallax within 6 hours would have been much greater than the proportion of the observed motion allows; and therefore he places the comet above the Moon. He affirms that the tail pointed exactly opposite the Sun, that the comet was always less than a quadrant away from the Sun, that on the 30th it was in conjunction with the Sun in longitude, and that at the end it went from direct to stationary.

[Margin: Distance of this comet from the Earth.]

Assuming the motion of the Earth, moreover, and a rectilinear trajectory of the comet (to be explained below), he gathers that on the last day of observation, which was October 26, the comet's distance from the Earth was 13,187 semidiameters of the Earth — which, on his hypothesis, he says is more than eight times greater than the height of the Sun.

Ephemeris of the comet of the year 1607, from Kepler, with the places of the Earth as seen from the Sun, which are opposite to the places of the Sun as seen from the Earth.

Longomontani Obſeruatio Cometæ Anni 1607.

Longomontanus's observation of the comet of the year 1607.

Christianus Severini Longomontanus [Christen Sørensen Longomontanus], in the Appendix to the *Astronomia Danica*, which is entirely about new phenomena of the heavens, chapter 9, reports his observations of this very comet. Their substance is this. On September 28, New Style, in the evening, a comet appeared in the north, rivalling Jupiter in apparent magnitude but Saturn in

[10] on October 1 the sign of Libra is printed once, with a double base bar.

the leaden hue of its light. It had a very long tail, dense and compact, of the same colour as the head, and pointing throughout its whole duration towards the quarter opposite the Sun.

[Margin: Apparent magnitude of the comet.]

He affirms, moreover, that the comet did not shine out before September 25, since on the 24th he observed Jupiter and saw nothing new in the sky.

[Margin: Motion of the comet.]

And since the mean opposition of the Sun with Jupiter fell on the 25th, he thinks it very fitting that the comet first shone then — the time at which there was a conjunction of Mercury with the Sun and a trine aspect of Saturn with Mars. Its motion, he thinks, was extremely rapid at the beginning, so that in the first days it ran through 9 degrees and more on its own great circle, and afterwards it decreased in proportion with its magnitude.

[Margin: Parallax of the comet 3 minutes.]

Now, on October 22 at hour 6½ he observed the comet at Copenhagen [Hafnia] and found it at 1° 50′ of Sagittarius with a northern latitude of 9° 45′; and Kepler at Prague in Bohemia, on the same day, at the time of evening twilight, observed it at 1° 50′ of Sagittarius with a latitude of 9° 45′. Longomontanus marvels at this remarkable agreement, and at a parallax not so much slight as null. This is confirmed by the agreement of September 28, when at hour 7¼ Longomontanus at Copenhagen and Kepler at Prague observed the comet at a latitude of 40° 30′ and at the end of the 12th degree of Virgo, with some very small difference, namely 3′. One might suspect the cause of this difference from Kepler's words on p. 30, where he says: *"For there is no need of subtlety, since the observation is coarse. For they require the Tychonic instruments and a platform, a free horizon, a skilled observer as companion, and keen eyes — all of which I lacked at the beginning."*

[Margin: The comet above the ☾.]

But Longomontanus assumes the altitude of the pole at Copenhagen to be 55° 43′ and at Prague 50° 6′, the difference in time between the meridians scarcely 6^{m}, the Earth's semidiameter 860 German miles, and the greatest height of the vapours and exhalations above the Earth's surface 13 German miles. By a geometric analysis of triangles he then proves that, had this comet been some meteor in the highest region of the exhalations, there would have had to be a difference of 5 degrees between the place seen by Kepler and the place seen by himself, and the comet would have had to appear lower to Kepler by as many degrees. Since that parallax, however, was at most 3 minutes, he declares that the comet was above the Moon, and that here the Peripatetic strays many parasangs from the truth — even though he does not have enough observations to determine its distance from the Earth precisely. For Longomontanus's words are: *"Although how high it climbed aloft through the aether, the observations of it, made less precisely and less promptly, scarcely allow us to reason; therefore now, the web broken off, etc."*

Now let us have from Longomontanus a table derived from his own observations, which gives the motion of the planet in its proper circle, with its place in longitude and its declination.

[Margin: Years of Christ.]

Ephemeris of the comet of the year 1607, from Longomontanus, for hour 7 after noon at Copenhagen [Hafniæ].

Month	Day	Daily motion in its proper circle	Places in longitude	Declination, first northern, then southern
September	26	9° 40′	♌ 18° 0′	49° 0′ B
	27	9° 30′	♍ 0° 0′	47° 0′
	28	9° 10′	♍ 11° 50′	44° 0′
	29	9° 0′	♍ 23° 30′	39° 15′
	30	8° 40′	♎ 5° 15′	34° 20′
October, of the new calendar	1	7° 50′	♎ 16° 30′	28° 30′ B

	6	3° 0′	♏ 17° 0′	6° 20′ B
	7	2° 30′	20° 0′	4° 10′
	8	2° 10′	22° 30′	1° 50′
	9	2° 0′	24° 0′	0° 25′
	10	1° 50′	25° 30′	1° 0′ A
	11	1° 40′	♏ 26° 40′	1° 50′
	12	1° 30′	27° 30′	2° 40′
	13	1° 25′	28° 20′	5° 0′
	14	1° 15′	29° 10′	6° 45′
	15	1° 0′	♐ 0° 0′	8° 15′
	16	0° 45′	♐ 0° 50′	9° 30′
	17	0° 40′	1° 20′	10° 30′
	18	0° 30′	1° 30′	11° 0′
	19	0° 25′	1° 40′	11° 10′
	20	0° 20′	1° 45′	11° 18′
	21	0° 18′	♐ 1° 50′	11° 25′
	22	0° 15′	1° 55′	11° 32′
	23	0° 12′	2° 0′	11° 40′
	24	0° 10′	2° 5′	11° 50′
	25	0° 8′	2° 8′	12° 0′
	26	0° 5′	2° 10′	12° 10′
	Sum	97° 18′		

So between October 9 and 10 the comet crossed the equator, and from then on it became steadily more southern.[11]

[11] B and A in the declination column mark northern (boreal) and southern (austral) declination.

Obſeruationes Primi ac Secundi Cometæ Anni 1618.

Observations of the first and second comet of the year 1618.

[Margin: Year 1618.]

In the year of Christ 1618, besides fiery beams and flying dragons, three or four comets appeared.

[Margin: The first comet.]

The first appeared in Upper Hungary on August 25. As Kepler reports in his work on the comets of this year, p. 47, it came out before sunrise, around the third hour after midnight, casting its tail from east towards west — that is, turned away from the Sun, as comets' tails are. Its tail was short and broader than the head, so that it looked like a clothes-brush. On September 1 it was seen at Linz [Lincij] by Kepler a little below the left forefoot of Ursa Major, sinking towards the head of Leo, so that it seemed to be at 10° of Leo, with a northern latitude of 21½°. On September 2, keeping its latitude, it moved ahead by one degree with a retrograde motion, against the order of the signs; and after some days it became slower in its motion. On the 6th no tail could be observed with the naked eye, but viewed through the telescope it appeared fairly large, like a small cloud, with very short stumps of hair stretched upwards. On the 23rd it was seen to have reached ♋ 29° 42′ with a northern latitude of 23° 41′; seen through the telescope it was shaggy, with a broad and very short head of hair, but nebulous, and with a light that did not twinkle at all. On September 25 it disappeared at about ♋ 28° and a latitude of 23¼°.

[Margin: Kepler's opinion on the motion of this comet.]

Since, however, its parallaxes could not be deduced for lack of observations, nothing certain can be established about its distance from the Earth. Kepler nevertheless thinks, because it lost its tail so quickly, that it was[12] towards the Sun, on a line turned obliquely away from the Earth; and that, assuming the annual motion of the Earth, this comet at the beginning of its trajectory equalled with its daily motion the Earth's daily motion in longitude.

[Margin: The second comet.]

The second comet seems to be confused by writers either with a beam or with a flying dragon, or with the third comet. This is either because its tail appeared long before the rising of its head or its withdrawal from the Sun, or because, as Kepler on p. 50 thinks not improbable, it was afterwards divided into two — as Ephorus once related had happened, Seneca objecting in vain. Wilhelm Schickard [Vuilhelmus Schikardus], in Württemberg [Vuirtembergia], on October 20, New Style, saw a torch or flying dragon passing from the head of Andromeda through the northern Fish to the gaping mouth of Cetus. Perhaps this is the comet that Ursinus [?] reports was seen on October 30 at Cologne [Coloniæ Agrippinæ], with a long train of tail towards the north-east

[12] printed *ruiſſe*; read as *fuiſſe*, "was", the ascender of the f unprinted or a foul sort; *ruiſſe*, from *ruo*, would give "rushed"

[Borrhapeliotem], and which did not last long; but perhaps it was a meteor, not a comet.

Johannes Remus Quietanus [Io. Remus Quietanus], however, in a little book on this comet published at Innsbruck [Oeniponte], writes that at Novesium [Noueſij] in Silesia, on November 10, a fiery phenomenon was seen like an ostrich feather, and curved — the kind the ancients called *ceratias*. He adds that at Rome on November 10, from $16^h\ 20^m$ to $18^h\ 40^m$ after noon, a curved beam was seen, which the Roman observer called a comet with a huge tail at its side. One end of it, towards the horizon, was gathered into the form of a handle, but was no brighter than the rest of the body, nor distinguishable from any star — perhaps because of the nearness of the Sun; its other end lay between the autumnal intersection and 18° of Libra, deflecting from the ecliptic towards the south by about 15 degrees. Therefore, if it was a comet and turned its tail away from the Sun, its head must have been between ♎ 18° and ♏ 19°, near the last star of Hydra, since on that day the Sun stood at 19° of Scorpio.

But Georgius Sualbachus [?] says that he saw the comet at Speyer [Spiræ] on November 17, New Style. And at Linz, farmers outside the town had seen the same brightness about November 12, in the same quarter of the sky and at the same hour of the night as the Romans, on the testimony of Kepler, p. 52. Io. Bapt. Herbenstreitus [?] also testified that the same object was seen at Ulm [Vlmæ] by some travellers some weeks before December 4; and Herlicius [David Herlitz] writes that it was observed in Pomerania on November 19, and earlier in Prussia [Boruſſia].

[Margin: Retrograde motion of this second comet.]

Finally, the same seems to be the one that was seen in the form of a horn among the stars of Crater at Tübingen [Tubingæ] around November 20 by Johannes Straussius [?], and at Linz by Kepler on the same day among the same stars, at hour 5½ after midnight, with a retrograde motion and with its head hidden in the light of dawn. Kepler adds that on November 23, at hour 5 in the morning, it had turned aside from the stars of Corvus towards the south, in the direction of the Heart of Hydra. But he speaks of it in such a way that you cannot tell whether he recognises it as a comet properly so called, or as a meteor that was the forerunner of the third comet, or whether the third was born from this one when it divided into two. The cause of this confusion was that the head was not seen clearly enough by Europeans in the twilight; but in Persia and India the second was plainly distinguished from the third, as I shall shortly relate.

Obſeruationes Tertij Cometæ Anni 1618.

Observations of the third comet of the year 1618.

[Margin: The third comet of the year 1618.]

In the year 1618, about the middle of November, a third comet appeared, distinct from the second (on which see above) and from the fourth (on which

see below), and unknown to Kepler, Longomontanus and most European writers. Their third will be called our fourth; but in Persia the third appeared distinct from the second, and in East India this third appeared distinct from the fourth.

[Margin: Observations of García de Silva in Persia.]

For Longomontanus, in the Appendix to the *Astronomia Danica*, chapter 10, reports an observation of two comets made by García de Silva y Figueroa [Garcia Silua Figueroës], ambassador of Philip III, King of the Spains, in the town of Isfahan [Sphani], not far west of Persepolis, at a polar altitude of 31½°. It was extracted from his letter written to the Marquis of Bedmar [Marchionem Bedmarum] on February 25 [5. calend. Martij], 1619, which was translated into Latin and published at Antwerp in the year 1620. The closing passage of this letter was as follows: *"Account of the twin comets which were a spectacle for us in these days. The one began to shine on November 10, two hours before sunrise; its appearance, between the East and the South was noticed. Its colour was quite like the smoke that rises from very thoroughly refined sulphur powder when it is lit; its head, as it seemed to me, was in Scorpio. Its size was such that it would take up a sixth of the zodiac; its form was like a scimitar [acinacis], as some judged — the kind the Greeks call Xiphias — portending terrible events. To me this comet seemed rather to resemble a year-old palm shoot which, not yet spread out, curves gently at its tip. Its motion, moreover, was towards the south."*

From this, then, it is clear enough that this was the comet — resembling either a scimitar, or a *ceratias*, or an ostrich feather — that we have named, with Kepler, the second comet. García goes on as follows: *"On the twelfth or thirteenth day after the rising of this comet, the other appeared, maned or haired in the usual way, like the star of Venus in colour and equal to it in size, or a little larger. It took its rising straight from the equinoctial east; and although at the beginning it was much smaller than the earlier one, it grew from day to day by much larger increments, so that it nearly equalled the other. It moved with the motion of the primum mobile, and also with a proper motion, not far from the vertical line, towards the north. Then, three or four days after its rising, the other vanished. Both certainly had so short a period that the later one stopped appearing just after the tenth day. It was observed that, as it was ending, it grew redder."*

Now if by "the thirteenth day" you understand November 13, the day on which the third comet (which is García's second) rose, it follows that the second (which is García's first) was extinguished on November 17. But if by "the thirteenth day" you understand 13 days after the rising of the second (which is García's first), then the third comet rose on November 23 and ceased on December 3 — which is closer to the sense of the words. Either way, however, it is plain that this second comet of García's is the third with respect to the first one seen in Europe, and is not to be confused with that third comet which was famous among Europeans, which shone from November 24 until January 20 of the year 1619, and which really should be called the fourth. Longomontanus, it is true, confuses the two; and because of the growth it took on — which can

be understood of its tail — and because of its brevity, he thinks that García, either through carelessness or because of the hindrances of his embassy, did not persist in observing. But it is one thing not to have persisted, another to affirm that the comet ceased — and this García asserted so plainly that in the same letter he said: *"However that may be: if these comets portend evils, at least they will not be long-lasting, like the other things that are seen in great number in the world."*

Rather, it was proper to recognise from this that this comet was quite different from the one that the Europeans saw as the third. This is confirmed by the letters of Father Giacomo Rho [P. Iacobi Rhò] of our Society, written from Goa to Europe. They record observations of the last comet, begun on November 29, which we shall bring forward below in chapter 22, number 23, and compare with the European ones; but they also mention the other comet, although no observation of it is noted — because, that is, it vanished quickly. For so one reads in those letters, as Chiaramonti also has it in the supplement to his *Antitycho*, p. 34: *"One thing alone we could not, and ought not, pass over without serious notice: that when we had scarcely entered port, and were unprepared for that kind of observation, the sky was suddenly seen to shine with two comets in the morning hours. Among the Moors and the heathen, astonished by the novelty of the thing, this raised various rumours."* Afterwards he relates observations made with the astrolabe and the astronomical radius of the College of Goa from November 29 through a great part of December.

[Margin: Four comets in the year 1618.]

It is therefore clear enough that before the comet which appeared from November 24 to January 22, three comets shone in the sky this year. The first lasted about a month, from August 25 to about September 25. The second was seen from November 10 — not only until November 18 in Silesia, or the 19th in Pomerania and Prussia [Boruſſia]; in Persia and in Austria it was seen as well, until November 23. The third was seen in East India and in Persia from November 22 or 23 until December 13. The fourth, from November 24 to January 20, is the one called by antonomasia [Greek: ἀντονομαστικῶς (antonomastikōs, "by antonomasia" — par excellence)] the Comet of the Year 1618, the longest-lasting and most celebrated of all; we must speak of it shortly, and Kepler and the Roman observer call it the third.

[Margin: Two or three beams seen in the same year.]

Fiery beams, moreover, or torches distinct from the comets, were seen to the number of two or three. One was seen by us at Ferrara towards the end of August: as we were walking after supper in the garden of our College, it frightened us with its sudden apparition and very rapid flight. The second was seen on October 20 by Schickard in Württemberg. The third, from November 18 to 29, was seen by our Fathers at Rome and Parma. Remarkably, it moved with the motion of the primum mobile, appeared in the hours before dawn, and occupied nearly 40 degrees of the sky; by its proper motion, however, it advanced, and in those 11 days it advanced from Crater to the Heart of Hydra by 24 degrees, against the order of the signs. Some called it a comet, but

Biancani [Blancanus], in book 16 of the *Sphaera*, chapter 5, called it the tail of the great comet; and from the position of Crater and Hydra it seems to have been Kepler's second comet — although in a disputation held by our Fathers in the Roman College it was designated by the name of a beam. I also remember a fiery globe seen by us, in the month of August if I am not mistaken, rising under the full Moon together with it, and glowing red in a frightening way with a wonderful whirling, while our people ran together to the spectacle; and those nights were hotter and more sultry than any others.

What if so much matter was used up in so many comets and beams that year that, from then until this year 1650, in which we are inserting these words into this account, there was not enough matter left over for comets — and that for this reason, from 1618 to 1650, no comet shone in Europe, that is, for 32 whole years?

Obſeruationes Quarti Cometæ Anni 1618. & 1619.

Observations of the fourth comet of the years 1618 and 1619.

[Margin: Years 1618 and 1619.]

This, of course, is the comet which some writers, aware of only two, call the second, and others, who knew of only three, call the third; we have been compelled to call it the fourth, having weighed the indications in the accounts. This, I say, is the comet watched by so many observers in Europe and in East India, made famous by so many books brought out into the light, and raised above the Moon on so many wings or ladders of arguments — which, however, as I shall show in its place, are not evident. Its distances from the fixed stars, moreover — especially from Arcturus, Spica, the Crown, and the stars of the Bears and of Draco — I shall more conveniently report, and at the same time compare, in chapter 22, number 23. The rest of the more notable points, gathered in summary from various observations, I shall present here, with a threefold ephemeris constructed by our Cysat [Cyſato], by Kepler and by Longomontanus.

[Margin: When this comet first began to be seen.]

Before all else, however, its beginning must be settled. I find that this was on November 24, New Style: for on that day it was first seen, with head and tail very bright, at Budweis [Budouuici] in Bohemia, by the Emperor's soldiers living in winter quarters, as Maximilianus Marsilius [?] of the Society of Jesus, who was staying there at the time, affirmed to Kepler; and he saw it on the same day. Ursinus, however, records that it was seen at Frankfurt on the Oder only on the 26th, as do Millerus [?] at Leipzig and Hebenſtreitus [?] at Ulm. On the 27th, however, it was seen by Ambrosius Rhodius at Wittenberg and by Snel in Holland [Batauia]; and Johannes Remus Quietanus says it was first seen at Rome on that same day. But Vuelperus [?] at Worms, Benjamin Ursinus in the Mark, Gotthard Arthus [Gottardus Arthus] at Danzig [Dantiſci], Gaſpar Herſpachius [?] at Cologne, and finally Gallus Prouenzalis [?] at Paris record

that they saw it only from the 28th. On November 29, however, Biancani at Parma, Gassendi at Aix [Aquis Sextijs], Herlitius in Pomerania, Io. Strauſſiu [?] at Tübingen, and Kepler at Linz in Austria say that they first saw it. Finally, because of rains and fogs during the eight days before December 1 [Kalendis Decembris], it could not be observed either in Denmark or at Ingolstadt — by Longomontanus at Copenhagen, nor by Father Cysat at Ingolstadt — except from December 1.

[Margin: When it ceased to be seen.]

It ceased to be observed by Remus and Vuelperus on December 27, by Longomontanus on December 28, and by Biancani on the 31st, because its tail was small and its body rather dim; but by Ursinus on the Oder [ad Viadrum] and by Kepler at Linz on January 7, because no tail appeared any longer and they were not certain about the head, as Kepler admits on p. 69. Ambrosius Rhodius judged that it disappeared at Wittenberg around January 12, but Schickard on January 18. Father Cysat's last observation was not on the 13th, as Kepler has it from a corrupt sheet, but on January 22, as Cysat himself relates on p. 9 — where, however, he does not say that it was extinguished, but that rains and clouds followed for eight days, after which no further trace of it appeared. So this comet will have lasted from November 24 to December [?] 22, at least 59 days, and perhaps somewhat more, although Kepler sets only 55 days. It will be clear, moreover, from what is to be said, that its rising was 4° below the northern Scale [Lancem Borealem], and its extinction between the head of Ursa Major and the north pole of the world; that its motion was retrograde, obliquely against the order of the signs [in præcedentia], and slower every day, just as the size of the head also appeared smaller every day to the naked eye, though not so through the telescope; and that its latitude, or declination from the ecliptic, increased until January 8 and then decreased, its course bending somewhat towards the south. So it began at 18° of Scorpio with a southern latitude of 3½°, and ended at 21½° of Cancer with a northern latitude of 56⅓°.

[Margin: Year 1618, 1619.]

Obſeruationes Particulares Cometæ Anni 1618. & 1619.

Particular Observations of the Comet of the Year 1618 and 1619

Besides the observed longitudes, which I shall give in a table at the end of this history, and the distances from the fixed stars, which I shall present in chapter 22, number 23, I should like to gather certain other points from various observations.

[Margin: From Maximilianus Marsilius.]

Father Maximilianus Marsilius of the Society of Jesus, at Budweis in Bohemia, was the first of all — of those, at least, who are known — to observe this comet, with a clear light and with its head and tail very bright; for him, however, the second comet had disappeared on the same day, the dawn being already bright,

and yet the fourth comet overcame the dawn's light. So Kepler attests in his work on these comets, pp. 55 and 57.

[Margin: From the Roman observations.]

The Fathers of our Society at the Roman College, and especially Father Orazio Grassi [Horatius Graſſus], began to observe this comet on November 27, between the Scales [inter Lances], that is, about 4° distant from the northern Scale. On the 29th, at hour 12, they saw it 1½° from the same Scale, towards the Notapeliotes [Notapeliotem], commonly called the Sirocco, with a tail of 58° — as long as Kepler, p. 58, reports it was seen at Vienna at that time. On the 30th they saw that the comet had passed the Scale, with a tail at first of 23° and later much longer; through its middle, lengthwise, ran a clear and distinct line like the pith of a tree, while the tail curved somewhat and stretched from the right foot of Virgo towards her knees. On the 9th, with December 10 following, the comet was seen by them between Arcturus and Corona Borealis [Coronam Boream], with a very long tail, curved and swelling towards the south, fainter and more scattered on the left towards the north, but fuller on the right.

[Margin: Froidmont's observations.]

Libert Froidmont marvelled that on December 12, from the 9th and 10th hour of the evening until midnight, not even a hair of the comet's beard was to be seen beneath the wheels of the Wain [Plauſtri], where in the morning he had seen its long beard; but after midnight, as the Sun and the comet — which went a little ahead of the Sun — approached the eastern horizon, the beard returned beside the Wain and gradually grew.

[Margin: From Father Biancani's observations.]

Father Giuseppe Biancani of the Society of Jesus, once my teacher in geometry, saw at Parma on November 29 the fiery beam for the last time and this comet for the first time: ruddy in its centre, but yellowish at the edges. At hour 13¼, Italian civil time, he saw it about one degree below the northern Scale, but 7½° above Mercury, which was at 20° of Scorpio. Besides the distances of the comet from the fixed stars observed on very many nights, on December 14 at hour 8, Italian civil time, he saw it rising from the horizon with a tail of 36°; on the preceding and following days the tail seemed the longer, the darker the air was, or the nearer the comet was to the horizon. On the 20th, having considered the motion of the preceding days, he judged that it had been made along one and the same great circle, and he concluded that this was kept up until the 31st. On the 31st, around civil hour 13½, he saw the comet a little beyond the straight line drawn through the third star of the tail of Ursa Major and likewise through the third of the tail of Serpens, but so diminished in colour, motion and size that it was scarcely visible; so from then on he gave up his observations.

[Margin: Chiaramonti's observations.]

Scipione Chiaramonti, who wrote a little book on this "pogonarian" comet [Pogonari Cometa], gives few observations. In them, however, he affirms that the comet's head diminished daily; that on December 4 he saw the tail 21° long,

when the head was 64° from the zenith [vertice] of Cesena [Cæſenæ], at 12^{h} 40^{m} after sunset; and that on December 18, at the same hour, when the head was 37° from the zenith, he saw the tail 28° long.

[Margin: Gassendi's observations.]

Gassendi [Petrus Gaſſendus] observed this comet at Aix [Aquis Sextijs] from November 29 to January 5, the day on which he says the head was blended with the tail. Its proper motion, he says, increased daily until December 6, when it reached 3° 36′, and then decreased, so that on December 22 it was 2°, on December 31 1° 20′, and on January 5 1°.

[Margin: Snel's observations.]

Willebrord Snel [Villebrordus Snellius] in Holland began to observe the same comet from the 27th, although he admits that it was seen by Antonius Lucianus at Valencia in Spain on the 24th, without a head because of its nearness to the Sun; but that on the 29th the head emerged from the Sun's rays and stretched out a tail of 25° towards the west, turned away from Venus rather than from the Sun, although later it was turned exactly away from the Sun. Its motion began from the northern Scale and ran from there through Boötes and the tail of Ursa Major. From December 17 it no longer set for the Dutch, but moved among the stars that are always visible there. Finally, he says, it was extinguished around mid-January beyond Ursa Major.

[Margin: Longomontanus's observations.]

Longomontanus at Copenhagen [Hafnię] did not catch sight of this comet before November 21, Old Style — December 1, Gregorian Style — because of the storms and rains that raged for the 10 preceding days. Already on December 1 the comet's head was somewhat larger than Spica, its colour midway between Mars and Spica; he saw the tail turned directly away from the Sun, and as long as the stature of a fairly tall man. On December 3 he measured the tail at about 20°, though he could scarcely follow its extreme flickering with his eyes. On the 4th the tail was very long and remarkable for its flickering, and the head still of a larger disc than Spica, and fairly round. On the morning of December 10 the comet, rising almost with the Moon, flickered the rays of its tail beyond its usual extent, up to 104° — that is, as far as the left hand of Auriga — and they were turned away from the Sun; Longomontanus ascribes this to the disposition of the air. But as the comet rose higher, the tail became more contracted. On December 15 the comet's head was rather dim, diminished and ruddy to the naked eye, but livid through the telescope, and the rays of the tail were sparse. On the 24th, with the Moon shining opposite, the comet appeared much attenuated, and scarcely a trace of the tail appeared, as also on the 26th and the 28th, on which day it ceased to be observed at Copenhagen. Further, from the parallaxes he deduces the comet's distance from the Earth as at least 240 semidiameters of the Earth; and because he estimated the comet's head as larger than Spica, and of 3′, he makes its diameter to the Earth's diameter as 377 to 3600, or as 1 to 9½, and the body of the comet to the Earth as 1 to 870, and to the Moon as 1 to 20.

[Margin: Kepler's observations.]

Johannes Kepler [Ioannes Keplerus] at Linz in Austria began his observations of this comet on November 29, by estimating its place against the fixed stars by eye, since he lacked suitable instruments. On that day he saw the comet's head three Moons distant from the northern Scale. The tail flickered, partly yellow and partly ruddy, so that it seemed now long, now short. The head, inspected through the telescope, was round below [infrà] [?]; below, it faded away into hair, and appeared less bright than when viewed with the naked eye. He estimated the length of the tail at 30°, although he says that it was seen at Rome and Vienna at 58°, because of the inconstancy of its length. On the 9th the tail, spreading more and more, stretched as far as the breast of Ursa Major, and indeed seemed to flash out as far as Auriga; but its certain length, conspicuous to everyone's eyes, was 70°, namely up to the breast of the Bear — a tail such as, he denies, has been observed in the past 150 years. Nor was it turned exactly away from the Sun, but rather from Mercury; by its curvature it swelled towards the south, and it was fuller on the right and sparser and fainter on the left. On the 16th it began to be seen in the evening too. On the 23rd it spread its tail widely, as if towards the northernmost of the Wain; and the head, seen through the telescope, looked like a cloud. At last, on January 7, since the tail no longer appeared and he was not certain about the head, he stopped observing. He judges, moreover, that at the beginning this comet was midway between the Earth and the Sun, and thirty times higher than the Moon, that is, 1770 semidiameters of the Earth high, with a parallax of 2′; that it then crossed the orbs of Venus and Mars along a straight line; that when it ceased to be seen it was between Jupiter and Mars; and that on December 9 it had so long a tail that the tail was greater than the comet's distance from the Earth.

[Margin: Rhodius's observations.]

Ambrosius Rhodius, professor of medicine and mathematics at Wittenberg [Vuitebergę], began to observe this comet on November 27; his own observations, however, not as most certain does he put them forward.

But on December 14 he affirms that he saw the tail very long, up to 60°, or at least 50°. On the 17th he saw it contracted to 30°, as also on the 19th, again of 30°, and reaching the lower of the following stars in the quadrilateral of the Great Wain [plauſtri maioris]. Finally he judged that the comet disappeared around January 12 of the year 1619, near the penultimate star of the tail of Draco, at ♌ 4°, with its latitude decreasing.

[Margin: Vuelperus's observations.]

Vuelperus of Alsace [Vuelperus Alſatus] affirms that the comet was first seen at Worms [Vuormatiæ] on November 28; he himself observed it at Loræ, and he says that on December 7 a ray of the comet grazed the reddish star Arcturus and the right leg of Boötes — that same Arcturus which Hebenstreitus at Ulm took for Mars. On the 20th he saw the tail 18° long, and its course through the first Horse [primum Equum]. Beyond December 30 I do not find his observations, and he does not boast that they were the most certain.

[Margin: Habrecht's observations.]

Dr Isaac Habrecht [D.Iſaac Habrechtus] at Strasbourg [Argentorati], or Argentina, on November 30 noted in the comet a kind of triple star, its innermost nucleus shining like gold melted in a crucible [teſta], among the most violent fires of Capella; but this nucleus, he says, was surrounded by a circle of fainter brightness, and this in turn by another circle, inconstant and scintillating. On the same day a star was seen by others in the comet's head, like a young lady seated in a carriage, as was written to Philippus Millerus at Leipzig.

[Margin: Kepler's imperfect eye.]

Kepler, p. 59, attributes this in vain to a defect of the eyes, since he himself was dim-sighted and used to see, in place of one Moon, six or eight interwoven with one another, as he admits in the same place and in the *Astronomia Optica*. But compare these observations with the observations of our Cysat, made with the telescope and shortly to be adduced: you will see that this was no trick of the eyes. On the morning of December 18 Habrecht noticed the comet advancing midway between the shoulder and the wrist of Boötes, and on the 20th it reached the star of the wrist. On January 7 he saw the comet not far from Ursa Minor, and saw that it had already turned aside in its course towards the south, its latitude diminished.

[Margin: Millerus's observations.]

Philippus Millerus, professor of mathematics at Leipzig [Lipſię], began to observe the comet on November 26, and judged that on that day the tail reached the nearest star of the quadrilateral of the Great Wain, that is, was about 90° long. On December 14 he saw the head above the back of Boötes; on the 16th the tail set in between the two front stars of the Wain, and 30° long; and on December 23 he noted the comet between the last star of the tail of Ursa Major and the left star of Boötes. From about that day onwards, he wrote in the little book he published on this phenomenon, the comet bent its path somewhat towards the south; and his observations end at December 27.

[Margin: Remus's observations.]

Johannes Remus Quietanus, physician and mathematician to the Emperor Matthias, published a little book on this comet at Innsbruck [Oeniponte]. From November 27 he brings forward the first observation of others [?]. He set out from Rastadium [Raſtadio] to St Johann [S. Ioannem] in the County of Tyrol, where, lacking instruments on the journey, he observed some distances from the fixed stars. Afterwards he was at Innsbruck, where on December 13 he saw the tail 30° or 36° long, and at hour 3 the comet's head in the same vertical circle as the hip of Boötes; on the 16th he saw the tail touching with each of its ends the two front stars of the Wain; on the 18th the tail reaching up to the penultimate star of the tail of Ursa Major, but bending towards the upper parts of the Wain; and on December 21 he noted the tail between the last and the penultimate stars of the tail of Ursa Major. On the 22nd it was 7° long, and on December 27 he stopped observing.

[Margin: Schickard's observations.]

Wilhelm Schickard, in Württemberg [Vuertembergia] on the banks of the Neckar [Nicri], drew the path of this comet on a chart from his own observations. In this picture you may see, on December 9, the tail turned directly away from Mercury rather than from the Sun, full and gathered on the right but scattered on the left. On December 13 he places the northern edge of the tail faint and touching the lower star of the Great Wain, but the southern edge suffused with a more evident light and running out further; and on the 16th he paints the head beside the shoulder of Boötes. On January 7 he places the comet's head passing the star of Draco, and on January 18 he places the comet at ♋ 23½° with a northern latitude of 58½°. He does not extend his observations any further.

[Margin: Ursinus's observations.]

Benjamin Ursinus, astronomer of the Mark [Aſtronomus Marchicus], caught sight of this comet at Frankfurt on the Oder [Francofurti ad Oderam], or on the Viadrus, on November 28, around the Claws, or Scales, of Libra. On December 16 he saw the comet's head a diameter and a half of the Sun away from the star in the shoulder of Boötes. On January 6 he saw the comet almost touching the penultimate star of Draco, and on the 7th still very near it and verging towards the region of Ursa Minor.

[Margin: Other observers indicated.]

What Hebenstreitus at Ulm, Io. Straussius at Tübingen, Gaspar Herspachius at Cologne, Gallus Provenzalis at Paris, Arthus at Danzig [Dantiſci], Herlicius at Stettin in Pomerania, Nagellius at Magdeburg, Antonius Lucianus at Valencia in Spain, and Carolus Piso in Lorraine observed in this comet is not worth the trouble of begging for. I would rather pass on to the more accurate observations of Father Cysat, and refresh the reader's mind with them.

[Margin: Father Cysat's notable observations.]

Father Johann Baptist Cysat [P. Ioannes Baptiſta Cyſatus] of the Society of Jesus, ordinary professor of mathematics at Ingolstadt, had indeed in good faith shared his observations with others indiscriminately, on sheets he gave out. Some of these came, through Dr Johann Georg Herwart [D. Io. Georgium Heruartum], counsellor of the Duke of Bavaria, into Kepler's hands, as Kepler himself admits on p. 59; but they were mixed and confused with uncertain ones. Afterwards Father Cysat himself, at leisure, selected the more certain ones and described them in chapter 1 of his *Mathemata* on this comet; at its end he complains that those earlier, uncorrected observations were used by Kepler and published under the name of "the Ingolstadt observer". But certainly, as Ovid sings, *Puriùs ex ipſo fonte bibuntur aquæ* — "waters are drunk purer from the spring itself"; so we too must draw from the spring. And just as he sets out separately, in chapter 4, the observations of the tail and of the head, and in chapter 6 the singular phenomena of the head, so we too shall select these separately.

Before the Kalends of December, mists and storms had prevailed at Ingolstadt for 8 days and more; but on December 1 the north wind [Aquilo] drove away

the clouds and disclosed the comet to Cysat a little before hour 5 in the morning. At 5^h 45^m he saw the comet at an altitude of 12° 20′, distant from Arcturus 27° 6′ and from Spica 24° 48′, and therefore at 9° 24′ of Scorpio, with a northern latitude of 11° 37′. On the 4th the comet rose for him from the horizon a little before hour 4 in the morning. On the 7th, between hour 4 and 5 in the morning, the star of the third magnitude in the leg of Boötes was almost in the middle of the rays of the comet's tail, and at hour 7 at their far ends, near the head. On December 16, at hour 9 in the evening, the comet's tail seemed to pass through the middle of the quadrilateral of Ursa Major, while the head still lay hidden, either below the horizon or in the horizon's vapours, from which it emerged around hour 11 of the night. On December 20, at 3^h 54^m in the morning, the comet's head appeared to be very nearly one degree from the star of the fourth magnitude at the left elbow of Boötes, when the comet seemed 48° 30′ high; and it kept the same distance from the same star, without notable difference, almost until sunrise, that is, until the comet's apparent altitude was 76° — which seemed to him an argument for a small parallax.

[Margin: When the comet began to be among the stars that are always visible.]

From this 20th day until January 18 the comet never again set below the horizon, but moved among the stars that are always visible. On September [?] 27, at hour 7 in the evening, the sky was so very clear that stars of the sixth magnitude were distinctly seen, and yet nothing at all of the comet's coma appeared; the head was seen with the greatest difficulty, no larger than stars of the 4th magnitude and much dimmer than the other stars — because, that is, the fuller Moon had almost extinguished the comet, as it had the Milky Way and the nebulous stars. But on the 28th at hour 5 in the morning, with the Moon absent, the comet was more conspicuous, the head much larger, the coma much longer, and the air purer too. At hour 9 in the evening, however, with the Moon shining, nothing of the comet was seen, although stars of the 6th magnitude were visible. On January 7 the comet was in conjunction with the penultimate star of the tail of Draco. Finally, from January 22 onwards, for another 8 days and more (as was said at the beginning), the days were cloudy, after which no further trace of the comet appeared.

The rest, as to the distances from the fixed stars and the altitudes, we shall report in chapter 22, number 23, comparing these distances with the distances taken by others, so that a conjecture may be formed from them about the parallaxes of this comet; but the longitudes and latitudes observed by Cysat over many days we shall present shortly in the first table. There follow the observations of the tail, set most elegantly before the eyes in twelve diagrams of the stars.

[Margin: Position and length of the tail.]

On December 1 the head was a little below the northern foot of Virgo, from which the tail rose, not straight but curved, upwards convex, and somewhat concave downwards, and broader in the middle than the head itself, as happens

in the flames of lamps; at its end, however, it was not scattered like a broom but gathered to a point, which shone with sparser and fainter rays. The length of the tail was then at least 22°. On the 4th the comet's head scintillated seldom and languidly, and the tail undulated as if gently stirred by the wind, leapt with an alternating vibration, and was sometimes sharpened at its end and sometimes spread out into the shape of a broom — which was also noticed on many other nights up to December 28. On the 7th, at hour 7, it stretched out on an almost straight path; its breadth in the middle was ordinarily about 2° 30′, but because of its alternating ejaculation and spreading, sometimes 3½°. Its length appeared 57°, and it extended from the farther knee of Boötes to the stars of the left hind foot of Ursa Major, almost grazing Arcturus (not Mars, as the astrologaster Hebenstreitus thought). On December 8 the tail's length was 58°, its ordinary breadth 3°, its extraordinary breadth 4°. On December 9, at hour 7 in the morning, the tail stretched out up to 75° — namely from about Arcturus to the claws of the right forefoot of Ursa Major — the ordinary breadth of the tail being 2°. On the 17th, at hour 6 in the morning, the tail appeared notably curved, 56° long and a little more than 2° broad. On the 18th it was 54° long and a little less than 2° broad. On the 20th the tail was 34° long and curved, and passed from the wrist of Boötes through the last star of the tail of Ursa Major as far as the left shoulder of the Bear. On the 21st the tail was 20° long. On the 22nd, at hour 8 in the evening, the tail was so short that it seemed about to disappear; but on the 24th it received new increases, and was seen to undulate and to flicker its rays in alternating darts much more often than at other times, so that it reached from the hand of Arcturus as far as the most remote star of the Wain, and at times became 4° broad — which was also seen on the 28th. The tail's length on the 28th and 29th was 35°; it then decreased so much that on January 7 it scarcely seemed 8°. Finally, he notes that the fineness of the extreme rays and the length of the tail were seen differently by different observers, because of the variety of eyes, air and twilight; but that the tail always stretched directly towards the part opposite the Sun;

[Margin: Digression from the Sun.]

and that the comet's head had digressed from the Sun by 31° 27′ on December 1, by 90° 34′ on December 21, and by 123° 3′ on January 18, but on the 22nd by only 122° 2′.

[Margin: Observations of the head.]

Further, he found the comet's head, to the naked eye, on the first day of December far larger than any star of the first magnitude, its light dull and pale, not scintillating, but very like Saturn. Measuring it with an astronomical radius, he found it, until December 10, to be of 7′ or 6′; but on January 3 so diminished [?] that it scarcely equalled stars of the 4th magnitude. Using two telescopes [tubo∫picillis], however, one of 6 feet and the other of 10, he saw in the middle of the head a round nucleus of more condensed light, of greater diameter than any star of the first magnitude likewise viewed with the telescope, yet smaller than Jupiter's diameter as seen through the tube in those days, so that at most

it contained two-thirds of Jupiter's diameter. Around that nucleus was spread another, paler light, with a rim almost twice as broad as the nucleus's diameter, like a mane or halo. The nucleus's diameter was 2′, the rim's breadth 3′, and the whole diameter about 8′. On the 8th the nucleus taken by itself appeared twice as large as Arcturus, and of 3′ or 4′, whereas on the first day it was seen much smaller; nor was it round any longer, but split into three or four globules of irregular shape, cohering with one another. On the 17th and 18th of December, in place of that nucleus there were now several very small stars, with a very dull light spread between and around them; and on the 20th it appeared more plainly dissolved into many little stars, of which three were seen more distinctly, the largest of them like stars of the 5th magnitude. The diameter of this nucleus, or cluster of little stars, was 5′ or 6′, notably larger than on December 1. But on December 24 the little stars of the nucleus appeared more dissipated and with a much fainter light, and of those three conspicuous ones only one was seen; the others, all of similar magnitude, could not be counted because of their frequent scintillation and inconstancy. The nucleus's diameter, however, was seen to be 6′, the breadth of the surrounding rim 5′, and the whole diameter of the head 16′. Afterwards it could not be viewed with the tube, since those little stars were by then dissipated.

[Margin: The comet a cluster of little stars.]

It was remarkable, therefore, that quite the opposite happened for those viewing it with the naked eye: at the beginning it seemed larger, because of its condensed and dense body and its more intense light, and at the end it could scarcely be discerned and seemed of the smallest magnitude; whereas, on the contrary, through the telescope the head was seen as 8′ on December 1 and as 16′ on December 24. Chrysostomus Gall., afterwards public professor of mathematics in Portugal [Lusitania], was present; and the observation, repeated with different tubes and often on the same nights, frees the mind of the suspicion of a trick of the eyes. See also what Dr Habrecht saw at Cologne [Coloniæ], above. And here, at the end of this observation, is the figure in which the comet's head appeared from December 17 to the 20th. A similar cluster is seen with the telescope in the nebula of Cancer and at the end of Orion's sword. Finally, Cysat thinks that the distances from the Earth were such as we shall set out at the end of table 4, and that the comet moved on an epicycle around the Sun, although he does not deny that it could have moved along a straight line; and that the head was 175 German miles in diameter, its body 950 times smaller than the Earth but 22 times smaller than the Moon. Next I shall present the tables: first those of the observed longitudes and latitudes, then ephemerides put together from a few observations, but arranged by a probable conjecture of the motion and extended to many other days on which the comet was not observed.

[Margin: Effects of the comet, from Kepler.]

As to its effects, says Kepler, the winter of the year 1619 was dry and squalid, so much so that, although the south wind blew, the Moselle never overflowed as

it usually does. About this time the Empress Anna died, and then the Emperor Matthias, who had stripped Mansfeld of the Palatinate; from this came huge disturbances and disasters, the Bohemian war, the incursions of Gábor Bethlen [Bethlemi Gaboris] into Hungary, and many other calamities, which afflicted Germany and Italy in particular.

Diagram. An uncaptioned woodcut set in the right column beside the account of the comet's effects: the comet's head drawn as a ring of fine lines radiating outwards around a clear central disc, which holds a cluster of small six-pointed stars — the figure, announced in the text, of the head as it appeared from December 17 to 20. The block carries no letters, figures or labels.

TABVLAE Ex Obſeruationibus Cometæ Anni 1618. & 1619. Conſtructæ.

Tables Constructed from the Observations of the Comet of the Year 1618 and 1619

The places at which the authors listed below observed are these: Longomontanus at Copenhagen; Cysat at Ingolstadt; Snel in Holland; Rhodius at Wittenberg; Habrecht at Strasbourg [Argentinæ]; Remus at Innsbruck; Vuelperus at Loræ [Lorę] in Alsace; Schickard in Württemberg; Millerus at Leipzig; Ursinus at Frankfurt on the Oder; Kepler at Linz; Chiaramonti at Cesena; the Dillingen observer [Diligenſis] at Dillingen; the Roman Fathers at Rome.

Table I. Longitude and latitude of the last comet of the year 1618 and 1619, as observed. Latitude always north.

Day (New Style)	Observers	Hour after noon	Longitude	Latitude
November 28	Kepler	$18^h\ 30^m$	♏ 12° 43′	7° 30′
29	Fathers of the Roman College	✠	11° 30′	10° 0′
30	Longomontanus	$17^h\ 45^m$	9° 26′	11° 47′
	Father Cysat	$17^h\ 45^m$	9° 22′	11° 50′
December 1	Father Cysat	$16^h\ 48^m$	7° 56′	14° 31′
	Snel	✠	8° 24′	14° 12′
2	Longomontanus	$18^h\ 30^m$	6° 24′	16° 56′
	Rhodius	✠	3° 30′	16° 0′
3	Longomontanus	$18^h\ 30^m$	4° 53′	19° 33′
	Father Cysat	$18^h\ 52^m$	4° 56′	19° 18′
	Chiaramonti	$17^h\ 46^m$	3° 35′	20° 43′
	Habrecht	✠	3° 0′	19° 40′
	Rhodius	✠	1° 24′	20° 0′

The Remainder of the Preceding Table.

Day (New Style)	Observers	Hour after noon	Longitude	Latitude
December 4	Remus	$16^h\ 0^m$	♏ 2° 0′	22° 0′
5	Remus	✠ ✠	0° 45′	24° 30′
6	Father Cysat	$18^h\ 51^m$	♎ 29° 23′	27° 37′

Day (New Style)	Observers	Hour after noon	Longitude	Latitude
	Habrecht	✠	28° 30′	27° 30′
	Vuelperus	✠	29° 30′	26° 20′

CAPVT IV. De Proprietatibus ſeu Accidentibus Cometarum ex Præcedenti Hiſtoria collectis in vnum.

Chapter IV. On the Properties or Accidents of Comets, Gathered Together from the Preceding History

I. To satisfy those eager for learning, and so that many of the things usually needed for solving questions about comets may be ready to hand, I have decided to select from chapter 3 the properties, or conditions, of comets set out below.

Numerus Cometarum.

The Number of Comets

[Margin: 154 comets known for certain.]

Lavater [Ludwig Lavater] and Keckermann [Bartholomäus Keckermann] count 117 comets from Augustus to the year of Christ 1556. We, however, have counted 154 from the year 480 before Christ to the year of Christ 1618. About those that were not observed or recorded in history, or were not seen on the horizons of Europe, we can establish nothing certain. It is nevertheless very likely that many more have shone upon the whole world from the beginning of the world down to this day. Add that, as Seneca says in Book 7 of the *Natural Questions*, chapter 20: "We do not see many comets, because they are obscured by the rays of the Sun; Posidonius writes that during an eclipse of the Sun [quo deficiente] a certain comet appeared which the neighbouring Sun had hidden."

Numerus Cometarum eodem tempore.

The Number of Comets at the Same Time

II. It is a pronouncement of Aristotle (*Meteorologica* I.6) that "more comets than one have appeared at the same time"; on which Pliny (II.25) says: "Aristotle reports that several are seen at once — a thing found out by no one else, as far as I know." Yet it was found out by Bede in the year of Christ 729, in which, as Palmerius also reports in his *Chronicle*, two comets were seen for 15 days in the month of January, one in the morning, the other in the evening. The same is recorded to have happened in the year 761, so that one appeared in the east for 10 days and the other in the west for 21 days. In the year 1214, the *History of the Scots* reports two seen at once, one in the morning going before the Sun, the other in the evening following the Sun. Vuenceslaus Pantaleon affirms that while he was living among the Indians [apud Indos] two comets were seen at once; likewise in the year 1529, 4 comets are recorded to have been seen standing opposite one another; and Franciscus Fernandes says that five can be seen at once. In the year 1337, too, a solitary comet appeared in May, and another later joined it, visible together with the first in June, July and August. Julius Caesar Scaliger, too, in exercise 79 against Cardano, says that at the time when Charles, King of the French, invaded Italy, a comet was seen at sunset which a few days later went ahead of the Sun; and then he adds: "We saw two at once, one in the morning, the other in the evening, for many days, at different latitudes, not so many years ago." Sometimes, however, a comet that was really one has been believed to be twin, because from a morning comet it became an evening one, its declination and right ascension having changed — as Apian and Fracastoro noted happened in their own time with the comets of the year 1531 and 1532. But in the year 1618 two were plainly seen together in the morning by Franciscus Garcia in Persia and by Father Iacobus Rhò [Giacomo Rho] of the Society of Jesus at Goa in East India, as we related in the history of that year, chapter 3.

Cometæ in plures diuiſi aut reſoluti, aut ex pluribus Coaleſcentes.

Comets Divided or Resolved into Several, or Coalescing from Several

[Margin: One comet going off into several.]

III. In the year 450 before the Christian era, or thereabouts, Democritus saw a comet dissolved into several stars, as is found in Aristotle, *Meteorologica* I, chapter 6. Then, in the year 372 before Christ, the historian Ephorus affirms that the great comet of which Aristotle speaks in the same chapter, and which preceded the submersion of Helice and Bura, cities of Achaea, broke up into two stars. Seneca (*Natural Questions* VII.16), however, scorns this with arguments half drawn from rhetorical commonplaces [argumentis ſemitopicis], as we reported at that year. On Ephorus's side, by contrast, Kepler, in his book *On Comets*, p. 49, said: "No doubt the Romans, lords of the world and haughty, for whom contempt for a conquered nation counts as part of their wealth. And Seneca, in a declamatory style, rattling the boxes of commonplaces, plays his own part." Seneca, that is, was wholly bent on persuading, against Artemidorus, that comets are not a coupling of two known stars; but Ephorus had not said that the comet was resolved into two known stars, but into two unknown ones.

[Margin: Several comets coming together into one.]

So too in the year 13 before Christ, according to Dio, a comet that had long hung over the City was afterwards dissolved into many torches. Kepler, in the passage cited, thinks that the very same thing happened with the two comets seen in the year 1618. Nicephorus, on the contrary (*Ecclesiastical History* XII.37), reports of a new star, or comet, of his own time: "Little by little a huge mass of other stars gathered to it, like bees to their leader."

Tempus Apparitionis Cometarum.

The Time of the Appearance of Comets

IV. Simon Maiolus, in colloquy 1, and Junctinus [Francesco Giuntini], in his annotation, said that comets are generated more often in autumn; Hippocrates, in Aristotle (*Meteorologica* I, chapter 4), around the summer solstice; Suessanus [Agostino Nifo], in the same place, that the most suitable time for it is spring and autumn; Franciscus Resta, *Meteorology* I, tract 1, chapter 7, said that it happens more often in autumn, but that the other seasons of the year also have their comets.

Giovanni Camillo Glorioso, *On Comets* I, p. 12, says that it happens rarely in springtime, more rarely in summer, most rarely in winter, but most often in autumn, around the equinox or a little after. Froidmont, *Meteorology* III, chapter 4, article 6, declares that comets sometimes arise in every month of the year, but most of all in autumn and winter. What should really be said will at once become clear from the history, which you may see in the following synopsis, in the years of Christ — for before that it can scarcely be established in which particular month they appeared; as when Aristotle says that the great comet appeared in winter, when there was frost.

Years of Christ in which comets are established to have arisen in definite months.

Total 9	9	13	10

Summer therefore wins, and among the summer months August, among the winter months January, as far as is established from history. But if the definite times of the other comets had been recorded, and their true efficient cause and matter were evidently known, perhaps another season of the year and other months would carry off the palm — and perhaps not. We have already said above that some appeared as morning comets, others as evening comets, and others first as morning and then as evening comets: see the years 1530, 1531 and 1532.

[Margin: A comet staying up all night, or not setting.]

Some, moreover, either stayed visible all night, as in the year 1513, or never set below the horizon, as in the years 1513, 1533 and 1556; and the last comet itself, of the year 1618, began from December 20 to January 18 and was seen among the stars that are always visible.

Duratio Cometarum.

The Duration of Comets

V. Pliny (Book 2, chapter 25) certainly spoke far too narrowly about these when he said: "The shortest period during which they have been observed is recorded as seven days, the longest as eighty." But since Seneca (*Natural Questions* Book 7, chapter 21) affirms that a comet appeared continuously under Nero for 6 months, and Pliny cannot have been unaware of this, Muretus [Marc-Antoine Muret], in his notes on that chapter 21 of Seneca, judges that the letter C should be added to Pliny's number, so that it reads "C. Octoginta" [a hundred and eighty], because six months consist of that many days.

[Margin: The shortest duration of comets.]

The shortest duration, however, was that of the comet which the Coimbra commentators [Conimbricenſes] report (tract 3 on the *Meteorologica*, chapter 3): when it had risen a little above the horizon, it was suddenly dispersed and vanished from sight. Not much longer-lasting was the one which the astronomer Petrus Creusser saw in the year 1527 — terrible indeed, but lasting no more than five quarters of an hour, as Keckermann reports (*Systema Physicum* Book 6, p. 680).

[Margin: The longest duration of comets: a year.]

On the other hand, the longest duration of comets can be seen to be a year, if indeed, on the testimony of Josephus (*Jewish War* Book 7, chapter 17), a comet, the Xiphias, was seen for a whole year hanging over that city shortly before the destruction of Jerusalem. But Tycho (vol. 1 of the *Progymnasmata*, pp. 330 and 626), because he holds that all comets are supralunar, considers that this comet was not natural but extraordinary — as it were a supernatural portent kindled by God to terrify the Jews. For in this way it could hang over the city and not be carried round by the primum mobile, as the Peripatetics maintain of the others, and could terrify the Jews rather than other nations, and finally persist for a whole year. Froidmont (*Meteorology* Book 3, chapter 4, article 5), Glorioso (*On Comets* Book 1, p. 9) and Cottunius [Giovanni Cottunio] (Book 33 on *Meteorologica* 1, p. 312) subscribe to this view.

[Margin: Three comets lasting six months.]

With this one excepted, then, no other is reported to have lasted beyond 6 months, and I recall that only three of that kind have occurred. The first was under Nero, in the year of Christ 64. The second shone out around the year 603, at the rise of the most impious Mahomet. The third, in the year 1240, at the outbreak of the great Tamerlane. About the rest, different authors say different things; but here, drawn from the history in chapter 3, is a second synopsis for you, in which we take the months that comets are reported to have lasted as 30 days.

Synopsis of the Duration of Comets, in the years after Christ — but before Christ where A is placed.

Days	Year
0 5/96	1527
7	44 A
10	761 and 1531
11	1590
12	983
14	1312
15	1526
17	1531
18	1211
21	1314
25	1071 and 1506 and 1559, 1597

Days	Year
28	1618, 1585
30 or 31	676 and 1456 and 1533 and 1607
40	392, 1264 and 1530
55	1513
56	1532
57	1618
60	1347
79	1577
70	356 A, 336 A, 130 A, 119 A
71	1532
75	431 A
90	676 and 1264, 1363 and 1433
120	1337
180	64 and 603 and 1240
365	70

Magnitudo Capitis Cometæ Apparens.

The Apparent Size of the Head of a Comet

VI. The apparent size of the head of comets is usually very inconstant and varied. Few have written about it, and they have written little: Biancani (*Sphaera* Book 17, chapter 1), Piso (chapter 18 of the *Speculum*), Glorioso (*On Comets* Book 1, p. 4), Froidmont (*Meteorology* Book 3, chapter 4, article 5), Cottunius (lecture 32 on the *Meteorologica*, p. 283) and Resta (*Meteorology* Book 1, tract 1, p. 42); to these we shall add more. Many comets, viewed with the naked eye, were large-headed at first and afterwards gradually decreased; sometimes, however, they were seen small at first and larger afterwards, either with the naked eye, as Pontano observed in the comet of the year 1460, or at any rate when inspected with the telescope, as we shall shortly report from Cysat about the comet of the year 1618.

[Margin: A comet equal to the Sun.]

The greatest of all seems to have been the one that shone out in the year 146 before Christ, of which Seneca says (*Natural Questions* Book 7, chapter 15): "Shortly before the Achaean war a comet blazed forth no smaller than the Sun."

[Margin: Comets equal to ☾ □, and one three times greater than Venus.]

Large indeed, too, were those seen equal to the Moon at dichotomy — that is, shining in quadrature with the Sun — in the year of Christ 1200, on the testimony of Haly [ʿAlī ibn Riḍwān], and in 1521 and 1556, on the testimony of Cardano (*De Varietate* Book 14, chapter 69). Haly adds (on the *Quadripartitum*

[13] the first entry, given here as 0 5/96, is printed as a small round sort, then a 9 standing alone at mid-height, then a small 5 over 6 whose fraction bar spans the 6 only. The print can be read as 5/96 or as 9 5/6; 5/96 of a day, the five quarter-hours of Creusser's comet of 1527 in the text above, is a construal, not a reading of the bar.

Book 2, chapter 9) that the comet of the year 1200 had a head three times greater than Venus.

[Margin: A comet three times greater than Jupiter.]

Fracastoro, in the year 1532, as he relates in the *Homocentrica* (Book 3, chapter 23), saw a comet three times greater than Jupiter, with a tail two cubits long. And the comet of the year 1577, which Tycho brought under measurement with the astronomical radius and estimated at the beginning at 7′, as he has it in vol. 2, pp. 2 and 202, will have been twice as great as Venus at perigee, whose apparent diameter for the same Tycho (vol. 1 of the *Progymnasmata*, p. 475) is 3¼′.

[Margin: A comet twice as great as Venus.]

[Margin: Comets equal to Jupiter.]

The comet of the year 1585, at its first rising, appeared to Tycho almost equal to Jupiter, namely 3′; so too did the comet of the year 1590, as he himself relates in the *Epistolae*. The comet of the year 1618 also appeared as large to Longomontanus, since in the Appendix to the *Astronomia* (chapter 10) he says that it was seen a little larger than Spica, and of 3′; Tycho, however (vol. 1 of the *Progymnasmata*, p. 481), assigns Spica 2′ and Jupiter 3′. But Cysat (*On the Comet of the Year 1618*, chapters 1 and 4) speaks very differently. He says that the comet, observed with the naked eye by means of the radius, was seen at the beginning at 7′ and greater than any fixed star, and afterwards decreased down to a single minute; but that, viewed with the telescope on the contrary, on December 1 and 4 it had in the middle of its head a nucleus of denser light about 2′ in diameter, while the whole head, with its fringe of rarer light, was seen at 8′. On December 8 that nucleus was seen twice as great as Arcturus, if Arcturus too were viewed with the telescope; and on December 24 he saw with the telescope a nucleus of 6′, but the whole head of 16′, scattered into several stars, as he had seen it before as well — though of these only one, or a few lying nearer to one another, could be seen with the naked eye. And so on January 3, viewed with the naked eye, it appeared scarcely equal to stars of the 4th magnitude.

In view of these observations, it seems we should subscribe to our Biancani, who asserts that no comet has been seen at its beginning either greater than the Sun or smaller than the stars of the first magnitude. For Scultetus's statement that the apparent diameter of the comet of the year 1577 was 54′, and so almost twice as great as the diameter of the Sun, is refuted as false by Tycho, an eyewitness (vol. 2, p. 415), and must be attributed either to weakness of the eyes or to a halo which, perhaps poured round the comet, enlarged it optically. Here, however, one must remember that the radius is very deceptive in taking distances and diameters, as Tycho himself admits (vol. 1, pp. 247, 335, 343, 559 and 671; vol. 2, p. 31; and in the *Mechanica*). By what means the diameters of the fixed stars, of the lesser planets, and so also of the heads of comets can and should be observed more certainly and accurately, we have taught sufficiently in Book 7, Section 6, chapters 9, 10 and 11.

Magnitudo Apparens Caudæ vel Barbæ Cometarum.

The Apparent Size of the Tail or Beard of Comets

VII. The tail and beard of comets generally grow for a few days after the first appearance, and decrease at the end. It is already established from the preceding history that the comet seen by Aristotle in the year 341 before Christ

[Margin: Tail 60°.]

occupied a third part of the hemisphere, namely 60°. Equal to it were the comets of the years 1456 and 1460, of which one had a tail occupying two signs, the other more than 50°, on the testimony of Pontano. The tail of the comet of the year 135 before Christ must certainly have been very great; of it Seneca says (*Natural Questions* Book 7, chapter 15): "In the reign of Attalus a comet appeared, modest at first; then it raised itself and spread out and came as far as the equinoctial circle, so that, stretched out immensely, it equalled that region of the sky which is called the Milky Way." Apian found in the comet of the year 1533 a tail of 15°, but in the comet of the year 1538 one of 30° — as great as Mästlin too noted in the comet of the year 1577; granted that Johannes Praetorius made it only 25° long and 2° wide, and Tycho only 22°. But in the comet of the year 1585 Tycho could scarcely make out a tail a span long, and in the comet of the year 1590 one of 10°. No comet, however, was more remarkable for its size and for the variation of its size than that of the year 1618: on the same nights it was seen of different lengths not only by different observers but by the same observer, now short, now longer through the vibration and darting of its rays. But the variety of this and of the preceding comets will be more pleasing if it is brought into the following little table, in which the days and months are set out separately only where the diversity of the observations required it.

The Apparent Length of the Comet's Tail

Years	Observers of the tail	Length of the tail, in degrees
Years before Christ		
341	Aristotle	60
135	From Seneca, *Natural Questions* Book 7, chapter 15	Equal to the Milky Way, and immense
Years of Christ		
1456	Pontano	60
1460	Pontano	50
1533	Peter Apian	15
1538	Peter Apian	30
1539	Peter Apian	very thin
1577	Tycho	22
	Johannes Praetorius	25
	Mästlin	30
1585	Tycho	a span long
1590	Tycho	10

Years	Observers of the tail	Length of the tail, in degrees
1618		
November 26	Millerus	90
29	the Roman Fathers of the Society of Jesus	58; so too at Vienna
29	but Kepler	30
December 1	Father Cysat	22 at least
4	Chiaramonti	21
7	Cysat	57
9	Cysat	75
9	Kepler	70 at least
10	Longomontanus	104, with an enormous vibration
12	the Roman Fathers	60

January 7	Cysat	8
Foot: The tail of the comet of the years 70, 400, 1472 and 1543 was seen to reach down to the Earth.		

Magnitudo Vera Capitis & Caudæ Cometarum.

The True Size of the Head and Tail of Comets

VIII. This size depends on the distance from the Earth both of the comet's head and of the extremity of its tail, and on the apparent size. Moreover, most authors, because of the resemblance of comets to stars, suppose a comet's head to be round, and usually measure only the length of the tail; a few, however, also measure its thickness or solidity, just as if it were a kind of cylinder. How each is done geometrically I shall teach below, in chapters 23 and 24. Meanwhile, for those who pursue learning pure and simple and relish only the marrow, let the various opinions on the size of the head and tail, with their grounds, be set out in the following synopsis.

[Margin: Year of Christ 1472.]

Regiomontanus estimated the comet's diameter at 16 German miles, that is, 64 Italian miles. But Gurcensis estimated it as longer: the head together with the tail at 4000 German miles, the breadth of the head at 26 miles and that of

the tail at 81 German miles — each of which is usually equated with four Italian miles. From this, in chapter 11, number 15, we shall work out the solidity of the whole comet with its tail, relative to the Earth, as 32 to 296,000.

[Margin: Year 1532.]

Johannes Vögelin, setting the distance from the Earth at 8 Earth semidiameters, judged the diameter of the head to be 1¼ German miles, or 5 Italian miles, and the tail 182 German miles long. Hence Carolus Piso said that it is not impossible for comets to equal a mountain of one or two German miles.

[Margin: Year 1577.]

Tycho (vol. 2, pp. 202 and 205) judged that the comet of the year 1577, on November 13, was distant from the centre of the Earth 210 Earth semidiameters as to its head, but 157 Earth semidiameters as to the extremity of its tail; that the apparent diameter of the head was 7′, and the true diameter 368 German miles, in ratio to the Earth's diameter as 3 to 14 but to the Moon's diameter as 1 to 4; that the body, or solidity, of the head was to the solidity of the Earth as 1 to 101⅔, but to the solidity of the Moon as 1 to 2⅓; and finally that the apparent length of the tail was 25°, but its true length 95 or 96 Earth semidiameters, or 81,700 or 82,560 German miles. From this, in chapter 11, number 15, we shall work out the solidity of the whole comet with its tail to the solidity of the Earth as 14 or 33 to 296.

[Margin: Year 1577.]

Scultetus, however, as reported by Tycho (vol. 2, pp. 409 and 415), made the diameter of the head of the comet of the year 1577 124 miles, of which he gives the diameter of the Earth 1718 and that of the Moon 505; and the length of the tail 2623 of the same miles. But he supposed the apparent diameter of the comet and of the Moon to be 54′ — a manifest error indeed — and its distance from the Earth 8047 German miles, and the parallax 5° 22′.

[Margin: Year 1577.]

Snel (*On Comets*, chapter 6) supposed the same comet to be distant from the centre of the Earth 300 Earth semidiameters, and of apparent diameter 7′; and hence its solidity relative to the Earth as 8 to 27, but relative to the air compressed into a single globe as 8 to 1. We shall present his method in chapter 11, number 13.

[Margin: Year 1618.]

Longomontanus, in the Appendix to the *Astronomia* (chapter 10), estimated the head of the comet of the year 1618, on December 27, at 3′ in apparent diameter. From this, and from its distance from the Earth of 240 Earth semidiameters, he works out its true diameter as 175 German miles, in ratio to the Earth's diameter as 377 to 3600, and the solidity of the head to the Earth's globe as 1 to 870, but to the Moon's globe as 1 to 20.

[Margin: Year 1618.]

Father Johann Baptist Cysat, on this same comet (chapter 4), says that on December 9 the head was distant from the centre of the Earth 100 Earth semidiameters, and its apparent diameter 7′, but its true diameter 175 German

miles, its circumference 550 German miles, and its solidity to the Earth's globe as 1 to 950, to the Moon's globe as 1 to 22; and that the length of the tail varied on various days, as in this little table.

Day of December	Earth semidiameters	German miles
1	45	38700
9	137	117820
17	185	159100
29	445	382700

[Margin: Year of Christ 1618.]

But our Fathers at the Roman College, on the hypothesis that the distance of the comet of the year 1618 was at least as great as the least distance of the Moon in Ptolemy, namely 34 Earth semidiameters, and taking the apparent length of the tail as 60° and its breadth as 2′ — as they say it appeared on December 12 — assign to the tail 127499 Italian miles in length and 70 5/7 miles in breadth, and to its cylindrical solidity 490871150 cubic miles. So Chiaramonti also reports (*Anti-Tycho* Book 2, chapter 30), and Cottunius (lecture 33 on *Meteorologica* 1), who adds, however, that by others, who place the comet far below the Moon, it was estimated at only 1300 cubic miles.

Chiaramonti, on the other hand (*Anti-Tycho* Book 2, chapter 30), supposing that on December 4 the tail appeared to him as 21°, the comet's distance from the Earth as 5000 Italian miles, and the breadth of the head as 2′, works out the breadth as 2 9/10 miles, the length as 1834 miles, and the cylindrical solidity of the tail together with the head as 12,838 cubic miles.

Situs Caudæ reſpectu Solis, Veneris, aut Mercurij; & Plaga Cæli, in quam vergere viſa eſt.

The Position of the Tail with Respect to the Sun, Venus or Mercury; and the Region of the Sky toward Which It Has Been Seen to Point

IX. The position of a comet's tail could have been conjectured long ago from the words of Dio about the comet conspicuous during the reign of Macrinus, where he says: "A star stretching its tail from west to east for many nights brought us grave disturbance"; and more clearly from the account of the comet of the year 1472 seen by Regiomontanus, for it is said: "It happened that immediately after sunset the tail faced the east; in the middle of the night, the south; after the middle of the night it faced the west." Even so, the first — as Tycho and Gemma Frisius noted — was in fact Peter Apian, who observed that comets always cast their tail toward the part turned away from the Sun. Consequently, comets that run ahead of the rising Sun in the morning are seen bearded, and their beard, turned toward the west, rises before the head; whereas evening comets, which follow the Sun after it has set, go down head first, before the tail. This, I say, he observed in five comets of his own time, namely those of the years 1531, 1532, 1533, 1538 and 1539, by observing the moments of time

and the place of the head and of the end of the tail in longitude and latitude, the Sun's place at that moment being already known from the Alphonsine Tables. Fracastoro observed the very same thing at the same time in three comets, of the years 1531, 1532 and 1533, and Gemma Frisius in 8 comets from the year 1532 on, which he records in his treatise on the astronomical radius, chapter 19, and in the *Astrolabe*, chapter 82; and his son Cornelius Gemma subscribed to him (*De divinis naturae characterismis* Book 1, chapter 6). Of the same opinion — that the tail is turned away from the Sun — were, later, Cardano (*De subtilitate* Book 4), Scaliger (exercise 79 against Cardano), Mästlin on the comet of the year 1580, Cysat on the comet of the year 1618 (chapter 4, proposition 2), Biancani (*Sphaera* Book 16, chapter 12), Cottunius (lecture 33 on *Meteorologica* 1, p. 307), Froidmont (*Meteorology* Book 3, chapter 4, article 1), Cabeo [Niccolò Cabeo] (*Meteorologica* Book 1, text 37, question 7), Longomontanus (Appendix to the *Astronomia Danica*, chapter 6), and Tycho in five comets that he observed.

Thus in the *Epistolae*, p. 173, on the occasion of the comet of the year 1590, Tycho says: "It directs its tail, thin but about 10° long, exactly opposite the Sun and toward the zenith"; and on p. 177 he says of the same comet: "It also directed its tail, very thin and rather sparse, exactly toward the parts opposite the Sun, for as long as it could be made out";

[Margin: Tycho's genuine opinion on the position of the tail.]

and a little below: "From the extensions of the tail which we have indicated, it is evidently gathered that it was everywhere turned exactly away from the Sun, provided only that the positions of the Sun are compared with the places of the comet's head which they occupied at the same times." He teaches the very same expressly in vol. 1 of the *Progymnasmata*, p. 651. And although in vol. 2, chapter 7, he judged that the tail of the comet of the year 1577 was directed not exactly toward the part opposite the Sun but toward the part opposite Venus, in chapter 9, p. 204, he does not rest content with this because of the weak light of Venus. For that reason, in a letter of the year 1589 to Rothmann [Christoph Rothmann], p. 142, he says: "As regards the drawing out of the tail, I showed that in the comet of the year 1577 it constantly faced the star of Venus — although afterwards I would rather incline toward the side of the Sun, because of some hidden optical reason, since it can scarcely be believed that the star of Venus emits such strong rays."

[Margin: Venus powerless to produce a comet's tail.]

And although in the same place he grants to Giovanni Battista Benedetti that the part of the Moon that is dark in itself is nonetheless lit somewhat by Venus, he adds: "Yet to tell the truth, this reasoning does not satisfy me so far that I would dare attribute to Venus so great a power of its rays as could have produced the tail of a comet." Resta (*Meteorology* Book 1, tract 1, chapter 1) therefore wrongly attributes the opposite view to Tycho.

So, whether because of a hidden optical cause, as Tycho suspects, or because the comet's head is not exactly spherical, as Cabeo thinks in this controversy, it happens that the tail sometimes seems to recede a little from the point opposite

the Sun — so that Kepler (*On Comets*, p. 54) said: "It is customary for comets that their tails deflect somewhat from the point opposite the Sun." The same must be said of the comet of the year 1618, whose tail Kepler and Schickard saw on December 9 stretched out opposite Mercury rather than opposite the Sun, and Snel saw it stretched away from Venus, although they admit that it afterwards directed itself opposite the Sun. So too with Mästlin: the tail of the comets of the years 1577 and 1580 at first deflected from opposition with the Sun, but afterwards was ranged in the same great circle with the Sun and the comet's head, and turned directly away from the Sun. Johannes Hommel too observed that the tail of the comet of the year 1556 did not appear turned exactly away from the Sun for as long as the comet was less than a quadrant of the circle away from the Sun, but afterwards stretched directly toward the region opposite the Sun. As for the Landgrave of Hesse appearing, in the year 1558, to see the tail deflect 10° from the point opposite the Sun, Tycho attributes that to the deceptiveness of the torquetum, since Gemma's son observed the same tail in the same year stretching toward the part turned away from the Sun. From all this it is gathered that the deflection from that direction arises accidentally from the position of the Sun, the comet and the observer — other causes perhaps contributing that lie hidden in the matter and figure of the head, or in the distance and transverse motion of the comet — but that of itself the tail is always carried toward the region opposite the Sun.

[Margin: The turning of comets' tails away from the Sun confirmed.]

Finally, many phenomena indicated by Tycho (*Epistolae*, p. 143) confirm this very point. For comets that were seen to stretch toward the point opposite the Sun, such as the comet of the year 1585, showed no tail or a very small one, since the tail lay hidden behind them and was concealed from us, who stood between the Sun and the comet's head; whereas those that were nearer the Sun, such as the comets of the years 1580 and 1582, were seen to put out their beard more and more. Hence it is that morning and eastern comets are bearded, with their rays extended toward the west, as in the year 1363, while evening and western comets are tailed, as in the year 1577, with their rays turned away from the west toward the east; and that, when the Sun is very far depressed below the horizon, the tail of comets seems raised up toward the zenith, and the beard of a morning comet rises before its head, whereas the head of an evening comet sets first.

[Margin: The regions of the world toward which a comet's tail points.]

Granted, by reason of the declination of both the comet and the Sun the tail has commonly been seen to point toward other regions and to portend something to them. Thus the comet of the years 726, 1314 and 1347 is said to have stretched its tail toward the north; that of the year 1211 over Russia; that of the year 1533 toward Africa; that of the year 1558 toward Rome and Spain; and that of the year 1532 more toward the south each day, and then to have bent toward the north. But the tails of those comets that were seen to slide down to

the earth so as to lick up and swallow streams were meteorological kindlings similar to comets, but not properly comets.

Plaga Cœli in qua Orti, & in quam delati, & in qua extincti ſunt Cometæ.

The Region of the Sky in Which Comets Arose, toward Which They Were Carried, and in Which They Were Extinguished

[Margin: The prerogative of the northern hemisphere over the southern.]

X. I have said elsewhere that the northern hemisphere is furnished with more fixed stars than the southern; that the Sun spends about 8 days longer in it than in the southern; and that it holds more habitable land, and the greater and better part of the human race. What wonder, then, if the greater — indeed the greatest — part of the comets observed was on this side of the equator, for either the whole or the greater part of its duration? For it was fitting that more things should be signified and portended from heaven to these regions — granted that Aristotle (*Meteorologica* Book 1, chapter 3), though citing no history, says: "And toward the south many have arisen"; for him, however, it is enough that they arose beyond the equator. But Seneca (Book 7, chapter 11) says that they arise

[Margin: Years of Christ.]

most frequently around the north.

As for the points from which and to which comets have made their passage, there is scarcely one, so far as is yet established, that has crossed directly from one of the four cardinal points of the sky to the opposite cardinal point; all of them have taken an oblique path, with an unexpected variety, as a few examples will make clear. I said "scarcely", because perhaps the comet of the year 1200, observed by Haly, travelled from east to west by a straighter route, since he says that it was carried by the motion of the primum mobile from east toward west, from the 15th degree of Scorpio to the 15th degree of Virgo.

[Margin: Comets from east toward west or north.]

From east toward west, but obliquely, the comets of the years 392, 405, 1471, 1475, 1532, 1533, 1539, 1556 and 1618 swam across the sky. For the comet of the year 392, see what I reported under that year from Nicephorus; and of the comet of the year 405 Claudian sang thus in *De bello Getico*:

[Margin: Path of the comet of the year 405.]

> And the comet, never seen in heaven with impunity, which, first brought forth from the rosy rising of Phoebus, where old Cepheus glitters with his star-bearing wife, then, driven little by little from the Lycaonian Bear, defiled with its wandering hair the stars of the Getic Wain, until, dying, it faded into a meagre fire.

So it was heading from the summer rising point, or short of it, through the Bears toward the west. Of the comet of the year 1471, Pontano says at the end of the *Centiloquium*: "In these recent years another comet was seen, at first with a slender head and a very short coma; soon, having grown to a marvellous size, it began to turn aside from the east toward the north, etc., until it reached the

Bears themselves, from where it bent its path toward the west." I have reported the rest of his words in chapter 3, under the year 1471.

[Margin: Path of the comet of the year 1471.]

[Margin: Path of the comet of the year 1472.]

Next, the comet of the year 1475, or rather 1472, observed by Regiomontanus, began its path from nearly the equinoctial rising point, near Spica, and went on through the legs of Boötes, between the two poles of the zodiac and of the world, through the feet of Cepheus, the breast of Cassiopeia and the belly of Andromeda, as far as the northern Fish; and a little beyond the equinoctial setting point it set heliacally with the stars of Cetus. The comets of the years 1532 and 1539 too, if you weigh Apian's words properly, crept out from the east with southern latitude and, having then acquired northern latitude, went in an oblique course roughly toward the summer setting point. But the comet of the year 1533 went from the Goat [Hircus] through Cassiopeia to the north and against the order of the signs [in praecedentia], as Gemma Frisius testifies.

[Margin: Path of the comet of the year 1533.]

[Margin: Path of the comet of the year 1556.]

Again, the comet of the year 1556, very like that of Regiomontanus, rising nearly at Spica, or a little beyond the equinoctial rising point, ascended through the knee of Boötes and Arcturus toward the pole of the zodiac, then toward the pole of the world; and descending from there through Andromeda, it turned to the sign of Pisces, where it was extinguished, as Johannes Hommel saw. To this belongs the comet which, as Vicomercatus relates without indicating the year, rose from Vindemiatrix, was carried to the north and expired among the coils of Draco. Finally, the comet of the year 1618, seen in the morning a little beyond the equinoctial rising point, set out from Libra through Boötes to the tail of Ursa Minor — in such a way, however, that, as Cysat, Snel and others observed, it described at the end something like a spiral around the pole of the world, or a circle, remaining within the circle of perpetual apparition from December 20 to January 23 and never descending below the horizon of Ingolstadt. The path of these comets, then, was from east toward west and north.

[Margin: Path of the comet of the year 1618.]

[Margin: Comets from the west toward the east.]

[Margin: Path of the comets of the year 373 before Christ and 1577 after Christ.]

Others, by contrast, held their course from the west toward the east, some turning toward the south, others toward the north. For the great comet seen and described by Aristotle in the year 373 before Christ began from the equinoctial setting point and went from there as far as the belt of Orion, where it was also extinguished. And in the year 1577 the evening comet, first seen by Tycho a little above the head of the starry Sagittarius, beginning on November 9 or 8 beyond the equinoctial setting point, crossed the equator on the 22nd by the left hand of Antinous; passing the tail of Delphinus, it went through the nostrils

of Equuleus and, leaving the head of Pegasus to the south, made straight for Scheat of Pegasus, until it faded away between Scheat and two small stars that glitter in the breast of Pegasus; nor did it ever reach the meridian.

[Margin: Path of the comet of the year 1585.]

Again, the comet of the year 1585, observed by the Landgrave of Hesse and by Tycho, rising between the equinoctial and the summer setting points, stood about 5° from the cord of Pisces toward the east; then, passing through the whole constellation of Aries, it emerged by the back of Taurus toward the north and ceased to be seen not far from the Pleiades, which it surpassed in northern latitude but did not reach in longitude.

[Margin: Years of Christ.]

[Margin: Path of the comet of the year 1590.]

Not much later, namely in the year 1590, a comet began to be seen in the evening in the western region of the sky, at the head of the northern Fish, near the summer setting point; it vanished toward the feet of Andromeda, at the feet of Cassiopeia, having acquired a greater northern latitude and declination day by day.

[Margin: Path of the comet of the year 1607.]

Lastly, the comet of the year 1607 began to be seen on September 26 between the north and the summer setting point, with a northern declination of nearly 50°; then, continuing its motion in the order of the signs [in consequentia], it crossed the equator on October 10 and vanished at the leading shin of Serpentarius, having attained a southern declination of 12° and more.

[Margin: Path of the comets of the years 1513 and 1450.]

The comet of the year 1513, which flew from the end of Cancer to the end of Virgo, also seems to belong with these; but the comet of the year 1450 plainly belongs here.

[Margin: Comets that arose from the north.]

From the north itself, I note, one was carried toward the east, namely in the year 54 of Christ, under Claudius; another toward the west, in the year 64, under Nero; a third, in the year 1313, as also in the year 1531, toward the south. On the first two the evidence is Seneca (*Naturales quaestiones* Book 7, chapter 21), who says: "This one, which we saw in the most happy principate of Nero, went round in the opposite direction to that of Claudius: for that one, rising from the north toward the zenith, made for the east, growing ever dimmer; this one began from the same part but, heading toward the west, bent toward the south and there withdrew itself from our eyes."

[Margin: Path of the comets of the years 54, 64, 1313 and 1531.]

Of the third, Johannes Praetorius testifies, saying that it ran forward from north toward south and followed the motion of Mars; for that reason I would not believe that it went quite straight to the south, but that it deflected somewhat to the sides. Finally, many others are said to have risen from the north: above all the one that appeared in the year 44 before Christ, after Julius Caesar was killed, and that of the years 1500, 1506 and of the year 1533. But since the carelessness

of the old observers forbids us to say more about the path of comets, let us pass to other conditions. From what has been said, however, it is clear that Pliny the Elder (Book 2, chapter 25) spoke too confidently: "almost all under the north itself, in no fixed part of it, but most of all in the white region that has received the name of the Milky circle." This notable frequency of comets in the Milky Way has the support of Tycho (vol. 1 of the *Progymnasmata*) and of Aristotle (*Meteorologica* Book 1, chapter 7), who says: "Most of all it gathers in the region of the Milk."

De Motu Cometarum in Conſequentia vel in Præcedentia, & de Motu Primi Mobilis.

On the Motion of Comets in the Order of the Signs or against It, and on the Motion of the Primum Mobile

XI. It is clear from what was said in the preceding paragraph that some comets moved in the order of the signs, because day by day they appeared more easterly than the fixed stars, and others against the order of the signs, because they ran ahead toward the west with a swifter motion than the motion of the primum mobile carries. To have them gathered together: the comets of the year 373 before Christ, and after Christ of the years 54, 1450, 1513, 1532, 1533, 1577, 1585, 1590 and 1607, advanced in the order of the signs; the comets of the years 64, 405, 1200, 1471, 1472, 1539, 1556 and 1618 moved against it. Even so, it must be added that some comets, from being retrograde and moving against the order of the signs, became direct and began to go in the order of the signs, as the comet of the year 1556 did; and that some, from being direct, became retrograde or stationary, as the comets of the years 1569 and 1582 did.

[Margin: The daily motion of comets, or that of the primum mobile.]

The daily motion, which they call that of the primum mobile, was shown to be included in the motions already mentioned by the fact that most of the morning comets returned at dawn or before dawn, and were not seen at sunset or as the night came on in the place where they had been seen in the morning — as they would have had to be if they had stayed in the same place, or had moved only by their own motion — but only as daybreak approached. Just so, most of the evening comets appeared after sunset near the western horizon in such a way that, notwithstanding their effort in the order of the signs, some nevertheless went down below the western horizon before midnight, others at least before sunrise. Among them, however, some rose with a true evening rising and set with a morning setting, as the comet of the year 119; some were seen all night, or even never set at all, being enclosed within the circle of perpetual apparition, as were the comets of the years 1513, 1533 and 1556, and that of the year 1618, but only from December 20 on.

[Margin: Comets seen all night or never setting.]

But whether the comet that was seen hanging above Rome in the year 13 before Christ, and the one that in the year

[Margin: Whether comets are moved or motionless.]

of Christ 70 hung over Jerusalem for a whole year, were driven by any motion, common or proper, is unknown to us; nor is that saying of Pliny the Elder (Book 2, chapter 25), "Some move in the manner of the wandering stars, others stay motionless", necessarily to be understood of both motions.

De Arcu ſeu Via Cometarum, eiuſq. quantitate, & de Diſtantia à Sole apparenti.

On the Arc or Path of Comets and Its Size, and on the Apparent Distance from the Sun

XII. There is a great controversy, to be argued further on, in the last chapter, whether the path of all comets, or of many, runs along a straight line, as Kepler, Guiduccius [Mario Guiducci], Galileo, Cysat, Glorioso and Froidmont hold, or along a circular one, as most do; and, if along a curved one, whether in the plane of a great or greatest circle in the sphere, as Regiomontanus, Tycho, Longomontanus and many of the more recent writers contend. This cannot be adequately explained from the simple history of observations that we follow here, without trigonometry and diagrams. Yet even if we were to grant that the path runs along a straight line projected upward or downward, that apparent motion, at so great a distance from the Earth, is still similar to the motion of the planets, which we judge to take place along an arc. This apparent arc, then, was shorter in some comets and longer in others. Its size is gathered from the daily proper motions in the comet's own course, added together into one; or from the end-point at which the motion began to the end-point at which it ceased, the comet's path being marked on the surface of a globe and taken off with compasses; or else by the observer's bare estimate by eye — in the way that Seneca (*Naturales quaestiones* Book 7, chapter 29) says that the comet seen under Nero ran through half the sky in six months. For the size, then, consult the following small table, for a few comets; for the rest it has not yet been possible to determine it.

Years of Christ	Arc	Days
1472	about 170°	✠
1533	about 50°	30
1556	about 180°	✠
1577	91° 46′	79
1585	39° 21′	28
1590	42° 10′	11
1607	97° 0′	31
1618	107° 30′	28

[Margin: Distance from the Sun.]

Add, however, from Wendelinus [Govaert Wendelen] and Froidmont, that comets sometimes twist themselves like a spiral and deflect from the segment of a great circle, as did those seen toward the end in the year 1618. Apian observed the apparent distance of the head from the Sun in the comet of the year 1533 as

88°; it is false, therefore, that comets do not stand more than 30° or 60° from the Sun.

De Velocitate Cometarum.

On the Speed of Comets

XIII. Three questions can be asked about this speed: whether it was uniform or non-uniform, that is, unequal; and, if unequal, whether it was greater at the beginning, in the middle or at the end; and finally how great it was. To the first the answer is that, if one may judge of the rest from the few that are established, it was unequal — and rightly so, since not even to the planets is equality of apparent motion granted.

[Margin: Comets faster at the beginning.]

To the second I reply that some comets were fast from the start and gradually became slower: such were the comets of the years 1577, 1585, 1590, 1607 and 1618, although Kepler thought this last slower at the beginning.

[Margin: In the middle.]

Others, again, were faster in the middle than at the extremes, such as the comet observed in the year 1472 by Regiomontanus, the comet of the year 1531 observed by Apian, and the comet of the year 1556 seen by Hommel.

[Margin: At the end.]

Finally, some were faster at the end, an example of which we have in the comet of the year 1471 seen by Pontano, who, besides the words from the *Centiloquium* reported by us above under that year, sings of it thus in the *Meteora*:

> For I remember how once, fallen from the Icarian star, it bore its squalid hair before it, and with slow course bent beneath the cold orb of piercing Boreas; how from there it bore its head before it again, and with a favouring course turned to the west and pressed on with slackened reins, until it felt the fierce horns of Agenor's Bull.

The measure of the greatest speed in the comets already mentioned (for of the others it is not clear) is set out in the following small table.

Year	Greatest daily motion
1471	30° 0′
1472	40° 0′
1531	6° 0′
1556	15° 0′
1577	6° 2′
1585	2° 18′
1590	7° 34′
1607	9° 40′
1618	3° 20′

De Loco Cometarum, ſeu Diſtantia à Terra.

On the Place of Comets, or Their Distance from the Earth

XIV. We shall have to discuss this matter at greater length below, from chapter 15 to chapter 23, in paragraph 5 of which I shall present a table of the altitudes and parallaxes that some have assigned to comets. For now I shall list only the bare names of the authors, divided into three classes, as can be gathered from the passages of chapters 6 and 23 to be reviewed later.

[Margin: First class: placing all comets below the Moon.]

The first class is of those who asserted that all comets, or comets without qualification, were below the Moon. Such were Aristotle with the Peripatetics, Xenophanes, Metrodorus, Strato, Heraclides, Epigenes, Bohetus, and many of the Stoics; Regiomontanus, Pontano, Johannes Vögelin; Fracastoro; Peter Apian, Iacobus Milichius [Jakob Milich], Franciscus Iunctinus [Francesco Giuntini], Julius Caesar Scaliger; Bernardinus Telesius [Bernardino Telesio], Io. Paduanus; the Coimbra commentators [Conimbricenses]; Petrus Surdus; Chiaramonti; Cottunius, Piso; Laurentinus; Raphaël Auersa [Raffaele Aversa]; Bartholomaeus Mastrius [Bartolomeo Mastri]; Bonauentura Bellutus [Bonaventura Belluto]; Andreas Nolthius; Georgius Buschius, Theodorus Graminaeus, Nicolaus Vuinchlerus, Conradus Dasypodius [Conrad Dasypodius], Valentin Steinmetz, Georgius Henischius [Georg Henisch], Nicolaus Bazelius, Ioannes Huuernius, Thomas Erastus. But that Hájek is wrongly counted among these by Aversa and Mastri I shall show in chapter 6, scholium 5.

[Margin: Second class: placing all comets above the Moon.]

The second class places all comets above the Moon. In this class were the Chaldeans, the Pythagoreans in Italy, Democritus, Anaxagoras, Zeno, Artemidorus, Apollonius of Myndus; Seneca, Cardano, Tycho, Longomontanus, Galileo, Mario Guiducci, Io. Echius, Biancani, Santucci, Isaach Habrechtus [Isaac Habrecht]; Libavius, Iordanus Brunus [Giordano Bruno]; Oddus Patauinus; Cornelius Frangipanius, Marcellus Squarcialupus [Marcello Squarcialupi]; Ambrosius Rhodius, Thomas Fienus [Thomas Fyens]; Christoph Rothmann, once he yielded to Tycho; Erycius Puteanus; Snel, Ludouicus Columbus [Ludovico delle Colombe]; Aresius [Paolo Aresi], and Renatus de Cartes [Descartes]. That Fracastoro, Abū Maʿshar, Nicephorus, Proclus and Piso are wrongly listed among these I shall show in chapter 6, scholia 3, 4 and 5.

The third class places either some comets above the Moon and some below it, or the same ones now below and now above the Moon. In it were Mästlin, Cornelius Gemma; Hájek, Elisaeus Roeslinus [Helisaeus Röslin]; Bartholomaeus Scultetus [Bartholomäus Scultetus]; Johannes Praetorius, Philippus Apianus [Philipp Apian]; Elias Camerarius, Gulielmus Hirsaugensis [William of Hirsau], Glorioso; Clavius; Franciscus Maurolycus [Francesco Maurolico]; Adamus Tannerus [Adam Tanner]; Froidmont; Fortunius Licetus [Fortunio Liceti]; Cabeo; Rod. Arriaga [Rodrigo de Arriaga]; Franciscus Ouiedus [Francisco de Oviedo]; Resta, Balthasar Tellez [Baltasar Téllez]. But in Hájek and Scultetus it is the later, not the earlier, opinion that must be considered. That one and

the same comet was below the Moon on one day and above it on another is admitted by Kepler and Ioannes Baptista Cysatus [Johann Baptist Cysat] — though mostly above the Moon.

Figura, Color, Odor, Diaphaneitas Cometarum.

The Shape, Colour, Odour and Transparency of Comets

[Margin: Comets with short coma, and round.]

XV. The shape of comets is varied. From our history, however, some were seen round, or hairy or comate all round, or with short hair — those that some call *circaei* — such as the comet of the year 44 before Christ, and those of the years 1200, 1521, 1556 and 1585 after Christ, although this last had for two days a ray a span long.

[Margin: Acontias.]

[Margin: Lance.]

[Margin: Spit.]

[Margin: Rhomphaea.]

Some had the shape of a javelin or spear and were called *acontiae*, as in the years 348 and 76 before Christ and 1533 after Christ. Little unlike these are those that imitated either a lance, as in the year 557, or a spit, as in the years 1391 and 1558. Others had the form of a rhomphaea, as in the year 1450; others the image of a sword, a dagger or a blade, as in the years 392, 603, 662, 1526 and 1532 — those which we said are called *xiphiae*.

[Margin: Xiphias.]

[Margin: Pogonias.]

[Margin: Tailed.]

Many, as long as they preceded the Sun as morning comets, were seen bearded, or *pogoniae*, as in the years 1531 and 1618. Many evening comets that followed the Sun were tailed, as in the years 1211, 1539, 1577 and 1607, and that very comet of the year 1531 which, from morning and bearded, turned out evening and tailed. But reread what was said in chapter 2.

[Margin: Bright and shining.]

[Margin: Fiery or red.]

[Margin: Yellow.]

[Margin: Silver.]

[Margin: Leaden.]

[Margin: Black or dusky.]

The colour mixed with the light, as observed in comets, was sometimes bright and shining like the Sun, as in the year 119 before Christ and in 1264 and 1521 after Christ; sometimes fiery, ruddy and glowing red, as in the year 146 before Christ and in 662, 1526 and 1556 after Christ. In others it was yellow or golden — those they call *chryseoi* — as in the year 1533, which, however, afterwards degenerated into a blackish colour; in others silver — those they call *argenticomi* — as in the year 1200; in some it was leaden and livid, as in the year 1607. Some turned blackish, or were seen dusky with a cloudy light rather than

shining, as in the years 1477 and 1585; and finally some became of every hue and variegated in succession, as in the year 1513.

[Margin: Odour.]

A sulphurous odour could be perceived in a single comet only, that of the year 396.

[Margin: Transparency.]

Transparency seems to be attributed to all comets by Seneca, who says in chapter 26: "We send our sight through comets." Piso subscribes to this (*Speculum*, chapter 18), adducing the experiments of Father Philippus Plumeiesi [P. Philippi Plumeieſi]; and Tycho experienced the same in the comet of the year 1577, for he saw fixed stars through its tail, as he testifies in the *Epistolae*, p. 143. But transparency fits at least all those comets whose tail or beard is nothing other than a propagation of the Sun's rays through the head, shining through it as through a glass sphere, in line with what is to be said below. Seneca, however, speaks from the opinion of others, for he adds: "First, if this happens, it happens not in that part where the star itself is of dense and solid fire, but where a thin splendour runs out and is scattered into hair: you see through the intervals between the fires, not through the fires themselves."

So much for the accidents of comets that are manifest to sense and experience, except their altitude and the shape of their path, from which their place, matter and efficient cause will have to be gathered hereafter.

SCHOLIA.

Scholia

[Margin: Pliny's error over the text of Aristotle.]

I. That saying of Aristotle (*Meteorologica* Book 1, chapter 3): "Moreover, all the comets that have been seen in our times disappeared without setting, consumed little by little in their place above the horizon, so that the body of no single star was left behind them, nor of several." Pliny the Elder (Book 2, chapter 25) rendered this passage very badly, as Milichius pointed out against him; for Pliny's words are: "But a comet is never in the part of the sky that is about to set."

[Margin: Comets extinguished before setting in the time of Aristotle.]

For Aristotle did not deny that comets, even of his own age, descended below the horizon or appeared in the west. Rather, he argues against Democritus, who said that comets are an aggregate of stars and are dissolved into them, and he destroys that universal claim by the example of the comets of his own time, which, by night, before they reached the horizon, were extinguished, leaving behind them no trace of one star or of several. So Glorioso (*De cometis* Book 1, p. 10) and Cottunius (lecture 1 on *Meteorologica* 1) rightly understand and explain this text — although he also embraces the other exposition, concerning the heliacal setting, which was the interpretation of Kepler (*De cometis*, p. 96), who thought that Aristotle was arguing against the Pythagoreans, denying that

comets usually go out, and holding instead that on approaching the Sun they are hidden under its rays.

[Margin: The interpretation of Kepler, Apian, Praetorius and Tycho is foreign to the text.]

But this interpretation, though it does no harm to Aristotle's argument, is nevertheless foreign to the text. For it is clear from the text that he is arguing against Democritus, and the Greek expression signifies not an occultation or heliacal setting, which is usually called [Greek: κρύψις (krypsis, "concealment")], but a descent or sinking below the horizon; for the words of the text are [Greek: ἄνε[?] δύσεως ἠφανίσθησαν (ane[?] dyseōs ēphanisthēsan, "they disappeared without setting")], that is, "they disappeared without a descent". Apian, moreover (*Astronomicum Caesareum* part 2, chapter 1), says of the comet of the year 1531 that when it was nearer than 4° to the western horizon its flame seemed to go out. In this way he himself and Johannes Praetorius understand Pliny's words: not that comets really go out and are afterwards reborn, but that, because their light is less compact and less vivid than in other stars, they cease to appear before they set. In this sense Tycho too understands Pliny (*Progymnasmata* vol. 1, p. 400, and vol. 2, p. 450). But this happens, other things being equal, in any position of the horizon, if comets and the smaller stars are only a little way from it. Let us admit, therefore, that Pliny erred through misunderstanding Aristotle — no differently from the man who, as reported by Glorioso, said that Aristotle spoke of comets enclosed within the circle of perpetual apparition and therefore never setting: certainly a careless and crass opinion. For Aristotle relates that a certain comet of his time, setting out from the equinoctial setting point, went as far as the belt of Orion and was extinguished there; yet the whole of Orion, let alone its belt, was, with respect to Greece, outside the circle of perpetual apparition.

II. It is certain that the star of Venus near the horizon has quite often appeared among vapours so enlarged by rays, all round or toward one side, that many have believed it a hairy star, or comet. And — not to stray too far from my own memory — Claudius Achillinus [Claudio Achillini], formerly public professor of jurisprudence at Parma, came running to me at the prompting of some astrologer or other, announcing that a comet was to be seen in the evening from the tower of the Franciscan Fathers.

[Margin: Venus taken for a comet.]

I replied that it was the evening Venus, and so it was. The very same thing happened here at Bologna, so that three times there was doubt about a comet, when I asserted — and truly — that it was Venus. But whether that star of which Claudian sang in *On the Fourth Consulship of Honorius* was Venus, or a comet, or some new star —

[Margin: A star or a comet in the time of Honorius.]

> A star was seen even at midday, while the peoples marvelled, a bold star, in no way to be doubted, nor faint with blunted hair, but as great as Boötes is reckoned by night —

is quite uncertain; for we have more than once seen Venus at midday here at Bologna, and Father Grimaldi has shown it to many. Tycho, however (*Progymnasmata* vol. 1, p. 543), suspects that Claudian's portent is to be referred to the year and birthday of Honorius, which was the year 388 or 389, in which, as Cuspinianus [Johannes Cuspinian] reports, a certain star was seen to rise from the north around cockcrow, to shine like Lucifer, and to disappear within three weeks. But how does Tycho reconcile cockcrow with midday?

CAPVT V.

Chapter 5

De Prognoſticis, & Cauſa Finali Cometarum.

On the Prognostics and the Final Cause of Comets

I. A most widely received opinion has sat in the minds of mortals from every age: that comets are certain funeral torches, certain secret thunderbolts, and lamps of death rather than of life; and that they never appear without portending, with most certain terror — like the threatening eyes of divine vengeance and the tongues of an angry deity — the death of princes, plague among peoples, famine, earthquakes or dreadful storms. Very few are excepted, and even these, though they seemed favourable to someone, were equally unfavourable and hostile to others. To begin, then, with the prince of the Peripatetics: he laid it down thus in *Meteorologica* Book 1, chapter 7: "That a comet is of fiery consistence is shown by the fact that many such comets, when they come about, signify winds and droughts."

[Margin: The opinion of Aristotle and of Seneca.]

And Seneca (*Naturales quaestiones* Book 7, chapter 28) thinks that comets are at once natural signs and causes of storms, even though he thinks them stars; for he says: "Ari- stotle says that comets signify a storm, and an excess of winds and rains. Why, then, do you not judge it to be a star, since it announces the future? For it is not a sign of storm in the way that these are signs of coming rain:

Oil sparks, and rotten fungi thicken,

or the way it is a sign of a raging sea if

Sea-coots play on dry land, and the heron leaves The familiar marshes and flies above the high cloud.

It is a sign rather in the way the equinox is a sign of the year turning to heat and cold; or in the way of what the Chaldaeans chant — what a star sets down as sad or happy for those being born. To show you that this is so: a comet, once risen, does not threaten winds and rains at once, as Aristotle says, but makes the whole year suspect. From this it is plain that it did not draw from close at hand the signs it would give for what is close at hand, but holds them stored up and compressed by the laws of the universe."

In chapter 17 Seneca had assumed that the greatest part of comets labour under the infamy of misfortunes, saying: "Nor this one, which appeared under

Nero Caesar and took the infamy away from comets." Why? Because in chapter 21 he adds: "For this one, which we saw in the most joyful principate of Nero, showed itself to be watched for six months." Most joyful, really? Was this flattery not unworthy of Stoic gravity? Or had Nero not yet begun to spew the poison of his cruelty on others, so that Seneca might fear for himself? So not even this comet should have been made an exception. Cicero, *On the Nature of the Gods* 2: "Both by torches seen in the sky and by those stars which the Greeks call comets and our people *cincinnatae* [curly-haired], which recently, in the Octavian war, were the forewarners of great calamities."

[Margin: Pliny's opinion.]

Let us now hear Pliny the Elder, Book 2, chapter 25. He first says: "But the comet is for the most part a terrifying star, and not lightly expiated, as in the civil disturbance when Octavius was consul, and again in the war of Pompey and Caesar; in our own age, about the time of the poisoning by which Claudius Caesar left the empire to Domitius Nero, and then during Nero's principate, almost continuous and savage." He calls the comet continuous because it shone for six months, and savage from its effects, from Nero's savagery. It was therefore not most joyful, nor did it take the infamy away from comets — if it is an infamy to serve divine Providence. Pliny goes on to say that for the kind of portent it matters in which direction the comet darts its rays, or from which star it receives its powers, or what likeness it displays: if it has the appearance of flutes, it portends something for the art of music; if it is triangular, for talents and learning. He adds, however, that in one place in the whole world a comet is worshipped as a favourable star, because it signified both the soul of Caesar received into heaven and the monarchy of Augustus, as I reported in chapter 3 at the year 44 before Christ; and so he concludes: "And if we confess the truth, it was salutary to the earth."

[Margin: Nero's terror at comets.]

But I return to Nero, who, by the very fact that he feared the comet, made it something for others to fear. For Tacitus, in *Annals* 14, after recording certain prodigies seen in the consulship of Nero (for the fourth time) and Cornelius Cossus, adds: "Among them a star also shone out, of which the common opinion is that it portends a change for kingdoms"; and a little below: "the common people everywhere, as if he were already driven out" — namely Nero — "were asking who would be chosen." But since many comets arose throughout his principate, he used to expiate them with illustrious blood, to turn the disaster away from his own head, taught by the astrologer Babilus, as Suetonius relates in his *Nero*, chapter 36. And Tacitus again, in *Annals* 15, says: "At the end of the year prodigies are spread abroad: a force of thunderbolts more frequent than ever before, and a comet star, always expiated by Nero with illustrious blood."

[Margin: The opinion of Tacitus and Suetonius.]

Tacitus, it is true, attributes the fear of the divine power to common opinion, and so does Suetonius in his *Nero*, saying: "A hairy star, which is commonly thought to portend destruction to the highest powers." Yet in his *Claudius*,

chapter 46, Suetonius speaks outright, as if giving his own opinion: "The chief presages of his death were the rising of a hairy star, which they call a comet."

[Margin: Vespasian mocks the terror of a comet.]

Vespasian, milder and wittier, replied when a comet was pointed out to him that it concerned the king of the Persians, whose hair was more flowing, as Aurelius Victor relates; or the king of the Parthians, because "he," he said, "is long-haired, and I am bald," as Dio relates.

II. We have heard some philosophers and historians; now let us lend an ear to the poets.

[Margin: Aratus.]

Of these the most ancient, Aratus, rendered into Latin, sang thus:

A dry season often brings dreadful comets.

And elsewhere:

That a happy and golden year may fall to one who prays for it, Let no hairy star ever be seen in the air; Let not one comet shine, nor two, nor more; For a dry season breeds many comets.

[Margin: Claudian.]

For there was a proverb among the Greeks, Οὐδεῖς κομήτης ὅστις οὐ κακὸν φέρῃ [Greek: "no comet that does not bring evil"]: "No comet was ever seen that did not bring evil." With it agrees that line of Claudian:

And never was a comet seen on earth with impunity.

Manilius alludes to this in the verse:

Never has the aether blazed with idle fires.

[Margin: Virgil.]

But the prince of poets had gone before, in *Georgics* I. Among the other portents that followed the murder of Caesar, when civil war was about to rage again on the fields of Philippi, he counts this one too:

Never did more lightning fall from a clear sky, Nor did dire comets so often blaze: So Philippi saw Roman ranks clash again With equal standards, and the gods did not think it unworthy That Aemathia and the broad plains of Hemus should twice grow fat with our blood.

[Margin: Lucan.]

Lucan too, in Book I, sang this of the same portents before the civil war:

Dark nights saw unknown stars, The pole burning with flames, and torches flying Slantwise through the void of the sky, and the hair of the dreaded Star, the comet that changes kingdoms on earth.

[Margin: Silius.]

No differently Silius Italicus, first in Book I of the *Punica*:

As when a comet with flame-bearing hair terrifies fierce kingdoms, Scattering blood-red fire, the torch vomits dark, reddening Rays from the sky, and the star, flashing with savage light, Sparkles and threatens the earth with the worst.

Then in Book 8:

..... Not one comet with flashing hair, Overthrower of kingdoms, has glowed red with death.

[Margin: Tibullus.]

And before him Tibullus, Book 2, elegy 5, had called comets

..... evil signs of war.

Valerius Flaccus, *Argonautica* 6:

..... and comets, summoned by angry Jove, fatal to unjust kingdoms.

[Margin: Pontano.]

Nor is Pontano unworthy of their company: in his *Meteora* he gathers many arguments on this subject in this elegant poem:

Comets will also give you sure signs of winds. They threaten, too, the commotions of war and fierce arms, And the slaughter of great peoples, and the funerals of kings. As when, whether toward the setting of the sky or toward the rising of the Sun, They have lifted their unlucky head, and with threatening hair Have filled cities far and wide with horrible terrors: If they stand still and fix their footsteps in a fixed place, Neighbours will invade in war, and civil arms Will defile allied hands with kindred blood. But if they make toward the East, know that foreign wars Are being stirred, and that an enemy will come from foreign shores.

[Margin: The opinion of St John of Damascus.]

III. But it is better to appeal to the Fathers and theologians. Let St John of Damascus stand for them all, in Book 2 of *The Orthodox Faith*, chapter 7, where he speaks expressly of comets thus: "Comets also frequently come into being, certain signs of the death of kings. They are not among the stars that were made at the beginning of things, but by divine command are formed at certain times and dissolved again."

[Margin: Tertullian's opinion.]

Speaking generally of these and similar portents, Tertullian, *To Scapula*, chapter 3, concludes after a long discussion of the matter: "All these are signs of the imminent wrath of God, which we must, in whatever way we can, both announce and proclaim, and meanwhile pray that it be local. For the universal and supreme wrath will be felt in its own time by those who interpret its examples otherwise."

[Margin: St Augustine's opinion.]

Yet one could say of these what St Augustine said, in the book *On the Destruction of the City* (tome 9), of a certain comet or chaumate [?]. When it threatened the city of Constantinople, around the year 496, a revelation was made first to a certain soldier and through him to the bishop, and the bishop called the people together and drove them to penance and to seek the sacraments. "For God," says St Augustine, "wishing to terrify the city and by terrifying to amend it, by terrifying to convert it, by terrifying to cleanse it, by terrifying to change it, to his faithful servant, a soldier, as they say, etc."; and after a little: "At the beginning of the night, as the world was already darkening, a fiery cloud was seen from the East, at first small; then gradually, as it came over the city, it grew, until it hung hugely and terribly over the whole city. A horrible flame seemed to hang there, nor was the smell of sulphur lacking. Everyone fled to the church; it could not hold the multi- tude. Everyone

wrested baptism from whomever he could. Not only in the church but through houses, streets and squares the saving help of the sacrament was demanded, so that the wrath might be put to flight — not, to be sure, a present wrath, but one to come. The people, moreover, fled with Arcadius outside the city and flocked together in one place to pray to God, and they did not return into the city until that cloud vanished into smoke and they were rid of the danger." St Augustine concludes: "What shall we say? Was this the wrath of God, or rather his mercy?" and after a little: "Exactly so are hands usually raised to strike, and, once the one who was to be struck is terrified, called back by pity: so it happened to that city." Read the same author, *City of God* Book 21, chapter 8, Book 2, chapter 23, and Book 3, chapter 1, together with Nicephorus, Book 3, chapter 4.

Nor does the oracle of the Erythraean Sibyl, who is also called the Babylonian, seem contemptible. It is read in Book 4 of the *Sibylline Oracles*; to whatever time it finally refers, granted that it seems to look to the last times of the world:

Then a huge Sign will be given from heaven, For a most brilliant star will shine out, Very like the bright one of the Crown, flashing in the shining sky, And for many days will be seen by the world, a thing to watch: But under the setting Sun a star called a comet Will shine, a herald to mortals of the sword, And of famine and death, and of the destruction of illustrious men And of great leaders and nobles.

And elsewhere:

But from the fourth year after a huge star has shone, A Star will come from the heavens which, hurling flame, Will flash through the great sea and the deep Pontus.

Granted that Tycho, *Progymnasmata* tome 1, page 815, draws this last oracle to the comet of the year 1577, and the first to the new star seen in Cassiopeia in the year 1572, because four years passed between the one and the other. Yet the same Sibyl sings of happier things after that time:

..... Again the God who dwells in great heaven Will preserve the remnants of men utterly, everywhere. Then peace and the highest wisdom of truth will flourish, And the fruit-bearing earth will bear more abundant crops, No longer divided, nor to be enslaved from then on.

For the other Fathers, who refer such portents to divine Providence threatening mortals for their good, see our Father Adam Tanner in his *Dissertation on the Heavens*, question 7, paragraph 4; he too admits that this is a way of philosophizing worthy of a Christian.

Astrologorum Placita.

The Tenets of the Astrologers

IV. It neither befits me, nor have I the leisure, to follow up or pursue at length the opinion of the astrologers on the presages of comets; yet it should not be passed over entirely.

[Margin: Ptolemy's opinion.]

Their leader, Claudius Ptolemy, in the *Centiloquium*, aphorism 98, decrees thus: "Shooting stars [traiectiones] and comets [crinitae]," in Greek διάττοντες

καὶ κομήται [Greek: diattontes kai komētai, "shooting stars and comets"], "hold the second place in judgements" — for in aphorism 96 he had given the first and chief place to eclipses.

[Margin: The prognostics of shooting stars.]

Then in aphorism 99 he adds: "Shooting stars indicate dryness of the air. If they are carried toward one part, they indicate wind from that quarter; but if in different directions, they indicate the diminishing of waters, disturbances of the air, and the incursions of armies." These shooting stars are the ones Virgil described in the *Georgics*:

And long trails of flame grow white behind them.

And Pontano, in his *Meteora*, following Ptolemy:

Moreover, where the glowing fire has lifted itself at night, Marking the clear air with a bright trail, From there the wind will rush as soon as its gates are open.

Finally Ptolemy, in the last, or 100th, aphorism: "Comets whose interval from the Sun is eleven signs: if they appear in the angles [cardines], the king of some kingdom, or one of the princes of the kingdom, will die. But if in a succedent place, the things that pertain to his treasuries will go well, yet he will change his government. And if in a cadent place, there will be diseases and sudden deaths. But if they move from the west to the east, a foreign enemy will overrun the regions; if they do not move, the enemy will be a provincial one." We have already seen this opinion expressed by Pontano in the verses quoted at no. 2.

[Margin: Ptolemy on the distance of comets from the Sun, explained and defended.]

At this place many attribute to Ptolemy so great a distance as to have him declare that all comets are eleven signs distant from the Sun. But he meant nothing of the kind. Rather, he attributed visibility to those alone that are so distant, and — compared with those that are less distant — the power of signifying the death of kings, because of their approach to the mean conjunction with the Sun, which they approach by their proper motion in the order of the signs when it is a single sign away. For if they recede from its wide [platica] conjunction, they do not have that power, granted that they may be visible; and if they are less distant from the Sun than one sign, or thirty degrees, they do have a great power of themselves, but accidentally they cannot signify it, because, overwhelmed by the light of twilight and the nearness of the Sun, they do not appear. For them to have the power of signifying the death of kings and princes, then, two things are required: that they approach conjunction with the Sun, and yet be so far from it that they can appear on the eastern horizon. I later found nearly this interpretation in Pontano on that aphorism.

[Margin: Ptolemy's second opinion.]

Again Ptolemy, in the *Quadripartite Construction*, or *On the Judgements of the Stars*, Book 2, chapter 9, text 53, declared: "Comets too must be observed, whether they shine at eclipses or at any other time, in universal considerations — those of the kind called beams, trumpets, jars, and the like," as Cardano's

version has it. But my Greek codex, with the notes of Porphyry, has ξιφοειδέσι, καὶ εἰδολομόρφοις, καὶ τὰ τοιαῦτα [Greek: xiphoeidesi, kai eidolomorphois, kai ta toiauta, "sword-shaped, and image-shaped, and the like"], that is, "sword-shaped, or image-shaped, etc. For the working of their nature is of the property of Mars and Mercury: of wars, heat, turbulence, and what usually follows these." And text 54: "The places in which these things will happen are designated both by the parts of the zodiac in which such stars have gathered and by the inclination of the comet and by its form. If they have a human form, they portend for humans; if a beast's, for beasts; if a beam's, for stakes or plants. The length of the duration you will know from the duration of the appearance: a short one indicates a short duration of the effects, a long one a long. From the schematism of the aspect, or the configuration to the Sun, we shall know whether the effects and the beginning of their working will follow at once or somewhat later. For when these portents are oriental, and precede the Sun and appear in the East, they signify the speed of the coming event; occidental and vespertine ones, its slowness." This, namely, is how I think the text should be translated from the Greek, since Cardano's version is both defective and corrupt. Yet his notes and Porphyry's on these two texts may be consulted, and Pontano's on the aphorisms cited.

V. We have heard the master; are the disciples not to be heard as well? But the matter is long-winded, and stuffed and infected with a great deal of vanity. Anyone who wishes, and is permitted, may consult Leopold of Austria, treatise 5, *On the Revolutions of Years*, and, standing for them all, Francesco Giuntini, after his *Astrological Calendar*, in the annotation on comets. There he sets out distinctly and at length the properties and prognostics of comets, running through each of the planets whose nature they imitate, and each of the signs of the zodiac in which they appear. So, to take at least a taste of it:

[Margin: The prognostics of a Saturnine comet.]

A Saturnine comet, that is, a leaden and livid one, appearing in the horoscope of someone's nativity, signifies melancholic and chronic diseases, that is, slow and long ones; in the horoscope of the beginning of the year, plagues, want, rainstorms, fogs, snows and lasting ice, locusts, etc.; and for men subject to the rule of Saturn, an incitement to and increase of spite, voracity, solitude, austerity, envy, avarice, sadness, obstinacy and very great malice.

[Margin: The prognostics of a Jovial comet.]

A Jovial comet, that is, a silver one, portends fertility and healthy rains, but also pleurisies, ophthalmias, measles, pneumonias, stones, colic pains, lethargies and lientery, especially for men of a Jovial nature, that is, beneficent, magnanimous, truthful, clement, etc.

[Margin: What a Martial comet portends.]

A Martial comet, which he says is ruddy and has the form of a pole or a spit, signifies the effects that usually proceed from hot dryness: winds, earthquakes, storms, thunder, lightning, dysenteries, erysipelas, very acute fevers, choleric phrenitis, and then incitement to brawls, seditions, wars, etc., especially for men

of a Martial nature, namely the red-haired, slender, talkative, restless, arrogant, crafty, fiery, untamed, eager for revenge, etc.

[Margin: What a Solar comet portends.]

A Solar comet, that is, a golden one rivalling the Sun, portends the death of princes, or at least tumults and a change of state, or the danger of a change, and also heats and droughts.

[Margin: A Venereal comet.]

A Venereal comet, that is, a yellow and reddish one, threatens the stomach, the womb and the kidneys, and threatens dropsy, paralysis, apoplexy, a change of laws, and of commonwealths. A Mercurial comet, or blue one, called *Dominus Asconae*, threatens phrenitis, lethargy, epilepsy, famine and plague, especially for the ingenious, the eloquent, the witty, the shrewd, the suspicious, etc. Finally, a Lunar comet portends some evil for the female sex and for the common people: sterility, light wars, dropsy, and diseases arising from excessive moisture. Comets of a mixed nature, which arise from the conjunction of two or more planets, are thought to presage mixed events as well. I forbear, moreover, from the examples of Alliacensis [Pierre d'Ailly], Nyphus, Giuntini, Surdus and Praetorius, by which they try to establish the power of comets to portend evils; for far more are available to us from the history set out in chapter 3. Nor do I heap up here the bundle of prognostics with which, on the occasion of the comets of the years 1577, 1607 and 1618, they filled Europe with innumerable pamphlets and with terrors that were for the most part false.

Meteorologorum Recentiorum Opinio.

The Opinion of the More Recent Meteorologists

[Margin: The opinion of Julius Caesar Scaliger.]

VI. As one turns from the astrologers to the astronomers and natural philosophers, the first to come to meet him is Julius Caesar Scaliger, in Exercise 79 against Cardano. He holds that comets are neither signs nor causes of calamities, and that it is ridiculous madness to think that a king is killed by a comet, let alone that a province is overthrown. For he says that a comet is not a sign of any evil in the way smoke is a sign of fire, but only through a certain coherence from a common cause — the way a hen's cackling is a sign of the egg she has laid, because the hen is the cause both of the laying and of the cackling, while neither depends on the other. And he adds: "Many comets, then, have been seen by us that were followed by no destruction of mortals anywhere in all Europe; and many very famous men have met their fate, many principalities have been overthrown, most illustrious families ruined, without any indication from a comet." He therefore thinks Cardano is joking when he writes that princes die more easily than other people in dry seasons, because of foods that are fragrant and seasoned with spices, or because they are worn out by cares and vigils: as if comets did not arise in winter too, or as if many of the common people or of the country folk who eat garlic, onions, bulbs, leeks, salt and

pepper — or smiths, rowers, glassmakers and reapers — were not more disposed to the diseases that spring up from an excess of heat and dryness.

[Margin: The opinion of Carolus Piso.]

A little more distinctly, Carolus Piso, in his *Mirror of the Comet*, from chapter 28 to the end, teaches that the troubles comets threaten are neither so certain nor so common to all regions of the earth, and that the comet is not the cause of evils but a sign of a concomitant or future dryness. For comets arise only from a great quantity of exhalations boiling upward, chiefly from the sea, and from lands heavy with sulphur and hot fat, and so they are generated by a concurrence of causes that brings dryness to the lands. The comets themselves, however, do not dry out the regions over which they pass, nor bring drought upon them: first, because they are very high and stand at an immense distance; second, because they change course not only from day to day but from hour to hour, and do not stand long directly over one region; and finally, because many comets have rather had very cold winters. "But neither," he says, "are they necessarily signs of famine. For dryness does not always bring famine, even if we granted that comets, dissolved into embers and ashes, fall back to the earth — just as the embers neither of Etna nor of Vesuvius harm the fertility of the crops and the greenery of the Sicilian or Neapolitan countryside." From this he infers that they are not necessary indicators of plague either, especially of the plague that usually arises from famine, not among the wealthy but among the common people and the poor. Plague that comes from an infection of the air arises from an extraordinary putrefaction owing to heat in moisture, as Hippocrates teaches in *Epidemics* 2, and Galen throughout his works; and it occurs when the south winds prevail. It therefore has nothing in common with comets, which signify an excess of heat and dryness, unless south winds prevail from some other cause. He grants, indeed, that winds are signified and even produced by comets, since their fumes, dispersed after the burning, are spread into the air; but he holds that for the most part the boilings of the sea — from which come floods and earthquakes about maritime places — are indicated by comets, not produced by them, because comets indicate winds shut up in the bowels of the earth and sea; for he denies that comets arise without a huge quantity of winds.

In his last chapter, moreover, he contends that the comet is unjustly ill spoken of as a torch of wars or a regicide, on the ground that a change of state and of laws is usually feared under a new king. For granted that princes are more delicate and more elated, and have humours more apt to inflammation, yet the headlong anger of the kings of Europe, especially the Christian ones, is rarely the cause of war; and if it were, they themselves are mostly out of the weapons' range; and most of them live soberly, or at their physician's nod. So he bids princes be free of fear from the comet of the year 1618.

[Margin: Piso's prudent [?] conclusion.]

At last, however, he concludes the chapter thus: "I think it must be held that by divine Providence various disasters usually fall upon the human race, so that

the fear may indeed reach many, but the punishment few. For it is not my mind to regard such portents as mere empty bugbears; and for my part, let this opinion sit more deeply in everyone's minds: that grave evils and calamities are portended by them, by which GOD — who both hears and sees what we do, and is also judge and avenger — usually avenges the injuries done to his name. Meanwhile, let fathers of families and stewards, warned by the comet, use their stored crops and fodder prudently and more sparingly, as befits thrifty people; and let magistrates and princes take timely care for the serenity and healthiness of the air, and strive with all care and zeal to turn future diseases and wars away from their own heads. Finally, let the preachers of the divine word be permitted seriously to rebuke and admonish the profligate, the gluttons and the impious: that the comet, from that most lofty station, announces and proclaims far and wide that rivers of eternal fire run hidden in the abyss of the earth, in whose never-dying flames wicked heads pay to divine justice the deserved penalties of their wickedness and impiety — penalties most bitter and immortal."

[Margin: Froidmont's opinion.]

VII. Froidmont, in *Meteorologica* Book 1, chapter 3, after much discussion with Thomas Fienus [Thomas Fyens], concludes that a comet is not a physical cause of calamities but rather a sign at the pleasure of God, who uses the comet, although it is a natural effect, to terrify and amend mortals in some place, as he used the rainbow to signify his covenant with our race. And although certain comets have been favourable to some people, or seemed so, they are yet not sent for this end, but to announce sadder things; and it would be an endless task to patch together the deaths of princes and the calamities that have happened with comets announcing them beforehand. Celestial comets, moreover, are more apt to portend these things than elementary ones, because the former, being higher and longer-lasting, are seen by more people and spread the fear of the divine power more widely; whereas elementary comets, according to Aristotle's opinion, indicate, but do not produce, the exhalations from which they arise and, from these, other related effects.

[Margin: The opinion of Cottunius.]

Cottunius, however, in lecture 33 on *Meteorologica* Book 1, toward the end, denies that disasters or the death of princes are presaged by a comet — granted that the death of princes is usually more noticed than that of common people — because those disasters did not happen when comets arose, or did not happen more than at other times; and conversely they have happened with no comet preceding. He grants, however, that comets are signs of blasts and winds, and of what is connected with them; and that if they are northern, they signify sterility arising from dryness, the stepmother of crops, and earthquakes, storms and fits of anger; but if southern, pestilences and floods.

[Margin: The opinion of Franciscus Resta.]

Franciscus Resta, *Meteorologia* Book 1, tract 1, chapter 8, says at the beginning that, of many effects attributed to comets, comets are nothing but signs, and perhaps lying ones. Yet he is of the same opinion as Froidmont: namely, that

God uses these natural effects as signs, by divine institution, to strike a salutary fear into us, as he once used the rainbow to relieve the fear of the flood; and yet that we do not stray from truthful philosophy if we say that celestial comets are formed by the ministry of angels for this very end.

[Margin: The opinion of Father Cabeo.]

Father Niccolò Cabeo, on *Meteorologica* Book 1, text 37, question 9, admits that some comets are unfavourable and some favourable, both of themselves and for everyone, and accidentally, because nothing is ever so harmful to one that it does not benefit another, and if one man loses an empire, another gains it. He then subscribes to Cardano: elementary comets, from the great quantity of sulphurous spirits that they summon, produce or signify droughts and an intemperate air, by which weaker bodies are more easily harmed, as well as those more delicately nourished, or subject to cares and vigils — of which kind he thinks princes are, and many children and delicate women; but the deaths of these are not noticed in the same way as those of princes. To celestial comets he attributes, in due proportion, as much power as the astrologers attribute to the planets themselves — on the hypothesis, however, that the astrologers have a sufficient induction for establishing general rules from experience. But at least they are signs that God displays, to give to those who fear him

a signification, that they may flee from before the bow; so that the comet is, as it were, a tongue of heaven, by which we are warned to flee from the wrath to come. So much for the principal meteorologists of our century.

Aſtronomorum Recentiorum Opinio.

The Opinion of the More Recent Astronomers

[Margin: Tycho's opinion.]

VIII. What the Phoenix of astronomers, as some call Tycho, has to sing on the prognosis of comets must be sought in volume 1 of the *Progymnasmata*, from page 800. There, treating of these and of the new stars alike, he condemns those who, because of the errors of the astrologers and the weakness of the human mind in attaining certain presages of these portents, take from them all energy and power of signifying — as if God and Nature were playing idly with these new spectacles and wished nothing to be foretold to the world. It is no wonder, however, he says, if the foreknowledge of them is conjectural [ſtochaſtica] and probable only by mere conjectures, since not even the motions of the stars that have shone perpetually in heaven from the origin of the world — let alone their particular faculty of influence — are sufficiently understood. The rest that he appends there pertains not to comets but to the prognostics drawn from the new star of the year 1572 seen in Cassiopeia, which is to be discussed in the following section.

[Margin: The opinion of Longomontanus.]

Tycho's pupil and assistant Longomontanus, in the Appendix to the *Astronomia Danica*, chapter 7, rebukes Thomas Erastus and others, who allow the ordinary stars a slight power of producing or signifying effects, but comets

none. For God and nature, he says, do nothing in vain, and God orders to a good end all the evils that comets signify: namely dearth of provisions and sterility, so that the earth, as though keeping a holiday, may meanwhile be prepared for an abundance of crops; storms of the air, so that the air, stirred up in this way, may come out purer; and diseases and wars, so that, with wicked men exterminated, the world may be renewed — according to those verses of Palingenius [Marcellus Palingenius Stellatus]:

[Margin: Palingenius's fine reflection.]

> *Such men, then — nay, shadows — at a fixed time God sends to arms, to be slain by a cruel death. So he purges the human race, and for many years those who remain live cheerfully, this part removed, until evil weeds grow up again, once more to be plucked out by bitter war and cut down by the sword. Then once again Jupiter skims the unclean pots; then once again, with furies let loose, he sweeps away the refuse.*

[Margin: An argument for divine Providence in the very calamities.]

Meanwhile, the innocent are harmed by these disasters only through a wrong opinion, because that golden saying of Chrysostom stands: *"No one is harmed except by himself."* And although these new phenomena are contained within the bounds of nature as to their matter and efficient cause, yet as to their end they are chiefly destined, by divine foresight, to signify the overthrow and changes of commonwealths and to prick the excessive security of men; and comets are prophets like Jonah, but mute, who announce the divine wrath and are signs of a world that is to perish. He then passes to chapter 8. He refers the variety of effects, whether from the stars or from comets, to the varying disposition of regions and of living things, or to the power of free will, which cannot be compelled by them but only inclined; and he teaches much toward the general use of astrology, which, however, he says must keep within the bounds of general judgement, on account of that first pronouncement of Ptolemy in the *Centiloquium*: *"Only those inspired by the divine power foretell particulars."* After this, in chapter 11, he erects a celestial horoscope for the rising of the comet of the year 1607, for September 15 at $15^{h}\ 24^{m}$ and a pole height of 56°. He considers that it arose at the mean opposition of Jupiter with the Sun, and nearly in the quartile of Jupiter with Saturn, and in a quartile aspect of the Sun with Mercury; that Mercury was lord of the ascendant, and Mars not far from the ascendant; the Saturnine colour of the comet; and finally the full moon that followed next, on the 25th, and its horoscope. He thinks it signified the winter of the year 1608, so savage in the Low Countries, Germany, Switzerland, France, Spain and Italy that many animals and men perished of cold, although it afflicted Iceland and Norway more mildly; and from it the dearth of provisions, and the chronic diseases, especially the quartan fevers so frequent in Germany from that time, and the wars of the year 1610 in Tartary, and things like these — extending the significations of this comet up to the year 1612. Erecting likewise a horoscope of the comet of the year 1618, both at its rising, for November 11 at 11^{h} before noon, and at the full moon that followed

next, on November 21, he contemplates its rising in the quartile aspect of the Sun and Jupiter, with the malefics Saturn in the 5th house, Mars in the 8th and Mercury in the 9th. He says that many ominous things were foretold by it, and that it was fatal to Archduke Maximilian of Austria (who had, however, already died on September 5), to the Empress, to Anne, Queen of Britain, and to the Emperor Matthias, who died in the year 1619 on March 10, Old Style. From here he does not hesitate to range out from this portent to other evils to be announced, especially in the year 1624; for although, according to the tenets of Ptolemy, this comet, having risen in the morning, would have had swift significations, yet from the size of its tail and body, and from the constancy and duration of its motion, they could extend up to that year. But it is wearisome to reduce to a summary the long heap of divination affected by this astronomer — a heap of words rather than of things; and this itch for divining you may also see, and lament, in Kepler.

[Margin: Kepler's opinion.]

IX. Kepler, however, treating the physiology of comets, puts forward many shrewdly devised ideas. For he says that comets were made for this end: that the ethereal region should not be empty, for so long a time, of its own monsters, so to speak, just as the Ocean is not empty of larger fish that go raiding on rare excursions; and that, the thick fat of the aether being gathered into one abscess as a kind of excrement, the celestial air may be purged — lest there should often happen what the histories testify once happened, namely that the Sun, for some days, as in the year 1547 from April 24 to 28, or for a whole year, as in the year of the murder of Julius Caesar, shone malignly, dulled to a rusty or blood-red colour. He then grants that comets, though rarely, reach down to the earth with their tail and bring in pestilence; but that comets for the most part move above the Moon, and that therefore the things attributed to them concerning the signification of winds and earthquakes are futile, since they rest on two false opinions, namely that comets burn and that they are below the Moon. The genuine cause, therefore, why a comet, though absent, changes the state of sublunary things he holds to be that animal faculty of the sublunary world by which, through its sympathy with heaven, he thinks minerals, rivers and rains are also produced; for this faculty is moved objectively by comets and stirred up to generate those things that bear an analogy to comets, and to rouse men's passions toward war. Yet for a comet to appear and signify in definite places, its trajectory must be directed and destined by some mind supremely intelligent in geometry and in the whole world — whether it be God, or another spirit, good or evil — which produces comets in the aether, like whales in the sea, as monsters and portents of heaven, or leads them, once produced, to definite limits. With this set out first, in Book 3 he passes to the significations of the comet of the year 1607, to which he attributes drought and dearth of provisions and many other evils to follow from it. But those words on page 111 are worth noting: *"For why should I alone speak against the universal consent of mankind, which each person confirms according to his capacity with very*

frequent histories? Therefore I affirm that this comet was displayed by God among the stars to be a testimony to each and every one of their mortality, and that they might be admonished that God has decreed shortly to remove from this world a good part of the human race, of every condition alike, by whatever law of fate: this being certain in general, but most uncertain as regards individuals. For the strong have no privilege over the weak, nor the young over the old, nor the seer over those who consult him. The celestial herald therefore warns each person to be reconciled to God for his own sake, to prepare himself for his departure, and so to settle these earthly affairs as he wishes to see them kept, once settled, after his decease." No less prudently he adds that, if these warnings are obeyed, it will come about that whoever death snatches away will depart happily, and that whoever survives will not take it ill to have been so happily deceived by the astrologer. He explains himself further, and denies that a comet has the power of killing men: rather, by the comet's indication, the universe and heaven itself are corruptible, and so a man must bear the condition of his mortality with equanimity when he sees a comet, a blemish of heaven, and must prepare himself for a departure that will not be so far off. And, he says, the histories, and the wisest historians and philosophers, testify that hardships follow shining comets — not only through the death of princes and the occasion it gives for revolution, but in a thousand other ways. Further on, after much else, he adduces the troubles and disasters after the comets that arose in the year 1531 in Switzerland, Saxony and the Baltic Sea; in the year 1532 in Westphalia and the Low Countries; and in the year 1533 in

[Margin: Years of Christ.]

Wittenberg and elsewhere; in the year 1538 in England; in the year 1539 in Meissen, Thuringia, the Mark of Brandenburg and Brunswick; in the year 1558 again in England, France and the Low Countries; in the year 1569 in Saxony; in the years 1577 and 1580 in very many places in Germany; in 1582 and 1585 at Cologne, at Aachen and in France; in 1590 and 1593 in Styria on the Rhine, and here and there in Germany; and in 1596 in Poland, Sweden and Styria. There are countless things, moreover, that he tries to predict by conjecture about the regions of Europe and about persons in general; but at last, recognising that his effort is vain, he concludes Book 3 in these words: *"And so I stop soothsaying, since even this may be too much."* He then appends the events after this comet of the year 1607, and relates that a very harsh and long winter followed, but that the crops came up excellently in Germany; that deaths were not heard of so frequently; and that of the monarchs of Europe none died except Mahomet. The other things he relates are separated from this comet by too great an interval of years, or are not so remarkable that the comet should seem to have been destined for them.

[Margin: Kepler's prognostic on the comet of the year 1618.]

X. There follows Kepler's judgement on the comet of the years 1618 and 1619. From its size and its tail — the longest of all that have shone within these 150 years — he says it is likely that sublunary Nature was violently struck, together with that faculty which resides in the globe of the earth and which, through

sympathy, rests on imagination; that from this a great part of the Bohemian and the imperial army perished of an unusual disease, and that a very snowy winter of two months followed. He then repeats from history the disasters of the comets of old, which we indicated in chapter 3.

[Margin: The opinion of Father Cysatus.]

XI. Our own Cysatus, in the *Mathemata* on comets, page 79, thinks it probable that comets portend great evils to the world and to mortals, but uncertain ones; that it is rash to assert what they portend, or to whom; and that, although they are natural, by divine providence they are nevertheless an omen of great calamities and of God's anger against the guilty — granted that the calamity does not reach everyone, but perhaps only those over whose heads the comet hangs perpendicularly, or above whose horizon it remains for many hours.

[Margin: The opinion of Father Guinisius.]

By contrast, our own Vincentius Guinisius, likewise, in his oration on the felicity of the comet, contends that the comet of the year 1618 promises no more unhappiness than happiness, because many comets have been favourable to many princes — for example, to Alexander the Great, Mithridates, Augustus and others — and with other arguments that we have already indicated above.

[Margin: Our opinion.]

Our opinion, finally, is this. If comets are elementary, they certainly signify naturally some notable change brought about in sublunary nature, whose effects have not yet entirely ceased but will come forth not much later, according to the disposition of the matter and the concurrence of other causes. But if they are celestial, they are certainly ordained by divine providence: first, so that mortals may raise their eyes to heaven and acknowledge that there are many things whose cause and nature they are forced not to know, and so lower their pride and their fasces before the divine wisdom; and then, so that they may expect from this something great, either in themselves and their own regions or in others — for the most part an evil, which will either actually come about if the Deity is not appeased, or is only threatened, so that through fear of the Deity they may thus be turned to sounder counsels; and so that from this, at least, they may conceive beforehand some sample of those prodigies of which our Saviour speaks in the Gospel: *"There shall be signs in the Sun and the Moon and the stars, etc."* and *"the stars shall fall from heaven, etc."* Prudently, therefore, on the occasion of the comet of the year 1460, that most holy man Ioannes de Capistrano [Giovanni da Capestrano], preaching, announced calamities to come unless mortals seriously amended their life and morals. For this agrees both with the history already set out in chapter 3 and with the wisest men, not only pagan but Catholic too. But to wish — I do not say to divine, but to attempt it, and to publish prognostics of comets to the common people from the rules of Ptolemy or of other astrologers — I judge utterly empty, and rather a provocation of a Deity already angered than the obedience or expiation owed to him. For a prognosis of this kind would require that several comets of the

same condition in every respect had appeared, whose ensuing effects or events had for the most part been very similar. But if you read the history of comets attentively, no comet can yet be shown to have shone similar to another in figure, place, motion, duration, season of the year, etc.; nor any comets, similar among themselves in a number of conditions, whose effects, or the events they signified, were also similar. Yet for the benefit of those who wish the comets favourable to some to be distinguished from the unfavourable ones, or who wish to see those that preceded the death of princes, it has pleased us to set out under one view the comets listed below, from our catalogue in chapter 3; a fuller knowledge of them must be sought from that same chapter 3.

Cometæ Faufti aliquibus. — *Comets favourable to some*

Years before Christ	**Persons to whom they were favourable**
356	Alexander the Great, then born
336	Alexander the Great, entering on his reign and on victory over the Persians
130	Mithridates, then born
119	Mithridates, entering on his rule and on victories from it
44	Augustus, taking from it an omen of empire
Years of Christ	
130	Usuardus, King of England, victorious
405	Stilicho, conquering the Getae
725	Charles Martel
800	Charlemagne, then created emperor
1200	The empire of the Tartars, beginning
1283	Adalbert, defeating Adolf
1456	Tamerlane, triumphing over Bayezid; and Io. Corvinus, repelling him
Years of the comets before Christ	**Leading men who died in the same or the following year**
336	Philip, father of Alexander the Great
336	Darius Codomannus, King of the Persians
44	Gaius Julius Caesar
Years of Christ	**Princes who died in this or the following year**
13	Agrippa
14	Emperor Augustus
54	Emperor Claudius
70	Emperor Vitellius
80	Emperor Vespasian
213	Emperor Severus
340	Emperor Constantine the Younger
363	Julian the Apostate
392	Emperor Valentinian
454	Emperor Theodosius
571	Alboin, King of the Lombards
603	Emperor Maurice
814	Emperor Charlemagne
837	Pippin, King of the Franks
839	Emperor Louis the Pious

Cometæ Fauſti aliquibus. — *Comets favourable to some*	
882	Emperor Louis the Bavarian
983	Emperor Otto II
1009	Pope John XVIII
1066	St Edward, King of the English
1106	Emperor Henry IV
1169	Malcolm, King of Scots
1214	William, King of Scots
1264	Pope Urban IV
1301	Andrew, King of Hungary, dies without children
1314	Philip the Fair
1341	Andronicus, Emperor
1375	Charles IV
1402	Tamerlane, and Galeazzo Visconti [Galeat.Vicecomes]
1450	Amurath, Emperor of the Turks
1456	Ladislaus, King of Poland
1457	Alfonso, King of Naples
1477	Charles of Burgundy
1505	King Philip
1506	Alexander, King of Poland
1512	Pope Julius II, and Bayezid, Emperor of the Turks
1521	Pope Leo X

Reſiduum Tabulæ præcedentis. — *Remainder of the preceding table*	
Years of Christ	**Princes who died in this or the following year**
1533	Clement VII; Alfonso, Duke of Ferrara; and the Duke of Milan
1558	Emperor Charles V; the Queens of Poland, England and Hungary
1559	Pope Paul IV; Henry, King of France; the King of England; the King of Portugal; the King of Denmark; the Doge of Venice; Ercole, Duke of Ferrara; and 15 cardinals
1577	Sebastian, King of Portugal
1585	Osman, Emperor of the Turks, and Stephen, King of Poland
1590	Pope Urban VII, and Archduke Charles
1607	Charles, Duke of Lorraine
1618	Emperor Matthias

CAPVT VI.

Chapter VI

Proponuntur ſummatim Opiniones de Materia Loco & Cauſa Efficiente Cometarum, ſumma fide ac diligentia conquiſitæ.

The opinions on the matter, place and efficient cause of comets are set out in summary, gathered with the greatest fidelity and diligence.

CAPVT VI.

I. Many have reduced all the opinions on the matter, place and effecting cause of comets to three main heads, but with differing distributions.

[Margin: Seneca's distribution of the opinions on comets.]

Seneca, indeed, in *Natural Questions* Book 7, chapter 19, does so thus: *"Some, then, think that there are no comets, but that appearances of them are produced by the reflection of neighbouring stars, or by the conjunction of stars that cohere. Some say that they exist, but have their own courses, and come out into the sight of mortals after fixed periods. Some say that they exist, but are not such that you could give them the name of stars, because they slip away, do not last long, and are dissipated in a short space of time."* As if he were saying: some say that a comet is a mere appearance, and that nothing new is produced or distinct from the known bodies; some, that comets are perpetual stars, but rarely appearing; some, that they are produced anew and do not deserve the name of star, because of their swift destruction.

[Margin: Piso's distribution.]

Carolus Piso, on the other hand, in the *Mirror of the Comet*, chapter 1, recognises only three probable opinions: namely those that affirm the comet to be *either some particle of heaven, whether a fixed or a wandering star; or an imperfect mixed body, and that truly on fire; or merely shining and flashing with another's light, namely the Sun's, which, having passed through it, then pours itself out further and farther beyond.*

[Margin: And Glorioso's.]

Giovanni Camillo Glorioso, in Book 1 of *De Cometis*, chapter 2, distributes the primary opinions into three classes in a slightly different way. The first, he says, is that of the Chaldaeans, who assert that comets are wandering stars. The second is that of the Peripatetics, who hold that comets are kindled terrestrial exhalations. The third and newest is that of certain more recent astronomers, who think that comets consist of ethereal matter, but illuminated by the Sun. For a comet is either an emphasis [emphaſis] — the appearance of a mere image; or a real hypostasis, but of an eternal body, that is, a star, or a symphasis [ſymphaſis] of stars; or finally a real one, but of a temporary body, either kindled or only illuminated. So he.

[Margin: Cottunius's distribution.]

After these, Io. Cottunius, in Lecture 32 on Book 1 of the *Meteorologica*, reduces to three heads the 25 opinions on comets collected by Fortunio Liceti in Book 2 of *De novis astris et cometis*, according to three general controversies, namely on the place, on the matter and on the tail of comets. As to place, there are three opinions: one of those who put all comets below the Moon, another of those who put them all in the heavens, and a third of those who put some above the Moon and some below. Again, as to matter, a comet is either something eternal or something temporary: if eternal, either one star or several stars together; if newly generated, it is either kindled in sublunary matter, or only illuminated, whether in elementary matter carried up into the heaven, or from celestial matter.

[Margin: Longomontanus's distribution.]

Longomontanus, in the Appendix to the *Astronomia Danica*, chapter 2, does it otherwise: he reduces the opinions to three kinds, but subdivides each in two. The first kind is taken from the matter: for a comet arises either from celestial or from terrestrial matter. The second is from the form of its appearance: for a comet is produced either by mere inflammation, like a kindled fire, or by mere illumination from the Sun or the other stars. The third is from place: for a comet is either above the Moon or below it, or sometimes above and sometimes below.

[Margin: Our division and subdivision.]

To me, however, setting aside the fables, of which I shall speak in the Scholia, all the opinions seem reducible to three classes, though these are to be subdivided. For a comet is either a mere appearance, or something real and eternal, or something real and newly made — which was more or less Seneca's partition. If it is something merely apparent, it is either an emphasis arising from the reflection, or also the refraction, of light in celestial or elementary matter, or a symphasis of several known stars. If it is something real and eternal, it is either some perpetual planet, unknown however and rarely appearing to us, having such a figure of itself, or illuminated by the Sun and from there taking on various forms; or it is a heap of several old small stars and unknown little planets coming together into one extraordinary planet. If, however, it is something real but newly made, it is either produced from elementary matter, by the generation of fire or by mere illumination, whether it remains below the Moon or ascends above the Moon; or it is produced from celestial matter, either by substantial generation or by mere alteration — namely of density, opacity and light — and it remains above the Moon or is carried below it; or it is produced from nothing by mere creation. Or, finally, some comets are celestial in place and origin, and some elementary. Thus 12 opinions will arise, to be set out distinctly in a moment.

[Margin: 1. The opinion of mere appearance through the reflection of light.]

II. The *first* opinion was that a comet is not something real and distinct from bodies already existing, but a mere ἔμφασιν [Greek: ἔμφασιν (emphasin, "appearance, reflected image")], that is, an appearance, arising from the reflection, or also the refraction, of the rays of the Sun or of the Moon, in much the same way as the rainbow, the halo and parhelia. So Panaetius held, of whom Seneca says in *Natural Questions* Book 7, chapter 30: *"With Panaetius, and with those who wish it to appear that a comet is not an ordinary star but the false appearance of a star, we must diligently discuss whether every part of the year is equally suited to producing comets."* He had indicated the other authors of this stamp, without naming them, in chapter 19, saying: *"Some, then, think that there are no comets, but that appearances of them are produced by the reflection of neighbouring stars."* In the same way Plutarch too, in Book 3 of *De placitis philosophorum*, chapter 2, after certain unnamed persons who thought that a comet is *"a reflection of*

our sight toward the Sun, very like the images in mirrors", a little later nevertheless names others akin to this opinion, but belonging rather to opinion 6.

[Margin: 2. The opinion of the co-appearance of several known stars.]

III. The *second* opinion likewise denies that comets are something newly existing on high; for it says that a comet is a mere σύμφασιν [Greek: σύμφασιν (symphasin, "co-appearance")], or co-appearance, of several stars already known, joined in a quasi-corporeal conjunction, as the astrologers say, and so presenting the appearance of a longer star. Of this opinion I have so far found no certain author. For Seneca, *Natural Questions* Book 7, chapter 19, says only: *"Some think that there are no comets, but appearances of them; or that cohering bodies are produced by conjunction."* And when he had said in chapter 3, *"Democritus too, the subtlest of all the ancients, says he suspects that there are many stars that move; but he gave neither their number nor their names, the courses of the five stars not yet being understood,"* he says later, in chapter 11: *"Let us leave Epigenes and pursue the opinions of others"*; and a little after, naming no one, he adds: *"This one thing must be agreed: that a new appearance of a star is seen beyond the usual, drawing round it a scattered fire. Some of the ancients favour this explanation: when one of the wandering stars has applied itself to another, their two lights being merged into one, the appearance of a longer star is produced. Nor does this happen only when a star touches a star, but also when it has approached; for the interval between the two is lit up by both and set on fire, and makes a long fire."* This opinion he at once attacks in chapter 12 with arguments that are truly very easy and obvious; for that notion is so crass as to be unworthy of Democritus, whom he had called the subtlest of the ancients, and who, as Cicero asserts in *Tusculan Disputations* Book 5, *"made such progress in every kind of philosophy that a Pentathlos, or Quin-*

quertio, he could be called." So Democritus spoke of planets, or of unknown stars, since, on the testimony of Diogenes Laërtius in his *Life*, he had been instructed by the Chaldaeans, from whom he learned theology and astrology; and the Chaldaeans held that comets were wandering stars, distinct from the seven planets commonly known. Accordingly, although Aristotle (*Meteorologica* Book 1, chapter 4) ascribes to Anaxagoras and Democritus this opinion of the co-appearance of planets already known, Cottunius — most devoted to Aristotle as he is — holds in Lecture 30 on *Meteorologica* Book 1, and Mastrius [Bartolomeo Mastri] with him (disputation 4 on the heavens, question 2, article 4), that Democritus and Anaxagoras were not of this opinion but of the fourth of those to be reported below. And rightly, granted that the Coimbra commentators (tract 3 on the *Meteorologica*, chapter 1), Resta (tract 1 on the meteors, chapter 3) and Glorioso (Book 1, chapter 9) held the opposite; as did Alexander, Philoponus, Olympiodorus and St Thomas, who take Democritus and Anaxagoras to mean the five lesser planets, namely Saturn, Jupiter, etc. Nor did Ptolemy, *On the Judgements of the Stars* Book 2, text 53, if he said that comets arise from Mars and Mercury, mean that they arise from the conjunction of those planets as from elements intrinsic to the comet itself, but as from concurrent efficient causes.

[Margin: 3. The opinion that a comet is an extraordinary planet.]

IV. The *third* opinion was that a comet is a wandering star, or some planet — not one of the seven already commonly known, but other, unknown ones, which appear rarely: either because of their small distance from the Sun; or because of their very great distance from the Earth, which they approach after long intervals and so become visible; or because parts of the heaven or of the air that are more transparent run between; or for some other cause. So held the Italic sect of the Pythagoreans, of whom Aristotle says in *Meteorologica* Book 1, chapter 6: *"Some of the Italians, those called Pythagoreans, say that the comet is one of the wandering stars, but that it does not appear except after a long time, and stands out only for a short time, which also happens to Mercury; for because it rises only a little above the horizon, it often does not appear, except after a long time."*

[Margin: The opinion of the Pythagoreans.]

[Margin: And of Hippocrates of Chios and Aeschylus.]

The same author adds that Hippocrates of Chios and his disciples, Aeschylus first among them, held this, although they said that this planet which is the comet does not have its hair [coma] of itself, but from moisture tinged by the force of the Sun's colour and refracting the light; and that for this reason it appears neither at the summer solstice nor within the tropics, because there the moisture is burned up by the Sun's passage, but outside the tropics; and rarely towards the south as well, because the greater part of the circle on which that planet is carried is below the horizon. And Plutarch, *On the Opinions of the Philosophers* [*De placitis*] Book 3, chapter 2: *"Some of the Pythagoreans said that the hairy star is one of those which do not appear continually in the heaven, but which, at fixed times, having completed a certain circuit, are accustomed to rise again."* And a little after: *"Diogenes: that hairy stars are truly stars."*

[Margin: Diogenes.]

[Margin: Favorinus.]

[Margin: The opinion of the Chaldaeans and of Apollonius of Myndus.]

For Favorinus too, in Aulus Gellius Book 14, chapter 1, argues sharply that there are many wandering stars still unknown; and the Chaldaeans, Apollonius of Myndus and Artemidorus (in Seneca) thought the same, and finally Seneca himself. For in *Natural Questions* Book 7, chapter 3, he has this: *"Two who say that they studied among the Chaldaeans, Epigenes and Apollonius of Myndus — the latter most skilled in examining natural things — disagree with each other. For Apollonius says that comets are placed by the Chaldaeans among the wandering stars and that their courses are known; Epigenes, on the contrary, says that the Chaldaeans have grasped nothing about comets."* And chapter 17: *"Apollonius of Myndus is of a different opinion. For he says that a comet is not made out of many wandering stars, but that many comets are wanderers. 'It is not,' he says, 'a false appearance, nor fire spread out where two stars meet; a comet is a star of its own, like the Sun or the Moon. Its form is this: not confined to a round, but taller and drawn out lengthwise. Its course, moreover, is not open to view: it cuts through the higher regions of the world, and appears only when it has come to the lowest point of its course. Nor should we think that the one seen under Claudius was the same as the one we saw under*

Augustus; nor that the one which appeared under Nero Caesar, and took away the ill repute of comets, was like the one which, after the murder of the deified Julius, at the games of Venus Genetrix, emerged about the eleventh hour of the day. They are many and various, unequal in size, unlike in colour,'" etc. *"'They diminish and increase their light, as other stars do, which are brighter when they have descended; and they are seen larger from a nearer place, smaller and dimmer when they recede, because they withdraw further.'"* Thus far Seneca on the opinion of Apollonius.

[Margin: Posidonius favouring the Pythagoreans.]

Posidonius too seems to favour this opinion, or that of the Pythagoreans, who held that comets, like Mercury, do not appear unless they pass out from the Sun's rays on a wider circuit; for Seneca says in the same Book 7, chapter 20: *"We do not see many comets, because they are obscured by the rays of the Sun; Posidonius reports that, when the Sun was eclipsed, a certain comet appeared which the nearby Sun had covered."*

[Margin: The opinion of Artemidorus.]

But Artemidorus was plainly of that opinion. Of him Seneca, in the same Book 7, having argued in chapter 12 against those who say that a comet is a conjunction of several of the known planets, at once adds in chapter 13: *"Against this, Artemidorus says the following: that not only these five stars run their courses, but that they alone have been observed. Innumerable others, however, are carried along out of sight, unknown to us either because of the dimness of their light or because their circles are so placed that they are seen only when they have come to the extremity of them. Therefore certain stars,"* he says, *"new to us, run in between, which mingle their light with the stationary ones and put forth a greater fire than stars have."* For this reason Artemidorus held that these unusual planets draw their hair from their own light joined with the light of the fixed stars.

[Margin: Seneca's view.]

Finally, Seneca himself adhered to the opinion of the Chaldaeans and the Pythagoreans, leaving Zeno aside for the moment; for he says in Book 7, chapter 22: *"I do not agree with our people; for I do not think that a comet is a sudden fire, but that it is among the eternal works of nature."* And chapter 23: *"No fires endure except in their own: I mean those divine fires which the world holds as eternal, because they are its parts and its works."* And a little below: *"A comet has its own seat, and therefore is not quickly driven out, but measures out its space; nor is it extinguished, but passes beyond."* Then, meeting an objection — *"If it were a wandering star,"* he says, *"it would be in the zodiac [Signifer]"* — he replies: *"Who sets one limit for the stars? Who drives divine things into a narrow space? These very stars which alone you believe to move have circles that differ one from another. Why then should there not be some which have withdrawn onto a path of their own, far from these? What reason is there that the heaven should be impassable in some part? But if you judge that no star can touch anything but the zodiac: a comet can have so broad a circle that it still falls into the zodiac with some part of itself — which is not necessary, but possible."* Hence in chapter 24 he rises higher and continues: *"Consider whether this does not better befit the greatness of the world, that it be divided into many paths,*

and not wear down this one track while lying idle in its other parts. Do you believe that in this greatest and most beautiful body, among innumerable stars which adorn the night with varied beauty and do not allow the air to be empty and inert, only five are permitted to exert themselves, while the rest stand still, a fixed and motionless people? If anyone at this point asks me, 'Why then has their course not been observed, as that of the five stars has?', I shall answer him: there are many things which we believe to exist, but what they are like we do not know"; and he brings the example of our soul and of God. And chapter 25: *"Why then do we wonder that comets, so rare a spectacle of the world, are not yet held by fixed laws, and that their beginnings and ends are not known, since their return is from vast intervals?"* etc. *"The time will come when daylight and the diligence of a longer age will draw into the light the things that now lie hidden. A single age is not enough for the investigation of things so great, even were it wholly free for the heavens."* And finally chapter 26: *"Someone will one day show in which parts comets wander, why they go so far apart from the others, how large they are and of what kind. Let us be content with what has been found; let posterity too contribute something to the truth."* The tail of comets he ascribes, in the same chapter, to the splendour of the comet: *"For who will grant you that comets are long? Their nature, like that of the other stars, is a globe; but their brightness is extended. Just as the Sun sends its rays far and wide, yet the Sun itself has one form and the light that flows from it another, so the body of comets is itself rounded, but its splendour appears longer than that of the other stars."*

[Margin: Summary of these opinions.]

Accordingly the Italic Pythagoreans, the Chaldaeans, Apollonius of Myndus, Artemidorus, Seneca and perhaps Posidonius held that a comet is an extraordinary planet, and that comets do not appear for a long time either because they lie hidden within the brightness of the nearby Sun, as the Pythagoreans and Posidonius held, or because of the size and slowness of their circle, near whose perigee alone they can be seen, as the rest held; and that their tail is either the very form of the planet itself, as Apollonius held, or comes from moisture lit by the Sun's rays, as Artemidorus held, or from the splendour flung out by the comet, as Seneca would have it.

[Margin: Cardano.]

Among the more recent authors, this opinion was approved by Cardano, *De subtilitate* Book 4, who says, on the supposition that no generation takes place in the heavens, that comets are stars of a rarer substance, which

[Margin: Oddus.] [Margin: Renatus.] [Margin: Tannerus.] [Margin: Frangipanius.] [Margin: Columbus.] [Margin: Raymundus.] [Margin: Vallesius.] [Margin: Echius.] [Margin: Liceti.] [Margin: Fienus.]

cannot be seen except in very dry and clear weather; Oddus of Padua, *On the Plague* Book 2, chapter 4; Descartes, *New Philosophy* Book 3, number 132; and our Tannerus [Adam Tanner], *On the Heavens* p. 148, who attributes to the size of the epicycles the fact that comets come near us so rarely and become visible; Frangipanius, when he says of comets that they are tiny stars which are not seen except when their light is increased; Ludovicus Columbus

[Lodovico delle Colombe], who says that they are above the ninth heaven and are not seen except when a denser part of the heaven glides beneath them; Annibal Raymundus [Annibale Raimondo], in Resta, tract 1 on the *Meteorologica*, chapter 1: that they become visible because of fumes drawn up to them; Vallesius [Francisco Vallés], because of a denser part running beneath; Liceti, when they have fallen into the denser lower parts of very many spheres, along the perpendicular; Io. Ekius, that they are seen at the time when a rarer part of the heaven glides beneath. For to all of these, among the other opinions, this one seemed probable, as it did also to Thomas Fienus [Thomas Fyens], in Froidmont, Book 3 of the *Meteorologica*, chapter 2, article 2.

[Margin: 4. The opinion of a comet composed of many stars.]

[Margin: Anaxagoras, Democritus and Zeno.]

V. The *fourth* opinion was that comets are an aggregate of many small stars — eternal ones, or ancient ones — coalescing into one, and afterwards vanishing when they separate. For it is of these, and not of the commonly known planets, that Anaxagoras and Democritus are to be understood, as we showed in number 3; of them Aristotle says, *Meteorologica* Book 1, chapter 6: *"Anaxagoras, then, and Democritus say that comets are a co-appearance of wandering stars, when, because they come close, they seem to touch one another."* And a little below: *"Democritus contended for his opinion; for he says that, when comets dissolved, certain stars appeared."* Plutarch, too, is to be taken in the same way when he says of comets in *De placitis* Book 3, chapter 2: *"Anaxagoras and Democritus: that it is a synod of two or more stars illuminating one another."* Indeed Seneca, Book 7, chapter 3, testifies that Democritus spoke of stars unknown in number and in name, in these words: *"Democritus says that he suspects there are more stars which run their courses, but he set down neither their number nor their names."* Zeno held the same, as Seneca relates in Book 7, chapter 19, saying: *"Our Zeno is of this opinion: he judges that stars come together and join their rays with one another; that from this fellowship of light there arises the image of a longer star."*

[Margin: Probable to Tanner, Cysat, Liceti, Resta, Cardano, Bruno.]

This opinion Tanner, *On the Heavens* p. 150, and Cysat, *On Comets* chapter 7, thought very probable; and Liceti, Book 5, chapters 52 and 55, and Resta, *Meteorologica* Book 1, tract 1, chapter 3, adopted it as regards celestial comets; and before them Cardano, *De varietate rerum* Book 1, chapter 1, when he admitted that comets are knots formed from many small stars intersecting one another, but lit by the rays of the Sun and drawing a tail; and Iordanus Brunus [Giordano Bruno], in the book *De innumerabilibus*. Liceti, however, held this of the celestial comets, for he does not deny that some are below the Moon.

[Margin: 5. The opinion that a comet is a sublunary meteor and an exhalation catching fire.]

VI. The *fifth* opinion is that of Aristotle, *Meteorologica* Book 1, chapters 7 and 10, and of very many interpreters there, and the common opinion of the Peripatetics; but above all of the Coimbra commentators (tract 3 on the *Meteorologica*, chapter 3), of Cottunius (Lecture 31 on *Meteorologica* 1), and of

Chiaramonti in the *Antitycho*, Book 3, last chapter, and in all the other booklets he published on the sublunary seat of comets or in defence of the *Antitycho*.

[Margin: Aristotle.] [Margin: Coimbra commentators.] [Margin: Cottunius.] [Margin: Chiaramonti.] [Margin: Giuntini.] [Margin: Pontano.] [Margin: Regiomontanus.] [Margin: Vögelin.] [Margin: Milich.] [Margin: Nolthius.] [Margin: Vuinchlerus.] [Margin: Dasypodius.] [Margin: Steinmetz.] [Margin: Bazelius.] [Margin: Henisch.] [Margin: Huuernius.] [Margin: Graminaeus.] [Margin: Erastus.] [Margin: Surdus.] [Margin: Paduanus.] [Margin: Piso.] [Margin: Aversa.] [Margin: Mastri.] [Margin: Belluto.]

In this the Peripatetics were followed, among the astronomers or astrologers, by Giuntini in his *Adnotatio de Cometis*; by Pontano in the last aphorism on Ptolemy's *Centiloquium*; by Regiomontanus and Io. Vogelinus [Johannes Vögelin] in their observations of comets, the former of the comet of the year 1572, the latter of that of 1532; by Iacobus Milichius [Jacob Milich] on Pliny Book 2, chapter 25; and (if we believe Angestus, *On the Properties of Forms* Book 2, p. 34) by all the ancient astronomers. To these must be added the more recent: Andreas Nolthius, Nicolaus Vuinchlerus [Nikolaus Winckler], Cunradus Dasypodius [Conrad Dasypodius], Valentinus Steinmetz [Valentin Steinmetz], Nicolaus Bazelius, Georgius Henischius [Georg Henisch], Io. Huuernius, Theodorus Graminaeus, Thomas Erastus, Petrus Surdus, Antonius Paduanus and Carolus Piso, in their tracts on comets; Raphaël Aversa [Raffaele Aversa], *Philosophia* tome 2, from question 32; and Bartholomaeus Mastrius and Bonaventura Bellutus [Bartolomeo Mastri and Bonaventura Belluto], disputation 4 on the heavens, question 4, article 2, number 36.

The opinion of Aristotle and of these authors, then, is that a comet is a fiery meteor [meteoron], newly generated from a great quantity of exhalations raised up from the earth and the sea as far as the highest region of the air. This quantity, when that air is dispersed, is separated off and, well compacted, acquires consistency; and, carried round by the sweep of the primum mobile by which the highest air is revolved, it catches fire and burns for a long time, as long as that sulphurous, unctuous, fatty and oily or nitrous quantity of exhalations (these epithets are used not by Aristotle but by his followers), gathered either from the beginning or successively, supplies tinder or food for the flame; and when this fails, comets gradually diminish and at last are extinguished. Granted, Aristotle admits that some comets, which seem to move with the motion of some star, acquire hair or tresses from rays refracted in vapours drawn upward, and that exhalations suitable for this are separated off by the force of that star. By the same reasoning he thinks that, by the force of the very many and great stars which are above the Milky Way [lacteus circulus], those exhalations are separated off and intensified, so as to produce there a kind of perpetual comet — for that is what he calls the Galaxy in that chapter 10. In the same way he also affirms that one of the stars in the hip of the Dog was observed with some sort of hair, and that a comet followed its motion.

Pontano, however, Milich, Mastri and Piso hold that comets are not swept along by the daily motion of the air, but are kindled, or set aflame, by the stars and above all by the Sun; others, by the sphere of fire; others, by antiperistasis, as happens with lightning and shooting stars. Piso, moreover, places hairy comets in roughly the middle region of the air, but tailed ones in the highest, or even a little below the Moon.

[Margin: Strato.] [Margin: Bobetus.] [Margin: Xenophanes.] [Margin: Epigenes.]

Among the more ancient authors, certain others seem to be brought under this head, of whom Plutarch, *De placitis* Book 3, chapter 2, reporting the opinions on hairy stars, says: *"Strato: that it is the light of a star enclosed in a dense cloud, as happens also with torches; Epigenes: that it is a spirit having something earthy in it, carried aloft and catching fire there; Bobetus: that liquefied air presents an appearance of this kind; Xenophanes: that they are clusters or flashings of kindled clouds."* But on Epigenes Seneca is more explicit, Book 7, chapter 3: *"Epigenes, on comets: that they seem to be kindled by a certain whirlwind of agitated air"*; and chapter 6: *"There are,"* says Epigenes, *"two kinds of comets. Some pour out their heat on all sides and do not change place; others stretch out a wandering fire in one direction like hair, and pass by the stars, such as the two seen in our own age. The former, hairy on all sides and motionless as well, are generally low, and are formed from the same causes as beams and torches, and from the disorder of turbulent air, which turns over with it many dry and moist things exhaled from the earth. For spirit forced through narrow places can kindle the air placed above it, full of nourishment suited to fire,"* etc.

[Margin: Perhaps the Stoics too.]

Finally, there are also referred to this head those — whether they were Stoics or Latins — of whom Seneca wrote in the same Book 7, chapter 21: *"Our people therefore hold that comets, like trumpets and beams and the other portents of the sky, are created from dense air; and that for this reason they appear most often around the north, because there is a very great deal of sluggish air there."* And, giving their mind, he adds that a comet creeps to where the vein of its fuel leads, and does not advance like a star but feeds like a fire, etc.

[Margin: 6. The opinion that a comet is a sublunary meteor or exhalation, but illuminated by the Sun.]

VII. The *sixth* opinion is that a comet is indeed a sublunary meteor made of subtler exhalations [halitus] or vapours, but not so much inflamed as illuminated by the Sun because of a certain transparency, like glass phials tinted with a yellow or red colour and full of water; or, as Scaliger says in *Exercitation* 79 against Cardano (Telesius [Bernardino Telesio], *On Comets* chapters 2 and 3, favours him), and Apian in *On the Comet of the Year 1531*: that it is a subtle vapour carried up by its own lightness, or drawn by the stars into the highest region of the air, like a smoke or soot resembling twilight, but so thinned that it receives and then transmits the rays of the Sun. Thus, on the testimony of Plutarch, *De placitis* Book 3, chapter 2, Heraclides Ponticus thought that a

comet was a very high cloud lit by light; and Metrodorus, that it was the Sun striking more violently into the clouds and sparkling.

[Margin: Scaliger.] [Margin: Apian.] [Margin: Telesius.] [Margin: Heraclides.] [Margin: Metrodorus.]

[Margin: 7. The opinion that a comet is an earthly exhalation, but raised above the Moon and illuminated.]

VIII. The *seventh* opinion is that a comet is indeed made of elementary matter, that is, of subtler exhalations, which strive upward by their lightness so far that they climb above the Moon, and by their transparency drink in the rays of the planets, especially of the Sun, and transmit them behind them into a tail and beard. So Marius Guiducius [Mario Guiducci], in his treatise *On Comets*; Galileo, in Dialogue 1 *On the System of the World* and in his *Trutinator* [*The Assayer*]; Aresius, Johannes Praetorius and Christoph Rothmann, in his treatise on comets and in the letters to Tycho, pp. 91 and 161 — although Rothmann thinks that these exhalations are raised by angelic power right up into the heaven, to terrify mortals. Tycho, however, in the letters, p. 161, indicates that Rothmann retracted and conceded that comets not only are, but are also generated, above the Moon.

[Margin: Galileo.] [Margin: Rothmann.] [Margin: Aresius.] [Margin: Praetorius.] [Margin: Guiducci.]

[Margin: 8. The opinion that comets are made from celestial matter, con-]

IX. The *eighth* opinion is that comets are made anew from celestial matter, not through the generation of a new substantial form, but through condensation with a mixture of opacity and

[Margin: densed and illuminated.]

transparency, so that they receive and transmit the light of the Sun; or through an addition of light made in parts of the heaven.

[Margin: Libavius.] [Margin: Liceti.] [Margin: Tanner.] [Margin: Glorioso.] [Margin: Resta.]

So holds Libavius in a separate treatise, part 2, in the chapter on comets; and Liceti accepts this opinion above all others, *On Comets* Book 5, chapters 52 and 55; so too Tanner, *On the Heavens* p. 148, and Camillus Gloriosus [Glorioso], *On Comets* Book 5, chapter 1, as regards motionless comets and new stars; and Franciscus Resta, *Meteorologica* Book 1, tract 1, chapter 4. Froidmont had once embraced the same opinion, but afterwards rejected it, Book 3, chapter 2, article 5. If, however, this condensing [addensatio] is made from the small stars of the Milky Way, Liceti denies that it should be called condensation in the strict and proper sense. Froidmont, for his part, thinks that Tycho held this opinion, that comets were made through the condensation of the Milky Way.

[Margin: 9. The opinion that comets are generated anew from celestial matter.]

X. The *ninth* opinion holds that comets are generated anew in the heaven from celestial matter, and afterwards corrupted. Some hold this of all comets:

so Tycho indicates here and there in the letters and in tome 2 of the *Progymnasmata*, chapter 6 and the last chapter (for he uses the word "generation"), and Longomontanus in the Appendix to his *Astronomia*, chapter 3. Others hold it of very many, or without specifying: so Kepler, *Epitome of Astronomy* Book 1, pp. 55 and 57, and in the *Harmonice*, p. 242, but more fully in *On Comets* Book 2; Io. Bapt. Cysatus [Johann Baptist Cysat], *Mathemata* on comets, chapter 7; Thomas Fienus, Marcellus Squarcialupus [Marcello Squarcialupi], D. Habrechtus, Erycius Puteanus, Ambrosius Rhodius and Villebrordus Snellius [Snel], in their treatises or booklets on comets.

[Margin: Tycho.] [Margin: Longomontanus.] [Margin: Kepler.] [Margin: Cysat.] [Margin: Fienus.] [Margin: Puteanus.] [Margin: Squarcialupus.] [Margin: Habrechtus.] [Margin: Rhodius.] [Margin: Snel.] [Margin: Mästlin.] [Margin: Gemma.] [Margin: Röslin.] [Margin: Hájek.] [Margin: Scultetus.] [Margin: Glorioso.] [Margin: Froidmont.] [Margin: Cabeo.] [Margin: Teles.]

The same was held — not of all comets, but of some — by Mästlin, *On the Comet of the Year 1577*; by Cornelius Gemma in his *Physical and Mathematical Proof* [*Apodixis*] on the comet of the year 1577; by Helisaeus Röslin in his writing on the same comet; by Hájek, *On the Comets of the Years 1577 and 1580*, having retracted his earlier view, in which he had maintained that all comets are made from sublunary matter and are below the Moon, as Tycho relates, tome 2, p. 367; and by Bartholomaeus Scultetus, who himself also abandoned his earlier opinion on comets. Finally the same was judged — not of all comets, but only of the celestial ones (for they also admit elementary or sublunary comets) — by Io. Camillus Gloriosus [Glorioso], *On Comets* Book 5, chapter 1, as regards moving and wandering comets (for he holds that the motionless ones are made by condensation); by Froidmont, *Meteorologica* Book 3, chapter 2, articles 6 and 7; by Cabeo on *Meteorologica* Book 1, text 37, question 6; and by Baltazar Tellez [Baltasar Teles], physics disputation 40, section 1, and disputation 47, section 2.

[Margin: Various modes of this generation.]

Not all, however, explain this generation in the same way. For Tycho and Longomontanus think that comets are made from that matter of the heaven which is in the Milky Way, as being more nearly prepared and disposed for it, and that they are bodies not blazing, but transparent and translucent. Kepler, however, thinks that the ethereal air is crammed with thicker fumes and soots exhaled by the planets. Like excrements, these are gathered into one, like an abscess [apostema], by a certain animal faculty of the heaven, so that they may not cloud over the Sun and stars any longer — as he teaches they have done more than once; and at last, when by their transparency they have transmitted the rays of the Sun (from which they get their tail), they are dispersed. So the heaven is from time to time purged of these impurities; and as whales and monsters are begotten in the sea, so comets are begotten in the heaven in that extraordinary way.

[Margin: What the solar spots are.]

But Fienus, Snel, Puteanus, Cysat, Froidmont and Glorioso hold that comets, as to origin and matter, are made in the same way as the solar spots or faculae. Thus Snel calls them κατακαύματα [Greek: katakaumata, "scorchings"; glossed on the page by the Latin *exustulationes*], or scorchings emitted by the Sun, or rather breathed out from the surrounding [peristatic] matter of the Sun and blown far off elsewhere. Cysat holds that many of those faculae are gathered into one, and that for this reason a compact nucleus made of small stars is seen with the telescope, and these are afterwards dispersed. Puteanus, most elegantly, says that a comet is *"a citizen of the heaven, an offspring of the Sun, a part and a birth of the aether; a torch in its light, a wanderer in its motion; with a body of its own, a light not its own, a motion its own and not its own"*; and that it is generated from the corpuscles which spot the Sun, but purged and illuminated by the Sun. Froidmont holds that they are not breathed out by the Sun, lest this universal lamp of the world be exhausted, but drawn out from the other planets. Our Cabeo, by contrast, though he had said that the faculae of the Sun are spots, but now purged and illuminated by the Sun, and that comets are sometimes made from them, nevertheless denies that these effluvia or volatile soots are exhaled from the Sun alone, or chiefly from the Sun; rather, they are gathered from all the other stars, at least the wandering ones, towards the Sun, and are from there purged again into faculae and become comets. Finally, our Teles too recognizes that comets are generated from the exhalations of all seven planets. As to the remaining authors, it is not clear enough to me in what way they understood this generation of comets.

[Margin: 10. The opinion that comets are of celestial matter, but have come down below the Moon.]

XI. The *tenth* opinion — held so far, as far as I know, by no one except Kepler, as I shall say in the last chapter, but conceivable nonetheless — is that comets are made anew from celestial matter, but that some are sent down below the Moon, just as Opinion 7 said that they are made from elementary matter but ascend above the Moon. And certainly, if they were effluvia of the planets, there would be no necessary cause why those exhaled from the Sun, Venus, Mercury and the Moon at their perigees could not sometimes be carried below the Moon.

[Margin: 11. The opinion that comets are made by a supernatural creation or generation by God, directly or through angels, and are moved by the angels.]

XII. The *eleventh* opinion is that, if not all comets, then at least many, are either created by God from nothing, as Mästlin suspected (in Liceti), or else are made, and afterwards moved wherever it may please, through angels, out of whatever matter may please, celestial or elementary, with any form and figure whatever imposed on them, to terrify mortals and to signify the calamities discussed in chapter 5. And in this way all questions about comets are easily solved.

[Margin: St Damascene.]

St Damascene [John of Damascus] seems to approve this opinion, *On the Faith* Book 2, chapter 7, when he says: *"Comets too are frequently produced, certain signs of the deaths of kings; they are not of those stars which were made at the beginning of things, but are established by divine command at a fitting time and dissolved again"*; and he compares them with the star of the Magi as regards their supernatural generation.

[Margin: Tanner.] [Margin: Arriaga.] [Margin: Oviedo.]

The same opinion Tanner defends as highly probable and worthy of a Christian philosopher, *On the Heavens* from p. 141 to p. 147. Ambrosius Rhodius goes over to it absolutely, as does Arriaga [Rodrigo de Arriaga] in his single disputation on the heavens, section 2, subsection 3, to whom Oviedus [Francisco de Oviedo] subscribes (single controversy on the heavens, point 3, paragraph 3); and so does Gulielmus Hirsaugiensis [Wilhelm of Hirsau] in his *Institutes of Philosophy and Astronomy*, whose definition is: *"A comet is a fire kindled according to the will of the Creator to signify something."*

[Margin: Rothmann.] [Margin: Froidmont.] [Margin: Resta.]

As to the motion of comets, and their direction by angels towards the region that Divine Providence has appointed, this was the view of Christoph Rothmann; nor did it wholly displease Froidmont, *Meteorologica* Book 3, chapter 4, article 4; and it did please Franciscus Resta, tract 1 on the *Meteorologica*, chapter 6, where he teaches *a fortiori* that these temporary planets need the help of ruling angels, since not even the others are moved from within, and there is nothing that is, or is moved, in the heaven which is not subject to the administration of angels.

[Margin: Cabeo.]

And Cabeo, *Meteorologica* Book 1, text 37, question 8, having considered the conditions of the motion of comets, says that no sufficient cause can be assigned why they move as they do, unless recourse is had to some Intelligence moving freely towards a predetermined end.

[Margin: The view of Tycho and of Regiomontanus.]

Whether we speak of the making or of the motion of comets: although Longomontanus says in the Appendix, chapter 4, that our God does whatever he wills in the heavens, but mostly uses secondary causes, and in producing comets uses chiefly the conjunction, opposition or quadrature of Mars and Mercury, he nevertheless quotes words of Tycho commending Thaddaeus Hagecius [Hájek], which go far to support this 10th opinion. For Tycho, *Progymnasmata* tome 1, p. 513, speaks thus of Hájek: *"At the end of the same chapter he touches on some points concerning the celestial generation of comets. Although he frankly confesses that he does not know it, he does not on that account deny that it can happen, but ascribes how it comes about to the wonderful works of GOD, and asserts that it is far removed from our full knowledge — which I too do not deny,"* etc. *"Meanwhile I willingly agree with those who place comets among the secrets of nature not yet explained, and who assert that they arise from hidden causes, as Regiomontanus proves from Māshāʾallāh [Meſhala]."* Further, Regiomontanus says in his little work on

the comet of the year 1472: *"Comets come from hidden causes of nature; of which opinion is Meshala the Arab."* Here Seneca would exclaim, Book 7, chapter 30: *"How many comets besides these go about in secret, never rising for human eyes! For God has not made all things known to human eyes."*

[Margin: 12. The opinion admitting some comets above the Moon, others below the Moon.]

XIII. The *twelfth* opinion is not distinct from all the preceding ones, but rather distinguishes celestial comets from elementary, or sublunary, ones as to place and matter. For it admits that some comets are made below the Moon from exhalations of the terrestrial globe, whether inflamed or illuminated, but that others are above the Moon and made of celestial matter, in the ways reported in number 10. In this class are Mästlin, in Tycho, tome 2, p. 254, and, in the same author, Gemma, Röslin, Scultetus, Hájek, likewise Kepler in the *Hyperaspistes*, p. 82, and in *On Comets*, p. 99; Tanner, *On the Heavens*, question 7; Liceti, *On New Stars and Comets*, Book 5; Froidmont, *Meteorologica* Book 3, chapter 1, articles 1, 3, 4, 6; Cabeo on *Meteorologica* Book 1, text 37, questions 2, 4, 5, 6; Habrectus, in Longomontanus, in the Appendix, chapter 2; Resta, Book 1, treatise 1 of the *Meteorology*, chapters 3 and 4; and Rothmann, in Froidmont. Whether Aristotle should also be counted among these authors, as Liceti would have it, I shall discuss in Scholium 2; and whether Abū Maʿshar, Proclus, Haly and Nicephorus should be, as some think, in Scholia 3 and 4.

[Margin: The method to be followed from here on in this controversy.]

We shall therefore set out the foundations of these opinions, together with the arguments for and against them and the solutions of those arguments, so that this synopsis of the reasons may make it easier to pass judgement on them. Then we shall weigh separately those arguments that need deeper examination and that bear on several opinions at once: namely, on the motion of comets, whether curvilinear along a great circle or rectilinear; on the altitude of the regions of the air; and on the parallax and altitude of comets. The problems, however, and most of the geometrical figures that belong to this controversy and to a more refined examination of parallaxes, we shall set out from chapter 16 to chapter 22.

SCHOLIA.

Scholia.

[Margin: Bodin's ravings about comets.]

I. It was shameful indeed to count, among opinions in any way probable, the ravings of Bodin, who says in Book 2 of the *Theatre*: "The opinion of Democritus came to my mind, so that I think that comets are the minds of illustrious men, which, after flourishing on earth through countless ages, at last, when about to die, celebrate their final triumphs, or are called back into the starry heaven like splendid stars. And for that reason famines, epidemic diseases

and civil wars follow, as though cities and peoples were deserted[14] by those excellent leaders and governors who used to calm divided furies." He does add that he does not wish to assent to anything on such difficult matters; but by the very fact that he puts these things forward and does not condemn them, he fails in the office of a good statesman. He has therefore deservedly been condemned himself by Franciscus Resta, *Meteorology* Book 1, treatise 1, chapter 1, and by Froidmont, Book 3, chapter 2, article 2, who calls him a political fool, a rabbinical philosopher, and a scourge of the Peripatetics [Peripateticomastix].

[Margin: Comets are not the souls of illustrious men.]

And indeed, on what ground does he impose this foolishness on Democritus? Is it because Democritus thought that comets were celestial bodies and stars unknown to us? And what are those countless ages in which the heroes lived? Are these things not drawn from the Pythagorean transmigration, that μετεμψυχῶσι [Greek: metempsychōsis, "transmigration of souls"] so often condemned by Catholics? Next, how are comets the souls of illustrious men already dead, if the more common consensus of the wise is rather that they shine out for some days or months before the death of illustrious men? Do they die before themselves, and become comets twice, so as to be both the Lucifer and the Hesperus of their own deaths? Yet on the testimony of Suetonius and Pliny the Elder, Augustus wished it to be believed that the comet which arose in his time was Julius Caesar received into heaven, and he set a long-haired star on the crown of Caesar's statue — as Pliny and Plutarch also relate. Again Lucan, the Pompeian poet, so as not to make Pompey lesser than Caesar, sang that Pompey's soul was gathered into the eternal orbs; indeed, as the shamelessness of flattery grew, he boasted that Phoebus would yield his own star to Nero. And many others among the pagans, whether philosophasters or poets, have declared that the souls of heroes descend from the stars and return into them. Very well; but all these things come from the stench of paganism and of a foolish mythology, which, so far as lay in them, befouled or offended heaven itself with a most foul stink.

[Margin: Liceti's false opinion about supralunar comets recognised by Aristotle.]

II. It will be better worth the effort to see whether Aristotle recognised some comets as celestial, as Fortunio Liceti contends in *On New Stars*, Book 5, chapter 41. He argues from *On the Heavens* Book 2, chapter 7, where the Philosopher says that the stars are made of the body in which they have their motion [latio], and from chapter 8, that the stars are spherical and that this befits what generates them out of a spherical body, which is the heaven. Yet Aristotle does not seem to be speaking of the ancient stars, which he posits from eternity; therefore he speaks of stars newly generated from celestial matter. Moreover, in *Meteorology* Book 1, chapter 1, he affirms that comets are born in the place nearest to the motion of the stars; and in chapter 7 he said that

[14]printed *defererentur*, with f; construed as *defererentur*

when a condensation of exhalation occurs beneath some star, wandering or not wandering, then the comet becomes one of them, and when such a concretion occurs next to a star, the comet is necessarily carried with the same motion as that star, and so without parallax.

But Liceti is opposed by Froidmont, *Meteorology* Book 3, chapter 1, article 5; Cottunius, lecture 31 on *Meteorology* Book 1; Franciscus Resta, *Meteorology* Book 1, treatise 1, chapter 2; and Mastri, disputation 4 *On the Heavens*, question 2, article 4, number 43 — and rightly. For it is manifest that Aristotle, in *On the Heavens* 2, chapters 7 and 8, speaks not of some stars newly generated, but of all that are in heaven — those to which, as he confirms from their motion and roundness, celestial matter belongs, and which are generated (that is, from eternity, as Aristotle holds) by an eductive action out of matter, yet without that matter pre-existing by priority of time. And since in so many other places he asserts that the heaven is ingenerable and incorruptible, there was no call to beg little arguments for a new generation of comets in heaven from those two places on account of the particles "ex" and "genitum". Nor is it less manifest from Aristotle that the place of comets is the highest region of the air, in which ἐκπυρομένα φάσματα [Greek: ekpyromena phasmata, "ignited apparitions"] arise, that is, fiery appearances — granted that he says this region, compared with the lower regions of the air, is very near to the motion of the stars.

As for the second kind of comet, which he recognises in *Meteorology* Book 1, chapter 7, what kind it is is plain to anyone who looks at the text. For he meets an objection that someone could raise: that comets are sometimes seen nearest beneath the stars themselves and moving with the same motion without any parallax, and are therefore in heaven. And he says: "When, however, an exhalation has settled through the motion beneath one of the stars, wandering or not wandering, then one of these becomes a comet. For the coma does not form at the stars themselves; but just as halos [areae] appear around the Sun and the Moon and follow their motion, even though the stars are carried along, when the air has been so condensed that this affection occurs beneath the Sun's path, so also the coma is like a halo to the stars. Yet a halo of that kind arises through refraction, according to the apparent colour, whereas there the colour arises in the exhalations themselves." Just as the area, or halo, of the Sun or Moon therefore appears without parallax, as if it were a corona surrounding the Sun or Moon, and yet is really in the elementary region — because it forms in one part after another of a little cloud or of vapour spread beneath them, or at any rate because that vapour itself follows the motion of the luminaries by a motion either of impulsion or of attraction — so, when an exhalation condensed and mixed with vapour has moved with the motion of some star, it will seem to be immediately beneath that star without any variation of view, and the coma of comets will seem to be the coma of the star, or to be one thing with it, although in reality it is in an exhalation and in an elementary place.

[Margin: The Dog, Venus and Arcturus seen with their halo.]

Aristotle further adds the example of a certain star in the coma of the Dog, which he saw crowned as if with a kind of halo; just as we have often seen Venus wrapped about by a halo among vapours, so far as appearance goes. Froidmont, in the place cited, relates that he saw this very thing in Venus in the year 1618 and in Arcturus in 1624; indeed, we too have observed it in Jupiter more than once.

[Margin: Nicephorus wrongly adduced for a comet seen above Venus.]

III. I am no less doubtful whether, as our Cysat affirms in his *Mathemata* on comets, chapter 3, proposition 7, Abū Maʿshar observed a certain comet above Venus in the year of Christ 844, and Proclus another comet above Jupiter around the year 390. This very thing Giovanni Camillo Glorioso, *On Comets* Book 4, chapter 8, attributes to Proclus on Tycho's authority and to Abū Maʿshar on Cardano's, adding, about the comet seen above the sphere of Venus, that Nicephorus and Haly Ben Rodoan report that the same thing happened in their age; he cites Nicephorus, Book 12, chapter 37, and Haly on Book 2 of the *Quadripartitum*, chapter 9. But to begin with Nicephorus: already in chapter 3, at the year of the Lord 392, we reported his words, from which nothing is gathered about a place of the comet above Venus, but only that it appeared next to Venus and in light and apparent size was not much inferior to Venus — that is, a little less bright and large. Besides, as I said in the same place, and as Froidmont points out in *Meteorology* Book 3, chapter 2, article 3, Nicephorus lived around the year of Christ 1300, whereas the comet he describes shone out a little before the emperor Valentinian was found strangled in his bed, which happened in the year 392.

[Margin: The pseudochronism of Giovanni Camillo Glorioso.]

So Glorioso, inglorious in my view in this place, falls into a pseudochronism when he refers the observation of that comet to the age of Nicephorus.

[Margin: The doubtful testimony of Proclus for a comet seen above Jupiter.]

Nor does he skilfully lay at Tycho's door what is said of Abū Maʿshar and Proclus; for in tome 1 of Tycho's *Progymnasmata*, pp. 619 and 625, which Glorioso adduces, nothing of the kind is asserted absolutely by Tycho; only the words of Caspar Peucer are reported, who says: "Many have so far laughed, as at something incredible, at what Proclus noted somewhere — that a certain comet was seen above Jupiter, I know not when. In this indeed he could have been free of error if that comet was in conjunction with Jupiter: for the eyes could then have shown this; but if there was no conjunction, that philosopher ought to have shared with us how he had detected that it was higher than Jupiter" — as if he were saying that the comet could have been asserted to be higher than Jupiter if it had been seen so conjoined with Jupiter that Jupiter hid it by a kind of eclipse. Likewise, on page 625, the words of Wolfgang Schuler are adduced, replying to Peucer himself in this way: "To this kind, I judge, the comet too should be referred which Proclus mentions in the commentaries he wrote on Plato's *Timaeus*." But Wolfgang adds that he would have wished Proclus, or the anonymous author whom Proclus cites, to have added the time,

the place, the author and the manner of that observation, indicating that it was suspect to him; if, however, it is true, the comet should be placed among the extraordinary τέρατα [Greek: terata, "portents"], or signs sent by God beyond the customary course of secondary causes. Tycho himself, moreover, in the same place, p. 626, adds — not absolutely but hypothetically: "If Proclus asserts that some comet was observed above the revolutions of Jupiter, he has said nothing absurd." And a little later: "For it is not likely that he pronounced this without evident reasons, since he was without doubt not ignorant of the Aristotelian doctrines." But what if that observer said that the comet was seen higher than Jupiter, or above Jupiter, in respect of altitude from the horizon on a vertical circle? So that, if Jupiter appeared 40° high, the comet appeared 41° high or thereabouts. For Nicephorus indeed holds, in Book 1, chapter 13, that all comets are made in the elementary region.

[Margin: Was the comet seen by Abū Maʿshar and Haly higher than Venus?]

IV. Let us come to Abū Maʿshar. Tycho, in tome 1 of the *Progymnasmata*, p. 783, reports the words of Adam Ursinus of Nuremberg, who adduces from an aphorism of Cardano these words: "Abū Maʿshar said that a comet was seen above Venus; therefore it is not in the elementary region, contrary to the Philosopher." Tycho adds that Cardano said this rightly, because comets properly so called are ethereal. I, however, find in Cardano, *On Subtlety* Book 4, p. 155, these words, in which he attacks Aristotle's opinion that a comet is made in the elementary region as absurd: "There are many things besides this that show the absurdity of this opinion, from which I refrain: such as that saying of Abū Maʿshar, that a comet was above Venus; and Venus is much higher than the Moon." But perhaps Abū Maʿshar meant that Venus was lower than the comet in respect of altitude from the horizon. Further, the words of Haly, on Book 2 of the *Quadripartitum*, chapter 9, are these: "I wish to relate a portent which I saw when I was young and studying: a comet appeared whose solid part was of round shape and three times larger than Venus." From this, I think, arose the occasion for someone to read that it was three times higher than Venus. Nothing certain, therefore, follows from this.

[Margin: The error of Froidmont, Cottunius, Tycho, Mastri and Aversa in reporting authors.]

V. From the passages we adduced in the preceding chapter you will gather that certain opinions are falsely ascribed to certain authors, either through lapse of memory or through carelessness. For Froidmont, *Meteorology* Book 3, chapter 1, article 1, counts Piso among the champions of superlunary comets, though Piso plainly stands for sublunary ones. The same Froidmont, chapter 2, article 2, and Tycho, tome 2, p. 161, list Fracastoro among the defenders of celestial comets; yet he does not teach this, but only posits a circle passing through the heaven of the Moon and moving the Moon and the air beneath it, and by its means moving comets in latitude, in the way that he teaches they are carried in longitude by the motion of the lunar heaven. Indeed he plainly places them in the air, as will be clear to anyone who reads section

3 of the *Homocentrica*, chapter 23. Cottunius too, at the end of lecture 32, places Epigenes among those who asserted that comets are celestial and eternal, although it is evident from Seneca and Plutarch that Epigenes thought comets were a sublunary meteor kindled by the force of a whirlwind and of stirred-up air. Finally, Mastri, disputation 4 *On the Heavens*, question 2, article 4, number 39, following Aversa, lists Hájek among those who gave all comets a sublunary origin and seat.

[Margin: Hájek's palinode on the seat of comets.]

But he ought to have read Tycho, tome 2 of the *Progymnasmata*, p. 366, where Hájek, retracting his earlier opinion, says: "In the most recent comet, of the year 1577, for the reasons given above, I could not apply equal diligence. So it could very easily have happened that some error crept into my givens [didomena] too. For I myself have only now noticed, in these second thoughts of mine, that the parallax I assigned cannot correspond to the distance of the comet taken from the neighbouring stars at different hours and varying by scarcely 4′ or 5′. So I would judge that that comet too should be placed above the Moon." For he also set the comet of the year 1580 above the Moon, as Tycho relates in the same place.

CAPVT VII.

Chapter VII

Cometam non eſſe meram Apparentiam Luminis reflexi aut refracti, aut Coapparentiam plurium notarum ſtellarum.

That a comet is not a mere appearance of reflected or refracted light, nor a joint appearance of several known stars.

I. Against Panaetius, who said that a comet is a false appearance of a star, or a mere φὰσμα [Greek: phasma, "apparition"] and image, or against others who, as I said in chapter 6, number 2, held that it is a reflection of the visual rays made towards the Sun in a mirror of air, according to the first opinion on vision, that it takes place by extramission — against these argue Seneca, *Natural Questions* Book 7, chapter 30; Piso, in *The Mirror of the Comet*, chapters 13 and 14; Glorioso, *On Comets* Book 1, chapter 3; Franciscus Resta, treatise 1 of the *Meteorology*; Cabeo, *Meteorologica* Book 1, text 37, question 3; and Lotharius Sarsius [Orazio Grassi], *The Astronomical Balance*, p. 28, with Galileo's comments in *The Assayer* [Trutinator] from p. 113 to p. 121 — with roughly the following arguments.

[Margin: 1. Argument from long duration.]

First: phenomena that are mere emphases and consist in a kind of appearance — such as rainbows, rods [virgae], areae or halos, and parhelia — are not long-lasting, but quickly dissolve, and in that brief time, which seldom fills an hour, they take on various forms or positions. But comets persist through many days and months under the same principal appearance in which they first appeared, as is clear from what was said in chapter 4, number 5. Therefore comets are not mere phantoms [idola] of stars.

[Margin: 2. Argument from matter and place.]

Second: phenomena that have no real substance [consistentia], such as rainbows, coronas and the like, require a matter suited to marked refraction, or reflection, or both — namely a dewy cloud, or denser vapours, or a mirror, so to speak, of vapour, which is therefore raised little from the earth by its own weight and is not visible at the same time in widely separated parts of the earth. But the matter of a comet is seen raised far above clouds and vapours of this kind, as will be plain from what is to be said about the parallax of comets. Therefore comets are not mere images like a rainbow, a halo and the like.

[Margin: 3. Argument from the freedom [?] of motion.]

Third: phasmata, which are images of the Sun, the Moon or other stars, have such a connection with their prototype that they follow its motion — either towards the same side, if they are made by mere refraction, as halos are; or towards the opposite side, if by reflection with refraction, as rainbows are, which rise as the Sun descends and descend as it rises, since through the circular motion of the stars the angles of incidence on the reflecting matter vary — or else they are bound by a similar optical law to the motion of their prototype, as will be said in the scholia. But the motion of comets is its own master, and has no such connection with the motion of the Sun or of the other stars, as will be quite clear to anyone who rereads what we related in chapter 4, number 10.

[Margin: 4. Argument from an appearance [?] not bound by optical laws.]

Fourth: whatever things are mere emphasis, seen by reflection or refraction, are seen only by an eye placed in a determinate position, not by all, nor equally; and meanwhile some people in the same province or kingdom do not see them, even if nothing else prevents it. For when I see a rainbow or a halo at Bologna, someone at Ferrara or Florence does not see the same one, let alone someone at Rome. And if it is a halo or a corona, these must lie between the Sun or Moon and our eye, or be conjoined with their star; but if they are like rainbows, the eye must be on the same straight line between the Sun and the rainbow, which appears only in opposition to the Sun. Or at least, to see images of this kind the eye must be on the line of reflection, the line that makes angles in the reflecting matter equal to the angles of incidence; for to eyes moved outside that position they do not appear. But comets, with no necessity from these laws, appear at the same time, in the same form and shape, to the eyes of all, in diverse and widely separated regions; and scarcely a comet will be found that has appeared conjoined with the Sun or the Moon or another planet, or opposite to it.

[Margin: 5. Argument from the presumption of real being in everything that appears, unless the opposite is proved.]

Fifth: whatever appears to the eyes must be called real objects and true physical beings, unless we are convinced on other grounds, by strong arguments, that they are mere phenomena, or fleeting and empty images of bodies (as we are convinced by optical and geometrical arguments of the mere appearance of rainbows, parhelia and halos). This holds, first, because one must not presume that what appears to be is not, since possession stands for being rather than

for not being, and the burden of proof falls on whoever says that these things have no fixed and firm being; and secondly, because otherwise many other phenomena of the heaven and of the air could be called into doubt — and from the fact that images of the stars appear in waters and in other reflecting bodies, someone could assert that the planets are images of the Sun shining back from transparent little clouds, and so on for similar cases. Let it stand, therefore, by the common consent of the observers who have ever seen a comet, that it is not an empty spectre, or an illusory image appearing to us through the ἀνάκαμψιν [Greek: anakampsin, "reflection"] or ἀνάκλασιν [Greek: anaklasin, "refraction"] of the solar rays — that is, their rebound or refraction — but some true body, shining either because it is kindled or by a light it has received and retains.

Cometam non eſſe σύμφασιν, ſeu Coapparentiam duorum vel plurium ex iam notis ſideribus.

That a comet is not a σύμφασιν *[Greek: symphasin, "joint appearance"], or co-appearance, of two or more of the stars already known.*

II. We pass without any trouble from emphasis to the demolition of symphasis; for its overthrow is so easy, and this opinion so weak, that no named author, so far as I know, has taken up its defence. It was sufficiently shown in chapter 6, number 3, that it was not the opinion of Anaxagoras, Democritus or Zeno. But from whatever ancients it may have trickled down — in a timid whisper, I believe, and with the person concealed — the view that the oblong figure of a comet arises from the synod or conjunction of two or more of the stars we already know, and whose course we grasp after a fashion, such as Saturn, Jupiter and Mars, which seem as it were to touch one another and to light up the space between with a longer trail, is rejected by Aristotle, *Meteorology* Book 1, chapter 6; Seneca, *Natural Questions* Book 7, chapter 12; Glorioso, Book 1, chapter 9; Cottunius, lecture 30 on the *Meteorology*; and the Coimbra commentators, treatise 3 on the *Meteorology*, chapter 2. Granted, Guiducci, *On Comets*, p. 4, tries to weaken the last three of Aristotle's reasons; but they are firm, if they are taken in a sound way and without cavilling. I shall nevertheless add other arguments to them.

[Margin: 1. Argument from place.]

First, then: a conjunction of the common planets takes place only within the zodiac, whereas comets often appear with their whole body outside the zodiac and far from it, as is clear from what was said in chapter 4, number 10.

[Margin: 2. Argument from rarity.]

Second: conjunctions of the lesser planets with one another, as it were bodily, have often taken place, as is clear from the ephemerides — and indeed at night, when they could be observed — and yet nobody has said that a comet was made on that account. Conversely, when comets were made, never, so far as is known, was there at the same time an as-it-were bodily conjunction of these planets. (A platic conjunction does not suffice; they must as it were

touch one another in appearance, or cohere.) Aristotle gives the first part of the argument in these words: "The Egyptians say that conjunctions of the wandering stars take place with one another and with the non-wandering stars; and we ourselves have already twice seen the star of Jupiter pass beneath a certain star in Gemini and hide it, but no comet was made." A visible contact had, at any rate, preceded the occultation — lest you say with Resta that the occultation of a higher star by a lower one is unfit to generate the symphasis of comets. And if it were established that all the lesser planets had been observed separately on some night in different parts of the zodiac, and that at the same time a comet was seen distinct from each and all of them, we should have a new and most evident argument against this opinion. But we do not need it, nor is it worth the effort, in order to fish it out, to unroll the ephemerides and examine the places of the planets at the time of every comet seen. If, however, a comet were a conjunction of planets, it could be foreseen with certainty from the astronomical tables; and it is plain that this can by no means be done.

[Margin: 3. Argument from duration.]

Third: the conjunction and visible contact of the common planets, however slow, does not last beyond one day, and the conjunction of the luminaries itself does not exceed five hours; but most comets have appeared for whole months, and some for 6 months, as is clear from what was said in chapter 4, number 5.

[Margin: 4. Argument from size.]

Fourth: it is clear that a comet is not formed from a conjunction of the luminaries, since the Sun's apparent size is rather diminished when the Moon passes beneath it. And from a conjunction of all five planets, even if they were then also conjoined with one of the fixed stars of the first magnitude, no phenomenon so great can be composed as to equal many comets in apparent size, whether in the head or in the tail. For as to the head, some have been seen no smaller than the Sun, some nearly equal to the Moon; as to the tail, some occupied 22°, some 30°, some 45°, some 60°, some 75° in the sky, as may be seen from chapter 4, numbers 6 and 8. Moreover, some were smaller at the start and later became larger, from what was said in the same place, number 6, whereas the case ought to have been otherwise if a comet were a mere coalescence of two or more stars.

[Margin: 5. Argument from motion.]

Fifth: the falsity of this opinion is proved from the motion of comets. For many comets were carried obliquely against the order of the signs [in praecedentia] towards the north, and some towards the south, to a greater latitude, or departure from the ecliptic — 8° or 10° — than is granted to any of the common planets, as is clear from the comets of the years 1472, 1577, 1580, 1585, 1590, 1607 and 1618, and others. And some within one month completed an arc of a great circle, or a path, of 39°, as the comet of the year 1585 did; or of 50°, as in the year 1533; or of 97°, as in the year 1607. Some completed 42° in 11 days, as in the year 1590; some 107° in 57 days, as in 1618; some 180° within the space of three months. No planet, alone or conjoined with others, can complete so

great an arc in so short a time by its natural course. Finally, some were so swift in their own proper motion that in one natural day they got through 10°, 15°, 30° or 40°, as is clear from chapter 4, number 13, whereas none of the lesser planets, even when conjoined with another, can complete two degrees in the sky in one day.

[Margin: 6. Argument from setting or extinction.]

Sixth and last: some comets were seen all night in such a way that they did not go down below the horizon, remaining within the circle of perpetual apparition, which is granted to none of the common planets in our climes. And many were extinguished while still standing above the horizon in such a way that they were not dissolved into two planets or into two stars, as they would have had to be if the comet had been an aggregate of them — unless you say, raving still more, that they were extinguished because both ascended into the heaven towards their apogee and at the same time were diminished to the senses. For when does even a single one of the common planets, Mars for example, ascend so far that it ceases to be visible at night, when the Sun is absent?

[Margin: Seneca's arguments.]

III. But I wish to gather some of the arguments already mentioned in another way, and succinctly, in the words of Seneca himself, Book 7, chapter 12, who says: "To this we shall reply that the number of the moving stars is fixed, and that these and the comet usually appear at the same time; from which it is manifest that a comet is not made by their meeting, but is something proper and its own master. Moreover, a star frequently comes beneath the track of a higher star, and Saturn is sometimes above Jupiter, and Mars looks down on Venus or Mercury in a straight line; and yet a comet is not made on account of this course, when one passes beneath the other — otherwise one would be made every year. For in every year some stars are together in the same sign. If a star coming upon a star made a comet, it would cease to be in a moment; for the speed of those passing is very great. That is why every eclipse of the stars is brief: because the same course that brought them together quickly draws them apart. We see the Sun and the Moon freed within a short time once they have begun to be darkened. How much faster must the meeting be in stars so much smaller? Yet comets remain for six months, which would not happen if they were generated by the meeting of two stars; for those cannot cohere for long, and the law of their speed must separate them." And at the end of the chapter: "The stars have their course within the zodiac; they press upon this circuit. Comets are seen everywhere. There is no more a fixed time for them to appear than any place beyond which they do not go." In these words, however, I should think that Seneca said that all the planets appear at the same time separately from the comet out of confidence in a possible case rather than from any astronomical history or ephemeris; much less is it true that it is usual, or that every year there occur conjunctions of the lesser planets that are fitted to represent a comet by their coherence. For although they are conjoined as

to longitude — that is, the arc drawn and produced through them from the pole of the zodiac falls on the same place of the zodiac — yet the latitude, being greater in one planet than in the other, usually prevents their conjunction from being bodily, or as it were bodily. Rather, it most often takes place πλατικῶς [Greek: platikōs, "broadly"] — platically, I say, that is, in a broad manner, and with a large gap between them as to latitude, that is, as to departure from the ecliptic towards the north or towards the south.

[Margin: Philosophers without astronomy are prone to erroneous propositions in astronomical matters.]

It is no wonder, however, that such things as these slip out of philosophers only very lightly versed in astronomy. It would have been wiser for them either to consult more skilled astronomers or to refrain from pronouncing an opinion on matters they little understand. But the security of knowing that few are able to refute them emboldens them, so that at times they pronounce even more intolerable things — as I myself have heard more than once. Indeed, if even some of us who are commonly called mathematicians are liable to errors unless we examine these matters carefully and attentively, how much more so are others, who have despised mathematics, or have scarcely brought themselves to greet it from the threshold? See, then — not to go further afield — the following Scholia.

SCHOLIA.

Scholia.

I. Lotharius Sarsius — that is, Father Orazio Grassi, hiding under his persona — in the *Astronomical Balance*, p. 29, among the arguments by which he labours to show that a comet is not a mere phenomenon arising from reflection or refraction of the solar rays, brings forward this one: that images of the Sun of this kind follow the Sun with a motion that attends and obeys it, and are carried in the same direction as the Sun; whereas the comet of the year 1618 went in the contrary direction, that is, northward, from 29 November, although from that day the Sun, moving from the 7th degree of Sagittarius towards Capricorn, became daily more southern. Among other diagrams he uses the following one. In it let BO be the surface of the sea, the eye at A, and let the Sun ascend from the point O of the horizon to H. When the ray of incidence HI is drawn, the image of the Sun will be seen at I from the eye A, along the reflected ray AI, provided the angle of incidence HIO and the angle of reflection AIB are equal. Similarly, when the Sun ascends to G and radiates along the line GE to E, it will be seen at E along the reflected ray AE; and when it has ascended to F, it will be seen at D along the reflected ray AD. Conversely, as the Sun descends towards its setting from F, where its image was seen at D, at G it will be seen at E, and when the Sun is at H its image will be seen at I. From this he deduces the following proposition: "From these things anyone may understand that these appearances always move in the direction

in which the luminous bodies themselves, by which they are produced, are carried." Afterwards, however, he adds that if anyone imagines them to be carried the contrary way, they must still keep the same law: namely, that if the Sun's image is carried northward while the Sun recedes towards the south, then when the Sun afterwards returns northward the image must be carried southward; but that the contrary happened with the comet of the year 1618, which went on heading northward even after the Sun, from 22 December, had begun to return towards the north, the winter solstice being now past. This second assertion is sound and true.

Diagram. A woodcut set in the left column beside Sarsius's construction: a semicircle with its diameter upright on the left, a horizontal line running right from B (the surface of the sea), the eye A inside the semicircle on the left, and straight lines from A and from points on the arc meeting the horizontal line. The labels on the right-hand arc run from top to bottom.

- A (left, inside the semicircle): the eye
- B (left end of the horizontal line): one end of the sea's surface BO
- D, E, I (along the horizontal line): points of reflection
- F, G, H (upper right arc): successive positions of the Sun
- R (top right, head of a vertical line): end of the straight line OR
- Q (below R): not cited in the text
- P (right): not cited in the text
- O (right, on the horizontal line's end): the point of the horizon
- L, M, N (lower right arc): the Sun's image below the horizon, per §II

[Margin: Galileo's criticism of Sarsius.]

II. But Galileo, passing over in silence the second part of the doctrine just mentioned, and weighing the first proposition more subtly in his *Assayer* [Trutinatore], p. 118, teaches that it is not true that the Sun moves in the same direction as its image is carried, and he shows this in two ways. First, if the arc FO is continued below the horizon through ON, and AI is produced to L, AE to M and AD to N, the image of the Sun will appear, in the arc of the sky beneath the waters, to be carried in the contrary direction — namely from L to M and from M to N — while the Sun ascends the other way, from H through G to F; and the image will be seen to recede from the eye A while the Sun is seen to approach it. Again, if the luminous body were imagined to ascend along the straight line OR and to move further and further from the eye A, its image would nevertheless move from I through E to D, and approach the eye. It is false, therefore, that the image of a luminous body always moves in the direction in which the luminous body that produces it is carried. But let us leave these subtleties aside for now.

CAPVT VIII.

Chapter VIII.

CAPVT VIII.

An Cometæ ſint Planetæ Extraordinarij, ſed perpetui, poſt longiora temporum interualla nobis apparentes.

Whether comets are extraordinary planets — but perpetual ones — that appear to us after longer intervals of time.

[Margin: Arguments for this opinion.]

I. We showed in chapter 6, number 4, that this third opinion was held by the Chaldaeans, and in Italy by the Pythagoreans, as well as by Hippocrates of Chios, Aeschylus, Diogenes, Apollonius of Myndus, Artemidorus, Seneca and Favorinus; and that among more recent writers it found favour, or at least no disfavour, with Oddo, Renatus, Frangipanius, Tannerus, Columbus, Raymundus, Vallesius, Liceti, Echius and Fienus. And indeed at first sight it seems not only not unfitting but rather fitting to the vastness of the heavens and the majesty of their Maker that, besides the five planets already commonly observed, there should be some others, of a different shape and colour — such as comets are — which show themselves more rarely and at longer intervals, but for the most part lie hidden: either under the rays of the Sun; or because they have not yet descended towards their lowest apsis, around which they come nearer to our eyes; or because they are not in a position fit for reflecting the Sun's light to us; or because they are not yet purified enough to be illuminated and to pour their light back to us; or because parts of the heaven or of the air transparent enough to allow us to see them have not yet run beneath them.

[Margin: 1. Argument from the possible and from the vastness of the heaven.]

The first argument, then, is from the possible, and from the congruence drawn from the vastness of the heavens, or of the planetary system. To this is added the comparison with the many standing, or fixed, stars. For the number of seven planets seems too small when compared with the innumerable fixed stars, and the vast expanse of the planetary heavens would seem too empty and idle if only seven wandering stars ran within the zodiac, and there were not many other planets ranging through every region of the sky. Seneca touches on this argument in Book 7, chapters 23 and 24, in these words: "'If it were a wandering star,' you say, 'it would be in the zodiac.' Who sets a single limit to the stars? Who confines the divine within a narrow space?" etc. "Consider whether it does not better befit the greatness of the universe that it be divided into many paths, rather than wear down this one track and lie torpid in its other parts. Do you believe that in this greatest and most beautiful body, among the innumerable stars which adorn the night with varied beauty and do not allow the air to be empty and inert, there are only five that are permitted to exercise themselves, while the rest stand still, a fixed and motionless people?"

[Margin: 2. Argument from duration.]

Second: that a comet is among the eternal works of nature, as Seneca puts it, seems to be proved from its duration over some months, of which I have already spoken in chapter 4, number 5. For it is from this that Seneca argues, for his own view and against the Peripatetics, in Book 7, chapter 22: "I do not agree with our people. For I do not consider a comet a sudden fire, but one of the

eternal works of nature. First, whatever the air creates is short-lived, for such things are born in a fleeting and changeable element." And a little further on: "It cannot be that a definite fire should sit in a wandering body and cling to it so persistently." And in chapter 23: "No fires have any stay except in what is their own — I mean those divine ones which the universe holds as eternal, because they are its parts and its works." And shortly after: "I was saying just now that nothing kindled by a fault of the air is lasting; now I add further that it can in no way linger and stand still. For the torch, the thunderbolt, the shooting star and whatever other fire is squeezed out of the air is in flight, and does not appear except while it is falling. A comet has its own seat, and therefore is not quickly driven out, but measures out its course; nor is it extinguished, but departs."

[Margin: 3. Argument from the pursuit of fuel.]

Third: if a comet were not an eternal planet but something kindled in matter which it needed as fuel, it would follow its fodder in a wandering course and would sometimes descend towards the earth. For so the same Seneca argues in Book 7, chapter 12: "Further, if it clung to its nourishment, it would always descend; for it is thicker the nearer it is to the earth. A comet is never let down to the lowest region, nor does it approach the ground. Moreover, fire goes where its nature leads it, that is, upward, or where the matter to which it has clung, and on which it feeds, draws it."

[Margin: 4. Argument from size and shape.]

Fourth: if a comet were not something perpetual but a temporary fire kindled in sublunary matter, it would change its size and shape very quickly — the contrary of what is found to happen in comets. Hear Seneca again, Book 7, chapter 23: "For they would become larger or smaller on alternate days, if the fire were a gathered one, and sudden from some cause. For it would be smaller or larger according as it was fed more fully or more meagrely."

[Margin: 5. Argument from circular motion.]

Fifth and last: the circular motion itself along the same orb, or great circle — such as we indicated appears in comets in chapter 4, numbers 11 and 12 — is a sign that a comet is a celestial star rather than a sudden fire. This very point is pressed by Seneca, Book 7, chapter 23, where he says: "No fires, ordinary and celestial, have a curved path. It is proper to a star to trace an orbit. Whether other comets have done this I do not know; two have done it in our age." Add the constancy and the regular anomaly of the comets' motion, of which enough has been said in chapter 4, numbers 11 and 13, and of which more below, when this argument is explained at greater length.

[Margin: Solution of the arguments just mentioned.]

II. But in truth the four latter arguments do not show that a comet is a planet that has been in the sky since the beginning of the world; at most they show that it is not a sudden flame, kindled in rare matter, or in matter that is quickly combustible and variable. But, say the Peripatetics, if it is kindled in matter that is dense indeed and well compacted, but also viscous and smeared with much

grease, and at the same time lighter than the thicker air around the earth, it can last a long time under the same apparent shape and size, and can move not downward but in another direction, following the motion of the air or by the force of some other cause — since motion in a circle belongs to the sea, to rivers, to clouds and to elemental fire alike. To the first argument, moreover, one could reply that planets are multiplied in vain, and without evident or strongly probable cause, especially since there are equally probable arguments to the contrary — namely, that planets of this kind do not pre-exist before comets appear, as I shall say presently.

III. Accordingly, against this opinion rise the Coimbra commentators, treatise 3 on the *Meteorology*, chapter 2; Froidmont, Book 3 of the *Meteorology*, chapter 2, article 2; Glorioso, Book 1 *On Comets*, chapters 6, 7 and 8; Resta, treatise 1 on the *Meteorology*, chapter 1; and Cabeo, Book 1 on the *Meteorology*, text 37, question 6. Take their arguments, or ours.

[Margin: 1. Argument from size at the first phase.]

First: if there were very many planets in the sky which were not visible to us except because of their nearness — that is, after making a descent towards us by means of epicycles, or of orbs equivalent to epicycles — they would at first appear very small, like a star of the sixth or seventh magnitude, and then little by little, by a proportional increase, would be seen larger and larger. Having reached their greatest apparent size in the perigee of the epicycle, they would, as they re-ascended, decrease little by little through almost every degree as far as sight goes, until they became equal to a little star of the lowest magnitude among the visible ones; nor would they vanish at night above the horizon before such a decrease. Yet history shows that it happened otherwise in most comets, on which see also chapter 4, number 6. For several appeared very large from the very beginning, or a little after it, although they had never been seen anywhere before. Among these one was memorable — indeed, worth recording for Seneca — the one which, as he himself relates in Book 7 of the *Natural Questions*, chapter 15: "A little before the Achaean War a comet shone out, no smaller than the Sun. At first it was a fiery and ruddy orb, giving off a bright light, enough to overcome the night; then little by little its size was contracted and its brightness vanished; finally it disappeared entirely." That is, it disappeared whole, as great as it still was — smaller, granted, than at the beginning, but not yet become perceptibly very small. How then, good Seneca, did you deny that comets are extinguished, and prefer that they depart and vanish little by little as they ascend — in chapter 23, that is?

[Margin: 2. Argument from the vastness, number and variety of the epicycles.]

Second: if so many and such varied planets pre-existed, and appeared only for a few days or months while lying hidden for many years because of their upward motion, the portion of the epicycle that carries the comet and grants us sight of it would have to be incomparably smaller than the portion of that circle which would render the comet invisible through its distance from our

sight. For an epicycle of this kind would have to be larger than the whole sphere of the fixed stars, since in it a comet so great that even without a tail it was seen larger than Venus and Jupiter, and sometimes equal to the Sun, would certainly still be visible, seeing that stars of the sixth magnitude are seen in that sphere. Next: either the same comets frequently recur, and so their return would be observable; or they do not recur — which agrees better with history, because of the incredible variety of past comets — and so the epicycles would have to be immense in vastness, innumerable in number, and beyond conception in situation and position, because of the windings and labyrinths, and the mutually intersecting paths, which comets, compared with one another, have so far described by their motion — as will be plain to anyone who considers what we said in chapter 4, numbers 10 and 11.

[Margin: 3. Argument from rising and setting other than heliacal.]

Third: suppose that so many planets, of such varied form and of such size, had been moving in the sky ever since the beginning of the world, and were hidden not by reason of their ascent and their distance from our sight but because of their nearness to the Sun, as Mercury is often hidden — which seems to have been the view either of the Pythagoreans or of Posidonius. Then they would never rise for us except heliacally; and yet they would rise as soon as they stood from the Sun by an arc of vision of 10° or 12°.

[Margin: See Book 1, chapter 32, on this arc.]

For no greater distance than this is required for heliacal emergence in any of the planets, or in stars of the first magnitude — and many comets are known to have been larger than these. Likewise they would not vanish except by a heliacal setting, or occultation, as they returned to the Sun. But it is clear from the history of comets that many of them began to appear quite large when they stood from the Sun by much more than 12°, and departed from the Sun towards the north, directly or obliquely, and were extinguished there very far from the Sun.

[Margin: 4. Argument from the rarity of their sighting without a reasonable impediment.]

Fourth: if so many planets of such changing forms wandered roaming through the fields of the sky, and yet were hidden neither by their ascent in the epicycle nor by the glare of the neighbouring Sun, then they would be hidden either for want of rarity and of a pure and purified transparency, or of a notable serenity, as Cardano and Echius would have it — and this does not square with our sight of the fixed stars, which we see so frequently, though they are much smaller than comets, in every region of the sky on moderately clear nights; or for want of a denser part of the heaven, as Columbus, Vallesius and Liceti would have it — but since the regions of the heaven in which comets have appeared, and through which they have led their courses, have extended through almost every tract of the aether, that density would have to be lacking for the greatest part of the time in almost the whole heaven, and its absence would therefore render most of the fixed stars inconspicuous. Besides, so great

a variety of parts, infesting the whole heaven with so tangled an intersection, is incredible in itself. Or, certainly, they would fail to appear for this reason: that they did not have beneath them attracted humours or fumes in which the light propagated from them might shine in the manner of a tail, as Hippocrates, Aeschylus and Raymundus held. In that case they would at least appear without a tail; or if they did not appear even so, then they themselves, no less than the tail, are something new rather than ancient planets. And I say the same against Frangipanius, who said that these planets are not seen except when their light has been increased. For either this increase takes place all at once from the beginning — and then by the same argument by which the newness of the light is asserted, the newness of the whole phenomenon must also be asserted, unless the opposite is established; otherwise one could say that the flame of a furnace and live coals are perpetual, or that the Sun is perpetually above the horizon but is not seen except when its light is increased — or that increase takes place gradually and successively, and this is against the history of the origin of several comets.

[Margin: 5. Argument from the signs of their newness of being.]

Fifth: the tail, for the most part turned away from the Sun; the duration, so short in comparison with the permanence of the other stars; and the motion of comets, so varied, as may be seen in chapter 4, numbers 10 and 11 — especially their motion by a leap, as in the comet of the year 373 before Christ, which for that reason, on Aristotle's testimony, was called the Path [Semita], and in the year 1099, when another comet too ran about by certain leaps — are evidence of a new phenomenon, and by no means of an eternal one. And universally, whenever a multitude of new sensible accidents appears at once that did not appear before, it is physically evident that something has been made anew, at least by alteration, as clouds, rain and the like are made anew — unless the opposite is evident from elsewhere; and the burden of proving pre-existence lies on whoever asserts that the thing existed before.

Let this, then, be the conclusion:

It is hardly probable that comets are ancient planets, much less eternal ones; and it is more probable that they are made anew.

CAPVT IX.

Chapter IX.

An Cometæ ſint Aggregatum ex pluribus Stellis paruis, ab initio Mundi præxiſtentibus, ſed ſecundùm ſe incognitis, ſeu ſeorſim inconſpicuis.

Whether comets are an aggregate of many small stars that have pre-existed from the beginning of the world, but are unknown in themselves, that is, inconspicuous taken separately.

I. We reported in chapter 6, number 5, that Anaxagoras, Democritus and Zeno went over to this opinion, and we showed in the same place that it seemed not improbable to Cardano, Giordano Bruno, Tannerus, Cysatus, Liceti and

Resta — but above all to Francesco Resta, who, in treatise 1 of his *Meteorology*, chapter 3, distinguishing ethereal comets from elementary ones, contends that the ethereal ones are a concourse of many stars. And it seems that it can be urged by the following arguments.

[Margin: 1. Argument from observation.]

First: Democritus, as Aristotle reports in *Meteorology* 1, chapter 6, used to relate that when comets dissolved, certain stars appeared; and Ephorus the historian, in Seneca, *Natural Questions* Book 7, chapter 16, said that the comet which by its rising sank Helice and Buris split into two stars. Granted, Seneca there detracts from Ephorus's credibility, saying, with arguments that are by no means conclusive, that nobody besides Ephorus observed this in that comet, "which was nevertheless watched by the eyes of all mortals, because it drew after it the outcome of an immense event. For who could have observed the moment at which the comet, dissolved, was reduced into two parts? And how is it, if there is someone who saw a comet split into two, that nobody has seen one made from two? And why did he not add into which stars it was divided, since it must have been one of the five stars?" But these objections are empty. For the end of this comet could have been observed while its beginning was not observed, or was not recorded; and we, with Democritus, are speaking not of the five usual planets but of extraordinary ones. Moreover, Dio, Book 54, relates that the comet which appeared under Augustus at the death of Agrippa went off dissolved into torches. Conversely, Nicephorus, Book 2, chapter 31 — as I reported in chapter 3 at the year of Christ 392 — tells of a comet that was seen to which a huge throng of other stars gathered, like bees to their king. Finally, Father Cysatus, in the comet of the year 1618, observed with the help of the telescope a nucleus compacted of many little stars, which afterwards separated; we have already given his diagram of it in chapter 4, in the history of that observation.

[Margin: 2. Argument from the Milky Way.]

Second: most comets, as Aristotle admits in Book 1 of the *Meteorology* at the end of chapter 7, gather into the region of milk, that is, into the Milky Way; and Pliny asserts the same, Book 2, chapter 25, in these words: "Almost all of them under the north itself, in no fixed part of it, but chiefly in the white part, which has received the name of the milky circle." Tycho too noted this in tome 1 of the *Progymnasmata*, and from him Liceti, Book 2 *On New Stars and Comets*, chapter 40, and Froidmont, Book 3 of the *Meteorology*, chapter 2. But the Galaxy is nothing other than a heap of very minute stars, as the telescope has revealed. It is therefore highly probable that very many comets are made in it or along it for this reason: that they are made from those little stars when they are gathered closer together into one. This holds especially if it is necessary to admit some celestial comets; for it is less absurd to admit this mode than generation and corruption in the heavens, since that packing and condensing can be accomplished by the force of local motion alone.

II. Nevertheless this opinion does not please at all. It is rejected by Aristotle, *Meteorology* Book 1, chapter 6; Seneca, Book 7, chapters 15 and 16; Glorioso, Book 1 *On Comets*, chapter 9; Froidmont, *Meteorology* Book 3, chapter 2, tr. 3; Mastri, Disputation 4 *On the Heavens*, question 2, article 4, number 36; and Cabeo, *Meteorology* Book 1, text 36, question 6; and Cysatus himself, *On Comets*, p. 76, abandoned it and chose little planets formed anew out of the same matter from which the solar spots and faculae are made.

[Margin: 1. Argument against this opinion.]

First: suppose comets were made by an aggregation of little stars and dissolved into them again, or that those little stars were visible separately without the telescope, as is supposed in the first three cases of the first argument, those adduced from Democritus, Ephorus, Dio and Nicephorus. Then in all comets, when they first appear, those stars that were gradually being aggregated into one would have to appear beforehand, as in Nicephorus's case; or at least, at the dissolution of every comet, those two or more little stars, or little torches, would have to appear — in accordance with Aristotle's remark against Democritus, Book 1 of the *Meteorology*, chapter 6: "But this ought not to happen sometimes and sometimes not, but always." Yet apart from those three cases of a comet dissolved into several stars or torches, this is established of no other comet. On the contrary, it is established that many were extinguished before they went down below the horizon, without any such breaking up into several little stars or little torches — as Aristotle, Seneca, Pontano, Regiomontanus, Apian, Fracastoro, Tycho, Hommel and others who were able to observe the end of comets relate of the comets they saw, and as we related in chapter 3 at the years before Christ 373 and 348, and of Christ 54, 64, 392, 1264, 1267, 1471, 1472, 1532, 1539, 1556, 1577 and 1585. Much less is there any evidence of a composition such as Nicephorus reports at the origin of his comet. Granted, the first rising of several comets is scarcely observable, and only after some days does report of it, or a sure distinction from the other stars, prevail. The point is therefore concluded more evidently from the death of comets, especially of those which disappeared whole before they were reduced to a very small and imperceptible little star.

[Margin: 2. Argument against the perpetuity of the comet's parts.]

Second: even if it were established that all comets were made by an aggregation of semi-comets, or of small little stars, and that all were dissolved into little stars, it would still not follow from this that these had always pre-existed and would continue to endure — unless those very stars had always appeared, before and after, in that small quantity of theirs. Otherwise it would rather have to be said that they too had been made anew and had afterwards perished, than that they had been and would be perpetual: in the way that a great cloud is made from many little clouds, or from flakes of snow, and is afterwards dissolved. And this, it is prudently believed, is what happened in Nicephorus's comet.

[Margin: 3. Argument against [?]position from stars of the Milky Way.]

Third: if a comet is supposed to be composed of ancient and perpetual little stars of the Milky Way, many things stand in the way. For their colour is whitish, whereas that of comets is often fiery and ruddy, or even dusky. Next, the distance of the fixed stars from one another is always the same, and therefore so is the distance of these; and it must not be said that they change the distance they have had from the beginning unless this is proved by strong arguments. For possession stands in favour of the fixed stars, which are distinguished from the wandering ones chiefly in this, that they always keep the same distance from one another; nor has the telescope so far revealed otherwise. Besides, unless one has recourse to God, or to angels who would conglomerate those stars and drive them together into one comet, no other reasonable cause that gathers them together can be devised, except gratuitously and by mere fancy. Yet even with such causes posited, it is no easier for God or the angels, or for any other feigned cause, to gather the stars of the Milky Way than any others — especially since not all comets arose in the Milky Way, but far from it, nor did they return into it when dissolved. For it is one thing that many travelled along the Milky Way for some time, another that they arose in it and out of it. But if it is said that they are composed of wandering little stars which do not appear, because of their smallness or for some other cause, but which at certain times come together into one visible star — why are so many little planets not seen at some time through the telescope, as the satellites of Jupiter are seen? Why do they not more often obscure the Sun or the other planets? Or why, at least, do they not more frequently come together and conglomerate? And on what foundation, finally, except a gratuitous and purely arbitrary one, are innumerable little bodies, invisible in themselves, feigned to exist from the beginning of the world? For they must be innumerable, and almost infinite, if singly they are so small as to be invisible, and yet by their confluence they must make up a comet sometimes no smaller than the Sun, together with its tail, which sometimes occupies 60°, 70° or 180° in length. This is Seneca's argument, Book 7, chapter 15, about the comet which "shone out before the Achaean War, no smaller than the Sun", when he says: "How many stars, then, must come together to make so great a body? Gather a thousand into one, and they will never equal this circuit of the Sun." And soon after: "In the reign of Attalus a comet appeared, moderate at first. Then it raised itself and spread out, and came as far as the equinoctial circle, so that, stretched out immensely, it equalled that region of the sky which has the name of milky." How many [?], then, to have come together must the wandering bodies be, to occupy so long a tract of the sky with continuous fire?

[Margin: 4. Argument from duration.]

Fourth: if those innumerable little planets, or those little fixed stars of the Galaxy [Fixulæ illæ galacticæ], are gathered together to compose a single comet, then either they are gathered by a chance and tumultuous motion and concourse — and so would at once be dispersed again [digregarẽtur], as happens with straws and little balls that come together in some eddy of a river or of the sea and

are scattered shortly afterwards; whereas many comets persist for whole months, and for several of them. Or else there is some cause that of itself aims at their coming together, on account of which, once coupled, they dwell together for a long time, or migrate elsewhere in a close-packed and compact column, like cranes. In that case, since this opinion does not admit generation, corruption or corruptive alteration in the heavens, what is the reason why they do not keep that union always, or at least for far longer? For no contrariety stirs up that sedition and secession. You will say that the cause is indeed unknown, but that there are many things which we know to exist and yet do not know how they come about or exist. True enough — but that holds of things we know for certain to exist; and we are not yet certain that comets are an aggregate of many little stars produced from the beginning. For this is the very point under dispute.

[Margin: 5. Argument from the tail.]

Fifth: one may argue from the tail of comets, which, it is established, was for the most part — indeed in all those observed somewhat more accurately and by the more expert — turned away from the Sun. For either the tail too consists of a concourse of little stars, and then no reason can be given why that long train [ſyrma] inclines towards the region turned away from the Sun rather than elsewhere. Or nothing but the comet's head consists of those little stars, which, being semi-transparent, transmit the Sun's rays received within them out behind themselves into a longer tract. Then some semi-opaque matter must be brought in, fit to stop those rays and reflect them to our eye. Either, then, that very matter or subject coalesces out of semi-opaque corpuscles, and the previous argument returns, since not even for these can a reason be assigned why they should be arranged in this way only behind the back of the comet's head, and not surround it on every side, and so stop the Sun's rays and send them back to us from whatever region of the sky. Or that subject is some smoky matter carried there, or exhaling from the comet's head; and so in comets one must recognise newness — some new generation or alteration — and not merely a motion by which little stars congregate.

[Margin: Reply to the principal argument for the affirmative side.]

III. Now to the last part of the second argument for the affirmative side, where it was said that, if it is necessary to admit some celestial comets, the mode by which comets are composed by the force of local motion alone is to be chosen rather than generation and corruption in the heavens. The reply is to concede this if the comparison of local motion with generation and corruption is made strictly; but to deny the assumption if this local motion brings with it inconveniences no smaller. For once it is posited, one must admit either that the fixed stars of the Milky Way are not fixed, but, against the common lot of the other non-wandering stars, are torn from their place and migrate into another — the space they occupied being meanwhile left empty, or filled by rarefaction or some other motion — and that they change colour. Or, whether they are fixed or wandering little stars, one must admit a certain tumultuous and

chance motion, through a heaven that is now liquid, by which they are gathered without any rule, and a composition of the tail made almost at random. Taken together, these things are no less unsuited to a celestial body than generation and corruption. Therefore, once that dislocation of the fixed stars, the fluidity of the heaven and irregular motions have been admitted, generation and corruption in a celestial body can be swallowed and digested with the same stomach.

CAPVT X.

Chapter X.

AN COMETÆ fiant ex elementarium EXHALATIONUM COPIA conſtipata ac incenſa, & in ſuprema regione aeris vel infra LUNAM permanente.

Whether comets are made from an abundance of elementary exhalations, packed together and kindled, and remaining in the highest region of the air or below the Moon.

I. This opinion of the Peripatetics and of the older astronomers — very widely held, and once received in most of the academies, as we said in chapter 6, number 6 — seems capable of being established by the following arguments. To these, however, we shall subjoin one by one their solution and the arguments diametrically opposed to them, so that, in Aristotle's dictum, opposites set beside one another may shine out the more, and may be weighed and assessed on either side as in a double scale. The remaining arguments that tell against this opinion, and do not bear on the immediate solution of the reasons adduced for the Peripatetics, we shall bring forward separately in chapter 11, together with their solutions too.

[Margin: 1. Argument from the dryness and winds that accompany a comet.]

II. First: when a comet is made, it is preceded or accompanied by a great dryness with winds. These either shake the very ground of the lands with earthquakes, or burst out through Vesuviuses, or swell the seas into a surge — hence the submersion of islands or of maritime cities — or rage in long-lasting storms and whirlwinds, and bring upon crops and animals other calamities akin to violent, or even virulent, winds. Not, indeed, always in every region, but in some regions more disposed to it, or over which the comet more predominates, as may be learned here and there from the history of comets set out in chapter 3 — especially of those which Aristotle reported, there at the years before Christ 373 and 341; read Aristotle's words there again. It is therefore a sign that a comet is made from an abundance of hot and dry sublunary exhalations, and that through it the comet does harm to the lands from nearby rather than from a distant and supralunar place. And this is the Philosopher's first argument, *Meteorology* Book 1, chapter 7.

[Margin: Solution of the first argument.]

The reply, however, is to deny the universal inference. For it is established that at times, when a comet was made, no such abundance of dry winds existed, nor any disaster arising from it — unless, out of the Peripatetic opinion already presumed, one were to assert, fictitiously and too confidently, that

it existed somewhere, and in places about which all history is silent. Indeed, it is established that a comet has at times had heavy rains and clouds near it, which hindered the beginnings and ends of the observation or disturbed[15] an observation already begun; or that health among the animals, abundance of crops and calm weather followed. Conversely, the evils and misfortunes enumerated in the argument have far more often occurred without any comet going before or following close upon them. For example, Vesuvius, notorious for twelve eruptions since the birth of Christ, scarcely once had a comet as a torch announcing it or as a hired mourner — namely under Titus, or again in the year 983. And who could enumerate the earthquakes, shipwrecks, swellings of the sea, famines, plagues and other calamities akin to these, by which mortals have perished with no comet shining before them or shining upon them? This sign, therefore, is not convertible with a comet, either simply or in a certain respect, and is universal from neither side. Let Aristotle, then, suffer to be turned back against himself what he himself hurled at Democritus in *Meteorology* Book 1, chapter 6: "But this ought not to happen sometimes and sometimes not, but always."

[Margin: 2. Argument from likeness with other fiery meteors.]

III. Second: all the other fiery impressions similar to comets — namely burning beams, flying dragons, torches, falling or running stars, will-o'-the-wisps [ignes fatui], leaping goats, the fire of the Tyndarids about the yards of ships, and so on — are made from a hot, dry, sulphurous or nitrous breath that has been kindled. They do not differ from a comet except in shape and duration; nor would they differ if that exhalation were denser, better compacted and fatter, or if fuel were supplied to it for longer — for running stars, which are extinguished for lack of fuel before completing their passage, would, if they had long-lasting tinder, fulfil their course over a longer time and become comets. This argument from likeness, with the dissimilarity already mentioned, is Aristotle's, *Meteorology* Book 1, chapter 7, where he reasons thus: "When, therefore, on account of the upper motion, a fiery principle has fallen into such a condensation — neither so strong as to burn out quickly and over much space, nor so weak as to be quickly extinguished, but great, and fit to last a long time — and at the same time a well-tempered exhalation happens to rise from the lower part, a comet is made, in whatever way the exhalation has been shaped, etc." And a little below: "For just as, if someone thrusts a firebrand into a great heap of chaff, or throws in a small beginning of fire, the running of the stars will be like this; for quickly, because of the suitable disposition of the kindled tinder, a conflagration follows along its length. If, then, this lasts, and is not consumed in a swift passage where the kindled tinder has been most densely packed, the motion, once begun, will certainly complete its course. Such too is the comet, a hairy star [Comata ſtella], as a running star is, but having the beginning and end of its motion complete."

[15]printed *intertubarunt*, for *interturbarunt*

[Margin: Solution of the 2nd argument.]

The reply, however, is that a comet is far more unlike the other meteorological inflammations, and in many other respects more like the celestial stars. It is so chiefly in splendour, in colour, and in its motion, which is for the most part uniformly difform, regularly unequal and yet constant, along a circle that is sensibly a great circle, or along a path of its own like the path of the planets. It is so, next, because it does not follow its fuel, nor leap across to lower places, plucking at tinder supplied to it, but rather, when about to die, is carried up on high. And it is so, finally, in its lasting for several months. Although such duration is no less in snows, and sometimes in clouds, because these have no destructive and resolving principle within them, in a body inflamed and kindled, as is supposed, it does not seem probable — especially since even the fire-vomiting chasms, full of sulphur and of bitumen far more viscid than the matter attributed to comets, scarcely anywhere spew out a continuous flame for 6 months, as comets have done, but now and then languish, or even go out, and are rekindled later. But since Aristotle compared comets with falling or flying stars, let us too compare their duration on the one hand with momentary and falling stars, and on the other with perpetual or ancient ones. One of the falling stars is lit almost in the twinkling of an eye and is extinguished in about two or three beats of the human pulse; that is, in its run it scarcely equals two hourly seconds. Now there are 3600 seconds in one hour, that is, 1800 lifetimes of running stars; but let us suppose there are only 1000, so that the life of a falling star is about four seconds. Then in one day there will be twenty-four thousand times, each equal to the time belonging to one glowing star, and in one month of 30 days there will be 720,000 such times, and in six months 4,320,000. But from the beginning of the world down to us not yet 6000 years have elapsed, that is, not yet 72000 months. Therefore the excess of the duration of the stars so far elapsed (for how great it will be in future is unknown, and it is probably believed that it will not be much greater) over comets of a month's duration, of which you may find many in chapter 4, number 5, is smaller than the excess of the duration of a single month-long comet over the duration of a single running star. For the former is as 72,000 to 1, but the latter as 720,000 to 1 — that is, ten times greater in the latter case than in the former. And if a falling star is compared with a comet of six months — of which kind it is established from history, and from chapter 4, number 5, that there were three, and it is probable that there were several others from the beginning of the world down to Christ — this excess would be sixty times greater. A greater likeness in duration therefore holds between comets and the celestial, permanent stars than between comets and the falling or running stars. It is therefore not expedient to uphold this Peripatetic doctrine so stubbornly with these topical arguments; for many others will be set against Aristotle when he uses this likeness, on which see chapter 11, argument 7.

[Margin: 3 [?]. Argument from the many and great sources of exhalations.]

IV. Third: if a comet is not a hot and dry exhalation kindled by some motion or from elsewhere, this is certainly because of its long-lasting and persistent flame, which sometimes perseveres for as long as six months. Yet this is no obstacle at all, if you look about at how many exhalations, imbued with a sulphurous, nitrous or vitriolic unguent, are perpetually drawn up on high — from the Ocean on the one side, and from the furnaces and seething chasms of the Earth on the other. For that the sea is oily, and in warmer weather sweats out a kind of oil, not only did Aristotle assert, when he said [Greek: ἀπὸ γ[[α/ὰ]]ρ τῶν ἁλῶν ἔλαιον ἀφαιρεῖται (apo gar tōn halōn elaion aphaireitai, "for oil is drawn off from the salts")], but it is also gathered from many experiments: its water stains clothes rather than washing them, by its fatness bears up swimmers more easily, and, thrown upon flames, rekindles them rather than putting them out, and for that reason it is congealed into ice only with great difficulty. The Earth, moreover, teems in innumerable places with sulphurous fires and has fire-vomiting mountains or flame-flowing chasms, from which hot, dry spirits and volatile salts endowed with some oil are perpetually exhaled. If these are collected into one mass, packed together, and brought to a certain temper which is apt to conceive a flame and, by its viscosity, to nourish it for longer, there seems to be no inconvenience in life and strength being supplied from that source even to comets lasting six months. That this happens rarely, however, is because those two conditions rarely concur: namely, that an abundance of such breaths is gathered into one place, and that it attains the sufficient packing and temper required for a long-lasting flame — its dryness preserved, in the sense in which dryness is opposed to watery humidity, and the fat, airy and unctuous moist not excluded.

[Margin: Reply to the 3rd argument.]

The reply, nevertheless, is that what has been said so far is indeed not improbable, so long as the opposite has not been made evident; but in this controversy the question is what is evident, or what is more probable. Therefore, if it is evidently established from the parallax of some comets that they are above the Moon, and in the highest aether, the probability just mentioned will collapse and will not be able to stand for all comets. For then the force of terrestrial and maritime breaths, especially of viscid ones, will be able to penetrate as far as the heaven far less, or perhaps not at all — and yet that force would have to be greater than if the comet were made in the highest region of our atmosphere, by as much as the same comet, seen under the same angle, that is, with the same apparent magnitude, is really of greater bulk if it is in the heaven than if it is near the earth. But let us grant for the moment that this is not yet evident from parallax. There are nevertheless many other arguments by which it is concluded, with equal or perhaps greater probability, that not all comets are generated from that matter and in that manner which the Peripatus suggests to us — as is clear from what was said in the replies to the 1st and 2nd argument, and as will further be clear from what is to be said in the following chapter.

[Margin: 4. Argument from manifest indications.]

V. Fourth: the sudden kindling and very wide diffusion of comets, made either by leaps, or their dispersal into torches, and their falling towards the earth — so that at times a sulphurous smell has not been lacking — and finally a partial eclipse of the Moon made by a comet gliding beneath it, are manifest indications of a sublunary comet and of a meteorological inflammation in elementary matter. On the sudden diffusion, see chapter 3 at the year before Christ 146; on the leap, see the same place at the year 373 before Christ and 1099 after; on a tail let down almost to the earth, sometimes with a sulphurous smell, sometimes even to the point of drying up a stream, see in the same chapter the years after Christ 70, 400 and 1543. On a comet inducing an eclipse on the Moon itself, see the same place at the year 1450. Finally, on dispersal into torches, see the comet of the year 13 before Christ, about which Dio writes, Book 54.

[Margin: Reply to argument 4.]

The reply is that this argument holds not for all comets but only for some, and that therefore some sublunary comets must certainly be admitted.

[Margin: 5. Argument from disordered motion.]

VI. Fifth: Chiaramonti, in the *Antitycho*, Book 3, chapter 1, argues from the irregularity of cometary motion, which he tries to prove from Tycho's own observations; and Carolus Piso does the same in the "Mirror of the Comet" [ſpeculo Cometæ], chapter 27, on the comet of the year 1618, although he also mixes in other accidents and indications of a sublunary inflammation. For he says: "For if, even before the comet's appearance, a certain black and murky cloud, like a huge beam, was seen hanging for a long time in the highest air towards the south, by the report of the Romans; and the brightness of the comet, once kindled, was by no means pure and clear, but rolled much smoky burning about itself, and differed from the purer light of the stars; and its motion, moreover, was singular, disordered and wandering, and wholly most unlike the constant and ordered motion of the stars; and finally its magnitude was such that it was gradually drawn in, and its brightness faded, and at the very last the whole comet perished — why do we doubt to declare the recent comet a tumultuous and improvised fire residing in the fluid elementary region, rather than to name it an eternal work of nature and assign it to the eternal fires?" This argument, put into syllogistic form, we shall bring forward more opportunely in the following chapter, number 10.

[Margin: Reply to the 5th argument.]

The reply, however, is that the comets' sublunary origin and nature are so far from being proved by their motion that, on the contrary, most people probably affirm that the comet should be counted among the celestial rather than the elementary bodies. They do so in view of its uniform difformity, and of an inequality which is real but regular, increasing or decreasing in a certain proportion and like the anomaly of the planets; and further from its constant motion along one arc of a great circle, or from the comet's proper motion, much slower than the motion of the Moon. But we shall have to discuss this

motion separately in the following chapter, arguments 4 and 5. Meanwhile, if some comet is found to wander with a disordered and irregular motion — like the one of the year 1472, slower at first, then suddenly so headlong that it flew across 40° in a single day, and afterwards slackened — the argument is not on that account valid when extended to all comets, and much less to those which are established to have completed their course with an ordered motion.

[Margin: 6. Argument from the ease of explaining the accidents of comets.]

VII. Sixth: if it is asserted that a comet is generated from a hot, dry and fatty mass of exhalations, well compacted and tempered, and kindled either by the motion of the air or of fire under the force of the primum mobile, or by antiperistasis, or by the very temper closely disposed to receive fire and to produce it in the same subject, then many things that appear in comets are easily explained, and a sufficient reason is given for them. For example, why comets are not made within the tropics except very rarely: namely because exhalations raised upward in that tract, by the excessive heat of the Sun and the swifter motion of the primum mobile there, are either cooked away or dissipated, so that they cannot be packed together into one; whereas outside the tropics, especially towards the poles of the world, where the air is thicker and fatter, they are condensed more easily. Likewise why comets occur more frequently in autumn: namely because many exhalations, already raised in the preceding summer and after that equinox made fatter but not yet dissipated, are able to hold together. And so with similar cases.

[Margin: Reply to argument 6.]

The reply given by the opponents is to deny the antecedent. For there are many other properties of comets which are explained only by force, or not very probably, in this Peripatetic hypothesis: such as their enormous duration; the constancy and order in the motion of many comets; a splendour and scintillation much like that of the celestial stars; the diaphaneity of the tail, and its turning away almost always from the Sun into the opposite part; the same apparent magnitude whether the comet is viewed through the telescope or with the naked eye; the monstrous bulk of the comet's body at so great a distance from the earth as many have measured, whether they place comets below or above the Moon; their motion, slower than the Moon's; and their long stay above the horizon. As for what is said about comets being more frequent in autumn, it is established to be false from our Epilogue to the history of comets, on which consult chapter 4, number 4: for more appeared in summer — a time at which fewer ought to have appeared, because the exhalations in our climes are consumed by the heat of the Sun, or too much attenuated and dissipated, if it is for a similar cause that comets are not so frequent within the tropics.

[Margin: 7. Argument from parallax.]

VIII. Seventh: Chiaramonti, in the *Antitycho*, argues from parallax, which he contends was greater than the Moon's parallax in all comets observed with mathematical instruments. Now it is certain that a phenomenon is nearer the earth whose variation of view, or parallax, at an equal altitude above the horizon

is greater — that is, whose difference between the place seen from the surface of the earth and the true place reckoned from the centre of the earth is greater — as we taught in Book 1, chapter 35.

[Margin: Reply to the 7th argument.]

The reply: "This is the task, this the toil." On this the reader must suspend judgement until the examination of these parallaxes, to be carried out below; for geometers and astronomers in no way inferior to Chiaramonti — Tycho, Longomontanus, Kepler, Mästlin and many others — affirm that they found parallaxes smaller than the lunar ones in the comets they observed, and on their authority very many more recent writers have gone over to that opinion with their feet rather than with their heart.

CAPVT XI.

Chapter XI.

Argumenta Contra Opinionem Ariſtotelicam de Cometis, cum ſolutione qualicumque ipſorum.

Arguments against Aristotle's opinion on comets, with some solution of them, such as it is.

Primum Argumentum ab auerſione Caudæ à Sole.

First argument: from the tail's turning away from the Sun.

I. FIRST: the tail of all the comets observed in these last three centuries by astronomers — not by the common people or by those unskilled in astronomy — has been found by them to be turned away from the Sun and to stretch towards the part opposite the Sun, as is clearly established from chapter 4, number 9, and from the history set out in chapter 3. Hence it has come about that the tail emerged before the head, and from the same point of the horizon. But the Peripatetics can by no means adduce a reason for this phenomenon. For if a comet is an inflamed elementary exhalation, taking on whatever shape that exhalation, closely disposed for kindling, has acquired — as the Philosopher expressly teaches, *Meteorology* Book 1, chapter 7 — and is kindled because of the air stirred up by the force of the upper motion and carried round by the primum mobile, then it can have no connection with an opposition of position towards the Sun. The other fiery meteorological impressions have none either: by their own burning they stretch themselves out in whatever direction the matter and fuel have enticed them, without any relation to the Sun. Accordingly, the tail of such comets, if it is a flame rarer and lighter than the comet's head, would have to be either raised upward in the shape of a pyramid, as happens in the other flames around us; or always incline towards the east, because of the motion of the primum mobile snatching the comet's head along against the order of the signs [in antecedentia] — the head being denser and more apt to break through the air, while the hair meanwhile yields and streams out behind comets. Or at least the tail would have to stretch out in whatever direction

the tinder and the exhalation tempered for burning invite it — and you could only gratuitously say that this is always found in the part that lies behind the comet's trunk, in the region opposite the Sun. Finally, a comet that rises in the east in the morning and appears as a pogonias, or bearded comet, its streamers going before it towards the west, would not turn into the same comet tailed, that is, with its hair turned towards the east, when in the evening it follows the Sun after the Sun has already sunk below the horizon — as is established to have happened more than once, especially in some comets observed by Peter Apian, as we related in the history of comets. Therefore not the whole comet is a flame kindled in an elementary breath: its greatest part, taken adequately — namely the tail — is not.

[Margin: Reply to the 1st argument.]

II. The more recent Peripatetics reply that the outflow of the comet which we call its beard or tail is a thinner and spirituous matter exhaling from the comet's body — just as we see little rods streaming from some fires, like a dart or a javelin — or else that it is adventitious matter, newly joined to the comet, and rarer, yet becoming fiery around it. The part that lies between the comet and the Sun, they say, is not seen, because it is overwhelmed by the Sun's rays or consumed by them, and is effaced in front; whereas the part behind the comet appears, because it is neither consumed by the Sun's rays nor overwhelmed by a greater splendour, the density and opacity of the comet's head standing in the way. As for comets that are hairy all round, and whose locks stretched out towards the Sun the Sun does not shear off: either they are like haloes, or they resist the consuming or illuminating action of the Sun for longer because of their denser matter; or at any rate no argument founded on the turning-away of the tail, which is the present difficulty, is drawn from them.

[Margin: Objection against the reply.]

But if that exhalation floating about the comet appears only behind the comet's head for this reason — that it shines in the comet's shadow, while the rest lies hidden because of the presence of the Sun — then the comet's tail or beard would have to either taper into a turning-post, that is, into a cone, and be of the kind which the Greeks call Lampadias, or the figure of a two-edged sword display — such as was the comet we spoke of in chapter 3, from Nicephorus, under the year 392. For the Sun is larger than the comet's globe, and the shadow of the comet's head would be conical, as the optical law on the differences of shadows given in Book 5, chapter 3 requires. Or at any rate the tail or beard could not go out beyond the limits of the conical shadow, nor be columnar, or calathoid [basket-shaped], or widened and spread out like a broom; and much less could it escape from the boundary of the shadow so as to curve in the manner of a sickle, or a Persian scimitar, or a mane bent downward — and yet it has been observed more than once that the tails or beards of comets had these very figures.

[Margin: Carolus Piso's weak reply.]

Therefore Piso was wrong to assert, in the *Speculum Cometae*, chapter 14, that the tails of comets do take on various forms according to the comet's greater or lesser distance from the Sun, but stay within the cone of the solar rays; and that a comet which is nearer the concave of the Moon but farther from the Sun — such as he thinks the comet of 1618 was — can have a coma equal in breadth to the head, that is, cylindrical, because the Sun's rays then cut nothing away from it. For although a globe smaller than the Sun casts a wider and longer shadow the farther it recedes from the Sun, the shadow is always conical, and the more pointed the longer it is. For it to become, to the senses, as it were cylindrical, an almost immense distance from the Sun would be required, or at least a difference of distance much greater than the interval between the Moon and the Earth. Finally, what would Piso do with comets that have a calathoid and sickle-shaped tail, as regards the part that is not covered by the comet's head but lies plainly exposed to the Sun's rays?

[Margin: Chiaramonti's slight reply.]

Chiaramonti, however, replied differently in the *Antitycho*, Book 2, chapter 31. There he admits this turning-away of the comet's tail from the Sun — indeed he affirms that he demonstrated it himself in his little book on the bearded comet of 1618 — but denies that it follows that comets shine not by their own light but by the Sun's: for the tail can lean toward the part opposite the Sun "*even if that impression glows with its own light, or because the head is turned toward the Sun with its right side, as we judged probable in the book on that same bearded comet, or for some other reason.*" So he scarcely deigned to answer an argument of such weight, as Glorioso taunts him in Book 3, chapter 8. Yet Apian, Cardano, Scaliger, Telesio, Guiducci, Galileo, Rothmann, Tycho, Kepler, Longomontanus, Cysatus and Aresius, besides others listed in chapter 6, number 10, made so much of this argument that on its account they held that the tail of these comets is not flame, but the Sun's rays transmitted through the comet's transparent head and refracted in various ways according to the disposition of the matter surrounding the comet and the varied figure of the head. But since this question about the tail is entangled with geometrical difficulties and optical intricacies, we must weigh it separately in chapter 25.

2. Argumentum à Motu Cometæ Diurno imitante motum Primi Mobilis.

Second argument: from the comet's diurnal motion, which imitates the motion of the primum mobile.

III. SECOND. Aristotle supposes that fire, and nearly all the air, lying between the lunar heaven and the Earth, are moved circularly, and that by this agitation a dry and hot exhalation is kindled, when it has been well tempered, and blazes up into comets. For he says, in *Meteorology* Book 1, chapter 7: "*For we suppose that the first part of the world, the part around the Earth, the whole of which lies under the circular revolution, is a hot and dry exhalation. This, and a great part of the air still below it, is continually carried round the Earth by the revolution and circular motion*, etc."

[Margin: Whether comets are carried round together with the air by the celestial primum mobile.]

But all the arguments by which the solidity of the heaven is attacked — and how valid and solid they are will appear in Book 9 — also attack the motion of elementary fire and of the air around the Earth, if that carrying-round is supposed to be effected by the concave of a solid lunar heaven, in the way that, when a basin is turned round, the water enclosed in it is whirled round with it. But suppose instead that elementary fire and the greatest part of the air are set moving by a heaven, however fluid, in the way that, when water enclosed in a basin is turned round, the air nearer to it is also rolled round, though somewhat more slackly and sluggishly. (So Sarsius teaches, against either Galileo or Guiducci, in the *Libra Astronomica* from p. 43 on, and indeed by an experiment of Father Orazio Grassi: namely, of a small candle flame, or of a leaf of paper hung from a thread and let down near water. The leaf imitates the eddies of the water in a following circuit, whereas the flame leans to the side opposite the air set in motion.) If this, I say, is supposed, there is no reason why the whole of that small body of air which remains above the mountains and below them, right down to us, should not be moved by the same motion; or why clouds, when no wind is blowing toward the east, should not be carried perpetually westward by that motion — let alone papers or straws thrown upward. Since, then, neither the flames of a pyre, nor hairs or very light reeds set upright, nor the shavings or motes that we see floating in the Sun's rays let into a dark room, nor straws or paper balls thrown upward, or dropped down by us from a tower, nor threads let down perpendicularly from towers, nor finally clouds, however calm the weather and with no wind blowing against them, are carried toward the west, we seem to have much more probable indications that not even the upper part of the air is moved with the motion of the heaven, whether solid or liquid — and much less moved so rapidly that an exhalation catches fire from it — whatever effort Chiaramonti makes, in his little work on the sublunary seat of comets, part 2, chapter 12, to establish that motion.

[Margin: Reply to the 2nd argument.]

One can reply nonetheless that the motion of the primum mobile is not felt by us, both because of the enormous distance from the heaven and because of the sluggishness and thickness of the air in our parts. For if someone on a lake or a vast sea were to describe the circumference of a circle at a distance of 100 miles or more, the whole of the water would not on that account be stirred by a sensible whirling from that circumference right to the centre; rather, the parts nearer the centre would stay at rest just as before. And if it does not seem likely that the air nearest us is free from the motion of carrying-round, while the uppermost region of the air is snatched along by it at such a speed that an exhalation is kindled there into a comet, the Peripatetics will reply that the comet's matter does indeed arise from our exhalations, but afterwards rises higher, through the region of elementary fire, until it experiences the most

violent motion of the primum mobile. And indeed it is surely more likely that such a motion of the primum mobile is communicated to the already-mentioned region of fire — and even, at least more slackly, to an exhalation already raised to that place.

3. Argumentum à mora Cometæ ſupra Horizontem.

Third argument: from the comet's stay above the horizon.

IV. THIRD. Let it indeed be granted to Aristotle that the uppermost region of the air, into which hot and dry exhalations gather, as he himself holds, is carried round very violently by the motion of the heaven, and that comets therefore catch fire. Granted this, as soon as they had kindled they would be carried with the greatest speed toward the west and would be seen to fly there like flashes of lightning; and in this diurnal motion they would appear to us faster than the Moon and the other stars by as much as they are nearer the Earth than the Moon is; and the comets that were near the Equator would pass across from east to west not in 12 hours but in far fewer — which, however, does not agree with experience. This argument will be better understood from the diagram of chapter 9 in the section on parallaxes, Book 10. Nor could that speed be retarded by the comet's own motion striving eastward, in those comets which are established to have moved against the order of the signs, as we showed in chapter 4, number 11.

[Margin: Reply to the 3rd argument.]

The reply is that the comet's proper motion is so varied — by reason of the matter it follows as its tinder, and of the impelling principle, whether that is like the principle that drives the winds or thunderbolts, or something else — that it is not impossible, nor even very surprising, that a comet should be carried round in this way by the motion of the primum mobile and return to the horizon after the manner of the stars, and yet be borne, either obliquely toward the poles of the world or straight toward the east, in such a way that it retards that speed, so that in the space of one hour it is not advanced fifteen degrees westward by the motion of the primum mobile alone, but much less. Hence, then, it can happen that comets remain above the horizon for many hours — especially if the place of comets is not at the boundary of fire and air, as is attributed to Aristotle, but next to the concave of the Moon, which the Philosopher seems to hint at in *Meteorology* Book 1, chapter 1, when he says that the place of comets is very close to the revolution of the stars. But this argument will be discussed again below, in chapter 15, from Problem 7.

4. Argumentum à motu proprio tardiore Cometarum quàm Luna.

Fourth argument: from the proper motion of comets, slower than the Moon's.

V. FOURTH. If a comet were a meteoric inflammation below the Moon, the comet's proper motion toward the east would have to be faster than the Moon's motion. For the farther each star is from the Earth, the slower it is in its proper motion, as Aristotle himself admits in *De caelo* Book 2, text 58,

and as is evident to anyone who compares the Moon's motion with the Sun's, and the Sun's with that of Mars, etc. But many comets have been slower in proper motion than the Moon, as is evident from the history of chapter 3 taken together with chapter 4, numbers 10, 11 and 13. Therefore those comets at least are above the Moon and different from meteoric kindlings — granted that this argument does not hold for the comets, which I indicated in the same chapter 4, that were faster in proper motion than the Moon. Tycho uses this argument in volume 2 of the *Progymnasmata*, p. 104. There, having related that he had observed in the comet of 1577 a motion always slower than the Moon's from beginning to end, he had inferred: "*Hence it always kept a proper progress slower than the Moon's; and for that reason the harmony of the celestial circles and motions demands that it was far more remote from us than the Moon's orb is.*" Indeed, earlier, on p. 94, he had asserted of the same comet: "*It is a proof that this comet was by no means sublunary that its proper diurnal motion was never so great as to equal the Moon's diurnal course even at its slowest. For the Moon, when it appears slowest, completes more than ten degrees in one day; whereas this comet, at the beginning, when it was fastest, was found by us to advance not much beyond five degrees within a single revolution of the primum mobile. And that it therefore completed its course far above the Moon's sphere can at once be proved quite plainly from this: the farther the stars are from the Earth and the nearer to the eighth sphere, the slower the proper motions they appear to us to have; and conversely, the nearer they are, the faster they are seen to be moved. Therefore the comet is proved not only to have stood just above the lunar sphere, but to have completed its path not far from the orbs that* ♀ *and* ☿ *describe around the Sun.*" Finally, the same argument is put forward, and not resolved, by Biancani in *Loca Mathematica Aristotelis*, p. 93.

[Margin: Reply to Argument 4.]

VI. I REPLY that the argument already mentioned holds for stars that complete their revolutions and that are established on other grounds to be ordinary stars, or higher than the Moon; and that it does not hold unless that greater height is certain on other grounds — otherwise one would be allowed to put tortoises above the heaven. Indeed, it does not hold for every planet in every position and at every time. For in the Ptolemaic hypothesis Mercury and Venus are below the Sun, and yet in their mean motion in longitude they are as fast as the Sun, while in their apparent motion they are sometimes slower. In the Tychonic and the Copernican hypothesis, by contrast — indeed in the hypothesis of all the distinguished more recent astronomers — the same Mercury and Venus are sometimes above the Sun and sometimes below it; and Mars, which is slower than the Sun, is nevertheless much nearer the Earth than the Sun is when it has become acronychal, that is, when it is opposite the Sun, especially at the perigee of its eccentric — as Copernicus, Tycho, Kepler, Longomontanus, Lansbergen and Ismaël Boulliau concede.

As for Tycho, I say that when he wrote those things about the comet of 1577 he was younger, and that he did not himself bring out the whole of that volume 2; rather, he first published volume 1 of the *Progymnasmata*, while volume 2 as a

whole was published by his heirs after his death, as is clear from the letter to the reader prefixed to volume 2. So it is no wonder if Tycho did not correct those propositions of volume 2. For when he had become more learned than his former self, he recognized that this argument is only probable and establishes nothing certain for the greater or lesser distance of a phenomenon from the Earth.

[Margin: Does Tycho contradict himself, or correct himself?]

For in a letter to Rothmann of 1595 January 14, indignant that a certain Scot had thrown up to him the futility of this argument, he says: "*And because I would say that it is not without likelihood that that comet was slower in its proper motion than the Moon, and therefore higher, yet I would not have tied any necessity to these points — he has scarcely found sneers enough to attack me with.*" Yet, as we saw, he had once called this argument not merely probable but *plainly convincing*. But a man who corrects himself must be spared. For in a letter of 1588 August 17 to the same Rothmann, p. 118, he has these words: "*Although, to tell the thing as it is, speed and slowness of motion do not sufficiently distinguish the remoteness or the nearness of comets, so that what you seem to raise against us is no obstacle — namely, that the speed of motion in Regiomontanus's comet, which is put at 40° of a great circle in one day, proves that it was sublunary and had as great a parallax as he attributes to it. For if the comet of 1585 could lie in the highest orb of Saturn, even by your own judgement, and nonetheless complete a diurnal motion of three degrees at the beginning, while the star of Saturn itself, even at its fastest, completes only 8′ in one day — so that the comet was then more than twenty times faster than Saturn even at its swiftest — how, I ask, can it not also be granted that the comet described by Regiomontanus was above the Moon, even though it was about three times more rapid than the Moon's diurnal motion?*"

Rightly indeed. And consistent with this is what he says against Thaddaeus Hagecius [Tadeáš Hájek] in volume 1 of the *Progymnasmata*, p. 512, where he writes: "*That argumentation which Thaddaeus puts forward in the same chapter, from the proper motion of comets — that comets which resist the first motion faster than the Moon are below it, and those that resist it more slowly are above it — does not seem to me sufficiently apodictic. For comets can be moved by their proper motion in a swifter course than the Moon itself, whether forward, or in the order of the signs, or even sideways toward the poles, and yet by no means lie below the Moon. For comets have their own laws of motion, exempt from what is prescribed for the planets.*" But why do we fish for Tycho's mind in his other volumes? Did he not, in that very volume 2 in which he had called the argument already mentioned *plainly convincing*, later, on p. 440, call it merely *tolerable*? And on p. 441 he added: "*Thus the last comet, that of 1585, which beyond all doubt was carried far above the Sun — so much so that that most learned man Christoph Rothmann, the Landgrave's mathematician (who agreed with me closely in unravelling its parallaxes), did not hesitate to place it in the highest sphere of Saturn at the beginnings of its appearance — resisted the revolution of the primum mobile in its proper diurnal motion by a full three degrees, whereas the star of Saturn opposes it by at least 2′, Jupiter by 5′, Mars*

by 32½. It was therefore in no way subject to the same laws of motion as any of these three planets that are called superior, although in truth it was as far from the Earth as one of them; but it was carried from west to east with a much swifter impulse."

[Margin: Rothmann's admission of the weakness of this argument.]

Finally Rothmann himself, on this comet of 1585, p. 101, speaks thus: "*If motion in comets were an argument of height, the comet would have to be placed not only below Saturn, Jupiter and Mars, but also below the Sun, Mercury, and below Venus herself — which, however, the absence of parallax entirely refutes. And therefore, given and granted that the comets observed by Pontano, Regiomontanus and others were faster than the Moon, they are under no necessity of being placed below the Moon.*" To gather, then, what these men have said into a few words: with Tycho and Rothmann assenting, the comet of 1471 observed by Pontano could cover 30° in one day, and that of 1472 observed by Regiomontanus 40°, and so be faster than the Moon and yet be above the Moon; and the comet of 1585 could cover 3° a day at its beginnings, by Rothmann's observation, and so be faster than the Sun, Mars, Jupiter and Saturn and yet lie in Saturn's sphere. Just so, the comet of 1577 could cover only 5° and be slower than the Moon, and yet be below the Moon. And so from this slowness or speed of the comets' proper motion nothing certain is gathered about their distance from the Earth; and therefore this argument is rightly belittled and rejected by Chiaramonti in the *Antitycho*, Book 2, chapters 7 and 9; by Glorioso, *De Cometis* Book 3, chapter 6; by Cottunius on *Meteorology* Book 1, lecture 33; and by Mastri, disputation 4 *De caelo*, question 2, article 4, number 46. Granted that Kepler in the *Hyperaspistes*, p. 30, would have this argument be fairly probable in itself, or a matter of opinion — that is, to one who considers it rather crudely; for examined inwardly it is worth little or nothing. Meanwhile, partly from our limitation and partly with Chiaramonti in the *Apologia pro Antitychone*, Book 1, he lays down that the syllogism must be arranged thus: "*Every phenomenon that is a star and has a proper revolution slower than the Moon's is above the Moon; but a comet is of this kind;*

therefore, etc." In the minor premise, however, it must be said that a comet is a star — which the Peripatetics will deny.

5. Argumentum à Motu Cometæ per eumdem Circulum Maximum, & quidem Ordinato ac Regulari.

Fifth argument: from the comet's motion along the same great circle, and a motion, moreover, that is ordered and regular.

VII. FIFTH. If a comet were a meteorological impression and sublunary, its motion would not be along the same great circle, and it would be disordered and irregular in its own path — that is, not only unequal, but inconstant in its very inequality, and so not even uniformly non-uniform. For it would not go by a fixed law, except perhaps for a few hours; it would be snatched along in whatever direction it was called away by the tinder of the matter to be kindled in succession, or by air stirred up by blasts of wind. But it is established that

many comets both described one and the same great circle in the sphere and were uniformly non-uniform in their proper motion for many days and months — that is, kept a certain proportion in the increase or decrease of their motion — as anyone finds who rereads what we said in chapter 4, numbers 12 and 13, and the history of the comets of 1577, 1585, 1590, 1607 and 1618. These comets at least, then, were rather celestial, and generated or formed otherwise than Aristotle taught. Seneca presses this argument home elegantly and acutely, in his usual way, although he wrongly supposes that it is not known how far a comet has advanced in one day. For in *Natural Questions* Book 7, chapter 8, against Epigenes, who had asserted that comets are kindled in the air by the force of a whirlwind stirred up and twisted, he says:

[Margin: Seneca's opinion, but sprinkled with falsehood.]

"*Whoever said this does not note what the course of whirlwinds is like, and what that of comets is like. The course of whirlwinds is rapid and violent, and more agitated than the winds themselves; that of comets is gentle, and conceals how much ground it has covered in a day and a night. Again, the motion of whirlwinds is wandering and scattered and (to use Sallust's word) eddying; that of comets is composed and keeps to a set path. Would any of us believe that either the Moon or the five stars are snatched along by the wind or spun round by a whirlwind? I think not. Why? Because their course is not disturbed and uncontrolled. Let us transfer the same to comets. They do not move confusedly or tumultuously, so that anyone should believe they are driven by turbulent and inconstant causes.*" And in chapter 32, pointing to motion along a great circle, he says: "*No ordinary and celestial fires have a bent path. It is proper to a star to trace out an orbit; whether other comets have done this, I do not know: two have done it in our own age.*"

[Margin: Tycho's epicheireme for the celestial place of the comet of 1577.]

Tycho too relies on the same argument in volume 2, where he discusses the comet of 1577 from p. 92 to p. 105, and argues thus: "*Add that in this way, by reason both of the ecliptic and of its own path, it appears to have completed a quadrant of a great circle in the sphere; and this too does much to persuade us that a celestial, not an elementary, nature belonged to this comet. Therefore, since it has been sufficiently declared and demonstrated that this comet by its proper motion described a circle in the sphere that was exactly a great circle, contained midway between its poles, and never deviated from it in this direction or that during the whole time of its duration; moreover, that under this circle it kept an ordered and not an unstable motion, slackening gradually and step by step, as usually happens in the wandering stars; that it never displayed this motion faster than the Moon's slowest diurnal motion, but on the contrary much slower; and finally that it ended the places of the beginning and of the end of its motion within each of the tropics, near the limits of the Sun's digression, and in that way completed a quadrant of the sphere — therefore, since so many reasons and indications concur, drawn from the comet's proper path, which he observed through the whole time of its duration, it is proved clearly enough that it had a motion conforming to the ethereal region: it becomes manifest that its place and course lay in the immense capacity of the celestial world, and by no means in the*

sublunary and elementary orb. This we proposed to demonstrate first, by this more general way." You see, reader, from those marks — "*becomes manifest*" and "*we proposed to demonstrate*" — that Tycho judged this argument, if not in each of its parts, yet gathered from all of them together, to be not only persuasive and probable but also demonstrative and evident.

[Margin: How Kepler defends this argument.]

VIII. Now Kepler in the *Hyperaspistes*, upholding this argument not from his own opinion but in the person of a champion of Tycho, says on p. 19 that, since Tycho showed that the comet of 1577 described a great circle by its proper motion — if not most exactly, yet more exactly than the Moon describes one in its progress — he rightly inferred that that comet was rather celestial, and not lower than the Moon. And from p. 19 to 26 he teaches that the motion of the same comet, by Tycho's observation at least, was for three months so ordered and so uniformly non-uniform that in this it was far more like the celestial motions of the planets (in which all those skilled in astronomy know well enough that certain small irregularities are to be disregarded and do not impair the proportion of the whole motion, unless one goes looking, out of season, for a knot in a bulrush) than any elementary motions: for none of these keeps an ordered increase or decrease over several days, let alone months; and that Tycho therefore rightly argued from this that the comet was celestial rather than elementary. Yet Kepler admits in the same place, pp. 5, 18 and 19, that this argument is only probable, as will be clear from his words, to be adduced in chapter 18, number 3.

[Margin: Father Cysatus's similar argumentation.]

Cysatus uses the same argument — namely, that of motion ordered and along a great circle — to establish the comet's celestial region and origin, in *De Cometa anni 1618*, chapter 3, proposition 4, proof 1, in these words: "*For the comet, as is clear from chapter 2, from the day it first shone, advancing thereafter with a regular and proportioned motion, described a great circle beneath the firmament, midway between its two opposite poles, and did not sensibly deviate from that orbit, which divided the sphere into two equal hemispheres, any otherwise than the Sun proceeds along the ecliptic, or any other planet along its own path. Therefore this comet, no less than any other planet, just as it had celestial motions and laws, so too was endowed with an ethereal nature and place.*" And a little later: "*Finally, the comet's motion in this great circle was indeed unequal, but it consisted in a lawful and most ordered inequality: at the beginning, namely of December, it was swiftest, as exceeding 3°; afterwards it decreased gradually day by day, not by a random leap but by a reasonable falling-off, exactly as is the motion of the Sun and of the other planets too. Therefore the comet too is to be numbered among the planets.*" He strengthens this argument by a comparison with other fiery meteors: "*For an elementary fiery meteor,*" he says, "*must wander off in the air this way and that without law and without proportion of motion, being driven at random and violently by the impetus either of an agitating wind or of a seething fire — as is evident in falling stars, lightning, leaping goats, the flying dragon and other genuine aerial meteors.*" Understand this

not of a small portion of motion, or of a whole motion of brief duration, but of a whole and long-lasting motion. Meeting the objection that Chiaramonti later made much of, he says: "*Nor can it be said that the comet was snatched along by the heaven or by some star in so ordered a way: for no motion of the heaven or of any star tends from south to north, as this comet's did.*" Yet he at once admits that a more effective argument for this is taken from parallax.

[Margin: Lotharius Sarsius used the same argument.]

Guiducci, following Galileo's mind, had objected to the disputation held in our Roman College on the three comets of 1618, which had also used this same argument, that the motion of comets can be defended without any circle, let alone a great one, and can take place by a rectilinear passage. To this Lotharius Sarsius replies in the *Libra Astronomica*, p. 9, from the teaching of Father Orazio Grassi, that in this controversy it was supposed that the comet is carried with a circular motion, and that the disputation was with those who already supposed this; and on that supposition, that the comet's path was ordered along a great circle, it is rightly inferred from this that its nature is celestial rather than elementary — although he says that that rectilinear motion is entangled in great difficulties, of which more elsewhere, below.

[Margin: And Biancani.]

Biancani too, in *Loca Mathematica Aristotelis*, p. 93, puts forward both parts of this argument — from the great circle and from motion regularly unequal — yet he ventured to define nothing in this controversy.

[Margin: And Froidmont.]

But Froidmont, *Meteorology* Book 3, chapter 1, article 3, affirms from his own observation at Louvain as well that the comet of 1618 crept through Libra, Boötes and the Bear to the Arctic circle, and only toward the end strayed a little from the segment of a great circle; and that the same was observed by Kepler at Linz, by Cysatus at Ingolstadt, and, in the comet of 1577, by Tycho. From this, and from the regularity of the motion, he concludes thus: "*I conclude, therefore, and lay down as probable, that those comets, so composed and unwavering under the same cir-* cle — a great circle — gliding by their proper motion, are carried round in an ethereal region that is not so turbulent and unsteady as this sublunary one is.*"

[Margin: And Resta.]

[Margin: And Cabeo.]

Franciscus Resta [Francesco Resta] likewise uses this argument, in his *Meteorology*, tract 1, chapter 2, and so does Cabeo on Book 1 of the *Meteorology*, text 37, question 1. Gathering the argumentations of those already mentioned into syllogistic form, then, take it thus:

[Margin: Major premise.]

1 *No elementary and sublunary mobile, especially a fiery one, moves by its own proper motion for many days, let alone months, sensibly along the same great circle of the sphere, with a motion either equal, or unequal indeed but sensibly regular and ordered — or at least not as exactly as the Moon.*

[Margin: Minor premise.]

2. *But some comets have moved by their proper motion for many days, or even months, sensibly along the same great circle of the sphere, with a motion unequal but sensibly regular and ordered; and at least more exactly than the Moon.*

[Margin: Conclusion.]

Therefore *some comets are not elementary and sublunary mobiles.*

The *major* is evident by induction through all elementary mobiles, in none of which do all the conditions enumerated in the major of the syllogism concur; and it will become still clearer in the solutions of the replies. The *minor* is proved from the history of the observations set out in chapter 3, on the comets observed from 1577 to 1618. If you yourself mark on the surface of a celestial globe the places those comets passed through, point by point, you will see that many of them moved along the arc of a circle whose plane passes through the centre of that globe and cuts it into two hemispheres — which is the property of a great circle in the sphere, from Theodosius, *Sphaerica* Book 1, proposition 6. And if you compare the motion they made from day to day in the tables given in that chapter 3, you will see that several of them diminished their speed by a proportional decrement, with a difference either nil or smaller than that found in the motion of the ☾ or of the other planets.

[Margin: First reply to Argument 5.]

IX. It can be replied, first, as some Peripatetics reply on their side — namely Chiaramonti in the *Antitycho*, from p. 110 to p. 151, and in the *Apologia* for the *Antitycho*, from p. 15; and, following him, Cottunius, *Meteorology* Book 1, lecture 33, and Glorioso, *De Cometis* Book 3, chapter 5 — by denying the major premise. They add that even if it were granted that some comets moved with an ordered and regular motion, it by no means follows from this that they were celestial rather than sublunary or elementary. First, because the motion of comets, which these authors posit as made along a great circle, can be saved by a rectilinear trajectory without any circle at all, let alone a great one. So Kepler did in the *Optics*, p. 335, and in his little book on comets, where for that reason he said: "*Those who demonstrated the motion of the comet of 1577 by circles took on a most difficult task, and yet it did not wholly succeed.*" And in the *Hyperaspistes*, pp. 6 and 10, he granted Chiaramonti that this proposition is not at all necessary if it is taken apart from parallax — indeed, that the argument drawn from it is faulty and weak. On rectilinear motion Cysatus, *De Cometis* Book 2, proposition 8, and Froidmont, *Meteorology* Book 3, chapter 4, article 4, subscribe to Kepler; and, with Galileo, so does Mario Guiducci in his opuscule on comets. Next, because for a motion along a great circle in the sphere of the world it suffices that the circle of the motion be described from the centre of the world, and this can happen just as well with an elementary mobile, however near the Earth, as with a celestial one. Hence it does not follow from the nature of a great circle that the mobile is celestial rather than elementary or sublunary.

[Margin: Many elementary things travel in the plane of a great circle.]

Moreover, along the same plane of a great circle — and indeed keeping the same tenor, whether of equality or of sensibly uniform non-uniformity — there move many missiles, whether propelled by hand or by the bowstring through ballistas or other machines, or by sulphurous and nitrous powder; and thunderbolts, before they strike a resisting body and are twisted into spirals and vortices by some other motion *per accidens*; and certain perennial winds, driving sails and ships along the same great circle for many days; and certain canals led in a straight course over a long tract of land. For the example that Chiaramonti adduces of the sea, and of the ebb and flow of the sea keeping a proportional increase or decrease, is rightly rejected by Kepler in the *Hyperaspistes*, p. 21: the sea is not poured onto the land and drawn back with the tranquil tenor of a balance, but with waves driven back and forth in different directions, and with disordered motions, greater in one place and less in another. More to the point is Chiaramonti's instance on p. 117, about the motion of heavy and light bodies thrown in a circle by an external cause: for while these try to descend to the middle, or to ascend from the middle, they tend toward the centre and proceed along a plane cutting the sphere at the centre of the world. But what Io. Bapt. Benedictus [Giovanni Battista Benedetti] says in his letters — that ships always incline toward the equator, and, if land did not stand in the way, would rush to the equator so as to describe a great circle there — lacks solid foundation. For the ocean is not lower under the equator, however much vapour and exhalation the Sun draws from it there, such that the waters would have to flow down there because of the slope; and ships can describe a great circle by their own motion even when they are not at the equator, by proceeding along vertical circles, as we showed in the Geographical Book, where we treat of hydrography. Moreover, the motion of a pendulum held in the same plane, swinging up and down to and fro, takes place along the plane of a great circle.

As for the fact that no other fiery meteor persists for so long a time in the same great circle, and in a motion unequal in an ordered way, as some comets do: this happens (say the Peripatetics) because the other meteors do not have so much matter, or matter so densely packed and tempered, which, kindled all at once or successively, could feed a flame for many months or days, as comets have. In this respect comets are rather to be compared with certain vast lamps which, owing to the quantity of oil and a wick that is not quickly consumed, burn for many days, and for still more if crushed salt is mixed into the oil — unless you prefer to compare them with the lamps found in the tombs of the ancient Romans and shining there for whole years, about which Liceti wrote learnedly. That major premise, therefore, is not universally true, even if comets have some properties that are not found in other fiery meteors, and on account of which they have a somewhat greater agreement with the stars and planets. In the same way light has some properties in which it differs from all other corporeal qualities, and a certain greater likeness to spiritual things, and yet we do not conclude from this that it is a spiritual quality. Or again, the more

recent astronomers admit that the spots and faculae of the Sun are now and then generated and destroyed — in which respect they are more like sublunary fiery meteors than stars — and yet they will not forthwith concede to the Peripatetics that these are elementary or sublunary bodies.

[Margin: Glorioso recognised nothing but verisimilitude in this argument.]

Therefore, just as we saw in the reply to argument 4 that it does not necessarily follow from a motion slower than the Moon's — as Tycho himself at length acknowledged — that comets are above the Moon, however great their likeness in this respect to the planets slower than the Moon, so neither does it follow from motion along a great circle, and ordered motion, that comets are above the Moon. Glorioso frankly admits as much in Book 3, chapter 6, p. 141, saying: "*And so, although these reasons drawn from the speed and slowness of the proper motion, and also from the great circle, may seem in some way weak if they are put forward in this way and simply, nevertheless they are not at all to be neglected if they correspond with the other circumstances of the distances and of the motion. Since, therefore, the astronomers noticed that comets do not keep a wholly irregular inconstancy in the speed and slowness of their motion, nor in the straightness of their path and route, and since they saw that comets agree with the stars in very many things, they believed they could at least establish this quite probably: namely that comets are very far distant from the Earth and do not consist of flaming matter, which by its nature can keep no proportion and constancy either in motion or in path.*" Neither Kepler nor Froidmont recognised anything in this argumentation but a certain probability or verisimilitude; and to it the Peripatetics could nevertheless oppose a conclusion no less verisimilar, by replying through an instance, as follows.

[Margin: Reply 2, by instance.]

X. *It can be replied*, therefore, secondly, by turning a similar argument back upon the adversaries.

[Margin: Major premise.]

1. *No celestial body observable with the naked eye moves either outside the zodiac, or in such a way that it does not describe a circle parallel to the zodiac; nor is any sensibly generated anew and extinguished before completing one revolution.*

[Margin: Minor premise.]

2. *But very many comets move outside the zodiac, in circles not parallel to the zodiac; and they are sensibly generated anew and extinguished without completing even one revolution.*

[Margin: Conclusion.]

Therefore *very many comets are not a celestial body, etc.*

But who, unless his mind were already preoccupied by prejudice, or by a prior inclination toward the Tychonic opinion, would deny that, in this deviation of their motion from the zodiac and its poles — a deviation, indeed, as great as is gathered from what was said in chapter 4, numbers 10 and 11 — and in their rising and perishing, comets bear a greater likeness to sublunary things than to celestial bodies? With these topical arguments weighed on either side,

then, we are compelled to remain almost in equilibrium, until the weightier moments of other reasons incline us to one side.

[Margin: 3rd reply to Argument 5.]

XI. *The Peripatetics already named reply*, further, thirdly: granting or passing over the major of Argument 5, they deny the minor proportion [?]. They think that Tycho was refuted by Chiaramonti — as Chiaramonti himself also asserts — and that it was shown from data given by Tycho himself that the comets neither described the same great circle geometrically nor kept an exact proportion in the increase or decrease of their speed; especially since neither Tycho nor others observed the comets daily from the beginning of their first appearance until their extinction, but gathered the unobserved motion of the other days by probable conjecture from the observations of a few days.

[Margin: Chiaramonti's reasons against Tycho, and their solutions, as regards the progress along a great circle.]

That it did not describe a great circle, Chiaramonti proves in the *Antitycho. First*, on p. 119, because he had already shown in Book 1, chapter 11, that if a comet's true motion is along a great circle, its apparent motion cannot be along a great circle if the parallax is sensible. But from what will be said below in chapter 17, theorems 3 and 4 and the following, it will be clear that this holds only in proportion to the size of the comet's parallax. Hence if the comet's parallax is less than the lunar, as Tycho already presupposed at the time, the true motion along sensibly the same great circle can be deduced from the apparent one. He proves it *secondly*, in the same work, Book 2, chapter 6: when the comet's places in longitude and latitude given by Tycho are examined, it is gathered that the comet of 1577 did not keep the same inclination to the ecliptic in its course, nor describe the same great circle most exactly, as Tycho said, but followed a tortuous path, like the alternating windings of serpents. Indeed, at the beginning that arc cut the ecliptic at 20° 51′ of ♐, but later at 20° 20′ of ♐ — a difference not of only 5′, which Tycho acknowledged and judged negligible, but a difference of 31′, which does not seem negligible, and at times a difference of 55′. But this does no harm to Tycho, or to Kepler, his Hyperaspistes, who on p. 25 grants this difference, though always less than one degree, as Chiaramonti admits in those places. And this does not prevent its being said that the comet described the same great circle more exactly than the Moon, since Chiaramonti admits in the same chapter that none of those arcs deflects from its great circle by more than a sixtieth part of the lunar flexure, that is, of the amount by which the Moon deflects from its great circle. Would that astronomers could always keep within a certainty of one degree for the places of the nodes, or sections, and of the apsides of any planet! Astronomy would be happier for it, as Kepler admits in the same place. Tycho would nevertheless have spoken more cautiously if in volume 2, pp. 92, 93, 103 and 105, he had not called that circle of the comet "*a circle exactly, indeed most perfectly and most exactly, great*", and like the ecliptic, indeed more perfect than the Sun's course, and so given

Chiaramonti occasion to refute him on this point. But this argument will be discussed again more closely in chapter 18, from number 2 to number 6.

[Margin: Chiaramonti's other attempt against Tycho, repelled by Kepler.]

XII. The other part — namely that the comet's motion was not ordered — *Chiaramonti* tries to show in the same Book 2 of the *Antitycho*, chapter 6. He examines the observations of seven days and reduces Tycho's given longitude and latitude of the comet to geometrical calculation; from this he establishes that the proportion of decrement by a sixth part at each step, which he says Tycho asserted, was not kept; that the motion even increased at times by a sixth part; and that not only was the sesquialteral proportion not kept in the decrement, but no other kind of ordered and continuous proportion either. But *Kepler* in the *Hyperaspistes* denies that Tycho asserted a continuous sesquialteral proportion in the decrement of the comet's motion, or one made continuously by a sixth part of one degree. Granted, Tycho said in volume 2, chapter 6, p. 98, that from November 15 to November 20 the comet advanced so that in five days it completed 14° 3′, "*so that, if it had advanced equally each day, it was found to complete now not fully three degrees, falling short by about a sixth part*" — that is, falling short by about 10 minutes, so that the motion, if it is supposed equal, would have been 2° 50′ daily; whereas he says that from the 14th to the 15th it completed 3° 48′, and from this he gathers that it was swifter at the beginning and then decreased successively. But nowhere in that whole chapter 6 does Tycho mention a continuous decrement by a sixth part of a degree, or that sesquialteral proportion which Chiaramonti attributes to Tycho. Kepler read that chapter, I have reread it, and let anyone who wishes read it again: he will not find what neither Kepler nor I found. So far, indeed, was Tycho from meaning this that he recognised in that cometary motion a retrogradation and station similar to the motions of the planets, to which a continuous proportion in decrement certainly does not belong.

[Margin: Tycho's legitimate meaning on the proportional decrement of the comet's motion.]

For hear what Tycho says in that chapter 6: "*Add that in this very circle, although the comet was seen to move unequally, as the planets themselves also do in their orbs, it nevertheless by no means admitted a disordered inequality — one, that is, that would leap suddenly from slower to faster, and back again from this to that, with a wandering course — in the way that meteors generated in the elementary region are observed to have such an uneven and inconstant motion. Rather, this comet, under that portion of a great circle, was carried from a faster apparent motion into a slower one successively and proportionally, keeping a like course of inhibition, so that it was found to have, no less than the planets, an alteration of the restraint of their ordinary motion when from a faster course they end in stations. For on no following day did it become faster; it always slowed its motion by a like course, so to speak, until in the last days it scarcely completed a third part of one degree each day, whereas in the earlier days it seemed to complete five whole degrees, keeping meanwhile, as I said, the proportion of the ordinary falling-off.*" Nor does he say otherwise on pp. 102, 104

and 105, where he inculcates the same doctrine. It is true, though, that Tycho supplied the motion of some unobserved days by a verisimilar analogy, as is also done in the tables of the celestial motions and their equations, although immediate observations are not had for each and every day of the period.

[Margin: Cottunius and Glorioso subscribing to Chiaramonti with too little circumspection.]

Chiaramonti therefore interpreted Tycho with excessive rigour; and so did Cottunius, who copied certain numbers from Chiaramonti on p. 295 without examining Tycho closely, or Tycho's Hyperaspistes, which had come out long before. *Glorioso* too, *De Cometis* Book 3, p. 132, gave his vote to Chiaramonti against Tycho on this point far too hastily. Let it stand, then, that if the major proposition of the fifth argument were true, nothing in the minor would prevent some comets from being called celestial rather than elementary and sublunary. But because the major is not certain, only probable, it likewise becomes probable from this, though not evident, that the comet was above the Moon — saving, however, the probability of the opposite, until it is evidently refuted from another quarter.

6. Argumentum à Magnitudine Cometarum.

Sixth argument: from the size of comets.

XIII. SIXTH. It is scarcely likely that so great a quantity of exhalations is raised from the earth and sea up to the highest region of the air — let alone to a higher region — as is required to compose the bulk of comets, which sometimes rival the size of the Sun and with their tail occupy 60 or 70 degrees in length and more, as is certain from the history summarized in chapter 4, numbers 6 and 8. This is especially so when they last for several months, or when several comets arise at the same time in the same region, or in immediately following years, and not enough time passes for a sufficient heap of exhalations to gather little by little. For this is why earthquakes occur in the same region only very rarely; and so too the blasts by which the swelling ocean overwhelms islands or cities; and the eruptions of Vesuvius, of which only thirteen are counted from the birth of Christ to our own times. And indeed, if the conditions that the Peripatetics require for forming and kindling a comet are considered, it will be clear how little likely that reasoning is. For grant that exhalations of this kind are drawn not only from the sea but also from the earth (which, however, Plato denied, according to *Olympiodorus*, *Meteorology* Book 1, section 5, and so did *Io. Baptista Porta* [Giambattista della Porta], *De aeris transmutationibus* Book 1, chapter 8), and that by the force of their lightness they make for the upper region;

they still ascend only so far as their acquired heat lasts. But when they reach the colder region of the air — in which, even in summer, rain and hail form, and in autumn and spring hoar-frost, and in winter snow — a great part of them is chilled and their lightness is blunted, so that they penetrate no further. Mixed with vapours, and enclosed or hemmed in by clouds, this

matter either escapes, or rages in an oblique uprising into winds and storms, or rumbles and roars in thunder, or threatens an outlet in lightning-flashes and coruscations, or at last breaks out in thunderbolts once the prison of the clouds is burst. Indeed, if this matter had to be unctuous, that is fatty and oily, as the more recent Peripatetics prefer — so as to be better suited to cohesion and to feeding for a long time the flame it has conceived — it retains by that very grease a certain viscosity, in which the wings of its lightness, so to speak, are entangled as if in birdlime, so that it cannot fly up to the highest region. This is why odours from ointments and oils, however very sharp, spread only to a small distance unless they are carried further on the wings of the winds, while the other hot and dry exhalations, lacking oiliness, ascend much higher. And those small remaining quantities of such exhalations which, having broken through the battle-line and rampart of the second region, managed to struggle into the third or highest region, are either at once kindled by the heat of fire, if there is fire there, and, burnt up, fall down as ashes or very fine soot; or else — if one may use Aristotle's opinion against Aristotle — they are carried off by the motion of the primum mobile and dispersed rather than gathered, for on account of this carrying-off too the Philosopher denied, *Meteorology* Book 1, chapter 4, that there can be clouds in that highest region. Nor can any sufficiently probable cause be adduced that would gather those exhalations, since that motion of carrying-off is of itself uniform, and toward the west, and there are no winds there, or whirlwinds, or eddies of water, by which we see sand, chaff, straws, shavings, foam, filth and other such things otherwise scattered sometimes gathered at random into one heap or one mass. Therefore either those exhalations are purely hot and dry, and these are not fit for packing together, for mutual adhesion, and for a long-lasting tinder of flame; or they are viscous and steeped in a kind of oil, and then only a very small part of them can penetrate beyond the second region of the air and be gathered into as great a quantity as large, long-lasting and frequent comets demand.

[Margin: Seneca's sharp dilemma.]

Seneca indicated this in a few words in *Natural Questions* Book 7, chapter 9, against Epigenes: "*Let him choose, then, whichever he likes: either a light force will not be able to reach so high, or a great and agitated one will sooner break itself. Moreover, those lower comets (as they think) do not go out higher for this reason, that they have more of the earthy: their own weight holds them close by. And yet these longer-lasting and loftier comets must have fuller matter. For they would not appear for longer unless they were sustained by greater nourishment.*" Regiomontanus too, on the comet of 1472, says: "*No aerial impression can, from the natural causes of flame-bearing exhalations, supply the matter of a comet for the space of one year, such as was the one which Josephus testifies foretold the destruction of Jerusalem; but comets come from hidden causes of nature — of which opinion is Messhala* [Māshāʾallāh] *the Arab.*"

[Margin: How great the size of comets' heads is reckoned geometrically.]

XIV. But how vast a quantity of the exhalations already mentioned the size of comets demands cannot be estimated well enough by the physicists from their apparent size together with their altitude known by parallax, unless they take refuge with the geometers. You must recall their opinions at this point from chapter 4, numbers 6, 7 and 8.

[Margin: Snel's calculation of the size of a comet compared with the whole air.]

Here I wish only to bring forward what Villebrordus Snellius [Snel], in his book on the comet of 1618, chapter 6, concludes: that the head of the comet of 1577 was larger than the whole air, if the air were contracted into a single globe. For this calculation he supposes the height of the atmosphere to be 13 German miles, or 52 Italian, and the semidiameter of the Earth 1089 German miles, and therefore the whole semidiameter from the centre of the Earth to the top of the atmosphere 1102. Then, cubing 1089 and 1102 separately, the cube of the number 1089 comes to 1,291,467,969 cubic miles, while the cube of the number 1102 is 1,338,273,208 cubic miles. Now spheres are to one another as their cubes; hence from the difference between those cubes one obtains the proportion between the solidity of the air alone, gathered into one globe, and the solidity of the Earth, and it stands to the latter as 46,805,239 to 1,291,467,969, or as 1 to 27½. Now if the Earth were placed at a distance of 300 terrestrial semidiameters from the centre of the Earth, it would appear, he says, under an angle of 11′ 30″, and at the same distance the whole air, reduced into one sphere, would appear under an angle of 3′ 50″. But the comet of 1577, according to Tycho, subtended 7′ in diameter and was about 300 semidiameters of the Earth distant from the Earth. Therefore that comet was nearly twice as large in diameter as the whole solidity of the air reduced into one globe, and in solidity nearly eight times larger; and if it had had only 4′ in visual diameter, it would still have been larger than the whole sphere of the atmosphere. "Let this deep lethargy, then," says Snel, "be shaken off by men all too credulous, and let them recognise that not only all the exhalations of earth and sea together, but not even the whole air, suffices for the matter of the head of one comet."

[Margin: Size of the comet's tail.]

XV. The size of the tail, moreover, has varied, even in the same comet observed on different days, as is clear from what was said in chapter 4, number 7; but in many it was so great that with its length it occupied 70, 90 or 104 degrees, or even the whole tract of a hemisphere. But to propose two examples of true size, one for celestial comets and the other for those below the Moon, we shall use problem 3 of chapter 24, to be given below. From chapter 4, number 8, we shall take it, from Regiomontanus's measurements, that the comet of 1472 had a true diameter of head of 16 German miles, and a tail 4000 German miles long, as Gurcensis estimated. Multiplying 16 by 16, then, gives the square that can be circumscribed about the disc of the head, of 256 square miles; multiplying these by 4000 gives a prism of 10,240,000 cubic German miles, the third part of which is 3,413,333 cubic miles, if we wish the tail to have

been conical. But if we make, as 14 to 11, so 10,240,000 to another number, the cylindrical solidity of the tail will be 8,045,714 cubic German miles, which are 32,182,858 cubic Italian miles. In the terraqueous globe, however, there are 296,457,106,140 cubic Italian miles, as we showed in Book 2, chapter 7; hence the solidity of the comet was to the solidity of the Earth very nearly as 32 to 296,000. And let this be the example for a sublunary comet. For a celestial one: if, as I said in chapter 4, number 8, the true diameter of the head of the comet of 1577 was, according to Tycho, 368 German miles, and the length of the tail at least 81,700 of the same miles, the bulk of the whole comet is gathered by the same method in cubic German miles — cylindrical, 8,307,382,058; conical, 3,524,646,933. That is, compared with the Earth's solidity, the cylindrical is as 33 to 296, and the conical as 14 to 296.

[Margin: Reply to Argument 6.]

XVI. *It can be replied*, however — as Chiaramonti more or less replies in the *Antitycho*, Book 2, chapter 30, and in the Appendix to the three opuscula on the sublunary seat of comets, pp. 92 and 179; Cottunius, *Meteorology* Book 1, lecture 33; and, for sublunary comets, Froidmont, *Meteorology* Book 3, chapter 2, article 4, Cabeo, *Meteorology* Book 1, text 37, question 5, and Resta, tract 1, Book 1 of the *Meteorology*, chapter 4 — by denying that what is said is scarcely likely. For the arguments brought against the ascent and gathering of suitable exhalations prove only that it is difficult for so great a quantity of such exhalations to arise as the kindling, quantity and duration of a comet require, and that comets therefore arise rarely. Nor, however, is matter required that is actually unctuous: volatile salts suffice, which are such in virtue, that is, extracted from an oily substance. Nor is so great a density required as is supposed in that argument, but only that the matter be well compacted and concocted, so as to acquire opacity (which is no doubt different from density, as is clear in crystal, which is denser than smoke and yet less opaque), and at the same time a temper apt for conceiving and feeding fire — for which density is not required. For we see that the fresh smoke of an extinguished candle, if it is brought up to a flame from the side or even from below, is rekindled even though it does not touch the flame. Further, does not so much smoke rise from a single log — nay, from a piece of wood — that we see a whole room filled, even to the discomfort of our eyes? And this whatever may be said of that experiment of Snel's by which, as Froidmont relates in *Meteorology* Book 2, chapter 3, article 14 — and Cabeo and Resta after him, in the places just cited — he found that a grain of gunpowder expands into a flame of a bulk 125,000 times greater than that grain.

[Margin: Size of the flame of gunpowder.]

Besides, do we not see clouds occupy the whole vault of the sky, which, if they were raised much higher, would produce a body apparently equal to any comet. Or, to use a more apt example: do not those exhalations which become the twilight lamps as the Sun approaches the horizon encircle a very broad and long tract, so that with their whiteness they seem to occupy half the hemisphere

all round? What wonder, then, that over many years so great a quantity of exhalations should be gathered from earth and sea, which at last coalesce into one mass and blaze up into one comet or several — whether through the motion by which the highest region of the air is necessarily moved along with the motion of the lower air driven by the force of the winds, so that no vacuum may arise, or through their own wandering lightness?

As for what was said about the bulk of comets: first, it is replied that it is not necessary for their heads to be perfectly spherical globes, and their tails of cylindrical or pyramidal solidity; for they can be flattened like certain clouds, and so of smaller bulk. Next, if comets are in the highest region of the air, as Aristotle supposes, their bulk does not turn out so vast as to exceed the powers and the quantity of the exhalations required for a comet. This is clear a fortiori from Regiomontanus's comet. For if that comet, though several semidiameters of the Earth high above the Earth, was nevertheless to the bulk of the Earth only as 32 to 296,000, as we said in number 15, it would have been far smaller had it stood no further from the Earth than the clouds do, and would have been smaller in bulk than many clouds, which sometimes occupy the whole visible hemisphere in length. But if comets ascend as far as the Moon or beyond, their bulk does indeed turn out excessive when compared with the quantity of elementary exhalations, as we showed above in number 15 from a calculation resting on Tycho's foundations. That altitude, however, is not conceded by the Peripatetics unless they are forced by the force of parallax to concede it; and once that has happened, they will likewise concede that some comets are made from matter other than elementary. Parallax set aside, however, that altitude is not to be supposed against the Peripatetics; against them one must rather use the mere altitude of the highest region of the air.

7. Argumentum à Duratione Cometarum.

Seventh argument: from the duration of comets.

[Margin: Fracastoro's argument.]

XVII. SEVENTH. Granted that a quantity of exhalations sufficient and suitable for forming a comet could be heaped up, it is still not likely that a quantity so great could be either gathered from the beginning or substituted in succession that it should burn for many months with the same tenor of shape, and the same temper of colour and motion, without leap or rush of flame. That comets lasted several months, and more than once six months, we showed in chapter 4, number 5; and that many of them kept their former colour, shape and steadiness of calm motion is attested, among others, by Fracastoro in the *Homocentrica*, section 3, chapter 23, where he argues from it as follows: "*For that they follow their fuel does not seem likely enough. First, because it would be very wonderful that all comets should have that fuel in breadth so portentous* [?]; *and then it would seem still more wonderful that it should be set out through so great a space with such order and evenness, when in other kindlings of this kind that follow their fuel we see them borne without order* [?] *and as if by certain leaps, and see their shapes change*

according to the diversity of the fuel, and their colours, and the rest. But in the three comets already mentioned the same order, the same shape and colour, all remained unchanged." But long before Fracastoro, Seneca brought more to this argument in *Natural Questions* Book 7. For in chapter 22 he says: "*Whatever the air creates is short-lived, for they are born in a fleeting and changeable thing*"; and again: "*It cannot be that a fixed fire should settle in a wandering body and cling so stubbornly. Then, if it clung to its fuel, it would always descend; for it is the thicker, the nearer it is to the earth. A comet is never let down to the lowest region, nor does it approach the ground. Further, fire either goes where its nature leads it, that is, upward, or where the matter to which it has adhered, and on which it feeds, draws it*"; and in chapter 23: "*Everything that a temporary cause kindles quickly perishes: so torches burn while they pass; so thunderbolts avail for a single stroke; so the stars called cross-flying and falling fly past and cut the air. No fires have any stay except in their own — I mean those divine ones, which the world holds eternal.*" Add to this that not even the chasms or the fire-vomiting mountains — Vesuvius, Etna, Hekla and the like — belch out flames perpetually, or for several months; and yet the matter of that flame is fattier than that of comets, and more tenacious, as is recognised from the naphtha and bitumen they sometimes vomit forth; they rekindle the slumbering flame after intervals. The duration of snows and clouds, moreover, is in no way comparable with the duration of comets, because those do not have in themselves a principle that dissolves or consumes their matter as quickly as all burnt and inflamed things have. On the contrary, we showed in chapter 10, in the solution of Argument 2, that the duration of comets, even of one month, let alone of 6 months, is more like the definite and manifest duration of stars and planets than the duration of falling stars.

[Margin: Cardano's opinion.]

The force of this argument grows, moreover, if the duration of comets is combined with their bulk, especially that of the higher ones. This is what Cardano did in Book 4 of *De subtilitate*, when he said: "*Most comets exceed a second month, and some do not end even in the third; for this conflagration the whole fabric of the earth would not suffice. For it was shown above that fire is never in the same matter, but perpetually requires new. This star with a tail, however, is* [?] *for the most part in the aether as well: so it comes about that it is not smaller than the Moon. And that so much matter should burn, and last for three months, is altogether impossible.*" How much less for six? This argument taken from duration is used besides by many: above all by Biancani, on the mathematical passages of Aristotle, p. 93; Tycho, volume 2, chapter 6; Santucci, p. 23; Lotharius Sarsius in the *Libra Astronomica*, p. 33; and Thomas Fienus, *De Cometis*, p. 29.

[Margin: Reply to Argument 7.]

XVIII. A reply is made, however, partly by Chiaramonti in the *Antitycho*, Book 2, chapter 30, and in the opuscula on the sublunary seat of comets, part 2, chapter 10, and partly by Galileo in the *Trutinator*, p. 125: that the argument made is valid at most against Aristotle, who asserts that a comet is a kindled exhalation that needs fuel, but not against all who assert that it is sublunary.

For someone could say that its matter is purged and cleansed of dregs, and afterwards illuminated by the Sun; or that fire needs fuel in a foreign matter and region, but in its own no longer needs it; and that the comet, condensed or having acquired opacity, can shine and display a gleaming whiteness — in the way that the exhalations which reflect the light of twilight to us, and perpetually spread the light of the whitening dawn in some hemisphere from whose horizon [?] the Sun, placed below it, is about 18 degrees distant. By this example, it seems, Aristotle's opinion too can be defended; for it does not seem impossible that so great a quantity of exhalations could come together as to rival in duration the twilight, which is of itself perpetual if the Sun approaches. Others, indeed, use the example of sepulchral lamps, kindled in such matter that they can burn for many years. And certainly, if a cone with a wick is made from ground salt mixed with oil, the flame lasts much longer in a little oil than without the admixture of salt. What then forbids that the volatile salts of which a comet is made should come not from the spirit of nitre alone (from which falling stars perhaps come), which is very easily kindled but very quickly extinguished, but from another matter fit to preserve a flame for several months, until, that matter consumed, the whole comet is extinguished? For the example of twilight is indeed valid for mere brightness; but through it no account is given that fits a kindling, nor why the comet does not always last, or return at the Sun's approach, as twilight returns every day, but is extinguished and rarely returns — so much so that from the year 1618 up to this year 1650 no comet has been observable, or observed, in our regions.

[Margin: Second reply, according to the mind of Aristotle.]

Aristotle himself, however, would rather reply with the example of the Galaxy, since in *Meteorology* Book 1, chapter 10, he says that the milky circle is as it were a perpetual comet, or the stable hair of a great circle. For he holds that the Milky Way is exhalations in the highest region of the air which are in potency fire, so that, when the air is dispersed by the motion, such a consistency is separated out as there is in those comets that are kindled not by the mere carrying motion of the heaven of itself, but also by the motion and action of some star.

[Margin: How the milky circle is, according to Aristotle, a perpetual comet.]

For just as such comets are an exhalation kindled by the motion of the heaven and by the motion and action of that star, whose motion they therefore follow and from which they draw their hair, so by the motion of the heaven and the force of the very many great fixed stars that lie in the tract of the Galaxy, is separated out and kindled the quantity of exhalations that imitates the milky whiteness; and the milky circle is the perennial hair of that whole starry circle, and so a perpetual comet. For this is the legitimate sense of Aristotle in that passage. But Aristotle's reply is now refuted by the telescope, which shows us that the whiteness is an aggregate, and as it were a hedge, of very tiny little stars. Next, if the Galaxy is not only a brightness but a kindling, which nonetheless persists, why do the other comets too — by the force of the other stars, many

and great, that are outside the Galaxy — not either persist longer, small as they are, or return more frequently? Lastly, if the multitude of stars of the milky circle has so much force that it perpetually kindles that tract, or keeps it kindled, why does it not at last produce as great a splendour as has been seen in many comets that rivalled the Moon and the Sun? A comet, therefore, is something other than a mere kindling, and has another cause of its rising and perishing than the one that is chanted in the Peripatos.

8. Argumentum à Caudæ Diaphaneitate.

Eighth argument: from the transparency of the tail.

XIX. EIGHTH. No flame in packed and consistent matter, such as Aristotle requires for comets, is so transparent that through it — especially when it is placed far off — the remotest stars can be seen by us. But through comets, or at least through their tail, stars can be seen and have in fact been seen, as Tycho observed in the comet of the year 1577, from p. 143 of the *Epistolae*; and Carolus Piso confirms it, in the *Speculum Cometae*, chapter 19, by an experiment of Father Philippus Plumeretus on the comet of the year 1618.

[Margin: Seneca's opinion on the transparency of the tail.]

And long before, Seneca set this down as asserted by others, *Natural Questions* Book 7, chapter 18, raising it as an objection to himself and to Apollonius of Myndus, and saying: "*A star never appears through a star: our sight cannot pass out through the middle of a star so as to see the higher things through it. But through a comet the further things are seen no otherwise than through a cloud: from which it appears that it is not a star, but a light and haphazard fire.*" To this objection he replies in chapter 26 by granting the transparency of the tail, thus: "*We do not see further things through stars, you say; through comets we send our sight. First, if this happens, it happens not in the part where the star itself is of dense and solid fire, but where a thin splendour runs out and is scattered into hair. You see through the intervals of the fires, not through the fires themselves.*" The tail, therefore, is a ray emitted by the comet and not of the comet's substance, in Seneca's judgement.

The Peripatetics, however, *will reply* by denying that the flame of a comet cannot be like our flames in transparency — the transparency by which a candle placed and lit beyond a flame is seen through it, just as the image of that little flame is also seen in a mirror between which and the candle there is a larger flame, for instance that of a torch or of a lit pyre.

9. Argumentum à Magnitudine apparenti Cometæ per Telescopium spectati.

Ninth argument: from the apparent size of a comet viewed through the telescope.

XX. NINTH. A telescope usually represents distant objects as far larger than when they are viewed with the naked eye, but on this condition: that it shows the Moon, the Sun and the nearer planets larger by a notable increment, and increases their visible diameter twentyfold, thirtyfold and much more, if it is one of the more excellent telescopes; whereas the fixed stars, because they stand at a huge distance, it increases either not at all or very slightly. But the comets

of the year 1618, viewed at Rome and elsewhere with a very large telescope, received no increment; and people of earlier times would probably have found the same in several comets, had they known the use of the Netherlandish tube. It is therefore a sign that that comet and similar ones were above the Moon and stood at a very great distance from us. This argument, indeed, was used by the authors of the disputation held in the Collegio Romano, and by Lotharius Sarsius in the *Libra Astronomica*, p. 15.

[Margin: First reply, Chiaramonti's — but trivial, and in part false.]

XXI. Chiaramonti replies, *Antitycho* Book 2, chapter 32: first, that he had used a tube not wholly to be despised, by whose force, however, the Moon grew by no conspicuous increment; next, that comets therefore do not acquire from the telescope an increment such as the Moon does, because they are not such great and bright objects but, compared with the Sun and Moon, much smaller and dimmer, and do not have so great a sphere of activity. But Kepler, in the *Hyperaspistes*, p. 124, rightly censures him for seeming to deny that the Moon is enlarged by the telescope, since a single one of its spots — of those which scarcely equal a fortieth part of the Moon — is seen distinct in its parts and nearly equal to Jupiter seen with the naked eye. And indeed, from where does it come that with more perfect tubes not the whole Moon but only a part of it can be taken in by the telescope at a single glance, if not from its notable enlargement? Chiaramonti's second reply, moreover, cannot be fitted to the fixed stars, which in Chiaramonti's own opinion are larger and brighter than comets, and yet receive no notable increment from the telescope.

[Margin: Second reply, by others.]

XXII. A reply is therefore made, and a better one, by Mario Guiducci, *De Cometis*; Galileo in the *Trutinator*, from p. 65 and p. 217; Tannerus, *De caelo*, question 7, p. 138; and Mastri, disputation 4 *De caelo*, question 2, article 4, number 46. First, by turning the argument back against its own authors, who did not place the comet of the year 1618 above the Sun, as the force of the argument required, since by their own admission the Sun does in fact receive a notable increment from the tube. Second, by denying the causal proposition placed in the major premise of the syllogism — that is, that the cause why the fixed stars receive from the telescope no sensible increment, and none proportionally as great as the Moon and the Sun, is their enormous distance.

[Margin: The slip of Mastri and Chiaramonti.]

The cause of this difference that Mastri offers, taken from Chiaramonti — namely that a comet does not have a lively splendour and glitters less, whereas splendour and greater brightness contribute to acquiring an increment from the telescope — is not an adequate cause; nor can it be applied to the fixed stars, which glitter most brilliantly and twinkle, especially the Dog, and yet receive no increment from the telescope.

[Margin: The true cause of the differing increment produced by the telescope.]

The truer cause, therefore, which Tannerus gave in a few words and Guiducci and Galileo in more, is that stars, as also comets and flames, viewed from afar with the naked eye, appear to us crowned and girdled with certain adscititious rays, which are not, however, in the object itself or near it, but are an affection of our dilated pupil and a deception of our sight. That mane of spurious or adventitious rays is very small in the Sun, and almost nothing in the ☾, compared with the true size of the solar and lunar disc, so that it is a sixtieth or a fortieth part of their apparent diameter. But the corona that appears around Saturn and Jupiter is somewhat larger, and larger still around Mars; larger again around Venus and Mercury — larger, I say, compared with the true size of the apparent disc — and by far the largest around comets, flames of lamps viewed at a distance, and the fixed stars. Now the telescope so fortifies and protects the eye that it does not allow any prevailing in the pupil by its glare, and so takes away from the objects already mentioned those adscititious rays; on the other hand, by the force of the refraction produced by the crystal lenses, it widens the visual angle of any visible point, and so visibly enlarges the object, without however enlarging the adventitious rays, since it rather strips the object of them. The greater, therefore, the corona of adventitious rays compared with the object taken without them, the less the telescope will seem to enlarge that object which you previously viewed with the naked eye. For suppose that the corona around Venus, or the Dog Star Sirius, is of 10 parts, of which their true diameter is one, and that the Moon's corona is of one part, of which the Moon's diameter is 10 (which I feign for the sake of an easier example). Suppose next that the telescope has the power of multiplying or enlarging the true diameter of the stars tenfold. Then both Venus and the Moon, viewed through the telescope, will appear tenfold larger; but not tenfold larger than when viewed with the naked eye together with that corona. For Venus, stripped now of nine parts and keeping one, but that one increased tenfold, will appear through the telescope as large as she and her mane together seemed to the naked eye. But the Moon, since she is feigned to be stripped of a tenth, adscititious, part of herself (if indeed of herself), and keeps nine parts, which are made tenfold by the telescope, will appear nine times larger than when viewed with the naked eye. The true cause, therefore, why the telescope gives a notable increment to the Moon and the Sun and so on, but not to the fixed stars, is not the enormous excess of the distance of the fixed stars over the distance of the Moon and the Sun, since the telescope does not give, even to lamps viewed from a distance within one mile, that increment proportional to the increment of the Moon. It is rather that it strips them of a much greater corona of adventitious rays, without which the true object is much smaller than it was estimated with the naked eyes; and so it happens with comets. Moreover, the same telescope, with the same or a slightly different draw of the tube kept, enlarges comets and fixed stars in the same proportion as the Moon, if they are compared with one another without the rays that arose from the deception of our sight before the use of the telescope. Yet it does not make the heads of

comets appear as vast as the Moon, because they are not of so great a size in themselves.

[Margin: The telescope's differing effects from its differing extension.]

XXIII. But, you will say, why does the telescope so notably enlarge objects viewed within a single room, or a church or hall, and much more than proportionally to what it does with the Moon? Is this not a sign that greater distance is the cause of the smaller increment? I reply that this by no means comes from distance as such. Otherwise, since the distance of the Sun from the Moon is much greater than that of the Moon from the Earth, the Sun would have to acquire from the telescope an increment smaller than the Moon's by as much — and by much more — as the increment the Moon receives from it is smaller than the increment received by an object placed within a room. The cause of this difference, rather, is that an object too near cannot be seen with a telescope without confusion of many visual rays, nor well bounded, unless the tube is drawn out a great deal; and when it is drawn out, the object appears larger than when it is not. But when the object is remote — say beyond one, or at least ten, miles — the rays falling from from [recte: from] one point of the object on the lens of the telescope begin to approach parallelism. So it comes about that to view a remote object properly no notable difference in the drawing-out of the tube is required, but almost the same draw serves the same eye, whether it views the Moon or the fixed stars. These things, said perhaps at too great length, had nevertheless to be said against those who think that the difference in the increment produced by the telescope, or its differing draw, is an evident argument of a greater or lesser distance among great ones. Even if we were to grant that, to see the sunspots or represent them perfectly on paper, a longer-drawn tube is required when the Sun is at perigee and nearer than when it is at apogee and more remote, it could still be said that this happens not by reason of distance but by reason of the vapours that intervene in the winter season, when the Sun is at perigee. Or certainly, in our case of comets, it would have to be established by experiments that are not doubtful that a more contracted tube must be used to see the Moon clearly and distinctly, but a more drawn-out one for a comet — which is not yet established.

10. Argumentum ab Altitudine Cometarum requisita, vt à pluribus locis distantibus spectari queant.

Tenth argument: from the altitude of comets required for them to be seen from many distant places.

XXIV. TENTH. There is still in force the argument which, as Biancani says on the mathematical passages of Aristotle, p. 92, mathematicians used to employ before the new observations to show that comets cannot be in that highest region of the air which lies immediately above the clouds and does not exceed the altitude of the exhalations that make the twilight, that is, an altitude of about 50 or 60 Italian miles; and which was then used by Cysat, chapter 3; Froidmont, *Meteorology* Book 3, chapter 1, article 4; Glorioso, Book 3, chapter

3, number 24 — although in chapter 5, from number 22, he adds its solutions — and Kepler in the *Hyperaspistes*, p. 169. For on the one hand it is certain that the altitude of the exhalations that produce the twilight is less than 80 Italian miles, as will be shown in chapter 14; on the other, that the same comet — especially that of the year 1618 — was seen at the same time, and indeed for several hours above the horizon, in very distant places: namely at Rome, Florence, Goa, Parma, Milan, Antwerp, Innsbruck, Ingolstadt, Wittenberg, Tübingen in Batavia, Paris, Aix-en-Provence &c., that is, in almost the whole of Europe and in the East Indies. But for that comet to have been visible in such places at the same time for several hours above the horizon, an altitude far greater than 80 Italian miles is required. For if it had been only 80 Italian miles high, or 20 German, and had had no motion other than that of the primum mobile, it would have set within two hours, seen to fly from east to west, as will be shown below; and much less could it have described, over several nights, a circle around the pole of the world within the circle of perpetual apparition, as it did from December 20 to January 23, as Cysat observed. But this argument cannot be fully treated without many problems to be given below in chapter 15.

[Margin: Reply to Argument 10.]

Some Peripatetics, however, *will reply* that, to save phenomena of this kind, it suffices for the comet to be in the region of fire, provided it remains below the Moon; and that Aristotle is not against this, since in *Meteorology* Book 1, chapter 1, he said that comets are in the place nearest to the carrying motion of the stars, that is, the concave of the Moon. With these things laid down, its elementary origin from a quantity of kindled exhalations still stands; for by that name he comprehends the whole place of elementary fire, in which he granted that fiery meteors are made, when he says: "*These are whatever things happen according to nature indeed, yet with the disorder of the first body among the elements, about the place nearest to the carrying motion of the stars — such as concern the Galaxy, and comets, and fiery and moving images.*"

11. Argumentum ab Altitudine requisita, vt Cometa sit conspicuus extra Vmbram terræ.

Eleventh argument: from the altitude required for a comet to be visible outside the shadow of the Earth.

XXV. Apian uses this argument, supposing that comets, because of the perpetual turning-away of the tail from the Sun, are illuminated by the Sun, and so cannot be seen at night if they lie hidden within the shadow of the Earth; and that they are sometimes in such a position that, if they were not higher than the highest region of the air, they would lie hidden in the shadow of the Earth. But this argument cannot be fully understood except from problem 9, to be given in chapter 15. Meanwhile, however, it is not proved from this that these comets are above the Moon, because it suffices that they avoid that shadow at its sides.

12. Argumentum est à Parallaxi.

Twelfth argument: from parallax.

XXVI. This is the Achilles, this the Atlas of the astronomers; and therefore it is to be treated more fully below, and not without geometrical diagrams, from chapter 16 to 21.

SCHOLIVM.

Scholium.

[Margin: Was parallax known to Aristotle?]

Some have doubted whether parallax was known in Aristotle's age. For in Meteorology *Book 1, chapter 7, he recognised that certain comets follow the star from which the exhalation was drawn out and separated, and are carried along beneath it by the same carrying motion, as though affected by no difference of appearance as regards place; and in chapter 8 he taught that the milky circle is not a phenomenon arising from the reflection of our sight from that place of the heaven to the Sun, as from a mirror, because the Galaxy always appears in the same place of the heaven — which is the same as saying that the Galaxy suffers no variation of view, or parallax. But* Glorioso, *in* De Cometis *Book 4, chapter 6, rightly drew a distinction, and taught that the doctrine already mentioned is indeed connected with parallax, but that the parallax which astronomers after Ptolemy discuss — namely the one by whose force we investigate the distance of the stars, or of any phenomenon, from the Earth — was not known to Aristotle; for the controversy between him and the ancients was not about the distance of the milky circle from the Earth, but about its substance. Certainly the first to mention parallax was Hipparchus, in Ptolemy; but he himself treated it more clearly in the Moon, as I taught in Book 4, chapter 13; and the first who carried its use over to comets was Johannes Regiomontanus.*

CAPVT XII.

Chapter XII.

An Cometæ ſint ex materia Elementari, non accenſa ſed illuſtrata à Sole, & eleuata priùs aut ad ſupremam aeris regionem, aut ſupra Lunam.

Whether comets are made of elementary matter, not kindled but illuminated by the Sun, having first been raised either to the highest region of the air or above the Moon.

[Margin: On comets made of elementary matter below the Moon, not burning but shining.]

I. The first part of the opinion indicated in the title of this chapter, and in chapter 6, number 7, was taught by Scaliger and Telesius; nor does it seem very different from the view of Heraclides and Metrodorus, as we showed in the same place. The second part was handed down by Apian, Guiducci, Galileo, Aresius, Praetorius and Rothmann, as I said in the same place, number 8. That a comet is something separated out of elementary matter, but so compacted and tempered that it can receive the Sun's rays into itself — partly stopping them, so

that it shines for us, and partly transmitting them through its translucent body, so that it draws a tail from them — is urged by the turning of the cometary tail away from the Sun, about which much was said in chapter 11, in the first argument, and more must be said again in chapter 24. Against the first part stand all the arguments made against the Peripatetics in chapter 11, except the first; but in its favour stand the replies to those arguments, such as they may be.

[Margin: On the elementary matter of comets raised above the Moon.]

II. Against the second part — elementary matter ascending, or drawn up, above the Moon and shining there under the Sun — many points are gathered by Lotharius Sarsius in the *Libra Astronomica* from p. 27; by Tycho in his letter of 1589 November 24, p. 162; by Piso in the *Speculum*, chapter 2; by Cottunius, lecture 32 on Book 1 of the *Meteorology*; by Froidmont, *Meteorology* Book 3, chapter 2, article 4; and by Cabeo on Book 1 of the *Meteorology*, text 37, question 6.

[Margin: 1. Argument against the second opinion.]

The first argument is drawn from the solidity of all the heavens, in the opinion of Cottunius and Piso, or of the Moon's heaven, in the opinion of Cabeo. Cabeo holds that the heaven of the fixed stars and that of the Moon are solid: the Moon's, because of its kinship with the Earth, which it circles like an attendant and companion, and so that its solidity may prevent volatile salts from being raised to an infinite distance, lest sublunary nature be exhausted — indeed, so that they may be forced to return downward; the intermediate heavens, however, he concedes to be fluid. Now if at least the heaven of the Moon is solid, elementary exhalations certainly cannot penetrate it, however keen the subtlety with which they are endowed.

[Margin: Reply to Argument 1.]

The authors of the opposite opinion, however, will reply by denying that solidity, as will be said in Book 9.

[Margin: 2. Argument.]

III. Cottunius draws the second argument from the motion of comets toward the north and the south. Exhalations, by their innate lightness, are carried straight upward; or if, as Lotharius Sarsius contends, they are carried obliquely in a wandering and restless dispersal, and carried upward crosswise, it will never come about that they can be gathered at the heaven of the Moon into one comet, still less above that heaven.

[Margin: Reply to Argument 2.]

Those authors, however, will reply either, with Rothmann, that the exhalations are carried up by Intelligences to form a portent of this kind; or that, whether they are carried straight or obliquely, many of them, warmed by the Sun and made lighter, are nonetheless so tempered once they have ascended above the Moon that they can acquire a particular motion arising from some source other than lightness. How arbitrary an invention this is, there is no one who does not see. Galileo, however, is under a particular necessity to explain this motion, since he follows Copernicus, who explains the motion

of elementary bodies away from the centre or toward it otherwise than the Peripatetics do.

[Margin: 3. Argument.]

IV. The third argument, which seems to have greater force, and which Tycho, Froidmont and Cottunius point to, is drawn from the size of comets together with their duration. For if exhalations must ascend from land and sea above the Moon to form a comet, then either they must be thinned out and rarefied almost to infinity, so as to occupy as much space as a comet with its tail — and so they will not be fit to reflect so strong and vigorous a light from the comet's head — or else that matter must be packed close, so that it lasts so long and keeps its original shape, and at the same time, on account of its opacity, reflects so great a force of light to us; and then it is not probable that the whole earth and water would suffice with their exhalations to form a comet. At this point what was said about the size of comets in chapter 11, Argument 6, and about their duration in Argument 7, should be read again; from it, nonetheless, some replies may be gathered. As for those *hypecaumata* and glows which we believe to lie outside the Earth's shadow on summer nights: they are not in truth beyond the apex of the Earth's shadow, and so lit by the Sun; they are exhalations catching fire, in the way that shooting stars do, or, if they are above the Earth's shadow, they are rather effluvia of the planets.

CAPVT XIII.

Chapter XIII.

An Cometæ, ſi cæleſtes ſint & origine & loco, fiant per condenſationem vel ſolam alterationem partium Cæli, An per generationem ex materia effluente à Sole, cæteriſque Planetis.

Whether comets, if they are celestial both in origin and in place, come about through condensation or mere alteration of parts of the heaven, or through generation from matter flowing out from the Sun and the other planets.

I. It is assumed here that it is established — with certainty from the parallax of comets, and very probably from the constancy of their regular motion and the similar arguments adduced in chapter 11 — that some comets are above the Moon; and next, from what was said in chapters 7, 8 and 9, that a comet is neither a symphasis of two or more of the five commonly known planets, nor one or more of some perpetual but unknown bodies, whether fixed stars or planets, but comes into being anew and passes away. This granted, the question is whether comets come about through a merely accidental change, by which density, or opacity, or light, or all of these, are added to parts of the heaven, according to the opinion reported in chapter 6, number 9; or rather through generation, according to the opinion given in the same place, number 10. For once it is supposed that some comets are born and die in the heaven, one of these two must be said — unless someone wishes these comets to be made by God out of nothing, or out of some matter or other, by Him either directly or

through angels, by an extraordinary concurrence. Nor are the arguments of the Peripatetics, or of others, relevant here — those who contend that the heaven is both solid and incapable of generation or corruption, or of such alteration as is required to form comets, and who therefore assert that comets are all sublunary. For here, as I said, it is assumed as certain from parallax that some comets are celestial; and from this many of the moderns try to show that the heaven is fluid, and pervious to the passages and the truly very diverse motions of comets, and capable of generation and corruption, or of an alteration very like it — especially since they have very probable arguments for this both from the new stars and from the spots and faculae near the Sun. And as regards the authority of the Fathers and the Wise, so many are for the fluidity of some heavens, and the generability and corruptibility of some parts of the heaven, that they need not fear the authority of the other Fathers or Doctors who held the opposite.

[Margin: Arguments for mere alteration.]

II. In favour of a merely alterative change stands that well-worn but not contemptible argument by which philosophers contend that God and Nature do not do through more what can be done through fewer — that is, do not multiply entities without necessity. Therefore, if the phenomena of comets can be saved by the mere condensation of celestial matter, or at most by opacity mixed with transparency — so that they can reflect the Sun's light to us insofar as they are opaque, yet transmit it insofar as they are transparent, so that the tail is turned away from the Sun — no other, greater change seems to need introducing. Add that clouds too are sometimes so tempered that, partly by density and partly by transparency, they become fit to present shining globes to us.

III. Against mere alteration, however — especially condensing alteration — no few points are brought. First, if its efficient cause is natural, and operating in a natural way, [Margin: Argument against mere alteration, especially through mere condensation.]

it can be identified only with the greatest difficulty. For cold in the heaven cannot be imagined except gratuitously; nor would the motion of the planets suffice, driving the heaven and producing a moderate density in various parts of it so that no vacuum arises, since that density is dispersed, as it is in water or air when they are pushed. To attribute this to the substantial form of the heaven, as Liceti does — a form that would try to repair the parts of the heaven rarefied by the Sun's heat and restore them to their original density — is to weave and unweave Penelope's web: for as much density as is repaired while the Sun is absent would be removed on its return, and from these alternating vicissitudes a comet could never be formed. But if this cause is supernatural, or operates in a supernatural way, then it is all one to it whether it uses an alterative or a generative action. Moreover, condensation alone does not make an object visible and able to stop the Sun's rays unless some opacity is present. Besides, so that no vacuum arises, by as much as the heaven was condensed in one part, by so much would it have to be rarefied in another. Finally, if density and opacity

alone were added to one part of the heaven, that would suit motionless comets, as Camillo Glorioso holds them to be, better than moving ones. No evident arguments, however, are to hand either for this opinion or against it; and so I am loath to be more long-winded over these conjectures.

[Margin: Arguments for a substantial change in the heaven.]

IV. In favour of substantial generation, on the other hand, stand almost all the reasons that our Scheiner adduced in Book 4 of the *Rosa Ursina* for spots and faculae newly generated around the Sun, and that others adduced too, some of whom we indicated in Book 3, chapter 3, number 10. To these must be added the many named here in chapter 6, number 10: namely Cysat, Cabeo, and Tellez of our Society; then Kepler, Fienus, Snel, Glorioso, Puteanus, Froidmont, and most recently Johannes Hevelius in chapter 5 of the *Selenographia* and in its Appendix. The chief reason is that many of those spots and faculae perish and vanish in the middle of the Sun's disc before they reach the edges, while some appear there anew which had not been seen near the edges; and those that seem to return after about 26 days rarely keep the same shape. From this, then, it is inferred by a very probable argument that they flow out from the Sun, and are as it were soot, or corpuscles boiling up out of that immense furnace or fountain of the universe's heat. It is therefore not improbable that comets are made out of the same matter, or also out of effluvia of the other planets collected over intervals of time, thoroughly purged, and illuminated by the Sun; and that they are nothing other than faculae that are larger and further from the Sun.

[Margin: Two confirmations of this change.]

This is confirmed, first, because in the year 1618, in which three comets appeared, no spots appeared around the Sun, as I reported in Book 3, chapter 3, number 5 — although none appeared in 1632 either, for many months, during which there was a remarkable drought; but nothing is established about comets having arisen in that year. Second, because those obscurations of the Sun which were observed far from new moons (so that you could not say they were eclipses), and recorded in history, seem to have arisen from effluvia of this kind, as it were mists exhaled from the Sun or the other planets. On these see our Book 3, chapter 3, scholium 1, and Book 5, chapter 1, scholium 3.

[Margin: Obscurations of the Sun arising otherwise than from eclipses.]

To these add the darkness around the Sun lasting 17 days in the year 790, on the testimony of Paulus Diaconus as cited by Patrizi in Book 19 of the *Pancosmia*, p. 111. So too in the year 1547, from April 24 to 28, the Sun shone everywhere with a sad and rust-coloured appearance, as Froidmont reports in *Meteorology* Book 3, chapter 2, article 6; in that year, on March 31 [pridie Calendas Aprilis], Francis I, King of France, had died.

[Margin: Arguments against a substantial change of this kind.]

V. Against this mode, however, besides the corruptibility and fluidity that many think unworthy of the heaven, there are these arguments. First, if so many exhalations flowed out perpetually from the planets, and as large as certain

great spots that appear around the Sun when viewed through the telescope, their substance would seem bound to be exhausted. For that reason Froidmont preferred that the Sun — *an admirable vessel and the work of the Most High*, as it is called in Ecclesiasticus 43 — should, as the lamp of the universe, be immune from these evaporations, and he said that they are breathed out from the other planets: as though there were not more to fear on this account for the other planets, which even taken together are of smaller bulk than the Sun. Next, why do comets not appear more frequently, and around the Moon and the Sun? Finally, what drives those exhalations, with so great a variety of motions, out of the zodiac as far as the north or the south? Fienus, Puteanus and Froidmont reply, however, that far more frequent generations and perishings may take place in the heaven which we nevertheless cannot see, since they are either drowned by the Sun's splendour or hidden by their distance and smallness; and that there is no danger to such vast bodies if particles of them, or particles arising from them, perish. For if we were on the Moon or on the Sun, we could by no means discern the births and deaths of animals and plants, or even of cities or mountains when they are overthrown: for how tiny a part are these with respect to the whole globe? Therefore, just as the Earth remains, and the seas and the kingdoms of the lands remain, and in spite of those changes the Earth is still the Earth and the ocean does not cease to be the ocean, so the changes already mentioned in the heaven will not make it cease to be the heaven; indeed, not even any planet will cease to be of such a kind, or as large, as it is seen by us from the Earth.

[Margin: Our opinion is indicated.]

VI. These points, indicated within the bounds of probability rather than argued out, keep me greatly in suspense and wavering this way and that. The suspense is increased both by the so varied motion of comets and by their perishing, if they are made not of burning matter, so as to fail when their fuel fails, but of matter illuminated by the Sun or by the other planets. Nor do I care to sharpen my wits devising efficient causes that would keep both the substance and the motion of this celestial phenomenon in being for a definite time. I therefore lean strongly toward the opinion that attributes the contriving and governance of these portents to God or to Intelligences, according to what was said in chapter 6, number 12; or at any rate toward the one that counts comets among the secrets of the world and the most hidden miracles of Nature. This was done by Māshāʾallāh, Regiomontanus, Tycho, Hájek, Tanner, Ambrosius Rhodius, Arriaga, Oviedo and William of Hirsau; and we showed in the same chapter 6, number 12, that Froidmont, Cabeo and Resta did not shrink from it either. For why should God not display to the world these new and portentous spectacles, recurring in no order of times and at no intervals — both to raise them up toward heaven and prepare them for that signal catastrophe of the world which is to come at the end of the ages, and so that it may be manifest that He is held by no necessity or laws of nature from doing whatever He wills below and above the Moon; and so as to set a crux not only for the Peripatetics,

who have deserved ill of the Creator's freedom, but for every mind, or to propose a splendid enigma never to be solved?

The Philosopher's excuses are well known — noble tokens of a most moderate mind. In Book 2 of *On the Heavens*, chapters 3 and 5, he says that he speaks of celestial things *from afar, not as if in the place itself: and all the more so because we have perception of very few of the things that happen in the heavens*. Then he adds: *if anyone shall have attained more certain and more necessary reasons, thanks must be given to the discoverers*. And in Book 1 of the *Meteorology*, chapter 7, about to speak of comets, he declared: *Since, however, concerning things not manifest to sense, we think we have dealt with them sufficiently if we have brought our reasons to the point of saying nothing impossible*. On this, then, or on others of his sayings, Seneca, *Natural Questions* Book 7, chapter 30: *Aristotle says admirably that we ought never to be more reverent than when the gods are in question. If we enter temples composed, if, about to approach a sacrifice, we lower our face, draw our toga close, if we put on every mark of modesty, how much more ought we to do this when we discuss the constellations, the stars and the nature of the gods, lest we affirm anything rashly or impudently, either affirming in ignorance or lying knowingly?* These things the author brings in on the occasion of comets, as also the rest that we related in chapter 1, number 6. [Margin: The modesty of Aristotle.] [Margin: Seneca's opinion of the modesty of Aristotle's mind.]

CAPVT XIV.

Chapter XIV.

De Altitudine Exhalationum & ſupremæ regionis Aeris, infra quam Cometæ ſupponuntur eſſe non poſſe. Qua occaſione traduntur Problemata ad illorum Altitudinem ſpectantia.

On the altitude of the exhalations and of the highest region of the air, below which comets are supposed unable to be; on which occasion problems bearing on their altitude are set out.

I. Many things about the variety of the twilight, and about the altitude of the exhalations which, reflecting to us the light of the Sun as it approaches the horizon, or after it has sunk a little before below the horizon, produce morning or evening twilight for us, were said by us in Book 1, chapter 31, and it will be worth rereading them here. First of all it must be recalled that the varying altitude of these exhalations, which are broadly called vapours, depends both on the varying season of the year and the constitution of the air, and on the obliquity of the sphere, or of the horizon; and that its measure depends both on the depth of the Sun below the horizon at the beginning of morning twilight or the end of evening twilight, and on the size of the Earth's semidiameter — on which, if the authors adduced in Book 2, chapter 7, agreed about the size of the Earth, there would be less disagreement among them on this head about this altitude of the exhalations. Moreover, in the opinion of Kepler, Vendelinus [Govaert Wendelen], Glorioso, Gassendi and ourselves, it

depends on the refraction of the Sun near the horizon, which certainly makes the altitude much smaller. But since in surveying the authors on comets I have come upon certain other opinions about this altitude, it seemed good to present them in a single view together with those I reported in Book 1, chapter 31 — but first to set out here the problems bearing on this, which I had deferred to Book 10 of this volume or to the book on optics, adding the depth of the Sun below the horizon, which, however, not all of them state. If anyone wants the opinion of the authors listed below on the size of the Earth's semidiameter, let him consult either Book 1, chapter 31, in the last column of the second table, or Book 2, chapter 7.

[Margin: The altitude of the air, according to Tanner, Mastri and Chiaramonti.]

Speaking, however, of the subtler exhalations, which are not so opaque that they can make twilight, Tanner, *On the Heavens*, question 7, p. 140, thinks that they can ascend almost as far as the Moon. Mastri, on the other hand, *On the Heavens*, disputation 4, question 2, article 4, thinks it better to raise their altitude and the bounds of the air than to carry comets up into the heaven. Chiaramonti too, in Book 3 of *On the New Stars*, chapter 26, and in the opuscula on the sublunary seat of comets, p. 179, says that the altitude of the air is almost 26 semidiameters of the Earth, that is, about 90,000 Italian miles.

II. The authors I have seen on this matter are: Posidonius, as reported by Pliny the Elder, Book 2, chapter 32; Ibn al-Haytham, *On Twilight*, last proposition; Vitellio [Witelo], Book 10, proposition 60; Nonius [Pedro Nunes], Book 2, *On Observation*, from p. 82, and *On Twilight*, part 2, proposition 18; Clavius, *On the Sphere*, p. 131 in my copy, and in chapter 3 of the *Sphere*, in the digression on twilight, proposition 6; Cardano, *De subtilitate* Book 4; Abrahamus Roggembach, as cited by Tanner, *On the Heavens*, question 7; Barocius [Francesco Barozzi], *Cosmographia*, p. 198; the Coimbra commentators [Conimbricenſes] on *On the Heavens* 3, chapter 5, question 2; Maginus [Giovanni Antonio Magini], *On the Primum Mobile*, Book 11, problem 30; Gemma Frisius in the supplement to the *Astrolabe*; Tycho, *Progymnasmata* volume 1, pp. 95 and 733, and volume 2, p. 410; Scultetus, as cited by Tycho in the same place; Rothmann, in his letter to Tycho of 1588, of February 21 and 24; Biancani, *On the Sphere* Book 6, chapter 5, and Book 10, chapter 15; Simon Stevin in the *Cosmography of the Atmosphere*, that is, in the *Mathematical Memoirs*, Book 3 of the *Geography*, proposition 2; Longomontanus, Book 2 of the *Sphaerica*, chapter 11; Kepler, *Optics*, p. 288, and *Epitome of Astronomy*, pp. 74, 309, 369; Snel, *On Comets*; Froidmont, *Meteorology* Book 1, chapter 1, article 2, and Book 6, chapter 4, article 2; Cabeo, *Meteorology* Book 1, text 15, question 2; Gassendi, *Institutio Astronomica* Book 1, chapter 18; Glorioso, *On Comets* Book 2, chapter 2; Resta, *Meteorology* Book 2, tract 1, chapter 2; Cottunius, *Meteorology* Book 1, lecture 33; Wendelen, preface to the *Eclipses*, p. 5. Of these, Froidmont and Cottunius follow the ancients on the 52 miles, yet in such a way as not to reject the opinion of Nonius or of Stevin.

Problema 1. Data Solis Profunditate ſub Horizonte ad initium Crepuſculi Matutini, & Semidiametro Terræ, Inueſtigare Altitudinem Vaporum Crepuſculinorum Methodo Cardani.

Problem 1. Given the depth of the Sun below the horizon at the beginning of morning twilight, and the Earth's semidiameter, to find the altitude of the twilight vapours by Cardano's method.

III. Following Cardano, *De subtilitate* Book 4, let there be the globe of the Earth ADG, whose semidiameter AC is known in leagues, or miles, or stades; Cardano sets it at five thousand times a thousand paces, that is, 5000 Italian miles. Let there be given, at the beginning of morning twilight, the depth of the Sun below the horizon, which he sets at 19°, so that under the equinoctial circle there is about an hour and a quarter from twilight to sunrise. At the beginning of twilight let the Sun's ray be DB, touching the Earth at D and continued in a straight line as far as B, the vertical point, or aerial zenith, overhanging the head of the observer at A. For the altitude of the vapours at B will be AB itself, and the Sun's ray reflected from the vapours at B to the eye at A will be the same BA. Let AFE be the physical horizon, meeting BAC at right angles, and let the Sun's ray DB cut it at F. When the radius CD is drawn to the point of contact D, angle CDB will be a right angle by proposition 18 of Book 3 of Euclid, as is BAF; and angle B is common to, and the same in, the two triangles ABF and CBD. The triangles are therefore similar, and so angle BFA will be equal to the remaining angle BCD, that is, 19°, because BFA is equal to angle DFE; "for on account of the Sun's very great distance from the Earth, angle DFE is just as if it were at the centre of the Earth," says Cardano. From this, then, by analysis of the triangles he infers AB to be 288 miles, of which AC, or CD, is 5000. But if the twilight lasts two hours before sunrise, the depth of the Sun with respect to the equator — that is, angle BCD, that is, AFB — will be 60°, as Cardano estimates; from which he infers AB to be 772 miles, beyond which altitude he denies that rainbows, burning rods, parhelia and so on can be produced.

Diagram. Cardano's construction for the altitude of the twilight vapours, set in the right column. A circle (the Earth) with centre C; a vertical line runs from G at the foot of the circle up through C and through A on the upper rim, and continues above the circle to B. A short line through A, the physical horizon, carries F and ends at E on the right. A line from B descends through F to D on the right-hand rim (the Sun's ray touching the Earth at D). A dotted line joins C to D.

- B (top, above the circle): the vertical point, or aerial zenith, over the observer
- A (upper rim, on the vertical): the observer
- F (on the horizon line, right of A): where the ray DB cuts the physical horizon
- E (right end of the horizon line): end of the physical horizon AFE
- D (right-hand rim): the point where the Sun's ray touches the Earth

- C (centre): the Earth's centre
- G (foot of the circle): end of the Earth's diameter through A

[Margin: The altitude of a comet according to Cardano.]

Since he says that some comets were seen at Milan under the winter circle, he adds the following words to show that they are much higher than the altitude of the vapours: *Let us suppose, then, since we are distant from the circle of Capricorn by about 68°, that the eye is at D, at Milan, and that the point seen under the circle of Capricorn is B. It is established, then, that the ratio of CB to CD is about as 8 to 3. Since, then, CA is equal to CD, the ratio of CB to CA will also be as 8 to 3; therefore AC to AB as 5 to 3; therefore AB is 8000 thousand paces and 333 besides, which I do not trouble about. It is clear enough that the place which an inhabitant of Milan must see under the winter circle is more than ten times as far from the Earth as the altitude of the vapours reaches. But comets are seen by us there; therefore they are not made of vapours.* So he.

Reprobatur Cardani Methodus.

Cardano's method is rejected.

IV. But is this, Cardano, that subtlety of yours? On the contrary, there is great obesity and fatness in this false pronouncement of yours. First, who ever saw the air that stands perpendicularly over our heads whiten from the Sun's rays at the beginning of twilight, and reflect them from there to the eye? Do not any country people and rustics know that that whiteness rises from the eastern horizon and girds the horizon like a belt? Rightly, then, did Tycho, *Progymnasmata* volume 2, p. 411, say *that Cardano went enormously astray when he too inconsiderately laid down that the highest vapours producing twilight are to be observed near the vertex, since the first reflection of the ray that begins the twilight rather takes place at the horizon, and has never been seen by anyone near the zenith overhead*; and in the same place he rebukes Scultetus, who follows Cardano in this. [Margin: Tycho's censure of Cardano.] Second, angle DFE cannot be equal to the angle that the Sun's ray, drawn from the Sun's centre through the centre of the Earth, makes with the astronomical horizon, since that ray is not parallel to the ray drawn from the Sun's limb and touching the Earth, however great the Sun's distance from the Earth may be; angle DFE is smaller by as many minutes as the Sun's apparent semidiameter subtends, as we shall show in Problem 3. In the last reasoning, moreover, if CA is 5000 miles and is to AB as 5 to 3, then AB will certainly be 3000 miles. But perhaps there is a fault in Cardano's text.

Problema 2. Data Solis Profunditate infra Horizontem ad initium matutini, vel finem veſpertini Crepuſculi facti aut ficti à radijs Solis reflexis, ſed irrefractis; & Portione terræ à Sole illuſtrata: Inueſtigare altitudinem Vaporum Crepuſculinorum in partibus, qualiũ Terræ ſemidiameter nota fuerit.

Problem 2. Given the depth of the Sun below the horizon at the beginning of morning twilight, or the end of evening twilight, produced — or supposed to be produced — by

rays of the Sun that are reflected but not refracted, and given the portion of the Earth illuminated by the Sun: to find the altitude of the twilight vapours in parts of which the Earth's semidiameter is known.

V. This problem is that of Ibn al-Haytham and Witelo, and, with a few changes, of Magini and Longomontanus, at the places already adduced in number 2. Following them, in the diagram below, from the Earth's centre A describe the Earth's globe BCD; and the great circle EHKG of the solar heaven. Let GAH be the astronomical horizon, and LBM the physical horizon, touching the Earth at B and making right angles at B with the Earth's semidiameter AB, by proposition 18 of Book 3 of Euclid; and let AB be extended in both directions, to K, the zenith of the observer at B, and to T, the nadir. For KAT will be the vertical line, cut at right angles at A by the horizon GAH, which may also represent the plane of the meridian.

Diagram. The construction for Problem 2, used again for Problem 3, set in the left column. A large circle (the great circle of the solar heaven) with the Earth's centre A at its middle; about A, two close concentric small circles (the Earth and the sphere of the twilight vapours). A horizontal diameter G–A–H (the astronomical horizon); above it a horizontal chord L–B–V–M (the physical horizon), touching the inner small circle at B; a vertical line K–B–A–T. A line runs from F at the top of the circle down through V to N on the lower right, and F is joined to a point on the lower left near O; lines run from A to C, to V through I, to Z, to N, to E, and down through R. At the foot an arc through N, P and O (the Sun's disc), with its centre E on the great circle; a short mark Q on the line near N.

- F (top of the great circle, left of K): vertex of the shadow cone DFC
- K (top): the zenith of the observer at B
- L (left end of the upper chord), M (right end): ends of the physical horizon LBM
- B (on the upper chord, at the small circle): the observer, where the physical horizon touches the Earth
- V (upper chord, right of B): where the Sun's ray NF cuts the physical horizon
- I (on AV, at the small circle): foot of the altitude IV
- C (on the small circle, lower right of I): point of contact of the ray NC
- G (left end of the diameter), H (right end): the astronomical horizon GAH
- D (left of A, on the small circle): point of contact of the ray OF
- A (centre): the Earth's centre
- Z (on GH, right of A): where the ray NF cuts the astronomical horizon
- S (lower left of A, on the outer small circle): on the sphere of vapours VS
- R (below A, on the small circle): mid-point of the illuminated arc DRC
- P (in the lower arc): on the Sun's disc NPO
- N (lower right of the great circle): the Sun's limb

- Q (on the line near N): end of the portion QN, set in a script-like italic form
- O (lower left of the arc): the Sun's other limb
- T (bottom): the nadir, the point of midnight
- E (bottom, right of T): the Sun's centre

Now let the Sun's centre have passed T, the point of midnight, and be at E; from this point describe the Sun NPO, and so on. Let its central ray, drawn to the Earth's centre, be EA, and let the extreme rays, drawn from the Sun's limb on either side, be NF and OF, touching the Earth at C and D and enclosing the cone DFC of the Earth's shadow. To the point of contact C draw the Earth's semidiameter AC, which makes the right angle ACV by the same proposition 18 of Book 3. Further, draw the straight line AIV as far as the point V, where the Sun's ray NF cuts the physical horizon LBM. For VB will be the first ray reflected from the vapours at V to the eye at B, the one that makes the beginning of morning twilight; the sphere of the twilight vapours, described from the centre A through V, will be VS; and IV will be the altitude of the vapours that is sought. Finally, since EN, the Sun's semidiameter, is greater than the Earth's semidiameter AC, cut off from EN a portion QN equal to AC, and draw from A to Q the straight line AQ, parallel to CN; for by propositions 29, 33 and 34 of Book 1 of the *Elements* every angle of the parallelogram ACNQ is a right angle.

[Margin: First step.]

With these laid down: since the portion DRC of the arc illuminated by the Sun is known, half of which is the arc RC, the angle EAC, or RAC, will also be known. And since the Sun's depth below the astronomical horizon is given, namely EH, which is measured by the angle EAH, if this angle is taken from the angle EAC, the angle CAH will remain known; and this, taken from the right angle KAH, or BAH, will leave the angle BAC known. Now the triangles ACV and ABV are right-angled at the points of contact B and C; they have the common base AV and the equal sides AB and AC; and since the tangents VB and VC are drawn from the same point V, the sides BV and CV are also equal to each other, by theorem 58 of Book 1 of Witelo. Therefore these triangles are equal to each other, and the angle BAV is equal to the angle CAV, by proposition 8 of Book 1 of the *Elements*. But the whole BAC is known; therefore its half, that is, either of the equal angles BAV and CAV, is known as well.

[Margin: Second step.]

Secondly, then, in either of these triangles — say in the triangle ABV, right-angled at B — since besides the right angle the angle BAV is given, and the side AB, that is, the Earth's semidiameter, is known in determinate parts, say in stades or miles, you will easily find the base AV by the analysis of plane right-angled triangles. Subtracting from it the Earth's semidiameter AI, the altitude of the vapours IV will remain known, which was to be done. Briefly, then: to the logarithm of the semidiameter AB add the residue of the second

logarithm of the angle BAV, and the sum will be the logarithm of the base AV. Or otherwise: look up in the tables of sines the secant AV of the angle BAV, and make: as the radius, or whole sine, AB is to the secant, so are the stades or miles contained in the semidiameter AB to the stades or miles contained in AV; and when the stades or miles of AB, that is of AI, are taken from AV, there remain the stades or miles of IV itself, that is, of the altitude of the twilight vapours — if, that is, twilight were produced, as the ancients thought, by rays of the Sun that are reflected and not refracted at all in the denser air around the Earth. [Margin: A new short form of the rule.] You will work more briefly still if you subtract from the Sun's depth the excess of the semiarc of the Earth illuminated by the Sun over a quadrant, and look up the secant of half the remainder, and so on.

EXEMPLVM.

Example.

VI. According to Ibn al-Haytham at the end of his little work *On Twilight*, and Witelo, Book 6, proposition 33, the angle EAH of the Sun's depth below the astronomical horizon at the beginning of morning twilight is 19°, and the semiarc of the Earth illuminated by the Sun, that is, the angle EAC, is 90° 13′ 56″, by proposition 59 of Witelo's tenth book and Ibn al-Haytham's penultimate proposition. If the former is taken from the latter, CAH will be 71° 13′ 56″; and when this is taken from the right angle BAH, that is, from 90°, there remains BAC, 18° 46′ 4″, and its half, the angle BAV, 9° 23′ 2″, whose secant AV is 10,135,635 of the parts of which the whole sine AB is 10,000,000. But the circumference of the Earth according to Ibn al-Haytham, Abbomadus and Witelo is 24,000 miles. Therefore, by Archimedes, from what was said in Book 1, chapter 4, BR will be 7643 and AB 3821½. Let it be, then: as the radius 10,000,000 is to the secant 10,135,635, so is 3821½ to 3873 3,829,152/10000000. If you subtract 3821½ from these, there remains IV, 51 88/100 miles, or approximately 52 — although Ibn al-Haytham and Witelo, by the longer detours of chords, arrived at 51 miles 47′ 34″.

Problema 3. Altitudinem eamdem Vaporum Methodo Steuini & Glorioſi inquirere.

Problem 3. To investigate the same altitude of the vapours by the method of Stevin and Glorioso.

VII. Simon Stevin, in his *Mathematical Memoirs*, Book 3 of the *Geography*, proposition 1, and with him Giovanni Camillo Glorioso, *On Comets* Book 2, chapter 2, use the Sun's apparent semidiameter in place of the semiarc of the Earth illuminated by the Sun, because the arc that the Sun illuminates beyond the Earth's hemisphere differs by very few minutes from the Sun's apparent diameter — as anyone may see who compares this arc, which we treat in Book 3, chapter 11, problem 4, with the Sun's apparent diameter, treated in the same place, chapter 10. In our preceding diagram, therefore, since the Sun's limb N is less distant from the astronomical horizon HA than the Sun's centre E by

the arc EN — that is, less by as much as the Sun's apparent semidiameter — they accordingly subtract the Sun's semidiameter from the angle EAH of the Sun's depth; and when AQ is drawn parallel to the tangent ray NC, they are left with a known angle QAH, which is equal to the exterior angle NZH by proposition 29 of Book 1 of the *Elements*. For on account of the small bulk of the Earth compared with the Sun's distance, they think it is just as if the angle Z were made at the Earth's centre A and there measured the distance of the Sun's nearer limb from the horizon. In the same way Cardano too used the angle BVF, equal to the angle NVM, because this, owing to the parallelism of the horizons BM and AH, is equal to the angle NZH, which he assumed without any correction as 19°. Knowing QAH, then, and subtracting it from the right angle QAC, ZAC remains known; and when this is subtracted from the right angle BAZ, BAC remains known, half of which is BAV. With this and the semidiameter AB, the base AV is found in the triangle BAV, right-angled at B; and when AI is taken from it, the altitude IV becomes known. But the method of Ibn al-Haytham, Witelo, Magini and Longomontanus is certainly somewhat more accurate.

Probl. 4. Deſcribere idoneam figuram ad diſcernendum, An & quantùm altitudo Halituum Crepuſculinorum per radios Solis irrefractos inuenta, ſit ob radios Refractos diminuenda: Et Datis quæ in Probl. 2. ac præterea Refractione Solis horizontali, atq. altitudine Aeris refractiui; Inuenire punctum in ſuperficie Aeris, per quod ingreditur & egreditur radius Solis gemina refractione refractus.

Problem 4. To describe a suitable figure for discerning whether, and by how much, the altitude of the twilight exhalations found by means of the Sun's unrefracted rays must be diminished on account of refracted rays; and, given the quantities in Problem 2, together with the Sun's horizontal refraction and the altitude of the refracting air, to find the point on the surface of the air through which the Sun's ray, refracted by a double refraction, enters and leaves.

VIII. I suppose as certain, with Kepler in the *Astronomiae Pars Optica* [Aſtronomia Optica], pp. 79, 129 and 135, that on account of the greater lightness of the twilight exhalations and fumes than of the thick air, which watery vapours make denser for refracting the rays of the stars, the twilight exhalations are higher than the refracting air — granted that Tycho, *Progymnasmata* volume 1, p. 95, and Longomontanus, Book 1 of the *Sphaerica*, chapter 11, problem 2, take the altitude of the vapours that produce twilight and that of the refracting air for the same thing. We shall certainly show in Book 10, section 6, problem 51, that the altitude of the refracting air extends scarcely beyond 20 Bolognese miles; and yet the altitude of the exhalations, whether sought in the ancient way or by means of refracted rays, as below, is always greater, as we shall show below. With this laid down, the horizontal ray by which we first see twilight must be a refracted one; and the ray from which it comes must come from an exhalation that bounds the Sun's direct ray, as a little cloud would, and reflects it into the refracting air — but below the line of the physical horizon. Now,

so that the position of these rays may be understood in some fashion, let A be the Earth's centre, from which are described the terrestrial quadrant BD and the quadrant EF of the refracting air, enclosed by the true horizon AF and the vertical and perpendicular line AE.

Diagram. The figure for Problems 4 and 5, set in the left column: a quadrant construction for twilight with refraction. A vertical line from A up through B to E at the left, and a horizontal line from A along the foot through D to F; a quadrant arc from B down to D (the Earth) and a larger arc from E down to F (the surface of the refracting air); a horizontal line from B through S and H to T across the top. Straight lines fan out from A towards N, S, X, a, L, V, I, R and Q, Z, P and M. A line from G at the foot rises through Z to H; a line from K at the foot rises through M; short dotted lines run near H–V and P–M.

- E (top of the vertical): the top of the quadrant of the refracting air, EF
- B (on the vertical, below E): the observer's eye on the Earth's surface
- S (on the line BT): the point of the ray reflected to the eye
- N (on the outer arc, below S): end of the altitude NS of the refracting air
- a (small italic, below the line BT): the exhalation
- H (on the line BT): where the unrefracted ray meets the tangent TB
- o (small, just below H): the point O on the line AH
- T (right end of the top line): end of the physical horizon TB
- X (between N and the arcs): a point on the figure, not named in the text on this page
- I (on AH, below o): where the refracted ray Va cuts AH
- c (small, on the arc near I): the point C on the arc EP
- L (on the inner arc, on AH): mid-point of the arc BZ
- V (on the inner arc, right of L): the point of exit V
- R (on the Earth's arc, lower right): the point of contact R
- Q (on the outer arc, beside R): end of the line ARQ
- P (on the outer arc, below Q): the point P
- Z (below P): the point where the unrefracted ray touches the Earth
- M (on the outer arc, lower right): the point of entry M
- A (lower left corner): the Earth's centre
- D (on the foot line, at the inner arc), F (at the outer arc): ends of the quadrants BD and EF
- G (at the foot, below D and F): the unrefracted ray passing through G
- K (at the foot, beside G): the ray KM

Let the eye of the observer of the twilight be at B, on the surface of the Earth, which the line TB of the physical horizon touches at B. [Margin: First part of the problem.] Now let a ray issue from the Sun's right-hand limb, passing through G and through the air unrefracted, as the ancients thought, and touching the Earth at Z, until it meets the tangent TB at H. Draw the straight line AH to this point; for by it the arc BZ will be bisected at L, the arc EP at C, and the angle BAZ into the two equal angles BAL and LAZ, by proposition 1 of Problem 2, set out above; and by the same problem AH will

become known, and therefore also the altitude LH that the exhalations at H would have if the Sun's rays were not refracted. Now let there be another ray of the Sun from the same right-hand edge, namely KM, sensibly parallel to the former, GZ, because of the Sun's very great distance and the very small distance between the surface of the Earth and that of the air. Falling on M, this ray does not travel straight to P but is refracted towards the perpendicular and touches the Earth at R; proceeding from there, it issues through V, and would go straight on to O were it not refracted away from the perpendicular towards I. So the horizontal refraction of the solar ray is, at entry, the angle PMZ, and at exit, OVa. The ray, then, refracted a second time and proceeding along the line Va, before it reaches the horizontal line BT strikes exhalations — the atoms, as it were, of little clouds — which their opacity makes fit to reflect the Sun's ray to the point S, so that from there it is refracted to the eye at B. For if these exhalations were above the line BT, the ray reflected from them and falling into the air could not be refracted along the horizontal line to the eye at B; and so twilight would not be seen first by means of it, but some time after its beginning. Let us now suppose, for the sake of explanation, that the exhalation is at a, and that the ray reflected from there is aS. And although the lines AZ and AH are in reality much nearer to the line AB than you see in this figure, they are nevertheless placed in this position so that the narrowness of the space may not breed confusion among the lines and angles to be used below. Finally, from the centre A draw the straight lines ARQ through the point of contact R, AV to the point of exit V, Aa to the exhalation, and AS to the point of incidence of the last, the third, refraction. Now, so that it may appear that the point V of the exiting ray always lies between the lines AH and AQ, and so that its position — and indeed that of the point M of the entering ray — may be known, let us now complete the second part of the problem.

[Margin: Second part of the problem.]

IX. The ray MRV, then, touching the Earth at R, is the chord of the arc VQM, and its half VR is the sine of the arc VQ, as MR is of the arc MQ. Now the Earth's semidiameter AR is given, and when the altitude RQ of the refracting air is added to it, AQ is given in miles. Make, then: as AQ is to AR in miles, so is the whole sine AQ, of 10 000 000 parts, to AR, the second sine [Sinum Secundum] of the arc VQ, or QM; and so both arcs will be known. Now by Problem 2 the arc ECP is given, that is, the angle EAP, which is as great as the given depth of the Sun once you subtract from it the semiarc of the Earth illuminated beyond the hemisphere by the Sun's unrefracted rays; and its half is the arc CP, or LZ. But the ray refracted at M touches the Earth at R, beyond Z, with the arc RZ lying between, which is as great as the Sun's horizontal refraction, as is clear from what was said with Kepler, Book 5, chapter 5, problem 3. Subtracting RZ from LZ, therefore, LR, or CQ, will be known; if VQ is subtracted from this, the point V through which the Sun's ray exits will be known; and if to the point Q, now known, you add QM, equal to VQ, the position of the point M through which the Sun's ray enters will be known.

Now from the four extreme cases to be set out below in Problem 6 it will be clear that the point V always lies on this side of the line AH, towards AP; and it is demonstrated in general as follows. The semiarc of the Earth beyond the hemisphere illuminated by the Sun's unrefracted rays is not greater than 16′ 8″, from what was shown in Book 3, chapter 11, problems 4 and 5. The Sun's depth below the horizon at the beginning of morning twilight is not less than 16°, and at the end of evening twilight it is always greater, as is gathered from the observations to be reported in Problem 7. Therefore the angle BAZ, or the arc BLZ, is not less than 15° 43′ 52″, nor LZ less than 7° 51′ 56″. If you subtract from this RZ, the ordinary horizontal refraction of the Sun, which is about 34′, there remains LR, or CQ, 7° 17′ 56″. Now the altitude RQ of the refracting air, from what will be said in Book 10, section 6, problem 51, is scarcely greater than 20 miles; but let us grant it to be 30, of the parts of which AR, from what was said in Book 2, chapter 7, is 4139, so that the whole AQ is 4169. If one makes: as 4169 is to 4139, so is 10 000 000 to another number, AR will come out as 9 928 040, the second sine of the arc VQ of 6° 51′ 40″, which is less than the arc CQ of 7° 17′ 56″. But if you take RQ as 20 miles, AR will be 9 951 912 parts, the second sine of the arc VQ of 5° 37′ 16″. And so, the smaller the altitude RQ, the farther the point V will lie from the line AH, towards the line AP.

Probl. 5. Datis & inuentis quæ in Problem. 2. & 4. & Refractione triplici radij Solis horizontali Inuenire in linea altitudinis halituũ per irrefractos inuentæ, Punctum, per quod tranſeunt ſi producantur ad eam, radius Solis in egreſſu refractus & idem reflexus ad pũctum horizontis phyſici.

Problem 5. Given and found the quantities in Problems 2 and 4, and given the triple horizontal refraction of the Sun's ray: to find, on the line of the altitude of the exhalations found by means of unrefracted rays, the point through which pass, if they are produced to it, the Sun's ray refracted at its exit and the same ray reflected to the point of the physical horizon.

[Margin: First part, for the reflected ray.]

X. We begin with the reflected ray aS, but extended to O, a point of the line AH; and we seek the distance of the point O from H, which we shall find as follows. First, in the triangle BAH, right-angled at B, there are given, by Problem 2, AB, the Earth's semidiameter; AH, made up of the Earth's semidiameter AL and the altitude LH of the exhalations found in the ancient way; and the angle AHB, the complement to a right angle of the angle BAH. Therefore, by the laws of right-angled triangles, the side BH will become known. Secondly, in the triangle BAS there are given AB, and AS, made up of AH and the altitude NS of the refracting air; therefore, by the same laws, the side BS will become manifest, and this, subtracted from the side BH, will leave the side SH known. Thirdly, in the triangle SOH, the angle SHO is given, since it is the same as AHB, and the refraction of the entering ray, which is OSH, and therefore also the third angle SOH (the supplement of two right

angles). [Margin: By proposition 32 of Book 1 of Euclid.] Therefore, since SH is given, the side OH will not be unknown, by the laws of oblique-angled triangles.

[Margin: Second part, for the refracted ray.]

For the position of the refracted ray Va, cutting the straight line AH at I — that is, for the distance IH — draw the chord CV, so that the triangle COV arises. Now in the triangle AVR, right-angled at the contact R, the arc VQ was found by Problem 4, that is, the angle VAQ, whose complement to a right angle is the other angle, AVR; and the supplement of this to two right angles is AVO. [Margin: By propositions 32 and 13 of Book 1 of Euclid.] Next, by the same Problem 4 the arc CV was found, that is, the angle CAV in the isosceles triangle CAV. When this is subtracted from two right angles, therefore, the sum of the angles at the base CV is given, half of which is the angle ACV, and AVC. When this is subtracted from AVO, CVO remains; and when the refraction OVI is subtracted from this, IVC remains, known in the small triangle, in which ICV is also known, the supplement to two right angles of the angle ACV, and therefore also the third angle, CIV. [Margin: By proposition 5 of Book 1 of Euclid.] [Margin: By propositions 13 and 32 of Book 1 of Euclid.] Let there be found, then, in the isosceles triangle CAV, from the given angles and the sides AC and AV, the base CV; for the sides are made up of the Earth's semidiameter AL and the altitude LC of the air. Then with CV and the angles CIV and CVI you will find CI. Add this to the altitude LC, subtract the sum LI from the altitude LH found by Problem 2, and you will have the distance sought of the point I from H; the difference between this and the distance OH will be OI, which you should keep. And do not think that the rays of the Sun we use here hold some other position that conflicts with this demonstration; for from what will be said in Problem 6 it will be established that no false drawing [pſeudographiam] is contained in this diagram, that the twilight exhalation is at a, between AH and AS, and that the refracted ray Va falls below O — unless it meets the line AH at the same point at which the reflected ray Sa falls on it.

Probl. 6. Datis ac Inuentis, quæ in Probl 2.4. & 5. Inuenire Altitud. Halituum Crepuſcul. refractione radiorum Solarium Correctam.

Problem 6. Given and found the quantities in Problems 2, 4 and 5: to find the altitude of the twilight exhalations corrected for the refraction of the solar rays.

XI. If the difference IO found by Problem 5 were nil, the refracted ray VI and the reflected ray Sa would meet at the same point of the line AH; and so the portion OH, found by the first part of Problem 5 and taken from the altitude LH, would give the corrected altitude LO. But if they do not meet (as usually happens), use the triangle aIO, in which the difference, or side, IO has been found and all the angles are given. For aOI is the supplement to two right angles of the angle SOH, known by the first part of Problem 5; and aIO is vertically opposite, and equal, to the angle CIV, known by the second part of Problem 5; therefore the third angle, IaO, is also known. [Margin: By

propositions 13, 15 and 32 of Book 1 of Euclid.] Find, then, the side aI. Next use the triangle AIa, in which, besides the side aI just found, there is given the side AI, made up of the Earth's semidiameter AL, the altitude of the air LC, and the portion CI found by the second part of Problem 5; and there is also given the angle AIa, since it is the supplement to two right angles of the angle CIV, already known by the second part of Problem 5. The side Aa will therefore not be hidden; subtracting from it the Earth's semidiameter AX, the remainder will be the altitude Xa of the twilight exhalations, corrected for the refraction of the solar rays.

EXEMPLORVM 4. Epitome.

A summary of four examples.

XII. I have taken the Earth's semidiameter from Book 2, chapter 7; the altitude of the refracting air as at least 2 Bolognese miles and at most 20, from what will be said in Book 10, section 6, problem 51; and the Sun's depth as at least 16° and at most 26°, for in the temperate zones it is never usually outside these limits when twilight begins in the morning or ends in the evening. The ordinary horizontal refraction of the Sun's ray in the same zones I have taken from Tycho as 34′, and I have given no greater one to its ray reflected from the exhalations into the refracting air and refracted a third time to the eye. The semiarc of the Earth illuminated by the Sun beyond the hemisphere, by rays supposed unrefracted, I have taken as 15′, from Book 3, chapter 11, problems 4 and 5. The remaining angles and lines I have worked out, as in the following table, by applying Problems 2, 4, 5 and 6 in order.

Angles or arcs (altitude of the air →)	Sun's depth 16°, air 2 miles	Sun's depth 16°, air 20 miles	Sun's depth 26°, air 2 miles	Sun's depth 26°, air 20 miles
Use of Problems 2 and 4				
BAZ	15° 45′	15° 45′	25° 45′	25° 45′
BAL; LAZ	7° 52½′	7° 52′	12° 52½′	12° 52½′
BHA, SHO	82° 7½′	82° 7′	77° 7½′	77° 7½′
HSO	0° 34′	0° 34′	0° 34′	0° 34′
SOH	97° 18½′	97° 18′	102° 18½′	102° 18½′
ASB	88° 16′	84° 23′	88° 16′	84° 23′
Problem 4, second part				
LAR, or CQ	7° 18½′	7° 18′	12° 18½′	12° 18½′
RAZ, or RZ	0° 34′	0° 34′	0° 34′	0° 34′
VAQ, or VQ	2° 9½′	5° 37¼′	2° 9½′	5° 37¼′
AVR	87° 50½′	84° 22¾′	87° 50½′	84° 22¾′
AVO	92° 9½′	95° 37¼′	92° 9½′	95° 37¼′
CAV	5° 9′	1° 41¼′	10° 9′	6° 41¼′
ACV, and AVC	87° 25½′	89° 9⅓′	84° 55½′	86° 29⅓′
OVI	0° 34′	0° 34′	0° 34′	0° 34′
AVI	91° 35½′	95° 3¼′	91° 35½′	95° 3¼′
CVI	4° 10′	5° 53⅚′	6° 40′	8° 33⅚′
ICV	92° 34½′	90° 50⅗′	95° 4½′	93° 30⅗′

Angles or arcs (altitude of the air →)	Sun's depth 16°, air 2 miles	Sun's depth 16°, air 20 miles	Sun's depth 26°, air 2 miles	Sun's depth 26°, air 20 miles
CIV, and aIO	83° 15½′	83° 15½′	78° 15½′	77° 55½′
aOI	82° 41½′	82° 41½′	77° 41½′	77° 41½′
IaO	14° 3′	14° 3′	24° 3′	24° 3′
AIa	96° 44½′	96° 44′ + fraction [?]	101° 44½′	102° 4½′

Lines, in Bolognese miles (altitude of the air →)	Sun's depth 16°, air 2 miles	Sun's depth 16°, air 20 miles	Sun's depth 26°, air 2 miles	Sun's depth 26°, air 20 miles
Problem 5, first part				
AB	4139	4139	4139	4139
AS	4141	4159	4141	4159
LH	40	40	107	107
BH	572	572	946	946
BS	125	407	125	407
SH	447	165	821	539

IO	7	5 3/10	9 7/10	3 9/10
aO	28⅕	21⅗	23⅓	9⅖
aI	28⅐	21⅗	23 2/9	9⅖
Aa	4172	4174 6/10	4232⅘	4238⅗
Conclusion				
Therefore the corrected altitude Xa of the exhalations	32 7/10	35⅗	93⅘	99⅗
The uncorrected altitude LH was	40	40	107	107

Although, then, Kepler in the *Epitome of Astronomy*, p. 75, and in the *Astronomiae Pars Optica*, p. 288, Glorioso, *On Comets* Book 2, chapter 2, Wendelen in the *Eclipses*, p. 5, and Gassendi, *Institutio Astronomica* Book 1, chapter 18, rightly advise that the altitude of the twilight exhalations asserted by the older writers must be diminished, chiefly on account of refractions (for Kepler counts as part of the cause the inflamed matter around the Sun, which enlarges its diameter and apparently hastens its arrival at the horizon), Wendelen nevertheless did not speak rightly when he said: *The altitude of the twilights would come out at about 50 Italian miles, except that through refractions it seems to be contracted to only 24, which I hold to be truer.* [Margin: Wendelen's opinion on the altitude of the twilight exhalations is false.] But I, who hold that the least altitude of the refracting air is greater than two miles, and do not think that the Sun's depth below the horizon at the beginning or end of twilight reaches 26°, determine

from my own observations their altitude, which you see at the end of the table of Problem 7.

Probl. 7. Profunditatem Solis ſub Horiz. ad initium matutini, vel finem veſpert. Crepuſculi obſeruando Inuenire.

Problem 7. To find by observation the depth of the Sun below the horizon at the beginning of morning or the end of evening twilight.

XIII. I gave this problem in Book 1, chapter 31, scholium 2, but there I supposed that the time was to be gathered from the altitude of the fixed stars by Book 10, section 3, problem 25. Using this, then, we observed the Sun's depth at Bologna with the greatest diligence at the solstices and equinoxes. Tycho's disputes with Rothmann on this matter may be seen in Tycho's *Letters*, pp. 112, 124, 140, 152 and 158 — and no wonder, since the two did not observe at the same season of the year. The opinions of the rest, from the authors adduced in Book 1, chapter 31, I repeat here, so that they may be at hand for this controversy.

Altitude of the vapours or exhalations that produce twilight, in Italian miles, 4 of which make one German mile.

Depth assumed in deriving the altitude of the vapours — authors, with their passages reviewed at No. 2	Depth of the Sun below the horizon	Altitude of the vapours (Italian miles)
Posidonius, 400 stades	19°	50
Ibn al-Haytham, Witelo, Clavius, Barozzi	19°	52
The Coimbra commentators, Cottunius, Snel, Resta, Surdus	19°	52
Petrus Surdus, from another hypothesis	19°	73
Cardano, from a twilight of 1¼ hours	19°	288
Cardano, from a twilight of 2 hours	60°	772
Scultetus and Abram Roggembach	60°	772
Gemma Frisius, Magini, Biancani	18°	43
Petrus Nonius, from someone else's hypothesis	19°	68
Petrus Nonius, from his own observation	16° 30′	48
Tycho Brahe	16°	48
or	17°	52
Christoph Rothmann	24°	60
Christianus Severini Longomontanus	20°	52
Kepler, from various hypotheses of others and with refraction excluded; for he thinks the altitude of the vapours must be diminished on account of refraction	16°	34
	16°	48
	18°	40
	19°	44
Simon Stevin and Glorioso, neglecting refraction	18°	41
Gassendi, if refraction is neglected	18°	40
Govaert Wendelen, if refraction is neglected	19°	50
But with refraction taken into account	19°	24

We, from our own observation		Depth of the Sun	Altitude of the vapours, Italian miles: least	mean	greatest
At the equinoxes	morning	16° 0′	38	50	63
	evening	20° 30′	63	75	88
At the solstices	summer	21° 25′	70	82	95
	winter	17° 25′	46	58	71

Scaliger, Piso, Chiaramonti, Tannerus and Mastrius held, however, that lighter exhalations, which do not produce twilight, rise much higher, towards the Moon. Remember that 4 Bolognese miles, which we use, equal 5 ancient Roman miles.

[Margin: Kepler, Glorioso, Gassendi and Wendelen think that the altitude of the vapours is diminished by the force of refraction.]

CAPVT XV.

Chapter XV.

De Altitudine Cometarum ex vno, vel diuersis Terræ locis spectabilium, inuestiganda, independenter à Parallaxi.

The altitude of comets visible from one place, or from different places, on the Earth, to be investigated independently of parallax.

I. To understand the various problems that bear on this, the following figure must be set out. In it, from the Earth's centre A, describe the Earth's circle BCOD; the circle LNMP of the lower comet; and the circle EFGH of the higher comet. For convenience these are now to be understood as lying sometimes under the equator, sometimes under the meridian, as we shall need below. Let EAG be the vertical line passing through the zenith E and the nadir G of the inhabitant at B, cut in A πρὸς ὀρθὰς [Greek: pros orthas, "at right angles"], that is, at right angles, by the rational or astronomical horizon HAF; and at B let IBK be the physical or sensible horizon. Supposing EHGF to be the meridian, let QR be the equator and ST its axis, so that HT is the altitude of the pole and QF the altitude of the equator with respect to the inhabitant at B. Now let the two points I and K of the physical horizon be joined to A by the straight lines AI and AK, just as its points L and M have been deliberately joined to A by the same lines that represent the axis of the equator and the diameter of the equator. In the same way, deliberately, so as not to multiply lines, two straight lines drawn from E touch the Earth's circle at the points C and D, through which pass AI and AK, terminated at the extremities of the physical horizon — granted that none of this was at all necessary. Just so, the drawing of this whole figure is not needed for each of the following problems: one part serves for one, another part for another.

Diagram. The figure for Chapter XV, set in the right column. A large circle (the circle of the higher comet) with the Earth's centre A at its middle; about A, two concentric small circles (the Earth and the circle of the lower comet). A vertical diameter running from E at the top through N, B, A and P to G at the foot; a horizontal diameter H–C–A–D–F; above the centre a horizontal chord I–L–B–M–K (the physical horizon). Lines run from A to I and to K, and from E down to the small circle on either side. A line runs from T at the upper left through A to S at the lower right, and another from Q at the upper right through A to R at the lower left.

- E (top): zenith
- G (foot): nadir
- H, F (left and right ends of the horizontal diameter): the rational horizon HAF
- I, K (ends of the upper chord): the physical horizon IBK
- L, N, M (on the inner circle): the lower comet's circle
- B (above A): the inhabitant
- V (small, between L and B): label not named in the text on this page
- C, D (on the small circle, either side of A)
- A (centre): the Earth's centre
- O (small, below A)
- P (on the vertical, below the small circles)
- T (upper left), S (lower right): the axis ST
- Q (upper right), R (lower left): the equator QR

Problema 1. Quanta debeat esse Altitudo Cometæ sub Aequatore moti ad motum Primi Mobilis, vt possit apparere supra Horizontem Physicum tanto tempore dato, si Semidiameter terræ nota sit in suis partibus.

Problem 1. How great the altitude of a comet moving under the equator with the motion of the primum mobile must be for it to be able to appear above the physical horizon for a given length of time, if the Earth's semidiameter is known in its own parts.

II. In the preceding figure it is already plain that if one comet moves under the equator along the smaller circle LNMP, and another along the larger HEFG, with no motion other than that of the primum mobile, then — since the whole equator revolves with uniform motion in the space of 24 hours, and 15 of the 360 degrees of it, and of the circles similar to it, rise in one hour — the higher comet, rising physically at I, will remain above the physical horizon IBK for a longer time, before it reaches its setting at K by way of E, than the lower comet, rising at L and passing through N to its setting at M. For the arc IEK is nearly 180°, or comes closer to the semicircle HEF, than the arc LNM, which in this diagram is not a whole quadrant of its circle. [Margin: Cases 1 and 2.] Now let the time be given during which the lower comet has appeared above the horizon from its sensible rising in the east at L as far as the meridian N, or even as far as its setting at M. For when this is given and converted into

parts of the equator, the arc LN is given, or the whole LNM, whose half is LN, measured by the angle LAN. Therefore in the triangle LAB, right-angled at B by construction (as the intersection of the horizon with the vertical line requires), two angles are given, namely the right angle B and the acute angle LAN; given too are the stades or miles contained in the Earth's semidiameter AB; and so by the rules of triangles the base AL will become known. And since AN is equal to AL, as they are radii of the same circle, if from the whole AL, that is, from the whole AN, the Earth's semidiameter AB is subtracted, BN will remain known, that is, the altitude of the comet that was sought. In the same way, if the time of the higher comet from its rising at I to the meridian E, or to its setting at K, is given, the arc IE, half of the whole IEK, will also be given; it is measured by the angle IAE, that is IAB, in the same triangle right-angled at B. Therefore from the semidiameter AB the secant or base AI will become known, to which AE is equal; and so, when AB is taken away, the comet's altitude BE will be known, if its distance from the Earth's surface is sought; for if its distance from the centre is sought, it will be AE itself, or AI. And these are the first two cases.

III. [Margin: Case 3.] The third case is if the comet has been observed from its rising, say at I, up to its elevation at T, at which time it vanished because of the Sun's rising, and its distance from the meridian was then observed by azimuth (which will nevertheless be the true distance, notwithstanding that the parallax is unknown). For from the time from the comet's rising to its elevation at T the angle IAT will be given; and from the remaining part of its ascent to the meridian, derived by the azimuth, the angle TAE will be given, and so the whole angle IAE; with this, and with AB, as above, the distance AI will be known. [Margin: Case 4.] The fourth is if it happens that the comet appears at Q as the Sun rises, and the angle EAQ, or the arc EQ, is known from the azimuth; for this, subtracted from the arc IEQ, which answers to the time from the comet's rising to its position at Q, will leave the angle IAE known, as above. [Margin: Case 5.] The fifth case is if the comet appears at T as the Sun sets, and when its azimuth is taken the angle TAE becomes known; and when the time from T up to the comet's setting at K is counted, the arc TEK is known. For when the arc TE is subtracted, the arc EK will be known, that is, the angle EAK or BAK, with which, and with AB, the secant AK will become known. [Margin: Case 6.] The sixth case is if the comet appears at Q at sunset or a little after, and when its azimuth is taken the arc EQ, or the angle EAQ, becomes known; for this, added to the angle QAK, which is known from the time in which the comet came from Q to K, will make up the angle BAK, and so on. [Margin: The case is extended to the parallels of the equator.] From these, then, it will not be difficult to solve the other cases, whether the comet is under the equator or in a parallel of known declination, as will be said more fully in the problems of the primum mobile.

Meanwhile let it be supposed that it can be known that some comet moves under the equator, setting parallax aside — as if, for example, its motion had

been observed by another inhabitant in the right sphere — granted that this has perhaps never happened.

Problema 2. Data Cometæ altitudine seu distantia, sub Aequatore moti ad motum primi Mobilis, Inuestigare tempus, quo apparere poterit supra Horizontem.

Problem 2. Given the altitude or distance of a comet moving under the equator with the motion of the primum mobile, to find the time for which it will be able to appear above the horizon.

IV. This problem also includes six principal cases. For what is sought is either the whole time from its apparent rising to its setting, in which the comet runs through the arc IEK; or the time that passes between its first or last appearance at the point E of the meridian and its setting at K, or from its rising at I; or the time from its rising at I until its vanishing at T, the Sun now rising; or the time from its rising at I until its vanishing at Q, the Sun now rising; or the time from its appearance at T, or at Q, a little after sunset, until the comet's setting at K. Now in the first two cases we must use the triangle IAB or KAB, right-angled at B, in which are given the Earth's semidiameter AB and the comet's altitude, or distance from the Earth's centre, in the same kind of parts — that is, the secant or base AI or AK. From these three data, therefore, the angle IAB or KAB, which measures the arc IE or KE, will be found by the rules of triangles; and this arc, converted into times of the equator, will show the time from the comet's rising at I to its ascent to the meridian at E, or from there to its setting at K, and the sum of the two will be the time from the comet's rising to its setting. In the other cases, by contrast, the azimuths will show the differences of the angles that exceed or fall short of the angle IAB or KAB; and these excesses or defects, converted into times of the equator, will make plain the time desired.

I should like now to put into a small table the altitude of a comet, or its distance from the Earth's surface, corresponding to the whole time for which it can appear above the physical horizon under the equator or very near it, so that conjectures about the rest can be made from it — although it serves also for places situated under the same meridian, or under any one vertical, from which the phenomenon can be seen in the physical horizon of each.

Altitude above the Earth's surface necessary for a comet moving under the equator with the motion of the primum mobile to be able to appear above the horizon for the number of hours written below, from rising to setting.

Altitude of the comet: or semidiameters of the Earth	and miles	Italian miles	Time of stay	Arc of the equator
		10	$0^h\ 30^m$	7° 30′
		36	$1^h\ 0^m$	15° 0′
		146	$2^h\ 0^m$	30° 0′
		341	$3^h\ 0^m$	45° 0′
		641	$4^h\ 0^m$	60° 0′

Altitude of the comet: or semidiameters of the Earth	and miles	Italian miles	Time of stay	Arc of the equator
		1078	$5^h\ 0^m$	75° 0′
		1715	$6^h\ 0^m$	90° 0′
		2660	$7^h\ 0^m$	105° 0′
1	0	4139	$8^h\ 0^m$	120° 0′
1	2538	6677	$9^h\ 0^m$	135° 0′
2	3575	11853	$10^h\ 0^m$	150° 0′
6	2737	27571	$11^h\ 0^m$	165° 0′
14	1200	59146	$11^h\ 30^m$	172° 30′
29	2329	122360	$11^h\ 45^m$	176° 15′
47	1067	185600	$11^h\ 50^m$	177° 30′
90	1960	374470	$11^h\ 55^m$	178° 45′

Corollaria ex Præcedenti Tabella deducta pro Altitudine Cometarum.

Corollaries deduced from the preceding table for the altitude of comets.

V. First. If a comet were in the highest region of the air — taken as the region bounded at the altitude of the twilight vapours — it could not appear above the horizon for two whole hours, either with the motion of the primum mobile alone or with a motion against the order of the signs, towards the west, added to it; rather, it would plunge to its setting before two hours from its rising had passed. [Margin: Corollary 1, for comets not [?] exceeding the highest region of the air [?].] This proposition, understood with this limitation, is Cysat's, in the *Opusculum de Cometis*, chapter 3, proposition 1, and, from him, Froidmont's, in Book 3 of the *Meteorologica*, chapter 1, article 4. It is evident because, according to the preceding table, a comet that appears above the horizon for a stay of two hours requires an altitude above the Earth's surface of 146 Italian miles. But according to the last table of chapter 14, the altitude of the twilight vapours does not exceed 100 Italian miles, let alone 146, in the opinion of any author that can be tolerated; for the opinion of Cardano, Roggembach and Scultetus is intolerable and manifestly false, from what was said there at No. 4.

Secondly. [Margin: Corollary 2. An argument that the comet is above the Moon from its diurnal motion alone [?].] If a comet's diurnal motion under the equator by the force of the primum mobile takes very nearly 12 hours, so that it falls short of this by no more than 8^m, with refraction and parallax removed — or if it takes at least $11^h\ 52^m$ — the comet will be higher than the Moon. And this is what Froidmont meant to suggest in Book 3 of the *Meteorologica*, chapter 1, article 4, in these words: *Because many comets have drawn out a stay above the horizon equal to that of the stars, they are proved also to have had an altitude no lower.* Yet no comet is known to have moved under the equator. This is evident from the preceding table, in which a stay above the horizon of $11^h\ 50^m$ requires the comet to have an altitude above the Earth's surface of 47 terrestrial semidiameters and 1067 miles besides, while a stay of $11^h\ 55^m$ requires an altitude of 90 semidiameters and 1960 miles; therefore a stay of $11^h\ 52^m$ will require

an altitude of 64 terrestrial semidiameters. But the Moon's distance from the Earth's centre is about 64, and from its surface 63, as is clear from what was said in Book 4, chapter 14. The whole motion of the comet just described, from east to west, can, however, be known even if it has been observed for a few hours from its rising or before its setting, according to the methods indicated in Problem 1. Thus Cysat, as he has it in chapter 3 of *De Cometis*, proposition 1, observed on 1618 December 1 a comet that had risen on the eastern horizon at the 5th hour of the morning, that is, after midnight, at Ingolstadt, and had been elevated like the other stars, by the motion of the primum mobile, for three hours; when these had passed, at the approach of sunrise, it ceased to be seen, being distant from the meridian by an interval of more than two hours, indeed of nearly three. From this he rightly concludes that its semidiurnal arc was more than 5 hours, and its diurnal arc more than 10. On the following day it emerged from the horizon at the 4th hour of the morning, that is, 4 hours after midnight. That comet was therefore higher than three semidiameters of the Earth, as is evident from our table, and as Cysat shows in another way about that comet, in chapter 3, proposition 2; otherwise it would have set much sooner and risen much later, or (which comes to the same thing) it would have been above the horizon for fewer than 10 hours and below the horizon for more than 14. These things are truer of that comet at the time when it had a southern declination, since they are true of a comet under the equator itself.

[Margin: Corollary 3, for comets moved by a motion other than that of the primum mobile.] Thirdly. If a comet under the equator moves not only with the motion of the primum mobile but also with a proper motion against the order of the signs, what we said in the first and second corollaries is much more true. For motion against the order of the signs, that is, towards the west, goes along with the rapt motion [motus raptus], that is, the motion of the primum mobile; and the more it adds to that motion, the longer is the arc of the equator that would be owed to the comet from east to west if it were carried precisely by the motion of the primum mobile. So if this comet in one day completed 15 degrees by its proper motion against the order of the signs, and therefore rose one hour earlier than on the preceding day, then if it required two hours from its rising to its setting, that would be a sign that the diurnal arc of the equator was of three hours, or 45 degrees — one of which hours, however, it would have gained by its own speed towards the west. It is otherwise, by contrast, if the comet moves with a proper motion towards the east. For then, from the diurnal motion towards the west, unless this is corrected by subtracting as much as the eastward motion demands, so great an altitude of the comet cannot be inferred as from the motion of the primum mobile alone.

[Margin: Corollary 4, for comets declining from the equator.] Fourthly. If the comet declines towards the region opposite the observer, and moves only with the motion of the primum mobile, or only towards the west, what we said in Corollaries 1 and 2 is much more true. For the diurnal arc of the parallel,

because of the obliquity of the horizon, would be of fewer degrees than the diurnal arc of the equator, as will easily become clear.

Diagram. The figure of p. 91 set again in the left column (the text below calls it the figure set out at No. I). A large circle with the Earth's centre A at its middle; about A, two concentric small circles. A vertical diameter running from E at the top through N, B, A and P to G at the foot; a horizontal diameter H–C–A–D–F; above the centre a horizontal chord I–L–B–M–K. Lines run from A to I and to K, and from E down to the small circle on either side. A line runs from T at the upper left through A to S at the lower right, and another from Q at the upper right through A to R at the lower left.

- E (top), G (foot): zenith and nadir
- H, F: the rational horizon
- I, K: the physical horizon
- L, N, M (on the outer small circle)
- B (above A): the observer
- V (small, between L and B)
- C, D (on the small circle, either side of A)
- A (centre)
- O (small, below A)
- P (on the vertical, below the small circles)
- T (upper left), S (lower right)
- Q (upper right), R (lower left)

Problema 3. Data Cometæ ad oppositam spectatoris Plagam declinantis, Declinatione, sed vera, & Altitudine Poli, Inquirere minimam Cometæ à centro terræ distantiam.

Problem 3. Given the declination — but the true one — of a comet declining towards the region opposite the observer, and given the altitude of the pole, to find the least distance of the comet from the Earth's centre.

VI. Let the comet have been observed at the zenith by someone whose zenith's distance from the equator is known, and let the comet's true declination have been derived from this, independently of parallax. Or let the comet's true declination be supposed from some other source, feigned or given — the declination measured by the arc of the meridian, or of any great circle drawn through the poles of the equator, intercepted between the comet and the equator. On these suppositions, let the figure set out at No. I be repeated here, and let the observer be a northern one at B, whose altitude of the pole is HT, and altitude of the equator FQ, from which the comet declines to the south by the arc QK (the comet being feigned for the moment at K, a point of the physical horizon, when it appears on the meridian). For when EQ, the distance of the equator from the zenith (which is always as great as the altitude of the pole), is added to the declination QK, the arc EQK becomes known; and from it the angle EAK, which that arc measures, and hence the angle BAK in the triangle ABK, right-angled at B. In this triangle, therefore, since the Earth's semidiameter AB is supposed known — whether it is taken as 1 or as so

many miles — the base or secant AK can be found by the rules of triangles. So if you make: as the whole sine, or whole radius, that is, the radius AB, is to the secant AK of the angle BAK, so is the Earth's semidiameter AB, 1 or so many miles, to a fourth term, then AK will be known in semidiameters of the Earth or in miles. Or add to the logarithm of the side AB the residue of the second logarithm of the angle BAK, and the result will be the logarithm indicating the base AK. Now AK is the least distance of this comet from the Earth's centre; for if, as is supposed, it appears above the horizon outside the meridian, it will appear much higher above the horizon on the meridian. Therefore from its declination towards the opposite region a much greater distance of it from the Earth's centre than AK is inferred — which will also be clear to anyone who produces AK in a straight line. But if the comet is on the equator, its least distance is AM, which will be greater if it appears higher on the meridian, say at Q. By this device the following small table was constructed, or rather transferred from the preceding one to this use. It gives the least distance from the Earth's centre that a comet must have when placed on the equator, or declining towards the opposite region, corresponding to the comet's meridian distance from the zenith — a distance made up, namely, of the equator's distance from the zenith and the comet's declination just mentioned.

Least distance of a comet from the Earth's centre, corresponding to the altitude of the pole if the comet is on the equator, or to the sum of the altitude of the pole and the comet's declination towards the other pole, if it so declines.

Altitude of the pole, or its sum with the comet's declination	Least distance of the comet: semidiameters of the Earth	Italian miles
3° 45′	1 and	10
7° 30′	1	36
15° 0′	1	146
22° 30′	1	341
30° 0′	1	641

86° 15′	15	1200
88° 7½′	30	2329
88° 45′	48	1067
89° 22½′	91	1960

Corollaria ex præcedenti Tabella deducta pro Altitudine Cometarum.
Corollaries deduced from the preceding table for the altitude of comets.

VII. First. If the comet is under the equator, and the altitude of the observer's pole is not less than 15°, that comet will be higher than the twilight vapours. [Margin: Corollary 1, for comets moving under the equator.] For, according to the preceding table, it will be distant from the Earth's centre by one semidiameter of the Earth and 146 Italian miles besides, which far exceeds every probable distance of the said vapours from the Earth's surface, as is evident from the last table of chapter 14 and from No. 5 of the same chapter.

Secondly. [Margin: Corollary 2, for comets appearing in either of the tropics.] If the comet is on the tropic of Capricorn, or beyond it, and the altitude of the north pole is 65° 30′ or more, that comet will be above the Moon. For from the altitude of the pole, 65° 30′, and the declination of the tropic of Capricorn, which for me is always 23° 30′, there is made up a sum of

89 degrees. To this sum the preceding table assigns a least altitude roughly midway between 48 and 91 semidiameters of the Earth, that is, about 70 semidiameters, which exceed the Moon's distance from the Earth, from what was said in Book 4, chapter 14. How much more so if the comet, when it is on the meridian, is raised above the horizon, or is beyond the tropic of Capricorn. These things hold equally if the comet is on the tropic of Cancer or beyond, and the altitude of the south pole is not less than 65° 30′.

Thirdly. [Margin: Corollary 3, for comets seen at Milan on the tropic of Capricorn.] Some comets seen at Milan by Cardano or by others would have been distant from the Earth's centre by at least three semidiameters of the Earth, if some of them — seen at Milan on the tropic of Capricorn, as Cardano testifies in Book 4 of *De subtilitate*, and so declining to the south by 23° 30′ — had really been there. For at Milan the distance of the equator from the zenith, or the altitude of the pole, is 45° 28′; the sum is therefore 68° 58′, or very nearly 69°. To this sum the preceding table assigns at least 3 semidiameters of the Earth, since to 67 degrees are assigned 2 and 2538 miles, and to 75 degrees 3 semidiameters and 3575 miles — especially since this is the least distance, and the distance of those comets must necessarily have been greater, seeing that they were seen above the horizon on the tropic of Capricorn. Cardano, however, supposing there a distance of Milan from the circle of Capricorn of 68°, infers a smaller distance. I said "if they had been", because it does not follow from their having been seen on that tropic that they really were on it. For they could have had a much smaller true declination from the equator, and yet, because a large parallax depressed them towards the horizon, have seemed to decline from the equator as far as the tropic of Capricorn declines. [Margin: Cardano's slip concerning the altitude of comets.] Cardano's inference, therefore, which rests on the apparent declination, is false or uncertain. Similar to it seems the inference of our Father Cysat, who, on the comet of the year 1618, chapter 3, proposition 2, affirms that its least distance from the Earth's centre was 3322 German miles, because that comet was seen on 19 November at Frankfurt an der Oder when it had a southern declination of at least 23°, and so described the tropic of Capricorn by the motion of the primum mobile. He supposes, moreover, the

altitude of the pole at Frankfurt to be 52°, and the Earth's semidiameter to be 860 German miles. Indeed, if the same comet was seen on the same day in Prussia under a pole altitude of 54° (at Danzig, I believe, where for me it is 54° 23′), he infers that the comet must have been at least 3823 German miles distant from the Earth. But Cysat, aware that the parallax of this comet was smaller than the parallax of the Moon — although that had not yet been demonstrated at the time — seems to have taken as certain a true declination of the comet not less than 23°, especially since the comet was seen beyond the tropic of Capricorn; and yet he assumed it to be on the tropic itself.

Problema 4. Data diſtantia in circulo maximo inter duo loca Terræ, Cometam eumdem eodem tempore ſpectantia, & ſemidiametro Terræ, Inquirere minimam Cometæ à centro terræ diſtantiam, ſeu quanta ſaltem eſſe debeat.

Problem 4. Given the distance on a great circle between two places on the Earth that observe the same comet at the same time, and given the Earth's semidiameter, to find the least distance of the comet from the Earth's centre, or how great it must at least be.

VIII. With the figure set out at No. 1 repeated here, let there be two places on the Earth's surface, C and D — for convenience, on the equator itself, or under the same meridian, or under the same vertical circle — and let two straight lines EC and ED, meeting at E, touch those places. For when radii are drawn to the points of contact C and D, the angles at C and D will be right, by proposition 18 of the third book of the *Elements*. Let the straight line AE be drawn from the Earth's centre to the comet; for the least distance at which the comet can be seen will be AE — namely, if the comet is on the physical horizon of both places, CE and DE. But if it is seen above the horizon, it will of course be seen beyond E, and the comet's distance will be greater than AE; whereas we are seeking the least distance, below which it can in no case be seen except by the help of refraction. Therefore the distance of the two places under the same great circle, which is the arc CBD, when bisected, will give the arc CB, which measures the angle CAE. With this angle and the Earth's semidiameter AC, in the triangle CAE, right-angled at C, the least distance — that is, the base or secant AE — will easily be found. You see, moreover, that the problem is solved in the same way as Problem 3, for the triangles BAK and AED, or AEC, are equal and equiangular. Therefore the table placed at the end of No. 6 serves this problem too, if half the distance between the two places on the Earth is looked up in it.

Diagram. The figure of No. 1 set again at the head of the right column: a large circle; inside it, about the centre A, two concentric small circles; a vertical diameter through E, N, B, A, P, G; a horizontal diameter through H, C, A, D, F; a horizontal chord through I, L, B, M, K above the centre; lines from E down to the small circle; and two lines through the centre, from T to S and from Q to R. For this problem, C and D are the two places on the Earth's surface, E the comet, and EC, ED the tangents meeting at E.

- E (top): the comet, where the tangents EC and ED meet

- G (foot)
- H, F: ends of the horizontal diameter
- I, K: ends of the horizontal chord
- L, N, M (on the outer small circle)
- B (above A)
- V (small, between L and B)
- C, D (on the small circle, either side of A): the two places on the Earth
- A (centre): the Earth's centre
- O (small, below A)
- P (on the vertical, below the small circles)
- T (upper left), S (lower right)
- Q (upper right), R (lower left)

For example, if the places are 60° apart, look up 30° in the first column of the table; for to these corresponds a least distance of the comet of one semidiameter of the Earth and 641 Italian miles besides. Other places on the Earth, included within C and D towards B, will be able to see the same comet much more easily.

Corollaria ex hoc Problemate.

Corollaries from this problem.

IX. First. [Margin: Corollary 1, for a comet seen from two widely separated places on the Earth.] If two places on the Earth under the same great circle are not more than 176 degrees apart, it cannot be inferred from their seeing the comet at the same time that the comet is above the Moon, unless other conditions of the phenomenon are added. For from the table of No. 6 and the preceding problem, if those places are 176 degrees apart, half the distance is 88°, to which corresponds a least distance of the comet smaller than 30 semidiameters of the Earth — that is, smaller than the lunar distance, from what was said in Book 4, chapter 14. And unless something else is added, the comet can be said to have been seen on the physical horizon of both places. On this occasion, note that Giovanni Camillo Glorioso, in Book 2 of *De Cometis*, chapter 6, and Book 3, chapter 5, using this problem, rightly said that it cannot be argued from the comet of the year 1618 having been seen at the same time at Goa and in the Fortunate Isles that it was therefore above the Moon. For he assumes a difference of longitude between those places of 115° 10′ and an Earth's semidiameter of 3536 Italian miles, from which he deduces the secant AE, or least distance, as 5410 miles — that is, far smaller than the least distance of the Moon according to Ptolemy, which Glorioso puts at 178,672 miles. And Chiaramonti, in his opuscule *De sede sublunari Cometarum*, chapter 14, shows that the comet of the year 1618 could have been seen at the same time at Cesena and at Goa even if it had been no higher above the Earth's surface than 95 Italian miles — seen, I mean, from each place on its own physical horizon.

Secondly. [Margin: Corollary 2, for the same.] If two places on the Earth's surface that see the same comet at the same time are a whole semicircle of a

great circle apart, or at least 178 degrees, that comet will be above the Moon, unless an enormous refraction is feigned to stand in the way of this true altitude. For if they are 178 degrees apart, half the distance is 89°, to which the preceding problem, or the table of No. 6, assigns as the comet's least distance at least 68 or 70 semidiameters of the Earth, which certainly exceed the Moon's distance, from what was said in Book 4, chapter 14. And the comet will be all the higher, the higher it is seen above the horizon from both places. Would that we had a comet observed at the same time in two such places! But from what is to be said below, especially in chapter 22, No. 23, it will be established that such good fortune has not yet fallen to astronomers: for the comet of the year 1618, which of all comets was observed from the most numerous and most widely separated places on the Earth, was not seen over a greater interval than that between Goa and Antwerp — and not even at the same moment.

Problema 5. Data Cometæ diſtantia à centro Terræ, Inquirere ſpatium terræ, intra quod & non extra videri poterit eodem tempore.

Problem 5. Given the distance of a comet from the Earth's centre, to find the space on the Earth within which, and not outside it, the comet can be seen at the same time.

X. Giovanni Camillo Glorioso proposes this problem in other words in Book 2, chapter 5, of *De Cometis*. But it is easily solved by the preceding figure. For with the comet placed at E, and with its distance AE given — the secant or base in the triangle ACE, right-angled at C — and the Earth's semidiameter AC given as the radius or side, the angle CAE is easily found. For make: as AC, in the miles contained in the Earth's semidiameter, is to AE, the comet's distance, so is the radius or whole sine AC to AE, the secant of the angle CAE, which measures the arc CB. This arc, doubled, gives the arc of the Earth CBD, within which alone such a comet can be seen at the same time.

Problema 6. Data Cometæ Altitudine ab Horizonte eodem momento viſa ex duobus terræ locis, ſub eodem verticali cum Cometa poſitis, & Diſtantia locorum terræ in gradibus ac minutijs circuli maximi, nec non Semidiametro Terræ in Milliaribus; Inueſtigare diſtantiam Cometæ à Terra.

Problem 6. Given the altitude of a comet above the horizon seen at the same moment from two places on the Earth placed under the same vertical circle as the comet, and given the distance of the places on the Earth in degrees and minutes of a great circle, and also the Earth's semidiameter in miles, to find the comet's distance from the Earth.

XI. From the centre A describe the Earth's semicircle CBE, and the quadrants DS and VT, of which let VT be the one in which the comet moves. Let there be two places on the Earth, B and G, through which let the vertical lines ABD and AGL pass from A up to the zeniths, and let the places B and G be joined by the chord BG. An isosceles triangle ABG will thus arise, in which, from the arc BG of the distance of the places, the angle BAG that measures it is known; its supplement to two right angles will be the sum of the angles ABG and AGB, by proposition 32 of the first book of Euclid. Hence those angles at the base

of the isosceles triangle will be known separately, since they are equal to each other, by proposition 5 of the first book of Euclid. All the sides will also be known: for both AB and AG are the given semidiameter of the Earth, and BG is the chord of the arc BG, known from the tables of sines in parts of which AB is the whole sine. So make: as AB, the whole sine 100,000, is to the miles contained in AB, so is the chord BG to the miles contained in BG.

Diagram. A figure in the left column for Problem 6: an outer quadrant arc running from D at the top right down to S at the bottom left, and an inner concentric arc from V down to T; a vertical line through D, V, B, A on the right; a base line through S, T, C, A, E; a small semicircle of the Earth on the base, passing through C, G and B and down to E, with a short upright at m; and many straight lines drawn from the places B and G out to the two arcs. Star-marks for comet positions stand beside Y, beside X, and at the top of the outer arc.

- A (bottom, on the base): the Earth's centre
- C, G, B, E (on the small semicircle): C and E at its ends on the base; B and G the two places on the Earth
- D (top right): the zenith of B; V (on the vertical below D, on the inner arc): a comet position
- L, M, N, O, P, H, F, I (on the outer arc); H, F, I set close together at its top
- K, Q, R (inside, on or near the inner arc): comet positions named in the cases
- X, Y (left, beside the arcs, each with a star-mark)
- S (bottom left), T (on the base, below the inner arc)
- m (right, at the end of the short upright beyond B): end of the physical horizon Em
- one small letter-form below the star-mark at the top of the outer arc: [?]

On these suppositions, there are four cases of the problem.

[Margin: Case 1 of the problem.] The first case is if the comet is seen at the zenith of one of the places — for example, if it is at Q and is seen from G under the zenith L, or if it is at V, seen from the place B under the zenith D — but in the other place is seen to be distant from the zenith. Let it be, then, at Q. When the line BQM is drawn from B, the apparent place will be under M, but the true place under L; therefore BQA will be the parallax of altitude itself, or its measure, and it will be known. For in the triangle BQG, when the angle AGB is subtracted from two right angles, the angle BGQ will be known, by proposition 13 of the first book of Euclid; and by the same proposition, by subtracting from two right angles the sum of the angle ABG and the angle DBQ — which is known from the comet's apparent distance from the zenith D — the angle GBQ will be left known. Therefore, by adding this to the angle BGQ and subtracting the sum from two right angles, by proposition 32 of the first book of Euclid, the parallactic angle BQG, or BQA, will be known. Now, then, in the triangle AQB there are given the angle Q, the angle BAQ, known

from the arc BG, and the side AB, that is, the Earth's semidiameter. Therefore geometers cannot fail to know the side AQ, which is the comet's distance from the Earth's centre.

[Margin: Case 2.] The second case is when the comet is between the zeniths of both places, for example at K. The sign of this case will be if the comet is towards one region of the world for one of the places, but towards the opposite region for the other. So, drawing the lines BKH and GKI from B and G through K, and the line of the true place AKF, consider the triangle BKG. In it the angle GBK is known if you subtract from two right angles the sum made of the angle ABG and the angle DBK, known from the comet's apparent distance from the zenith D; the angle BGK is also known, if you subtract from two right angles the sum made of the angle AGB and QGK, known from the apparent distance from the zenith L. Therefore the third angle GKB too (which in this case is the sum of the parallaxes) will be known. But the base BG in miles is also known; so neither the side BK nor GK will remain hidden. Next, in the triangle ABK there are now given the two sides BK and AB and the angle ABK they contain, if DBK, that is, the comet's apparent distance from the zenith D, is subtracted from two right angles. Therefore the base AK, which is the comet's distance from the Earth's centre, will not remain hidden.

[Margin: Case 3.] The third case is when the comet is outside the arc comprehended by the zeniths of both places, as if it is at R. The sign of this will be if it is so distant from each zenith that for both observers it inclines towards the same region of the world. So draw through R the line of the true place ARN, and from the places B and G through R the lines of the apparent places BRP and GRO. First consider the triangle BGR, in which there are given the side BG and the angle GBR, if you subtract from two right angles the sum made of the angle ABG and DBR, which is known from the comet's apparent distance from the zenith D. The angle BGR is also known, if from the sum made of two right angles and the comet's apparent distance from the zenith L, which is the angle RGL, you subtract the angle AGB. Therefore, by proposition 32 of the first book of Euclid, the third angle BRG will be known, as being the remainder to two right angles (in this third case it is, and is called, the difference of the parallaxes). Find, then, the side GR. Next, in the triangle AGR, find the distance AR of the comet R from the Earth's centre; for in it there are now given the sides AB and GR and the contained angle AGR — namely, if you subtract the angle RGL from two right angles.

[Margin: Case 4.] The fourth case is when the comet appears to both observers on the physical horizon, or apparently distant from each zenith by 90 degrees; enough has been said of this in Problems 1, 2 and 3.

But if two places on the Earth are a whole quadrant apart, or more, only the second or the fourth case can occur. For let the two places be B and E, and let the comet be seen from B under the zenith D. It cannot be seen from E, because an observer can see nothing below the physical horizon Em, except accidentally by the help of refraction; much less will he be able to see a comet

placed beyond the straight line AD, towards K. Neither the first nor the third case, therefore, will occur.

Problema 7. Data Diſtantia Phænomeni à centro terræ, datoque vero Parallelo, in quo motu diurno vertitur, & data cuiuſuis loci terræ propoſiti Latitudine ac Semidiametro terræ; Inueſtigare Differentiam inter moram Phænomeni ſupra Horizontem Phyſicum, & Aſtronomicum in motu diurno.

Problem 7. Given the distance of a phenomenon from the Earth's centre, and given the true parallel on which it turns in the diurnal motion, and given the latitude of any proposed place on the Earth and the Earth's semidiameter, to find the difference between the stay of the phenomenon above the physical horizon and above the astronomical horizon in the diurnal motion.

XII. In the following figure, from the Earth's centre A describe the celestial meridian BOD, and under it the terrestrial meridian ECF; and let there be on it an inhabitant at C, whose vertical line is ACO. Let the natural or physical horizon GCK cut this line at right angles at C, and parallel to it let the rational or astronomical horizon BAD be drawn. Further, let the axis of the world be TAV, and the plane of the equator AL standing perpendicular to it, so that the altitude of the north pole is the arc BT, which is measured by the angle BAT, equal to the angle OAL, that is, to the distance of the equator L from the zenith O. Now, if the phenomenon is on the equator, draw from the point I, the common section of the equator with the physical horizon, the perpendicular IP to the astronomical horizon. But if it is on a southern parallel, describe that parallel to the equator, for example HF, and from the point of its common section with the physical horizon draw the perpendicular MN to the astronomical horizon; join H also to C by the straight line CH. If, however, the phenomenon is on this side of the equator, describe its parallel, for example QE, and from its common section with the physical horizon draw the perpendicular RS to the astronomical horizon — just as, if it passed through the zenith, the parallel to the equator OX would have to be drawn. On these suppositions we shall proceed as follows, with Chiaramonti, Book 3 of *De stellis novis*, chapter 30.

Diagram. A figure in the left column for Problem 7: a large circle, the celestial meridian, with O at the top; inside it, about the centre A, a small circle, the terrestrial meridian, with C at its top and F below; the horizontal diameter, the astronomical horizon, running from B through X, E, S, A, P, Z, N to D; the chord GK, the physical horizon, through C; the axis of the world from T at the upper left through A to V at the lower right; and many lines from A and from C out to the circle, with short perpendiculars dropped to the diameter.

- O (top): the zenith
- Q, L, H (on the circle, right of O, in that order downwards)
- K (right end of the chord), G (left end of the chord): the physical horizon GCK

- B (left end), D (right end of the diameter): the astronomical horizon BAD
- T (upper left), V (lower right): the axis of the world TAV
- A (centre): the Earth's centre
- C (top of the small circle): the inhabitant; F (on the small circle, below the diameter)
- X, E, S (on the diameter, left of A); P, Z, N (right of A)
- R, I, M (on the chord, from left to right)
- β, ε (small Greek letters, at the left, inside the circle)
- a (small italic letter, left of A, above the diameter)

[Margin: Case 1, if the phenomenon is on the equator.] The first case is if the phenomenon moves under the equator AL. Then use the triangle AIP, right-angled at P, in which there are given the side IP, as being equal to the terrestrial semidiameter AC, and the angle IAP, which measures the arc LD, that is, the altitude of the equator, or the complement of the altitude of the pole. From these, by the rules of triangles, find the base AI; subtract it from the whole AL, namely the given distance of the phenomenon from the Earth's centre, and IL will be left, known in miles. Reduce it by the rule of proportion to parts of which the whole AL is the radius 100,000: for IL will be the versed sine of an arc which, doubled, will give the arc of the phenomenon's diurnal revolution above the physical horizon. Convert its degrees, then, into times, which will give the phenomenon's stay above the horizon; and this, subtracted from 12^{h}, will leave the difference between it and the stay above the astronomical horizon. But if, in the triangle AGC, the horizontal parallax AGC has been found from the phenomenon's distance AG, its double, converted into times of the equator, will give the difference just mentioned very readily. These things, and what follows, are to be understood with refraction left out of account, which usually increases a stay of this kind.

[Margin: Case 2, of a phenomenon placed on a southern parallel.] The second case is when the phenomenon is on a southern parallel, for example under the tropic of Capricorn FH. Then first use the triangle ZMN, right-angled at N, in which there are given the side MN, as being equal to the terrestrial semidiameter AC, and the angle MZN, by proposition 29 of the first book of Euclid — for it is the exterior angle to the two parallels AL and ZH, equal to the interior LAD, which is known from the altitude of the equator, or the complement of the altitude of the pole. Find, then, the base ZM. Next use the triangle AHF, right-angled at F (since all the parallels of the equator cut the axis of the equator at right angles); for in it are given the base AH, namely the distance of the phenomenon from the Earth's centre, and the angle AHF, by proposition 29 of the first book, for it is equal to the alternate angle LAH, which is known from the declination HL of the given parallel. Hence you will be able to find the sides FH and AF. Afterwards, in the triangle AFZ, right-angled at F, since there are given the side AF, just found, and the angle AZF, equal to the angle HZD already known above, find the side FZ; add it to

the base ZM already found, and subtract the sum from the side FH found; for MH will be left. If you reduce it by the rule of proportion to parts of which the straight line FH is the radius 100,000, you will have the versed sine of the arc to be doubled, so as to have the arc of the whole stay of the phenomenon above the physical horizon. In the same way you will find ZH, that is, the versed sine of the arc to be doubled so that the arc of the stay above the astronomical horizon may be known; and these stays will be known when these arcs are converted into times of the equator, etc.

[Margin: Case 3, of a phenomenon placed on a northern parallel.] The third case is if the phenomenon is on this side of the equator, for example on the parallel aQ. In that case, in the triangle ERS, right-angled at S, find the base ER; for in it are given RS, equal to the terrestrial semidiameter AC, and the angle RES, equal to the angle LAD, exterior to the two parallels EQ and AL, that is, to the altitude of the equator. Next, in the triangle EAQ, find the base EQ and the side AE; for in it are given AQ, the distance of the phenomenon; the angle AQE, for it is equal to the co-alternate angle QAL, known from the declination QL of the given parallel; and the angle EAQ, composed of the right angle EAO and the angle OAQ, known from the distance of the parallel AQ from the zenith. Afterwards, in the triangle AaE, right-angled at a, there are given AE, just found, and the angle AEa, which equals the altitude of the equator: find, then, the side Ea. Subtract it from the base ER found above, and you will have aR. Subtract ER, moreover, from the whole EQ, and you will have RQ; so, by adding aR to this, you will have aQ. Now reduce these lines EQ, or also Ea, and RQ to parts of which aQ is the radius 100,000. Then RQ will be the versed sine of half the stay of the phenomenon above the physical horizon, and EQ the versed sine of half the stay above the astronomical horizon; or Ea will be the sine of the arc to be doubled and added to a semicircle, so that the stay above the astronomical horizon is made up.

[Margin: Case 4, of a phenomenon passing through the zenith.] But if the phenomenon passes through the zenith O: first, in the triangle AOX, right-angled at A, there are given AO, the distance of the phenomenon, and the angle O, which is equal to the alternate angle OAL, that is, to the distance of the equator from the zenith, which is as great as the altitude of the pole. Find, then, the base OX and the side AX. Next, in the triangle COε, right-angled at C, find the base εO; for the angle O is given, and the side CO, if you subtract AC, the Earth's semidiameter, from AO. Afterwards, in the triangle AβX, right-angled at β, in which the side or base AX has already been found, and the angle XAβ, that is, the altitude of the pole, is given, find the side Xβ. Then, when εO is subtracted from XO, Xε becomes known; and when this is taken from Xβ, εβ remains known; while Xβ, taken from the whole XO, will give βO. Reduce, then, both εβ and Xβ to parts of which βO is the whole sine 100,000, and you will have the sine εβ, whose arc, doubled and added to 180 degrees, will make the arc of the stay above the physical horizon; while the sine Xβ will be the

sine of the arc to be doubled, so that from it and 180 degrees the arc of the stay above the astronomical horizon is made.

From these you will work out any other cases without difficulty; but for the stay above the astronomical horizon you will be able, from the given declination of the parallel, to use the customary tables of diurnal arcs.

Problema 8. Data mora Phænomeni ſupra Horizontem vtrumq. loci, cuius data ſit altitudo poli; & data Paralleli, in quo Phænomenon verſatur, declinatione vera, vnà cum ſemidiametro terræ, Inueſtigare diſtantiam Phænomeni à centro terræ.

Problem 8. Given the stay of a phenomenon above both horizons of a place whose altitude of the pole is given, and given the true declination of the parallel on which the phenomenon moves, together with the Earth's semidiameter, to find the distance of the phenomenon from the Earth's centre.

XIII. You see that this problem is the converse of the preceding one, so it will be enough to indicate the method in a single case. Let us suppose, then, the phenomenon at H, turning on the southern parallel FH. First, then, convert the half-stay above the physical horizon into degrees of the equator, and look up their versed sine in the tables of sines: for you will have the side MH in parts of which the whole sine FH is 100,000 parts. In the same way, from the half-stay above the astronomical horizon converted into parts of the equator, and from their versed sine, you will have the side ZH, likewise in parts of which FH is 100,000; and by subtracting MH from this, the base ZM of the right triangle ZMN will remain known. In this triangle the angle MZN, that is HZD, is given, equal to the angle LAD, that is, to the altitude of the equator; therefore the side MN will not remain hidden, in parts of which FH is 100,000. Therefore, since MN is given in miles — inasmuch as it is equal to the Earth's semidiameter AC — the whole of FH will become known in semidiameters of the Earth by the golden rule [auream regulam]. Finally, therefore, in the triangle AHF, right-angled at F, with FH now given in semidiameters of the Earth, and with the angle AHF, which equals its alternate angle LAH, that is, the true declination of the parallel from the equator, you will find AH, the distance of the phenomenon from the Earth's centre. And by converting in the same way you will work out the remaining cases proposed above.

Corollarium duplex ex Problemate 7. & 8.

A twofold corollary from Problems 7 and 8.

XIV. [Margin: Corollary 1.] Infer from what has been said that, as long as we are uncertain whether a phenomenon undergoes parallax at its meridian altitude, and how much, we cannot use Problem 7 or 8, because these require the true parallel, or the true declination of the phenomenon. If it has a sensible parallax, Problem 7 will indeed yield the true stay above the horizon, but not the apparent one; and Problem 8 will not yield the correct distance from the apparent stay unless the apparent parallel is first converted into the true one, or the apparent declination of the phenomenon into the true one. For this conversion

the parallax must be known beforehand, since it always visibly depresses the phenomenon from the true parallel to the apparent one. Consequently, from a comet's stay above the horizon, if the parallax is not known, its distance from the Earth's centre cannot be determined with certainty. Scipione Chiaramonti noted this shrewdly in Book 3 of *De tribus novis stellis*, chapters 31 and 32, and in the supplement to the *Antitycho*, page 106, against Antonio Santucci and others, who think that from the mere stay of a comet or a new star above the horizon its distance from the Earth can be inferred, and from that the parallax, which was not known before.

[Margin: Corollary 2.] Infer, secondly, that since Problems 7 and 8 deal with the mere common diurnal motion of the primum mobile, if a proper motion of the phenomenon towards the east intervenes, the motion of the primum mobile must be increased, and if towards the west, diminished — as is done with the planets, whose diurnal arc is inferred from their proper motion.

Problema 9. Quanta ſit altitudo ſufficiens Cometæ à Sole lucenti, vt conſpici poſſit tota nocte, nec in vmbram terræ incidat: Datis Cometæ Declinatione, & loco Solis in Ecliptica, & portione terræ à Sole illuminata, ac Semidiametro terræ.

Problem 9. How great an altitude suffices for a comet lit by the Sun to be visible all night and not to fall into the Earth's shadow, given the comet's declination, the Sun's place on the ecliptic, the portion of the Earth illuminated by the Sun, and the Earth's semidiameter.

XV. From the Earth's centre A let the Earth's globe BDC be described, and another circle under the meridian, VGSL. Let an inhabitant be at B, from whose astronomical horizon GAL let the perpendicular line AV be erected towards the zenith. Let the Sun be imagined at midnight at S, whose extreme rays HF and KF, touching the Earth at C and D, form DFC, the cone of the Earth's shadow; and let the rays be supposed, for the present, unrefracted. Let AF be the axis of the shadow. Then let the Earth's semidiameter AC be drawn to the point of contact C, so that the angle ACF is right [Margin: By proposition 18 of the third book of Euclid.], and let the angle FAC be known from the arc CBO; for it is half the arc COD, which is not illuminated by the Sun.

Diagram. Set in the left column beside the construction of No. XV. A large circle, the meridian circle VGSL, with the horizontal diameter G–A–L (the astronomical horizon) through the centre A; about A a small circle, the Earth, with B above A and D and C on either side; above the large circle at upper left the point F, the apex of the shadow, from which two long lines run down to H and K, touching the small circle; the vertical AV from the centre to the zenith; a line from A through R to M; points I and E near the top of the circle; a small tailed comet drawn at T, with a dotted line running from it down to S on the lower part of the circle; an arc in the lower half of the circle passing through H and K. Star marks stand at E, P and R.

- F (above the circle, upper left): apex of the shadow-cone; the axis of the shadow is AF

- I, E (top of the circle, left of V): IV is the distance of the shadow's axis from the zenith; E is the comet at the border of the shadow in Case 3
- V (top): the zenith
- M (upper right, on the circle): end of the line ARM
- P (on the vertical below V): the comet at the border of the shadow in Case 2
- O, B (above A): B the inhabitant
- R (right of B): the comet at the border of the shadow in Case 1
- T (right, by the drawn comet): not named in the text of this page
- C, D (on the small circle): the points of contact of the extreme rays
- G, L (ends of the horizontal diameter): the astronomical horizon GAL
- A (centre): the Earth's centre
- H (bottom), K (lower right): ends of the extreme rays HF and KF
- S (lower part of the circle): the Sun at midnight

With these premises, let the comet be on the meridian, where there are two dangerous cases in which the comet's altitude may not be sufficient for it to avoid the Earth's shadow. The first is if the comet is diametrically opposite the Sun without any latitude; in that case it would have to be higher than the apex of the Earth's shadow. The other is if it declines, but only a little, from the axis of the shadow. [Margin: Case 1.] Let it be placed, then, at the border of the shadow at R — that is, if by reason of its declination it lies beyond the vertical line, towards the side opposite the shadow. For when the straight line ARM is drawn through it, the triangle ACR results, right-angled at C, in which the side AC, the Earth's semidiameter, is given, and the angle RAC. For from the place of the Sun, opposite and culminating, the declination of that place is known from the tables of declinations of the ecliptic; and accordingly, from the distance of the equator from the zenith, or the altitude of the pole, the distance of the shadow's axis from the zenith on the meridian will be given, that is, the arc IV, which the angle IAV, that is, OAB, measures. When the angle BAR, known from the comet's distance from the zenith on the meridian, is added to it, the angle OAR becomes known; this, subtracted from the arc OBC, which is known as we said above, leaves the angle RAC. With this angle and the side AC you will find the base AR, that is, the altitude of the comet sufficient for it to escape the Earth's shadow. For if there is a danger of its falling into the shadow at such a declination, the danger is greatest on the meridian, when the axis of the shadow also passes through the meridian, since the Earth's shadow is then raised highest. Yet it will not fall into it, because in reality the Sun's rays are refracted and the Earth's shadow is everywhere more contracted, as we showed in Book 5, chapter 5.

[Margin: Case 2.] But if the comet should appear on the vertical line, let it be at P, at the border; then use the triangle PAC, right-angled at C, in which AC is given, and the angle PAC, the remainder after the arc OB — known, as above, from the distance of the shadow's axis from the zenith — has been

subtracted from the arc OBC; and find the base AP. For that will be the comet's most amply sufficient altitude for avoiding the Earth's shadow all night.

[Margin: Case 3.] Finally, if the comet is on the same side of the zenith as that towards which the Earth's shadow inclines, let it be placed at E, the border of the shadow. When its distance from the zenith is subtracted from the distance of the shadow's axis from the zenith (for both will be known from the declination and the distance of the equator from the zenith), the angle IAE will be known; subtracted from the angle OAC, it leaves the angle EAC in the triangle EAC, right-angled at C, in which AC is given. The base AE, therefore, will not be unknown, that is, the comet's distance from the Earth's centre that is most amply sufficient for a comet holding the meridian to avoid the Earth's shadow even at the very middle of the night. For if it is placed off the meridian, or on the meridian indeed but with the shadow already inclined away from the meridian, its danger of eclipse will be much smaller.

E X E M P L V M.

Example.

XVI. Peter Apian, in Part 2 of the *Astronomicum Caesareum*, says that the comet he saw on 1533 June 25, declining from the pole of the world by 33° 20′, was visible around midnight and continuously until sunrise. He does not say, however, that it was on the meridian at midnight; on the contrary, he says it had climbed to the meridian when the Sun was about to rise. He puts the Sun at 11° 48′ of Leo, and the comet at 15° of Taurus with a northern latitude of 43°. He then says that if it had been near the Earth, that is, in the highest region of the air, as the older Peripatetics hold, it would not have appeared on those nights but would have lain hidden in the Earth's shadow; whereas in fact it was visible, even if it was wholly lit by the Sun, as he had shown from the projection of its tail towards the part turned away from the Sun.

But let us suppose, to make the danger greater, that it was on the meridian at midnight; that in longitude it was at 11° 48′ of Aquarius, where the axis of the shadow was; and that it declined from the pole by 33° 20′. The altitude of the pole at Ingolstadt, where Apian was then observing, is 48° 40′, and the distance of the pole from the zenith 41° 20′. Subtract 33° 20′ from this, and the arc VM remains, 8° — the comet, that is, being placed at R. The declination of 11° 48′ of Aquarius, under which the axis of the Earth's shadow is placed, is 17° 17′ to the south; adding to it the distance of the equator from the zenith, which at Ingolstadt is 48° 40′, gives the distance of the axis from the zenith, 65° 57′, namely the arc IV; joined to the arc VM of 8°, this gives the whole IVM, 73° 57′. Now, from what we said in Book 3, chapter 11, the arc OC is 89° 30′ 20″; therefore, when 73° 57′ is subtracted, the angle RAC remains, 15° 33′ 20″. And AC is, for us, 4139 Bologna miles. Therefore in the triangle RAC, right-angled at C, the base AR is found to be

4297 miles. Subtract 4139, and there remains the comet's distance from the Earth's surface, 158 miles — most amply sufficient for it to have avoided the

Earth's shadow in the greatest danger. How much more sufficient, then, was it, given that the shadow is narrower because the Sun's rays are refracted, and that the shadow declined from the meridian? For the comet appeared between the north and the east [inter Boream & Solanum] from midnight until sunrise, during which time the Earth's shadow was inclining more and more towards the west, to the quarter lying between the south and the west [inter Auſtrum & Fauonium].

CAPVT XVI.

Chapter XVI.

An & quantam vim habeat Argumentum à Parallaxi deſumptum ad determinandam Cometarum & cuiuſuis Phænomeni Diſtantiam à terra: & de vſu vel abuſu illius in communi Diuerſæ Opiniones præſertim Tychonis & Claramontij ſectatorum: Qua occaſione de vtriuſque Auctoritate in hoc genere.

Whether, and how much, force the argument drawn from parallax has for determining the distance of comets, and of any phenomenon, from the Earth; and the differing opinions on its use or abuse in general, especially those of the followers of Tycho and of Chiaramonti; and, on this occasion, on the authority of each in this field.

I. The chief argument for showing the distance of comets from the Earth is the one taken from the variation of view [diuerſitate aſpectûs], which the Greeks call parallax [Parallaxin]. It arises from the fact that we observe comets not from the Earth's centre but from its surface. For this reason their true place, marked by the line of the true place — that is, the line drawn from the Earth's centre through the comet's centre to the sphere of the fixed stars — differs from the apparent place, marked by the line drawn from the eye, stationed on the Earth's surface, through the comet's centre to the sphere of the fixed stars. This is called the line of the apparent place, and it never coincides with the line of the true place except when the comet is at the zenith, that is, at the vertex itself. Hence some of the older physico-mathematicians, and some of the more recent, constructed an argument of this sort: *Every phenomenon that, at the same apparent altitude above the horizon, has a greater parallax than the Moon is below the Moon; but comets are of this sort; therefore comets are below the Moon.* [Margin: Syllogism and counter-syllogism from parallax.] Not a few of the more recent, however, especially the Tychonics, argue in an entirely contrary way, thus: *Every phenomenon that, at the same apparent altitude above the horizon, has a smaller parallax than the Moon is above the Moon; but comets are phenomena that have a smaller parallax than the Moon; therefore comets are above the Moon.*

II. Faced with an argument of this kind, some have either dared to deny the major premise, or have admitted it in a wholly alien sense, because they did not understand the term parallax. [Margin: The term "parallax" unknown to some philosophers or astrologers.] Among them, a certain public professor of philosophy at Padua approached Galileo and asked him to explain what was meant by the term parallax; for he had already resolved in his mind to attack it,

having heard that some were using it against Aristotle's opinion on the place of comets. Galileo, smiling gently, said to him: "So, my lord, have you set your mind on disputing against a term whose meaning you do not know?" Another man in the same place, famous for his medical treatises, as Kepler relates in his book *De stella nova*, chapter 15, *dared to assert that astronomers are deceived in the doctrine of "paralapses"* [Paralapſeon] — meaning, of course, to say "parallaxes" [Parallaxeon]. Kepler mocked him splendidly in that place, and in the *Hyperaspistes*, page 2, says that he was Antonius Fabricius of Montepulciano. Petrus Surdus, too, in his book on comets, page 11, took the variation of view of the Moon for its different phases, in which it appears to us now full of light, now bent into a sickle, now swelling with gibbosity. Among the mockers and despisers of parallax, Longomontanus in the Appendix to the *Astronomia*, chapter 3, Glorioso in Book 3 of *De Cometis*, chapter 6, number 4, and Froidmont in Book 3 of the *Meteorologica*, chapter 1, article 2, list Bodin [Jean Bodin], John Craig the Scot, and finally Julius Caesar Scaliger.

For Bodin, in Book 2 of the *Theatrum*, calls the doctrine of parallaxes fallacious, and most ignorantly cites Ptolemy on his side in this — Ptolemy, who nevertheless gave a very great deal of weight to parallax in Book 5 of the *Almagest*. [Margin: Scaliger's ignorance about parallaxes is rebuked.] And Scaliger certainly seems not to have understood what a parallax sensible in itself is. For he says, in Exercise 79 against Cardano, that comets have a smaller parallax than the Moon because they follow a star as their author and are moved at an equal pace with its motion. Yet although this can happen with respect to some one observer, for others at widely separated places on the Earth's surface, if the comet is below the Moon, it will appear at the same moment to be far distant from that star — if indeed the comet is something real, and not a mere apparition [emphaſis] like a halo; and so it will have a parallax sensible in itself. Accordingly, Scaliger was given a thrashing by Christoph Rothmann in his little work on the comet of the year 1585, who says: *"But truly, my Scaliger, this subtlety of yours deserves the whip. You insultingly call the most excellent Homer, approved by all, a Greekling; what name, then, shall I call you here? But since one must not dispute with a man ignorant of the principles, I shall first hand you over to the mathematicians to be chastised and instructed, so that you may learn from them what parallax is, and where it comes from. Once you have learned these things, my contest with you will be easy; indeed you yourself will acknowledge your error, to the point of shame, and you will not deny that comets are lodged above the Moon in the spheres of the planets."*

[Margin: What those unskilled in mathematics should do in this controversy.] To these, then, and to men of this kind, our advice is this: either let them become versed in the doctrine of parallaxes — whether from elsewhere or from our Book 1, chapter 31, but more fully from Book 10, the penultimate section, which is on parallaxes — and only then approach this judgement; or, if they are unwilling or unable to learn this doctrine thoroughly, let them refrain from pronouncing an absolute verdict on matters they do not understand, so

as not to make themselves a laughing-stock to those who do. At most let them dispute on the nature and origin of comets on the hypothesis that the mathematicians have demonstrated that all of them, or some, are above, or below, the Moon; but let them leave the absolute judgement to the astronomers, and defer it to them as experts in their own art — just as Aristotle judged that, in matters pertaining to astronomy, one should defer to Eudoxus and Callippus, and appeal to them in doubtful cases.

III. [Margin: Authors doubting the use of parallax, or contending about its abuse.] There are others, however, who, understanding more or less what parallax is, grant indeed that it holds good for the fixed stars and for the planets, which are by now commonly known, but say that for comets it does not hold good, incidentally, or that only uncertain arguments are drawn from it. They say this either because the observations suited to determining a certain parallax are required to be so subtle and exact that they can easily escape anyone's diligence, as our Tannerus says, question 7 *de caelo*, page 37; or because refraction or the irregularity of the comet's motion renders this treatment [pragmatiam] uncertain, as Cottunius, together with Aversa, affirms in Book 1 of the *Meteorologica*, lectures 32 and 33, and Mastrius in disputation 4 *de caelo*, question 2, article 4, number 47. They confirm this from the disagreements of the astronomers: for some, while using parallax, have nevertheless placed comets far below the Moon, such as Regiomontanus, Vögelin, Nolthius, Sultetus [?], Vuinchlerus and Chiaramonti; others above the Moon, such as Apian, Gemma, Tycho, Longomontanus, Kepler, Rothmann, Cysat, Snel, Santucci and many others. Accordingly, they either deny the minor premise of the syllogism proposed in No. 1, or they evade it and twist it towards the uncertainty of parallax. Among these, however, Scipione Chiaramonti alone, so far as I know, appears to have undertaken this business by geometrical inquiry. [Margin: Chiaramonti's opinion on the place of comets from parallax.] In his *Antitycho*, after a whole first book on the kinds of parallax, he brings forward in Book 2 the reasons adduced by Tycho and others for the celestial place of comets, and contends that they are either false, or neither necessary nor evident; and in Book 3 he contends that from the observations of Tycho himself, and of others reported by Tycho himself, if they are accepted, it is demonstrated that those comets were sublunary. And yet in his *Apology* for his *Antitycho*, page 9, he later said: *If the observations of Tycho and of the Landgrave of Hesse, approved by Tycho, are accepted, the comets of the years '77 and '80 are concluded demonstratively to be celestial; likewise, if the observations of others too are accepted, as corrected by Tycho as well, it is demonstrated from their comparison with Tycho's that the comet of the year '77 was sublunary.* Indeed, a little before he had said: *If the observations of Tycho are granted, and the others of those who at the same time as Tycho observed, and of these the ones that Tycho approved and also corrected — then the comets of the years '77 and '80 are demonstrated most evidently and necessarily to be sublunary.* Yet he asserts the very same of the comets of the years 1475, 1532, 1556, 1582, 1590, 1593, 1597, 1607 and 1618: partly in Book 3 of the *Antitycho*, chapters 17 and 21;

partly in the *Apology* for the *Antitycho*, Book 2, from chapter 7 to 12; and partly in two little works entitled *De sede sublunari Cometarum*. Chiaramonti shows himself, moreover, highly skilled in geometry and in astronomical matters, to say nothing of Peripatetic philosophy; and he has candidly set out his theorems and problems, together with calculations arranged in order, for anyone to examine.

IV. [Margin: Opinions about Chiaramonti and the Tychonics.] Hence, again, disagreements have arisen among the Peripatetics of our time, and among the Tychonics and other mathematicians, and differing judgements on Chiaramonti's doctrine in this field, set against the assertions of Tycho, Kepler and other Tychonics, as to which of the two is rather to be believed. Kepler himself, in his *Hyperaspistes* of Tycho, tried to defend Tycho — and indeed himself too, since he knew that he could not stand if Tycho were overthrown. For so he himself speaks in the preface to the *Hyperaspistes*: *If I were to take up the defence of the part of Tycho Brahe, once my master, even in a lost cause, I believe that not only pardon for the defence but praise besides for the dutiful service would not have been wanting. Now, after I have for thirty whole years continued, secure and undisturbed, in the possession of this knowledge — that comets are seen above the Moon — and have already resolved to enter this possession, as part of my estate, to posterity, if posterity will have any care for my works:* [Margin: Praises of Chiaramonti from Kepler himself.] *behold, out of the blue there arises a learned man, skilled in geometry, accomplished in the doctrine of triangles and in the doctrine of parallaxes, which contains the foundations of my claim — not one who, like Antonius Fabricius of Montepulciano once, hallucinated childishly (an author I dealt with as his merits deserved eighteen years ago, in my book De Stella Nova Serpentarii, folios 79 and 80), but one who treats that whole part of sidereal doctrine most carefully in the entire first book of his work. This man, I say, armed with so many prejudgements and strong in so many clients, brings a suit against me, intending to eject me from this possession of mine. Truly, I think it concerns both the profit of all who have read me and my own private reputation that I be watchful, and that I enquire most diligently whether, now that my age is declining, I must unlearn anything of what I learned as a youth and taught as a man, and unteach it to others. This most illustrious man, who summons us to the pursuit of truth, must be humoured; and I must take care not so much lest, as author, I wrong my master Tycho by heaping false charges on him, as lest I wrong myself by cherishing errors once they are exposed.*

A little later, it is true, he adds: *For I have never thought that teachers should be praised in such a way that error is entrenched, nor that they should be spared in such a way that the truth lies hidden.* Yet after saying this, Kepler later, his bile rekindled, tried to dishonour Chiaramonti with many insults — whether deservedly or undeservedly, let others judge. [Margin: Kepler's inconsistency or forgetfulness.] And finally, on page 183 of the *Hyperaspistes*, as if he had forgotten what he said in the preface, he says of Chiaramonti's book: *The book is indeed of such futility that I would have scorned it; and so I declare even now that, unless Chiaramonti comes forward hereafter better instructed in our art — whether he*

chooses to harass Tycho or myself and the works I have published in the mathematical part of philosophy — I shall have no reason to undertake a defence and write a book publicly. Unless you say that Kepler praised Chiaramonti's first book and left the rest unpraised.

[Margin: Froidmont subscribes with Kepler against Chiaramonti.] On Kepler's side against Chiaramonti, however, stood Froidmont, in Book 3 of the *Meteorologica*, chapter 1, article 2, already prepossessed by the authority of Tycho; for he says: *But Scipione Chiaramonti makes greater trouble. In two books of his Antitycho he draws back into the air the comet of the year 1577, which Tycho had established in the ethereal region above the Moon by so many reasons. For he tries to show that it had a parallax larger than the Moon's, and that Tycho now set down a calculation badly, now did not sufficiently consider the refraction that was disturbing the parallax, and other things of that kind — which not a few would perhaps have believed, had not Kepler's Hyperaspistes promptly withdrawn credence from Chiaramonti. To try to refute his innumerable numbers and computations would be an endless task, and not in keeping with the scope of this book. Kepler has done it better than I could, and splendidly; consult him, if you like, in the Hyperaspistes. I add only this: unless we trust Tycho's instruments and that most skilfully made sextant of his, the credibility of all will have to be thrown away. For since the times of Ptolemy there has been no one — or perhaps never anyone — who has attended with greater care to this matter of instruments.* And after a few words on Tycho's instruments and his primacy in astronomy, he adds: *Nor was Tycho such an infant as not to know that refractions raise the stars which parallax depresses, or as not to attend to them in his observations where they might perhaps disturb the parallax somewhat.*

But you do not distinguish the times, my Froidmont. For there was a time when Tycho either did not know of refractions or did not use them — namely, when he wrote the volume on the comet of the year 1577, as I shall show below — granted that afterwards, grown more learned than his former self, he treated them splendidly. It is also false that Kepler examined Chiaramonti's calculations one by one, since he left almost all of them untouched. Further, although Tycho's observations of the comet of the year 1577 had been made with most exquisite instruments — some of them, however, were made by Tycho with the astronomical radius alone and with the azimuthal quadrant, instruments afterwards disapproved by Tycho himself and brought under suspicion of being deceptive — it still does not follow that the conclusions were evidently deduced from those observations. Nor should the mere mass of the Tychonics' instruments be thrust upon Chiaramonti, who denies this and resists with engines of argument to the contrary; for that is to resort to the machine rather than to untie the knot. I would say this, since the occasion has offered, not in order to bring out my own opinion here for either side, but to prepare the reader's mind for myself, free from all prejudice, for a true judgement on this matter to be passed later.

[Margin: Franciscus Resta casts his vote with Kepler and Froidmont against Chiaramonti.] Likewise, as a back-bench senator [Pedarius Senator], Franciscus

Resta subscribes to Froidmont, for Kepler against Chiaramonti, in Book 1 of his *Meteorologia*, tractate 1, chapter 2, saying of Chiaramonti: *He heaps up a good many things at some length, and sets them out so ingeniously that he could draw many over to his opinion, had not Johannes Kepler set his Hyperaspistes against him, exactly refuting Chiaramonti's arguments; which need not be done again here. Let it suffice to note what Froidmont adds, who considers that Tycho was the more celebrated in astronomical matters in his own age.* And a little below, of Tycho: *It is altogether unworthy to suspect of him that he treated these matters so childishly as not to notice at all the elevation that could arise from the refraction of vaporous air. And if we give room to these doubts of Chiaramonti, the things deduced from similar observations concerning the order of the planets, and concerning other astronomical observations, could at once be called into doubt.*

By no means, good Resta. For at another time, with better instruments, more experienced through practice and by then aware of refractions, Tycho left us many things about the planets that are more certain than those about the comet of the year 1577 — although even in the very things he discussed about the Sun and the Moon, because of an excessive solar parallax, assumed rather than observed, one may depart from Tycho without injury to Tycho, as is plain from what we demonstrated in Book 3, chapter 7, and Book 4, chapter 13.

[Margin: Father Cabeo defers in part to Chiaramonti, but more to Tycho.] Father Cabeo also favoured Tycho in this, on Book 1 of the *Meteorologica*, text 37, question 1, where he briefly weighs the tenets of Tycho and of Chiaramonti, though rather moderately. For he says, among other things: *I do not claim so much for myself that I can sit as judge in this suit*; and again: *I do not intend, as I also said above, to set up an examination of these difficulties, nor to call them to judgement; I do not wish to weigh the calculations or the demonstrations of either side.* Yet neither does he think Tycho's lie should be defended — about a certain observation fabricated on days on which, as he had confessed elsewhere, no observations could be made because of cloudy weather. After many solutions of Chiaramonti's reasons, however (always leaving the calculations untouched), he concludes that if one must deal with mere philosophers, or if judgement must be made from presumptions, the suit is rather to be awarded to Tycho, because of his experience of many years in observing and his diligence and good faith, long proven, in determining the motions of the planets exactly; nor should the omission of refraction be charged against one who even set up for us special tables of the refractions of the Sun, the Moon and the fixed stars. On this, I know well, Chiaramonti complained rather bitterly in a little book recently published: that in a mathematical controversy, to be argued out by geometrical reasons, his reputation had been diminished by a presumption in favour of Tycho's authority, and that he recognised a sentence pronounced against him, though under the appearance of suspending judgement.

[Margin: Cysat a supporter of Tycho.] Before all these, our Cysat too, in *De Cometis*, page 33, said that Tycho's observations ought not to be suspected by

even a single minute — which should have been understood of Tycho when he was already better instructed, but not universally.

V. There were nevertheless some who would rather give their vote to Chiaramonti — not only among those Peripatetics who made no great profession of the mathematical sciences, but also among those who seemed more than lightly versed in them. Thus Giovanni Camillo Glorioso, in Book 3 of *De Cometis*, chapter 5, number 21, and chapter 7, calls Chiaramonti's arguments against Tycho "sufficiently evident, and clearly demonstrated." Nor does he contradict himself in chapter 8, when he says: "If we begin to cavil at other people's observations on the strength of conjectures, the business of astronomy will collapse; one may depart from other people's observations only on the strength of evidence" — although in Book 5, without any mention of Chiaramonti, he sided with Kepler and Tycho in placing many comets above the Moon. [Margin: Glorioso's vote for Chiaramonti.]

Galileo likewise, in his *Trutinator*, page 24, has these words, rendered into Latin: "I say again that it is utterly false that I criticized the followers of Tycho, though I could rightly have done so, as his followers will in the end be able to see from the *Antitycho* of the knight Chiaramonti." Granted, once he learned that Chiaramonti rejected the Copernican hypothesis, which Galileo defends tooth and nail in his dialogues on the system of the world, he now thinks Chiaramonti's prolixity against Tycho's loquacity (as he himself puts it) superfluous, and now, in the person of Salviati, says: "The inconstancy of the observations on which the computation of parallaxes rests makes both these opinions and those equally suspect to me, especially since the *Antitycho*, as it seems to me, sometimes either accommodates observations to its own arguments, or accuses of falsity those that conflict with its purpose." [Margin: And Galileo's, formerly.]

But Cottunius, a Peripatetic, awards the palm outright to Chiaramonti, a Peripatetic, on Book 1 of the *Meteorologica*, lecture 32, where he says: "Scipione Chiaramonti, a man of solid learning, contended outstandingly on this subject in a twofold work: to one part he gave the name *Antitycho*; the other is *De tribus novis stellis*, on the three new stars that appeared in the years 1572, 1600 and 1604. In both he demonstrates that all comets, and also the said new stars, existed below the Moon, in the elementary region." And somewhat later in the same lecture: "Knowledge of this distance, which is derived from parallax, is so difficult that it does not afford a certainty in which the intellect can wholly rest. This is not because parallax, truly taken, cannot show the true distance of some phenomenon — to deny that would be foolish — but because, as Giovanni Camillo Glorioso candidly reports in Book 4, chapter 8, in all observations there is always some scruple and ambiguity; Chiaramonti says much on this matter." [Margin: Cottunius's testimony for Chiaramonti.]

Later, Bartolomeo Mastri and Bonaventura Bellutus [Bonaventura Belluto], in their disputations on the heavens and on meteors, disputation 4, question 2, article 4, number 47, conclude after much discussion: "From this it is plain that

many of Tycho's arguments, which he draws from parallax, do not conclude much; but whoever wants an exact solution and a subtle examination should consult Chiaramonti, Book 2, chapter 15." [Margin: Mastri's and Bellutus's vote for Chiaramonti.]

VI. The testimonies, then, sway this way and that — both for the use of parallax and against its abuse, on one side for the Tychonics and on the other for Chiaramonti and his followers. I myself have more than once been asked by friends what I thought of each side, and never had the leisure or sufficient opportunity — which I now enjoy by the kindness of GOD and of my superiors — to look thoroughly into a case of this kind. It is at last time, therefore, that with all the good faith, diligence and depth of inquiry I can command, I should separate the certain from the uncertain in so tangled a controversy, and weigh separately the arguments of each party drawn from parallax; for the remaining arguments have already been treated in chapters 10 and 11. So that I may do this with greater profit and happier success, I have resolved to ask four Postulates of the reader.

VII. *First*, I postulate that for the present we be allowed — not indeed to despise probability and mere likelihood, for later we shall draw our own assertions from it, but to pass it by as though with a deaf ear and leave it aside; and to direct the eye of the mind to the single goal of certainty and evidence — not, indeed, purely metaphysical certainty, but Phyco-Mathematical [?]. For this is what is required first and foremost, and Chiaramonti has very often professed expressly that this is what he is contending for. In this he cannot fail to be commended by mathematicians and astronomers, provided only that he is content with the kind of certainty on which most of the astronomers' doctrines rest; and to be commended more than Tycho and Kepler, who more than once confuse likely arguments with evident and necessary ones, as we showed of Tycho in chapter 11, number 6, and as will appear of Kepler below. [Margin: Postulate 1: probability is to be disregarded for the present.]

VIII. *Second*, I postulate that it not be put down to cavilling or sophistical inquiry — as though we were looking for knots in a bulrush — if in determining the parallax we require the subtlety that the evidence already mentioned demands. For although in the parallax itself, once it is established that it is many minutes greater or less than the lunar parallax, a difference of one minute or another harms neither side, yet in the very elements or data from which it is derived, the neglected error of a single minute can not infrequently cause us to conclude that the parallax is greater than the Moon's when in fact it is less, or less when it is greater. Thus we in the penultimate section, Book 10, chapter 12, numbers 11 and 12 — and Chiaramonti before us — have demonstrated that it can happen that the difference between the parallaxes of the same phenomenon, observed from different places on the Earth by different observers, is of only one minute, and yet a parallax of the phenomenon much greater than the Moon's follows from it. [Margin: Postulate 2: on subtlety in the inquiry into parallaxes.]

Let the Tychonics indeed remember how great a subtlety Tycho required in investigating the place of the New Star of the year 1572. For in volume 1, near the beginning of chapter 6, page 396, he said: "What we are now undertaking, however — namely, to know with certainty and to demonstrate evidently the star's remoteness from the Earth, and in which part of the world it shone — is a matter of far greater industry, labour and SUBTLETY, more arduous, and exposed to more windings of difficulty." How much more is this so in comets, whose place and motion are wandering and inconstant? And in the same place, page 413: "To measure the remoteness of a phenomenon from the Earth, and to demonstrate it, requires great subtlety." In volume 2 as well, page 145, censuring Regiomontanus's method of finding parallaxes as insufficiently scrupulous, he says: "For he builds the greatest things out of the least, so that an error of one minute or another in the time grows into an excessive deviation. Moreover, unless the azimuths and altitudes are obtained so scrupulously that nothing is lacking, you will have wasted your oil and your labour; for a slip of a few scarcely perceptible minutes in the time and the other data can easily produce a departure of several degrees from the mark of truth." He repeats things quite like these on page 210.

This was surely the reason why he thought little weight should be given to observations of azimuths and altitudes taken together with the same quadrant: a slight error in the time and in the azimuth, owing to the sudden great variation in altitude, passes on a great error to the conclusions derived from them. For in the *Epistolae Astronomicae*, page 295, against someone who preferred that a comet's parallaxes be deduced from altitudes and azimuths rather than from distances from the fixed stars, he says: "The method by distances, applied in due fashion, is more certain than the one taken from altitudes and azimuths, in which a scarcely perceptible error becomes extremely fertile." And in volume 1 of the *Progymnasmata*, speaking of the Landgrave's observations, page 604, he adds: "In the very times of the azimuths and altitudes taken (for this path of investigation was then proceeding too slipperily), a small discrepancy was able to vary the star's place perceptibly." The scrupulousness, then, that Tycho requires in others, it should be judged not unfair, but fair and equitable, to require equally of him.

IX. *Third*, we postulate that the authority Tycho deservedly gained from those observations which he carried out with larger instruments, and when he had himself become more learned, should bring no prejudice to this case, and should not be transferred to those observations of comets which he attempted with less suitable instruments, when he was younger and had not yet gained expertise in refraction and other matters. For the times must be distinguished here. In the years 1572 and 1577, when he observed the New Star and then the first comet, and wrote about it, he had only the astronomical radius, the first sextant (which served a single observer), and an azimuthal quadrant not quite two cubits in size, as he himself relates in volume 2, pages 1 and 31. And we saw just now, at the end of number 8, that azimuthal observations, especially

those made with so small an instrument, were later less approved by him. That the radius as well, and indeed that earlier sextant, were deceptive, he himself teaches in volume 1, pages 247, 335 and 343. Moreover, neither in 1572, nor in 1577, nor perhaps before the year 1582 or 1584, had he caught the scent of the power of refraction to raise the stars; for of those earlier years he himself speaks thus in volume 1 of the *Progymnasmata*, page 91: "Long before greater [Margin: Tycho's observations from different periods are not all equally accurate.]

and more exact instruments were at hand, I had a less well-ascertained understanding of refractions." And in volume 2, page 31, speaking of the year 1577: "For at that time I had not yet explored the impediments caused by this refraction." He repeats this in the addition on page 74. He came to suspect it, however, when he saw at the winter solstice that the Sun stood four minutes and more higher than the altitude of the pole of Uraniborg required — an altitude taken later, with larger quadrants, from the altitudes of a circumpolar star. Having had one larger instrument after another made, and always meeting with the same discrepancy, he at last began to suspect that it arose from refraction, as is found in volume 1 of the *Progymnasmata*, pages 15 and 91. This happened around the year 1584 — the year from which, according to volume 1, page 13, we have the first more exact observations of the equinoxes and solstices made by him — or at the most in the year 1582, in which, as he himself testifies in the same place, page 152, and in volume 2, page 32, he began to observe the fixed stars more accurately, and with larger instruments than before, by way of the distance of Venus between them and the Sun. Granted, not even these are entirely exact, because a parallax of Venus and the Sun larger than is right was used, as Kepler notes on page 15 of his *Ephemerides*. [Margin: Tycho: for how long was he ignorant of refractions?]

From this difference of periods and of instruments, and from his ignorance of refractions at first and his knowledge of them afterwards, it came about that in volume 1 of the *Progymnasmata*, part 1 — which is contained in chapters 1 and 2 and treats of the Sun, the Moon and the fixed stars from more exact observations — Tycho used a polar altitude for Uraniborg of 55° 54′ 40″ or 45″, an altitude of the equator of 34° 5′ 20″, and an obliquity of the ecliptic of 23° 31′ 30″, as is plain from volume 1, pages 17, 28, 86 and 218 taken together. But in volume 1, part 2, and in volume 2 he consistently used an altitude of the equator of 34° 7′ and an obliquity of the ecliptic of 23° 27′, as can be seen from volume 2, pages 31, 37, 38, 66, 109, 123, 148 and 152 taken together.

For he began to write volume 2, on comets, immediately after the appearance of the first comet in 1577, and he did begin to commit it to print, but did not publish it. For one thing, for twenty years and more thereafter he was wholly taken up with observations of the fixed stars and planets, the province of comets being set aside in the meantime — a task he intended either to entrust to Longomontanus or to complete himself later, as is related partly in the preface prefixed to volume 2 by his heirs, and partly at the end of the *Mechanica Astronomica*, page 44. And he dealt with this matter only occasionally and in

passing, either on the occasion of other comets or by a digression made to sheets already printed.

So in the year 1586 he noticed that the places of the fixed stars he had used in determining the place of the comet of 1577 differed by two, three or even six minutes from the places found with more accurate instruments; that refraction had been omitted; and that the altitude of the pole he had used was about three minutes smaller than was right, and the obliquity of the ecliptic by four. Yet since all the chapters of volume 2 had by then been printed — indeed the first 9 chapters had gone to press in the year 1578 — he was unwilling to correct them or to undergo the tedium of repeating so many calculations. Instead he was content for the present to warn the reader of this disagreement, by resetting folio 31 of volume 2 and the two following, and to indicate more correct longitudes of the fixed stars. Yet he applied no correction to the comet's distances themselves, none to the altitude of the pole, none to the obliquity of the ecliptic, nor did he take the benefit of using refraction, although he now recognized it — evidently from an assurance he had formed that no perceptible error could overflow from these into the parallaxes of this comet. And he scorned that scrupulousness which, as we showed in number 8, he required of others. You will learn of this assurance of Tycho's, reader, and of his acknowledgment of the rather crude observations of this comet, if you read through volume 2 from page 31 to page 34, and page 74. [Margin: Tycho acknowledges errors and does not correct them; and why?]

Whether, however, from all these small minutes running together into one, so great an error arises in Tycho's calculations as to make this comet sublunar, or uncertain of its seat, I would not yet affirm. The one thing I argue here is this: the claims of those (Froidmont, Resta and Cabeo, for instance) do not hold who apply Tycho's authority and his diligence in observing equally to all periods, or to the time of this comet; nor the claims of those who say that, because he was at some time acquainted with refractions, it is ridiculous or unworthy of him to have left refraction untouched in observing this comet. Granted, I would not compare Chiaramonti's observations with almost any of Tycho's, even those begun from the year 1572; for he himself says in the *Antitycho*, Book 3, chapter 20: "There remains the bearded comet [Pogonaris] of the year 1618, on which I published a little book poorly furnished with observations, but well enough supported by theorems and problems." And I have learned from elsewhere that he used to use few and small instruments.

X. For indeed Chiaramonti's praise is to be sought not from his observations but in geometry, and in calculations derived from trigonometry, in which he is almost always more exact than Tycho is in many calculations of volume 2. I said "almost always", for he himself, in the *Apology* for the *Antitycho*, Book 2, chapter 9, candidly admits that he erred in a calculation in Book 3 of the *Antitycho*, chapter 18, by using the comet's apparent distance as observed by the Landgrave in place of its apparent distance as observed by Tycho. And he greatly marvels at the sluggishness of Kepler, who, though his fiercest enemy,

did not throw this error at him, because he did not recognize it — Kepler, who would doubtless have trumpeted a triumph over the remaining calculations once this one error was detected, as though it were right to suspect crimes, or rather slips, in all the calculations from a crime in one. [Margin: Chiaramonti's praise comes not from his observations but from geometry, in which he was more skilled than Tycho once was.]

Grant that Chiaramonti erred once or twice; Tycho was no more fortunate in this, for he fell into a pseudographic and most fallacious semblance of a demonstration, one that conflicts with his own positions, as we shall show in Book 10, in the section on parallaxes, chapter 12, number 5. So much so that Kepler, in the *Hyperaspistes*, Book 2, chapter 13, after many evasions, conceded that Tycho's demonstration was pseudographic and erroneous, and said: "But by what Tycho was deceived, so as not to see that he was at this point acting wrongly, or to what errors he had wholly bound himself, from which he in turn is immune — on this, I think, something will become apparent. I will say nothing of the time at which this demonstration was conceived or worked out, nor of how we do not always progress with age, but sometimes even go backwards and forget these subtleties — as often happens to me too — distracted either by a multitude of studies or by domestic business, as Tycho indeed was." And in chapter 20 he says of the same thing: "I have conceded that that figure is pseudographic." [Margin: Tycho's pseudographic figure conceded by Kepler.]

But what displeases more in Tycho is that he invented, on doubtful faith, certain observations as made by himself. For in volume 2, in the history of the observations of the comet of 1577, November, page 3, after saying: "On the 15th, about 6^h, the comet was distant from the bright star of the Vulture 20° 25′, from the lower one in the horn of ♍ 16° 14′," he gives no observation for the following four days, and states the reason, saying: "On the following four days the air with us was filled with dense obscurities, which shut off the view of the comet, the 18th being not only dark but also very foggy, and the 19th raging fiercely with storms of wind and rain; so the observation of the comet was deferred until the 20th." After this he adds the observations of the 20th, 21st and 23rd, and once these are finished he immediately subjoins: "On the following day, the 24th, no clear sky shone on our horizon." [Margin: Tycho's good faith doubtful in places.]

Further on, however, wishing to compare some observation of his own with an observation of Tadeáš Hájek, so as to confirm his opinion on the place of comets from observations made in different places on the Earth, he forgets or conceals what he had related in the history already mentioned, and invents the same comet as observed by himself on the 16th and the 24th — that is, on the same days and at almost the same hour at which Hájek observed it at Prague. And on page 124 he says boldly: "Therefore we shall take the first observation of Tadeáš Hájek, made at Prague in Bohemia on November 16, from the bright star of the Vulture, where he measured the distance from the said fixed star with the radius as 17° 52′. We, however, here, with a similar instrument on the same

day, around six in the evening, found it 17° 50½′." Then on page 127: "Taking in the same way another distance, made by the same Tadeáš Hájek to the same fixed star on November 24, and comparing it with ours taken on the same day, we shall confirm the same thing. For on that day Hájek observed the comet's distance from the Vulture as 11° 43′, which we here found to be 11° 45′."

Is that so, Tycho? But how did you observe the comet on November 16 and 24, if from the 15th to the 20th its observation was deferred because of dense obscurities, fogs, storms and rains, and on the 24th no clear sky shone on your horizon? Or was it because, from the preceding and following observations and from an opinion already formed about the comet's motion, you had no doubt that its distance from the Vulture on those days would have been such, that you were therefore permitted to invent, in chapter 6, as observed, what in chapter 1 you had related in such plain words as not observed?

Rightly, then, are you compelled to bear the contradiction and inconsistency charged against you by Chiaramonti in Book 2 of the *Antitycho*, chapter 13, page 184. Nor could your *Hyperaspistes*, Kepler, in Book 2, chapter 13, cover your blushes with any other shield than by himself inventing observations made by Tycho on the sly on those days. For this is the reason he devises why Tycho did not enter the observations of the 16th and 24th in the catalogue: "For straight away in the catalogue of chapters, with its first word, he promises only the more certain observations, and on folio 1 only those which he obtained with the radius and the sextant together. So he scorned those stolen glimpses of the comet as less certain, content with the most certain ones of the days around them." [Margin: Kepler protects Tycho's fiction with a new fiction.]

And yet it is false that in that first chapter Tycho reports only the most certain or the more certain observations, as will be plain to any reader who looks through it. For he omits only the altitudes and azimuths, deferring mention of them to another place; but the distances of the comet taken from the fixed stars he promises to record, all of them, as many as appeared, since he says clearly: "But what I noticed in these very observations of the comet, on the days on which it appeared to us, I shall now record in order — at least as far as concerns the distances from certain fixed stars, which I diligently obtained with both the radius and the astronomical sextant. The altitudes and azimuths, which were found with the quadrant at certain times, I shall review in those places where their use requires; and I shall make no mention of any of them here, because they were much fewer than the observed distances." This is the sum of Tycho's promise. Let us now see what he actually delivered.

Thus in the history of the 13th he says: "Then, when the middle parts of the asterism of Orion were rising, the comet seemed to be heading for its setting — though clouds intervened and prevented exact certainty in this matter." And after relating the interruption of the observations from the 15th up to the 20th exclusive, he resumes the history and says: "On the 20th, although it was not altogether clear, it was nevertheless possible to observe diligently enough"; and after giving some observations of that night, he concludes: "This consideration,

however, was not exquisite enough, on account of clouds intervening from time to time." Of the 21st he adds: "That evening the head of the comet was also seen at an equal distance from the first star in the wing of Pegasus and from the tail of Cygnus, distant from each by more or less 46°, and this by the radius, at the seventh hour; but this observation has less exact certainty." Of the observations of the 23rd, on the other hand, he says: "And all these observations were exact, because the sky was perfectly clear on all sides for this whole time." By contrast, of the observations of the 25th he has this: "At $6\frac{1}{2}^{h}$ it was distant from Scheat of Pegasus by approximately 42°, which, however, could not be concluded exquisitely enough, because of intervening clouds"; and of the 28th: "But these observations were not exquisite enough, owing to a clear sky that did not last, and thin clouds, etc." Of the observations made in December, on the 2nd, he likewise testifies thus: "But in all these there is no exquisite certainty, owing to clouds intervening from time to time; for this reason too I made no observation worth recording with the instruments this evening." And of the 9th: "It was not yet possible to take any distances exquisitely, because of rather thin clouds; I noticed, however, etc." And on the 18th: "On the 18th, although because of intervening clouds nothing certain could be observed as far as the distances are concerned, I noticed the tail, however, etc." And of the 24th: "By the radius, however, it was seen to be about 16° from Scheat of Pegasus, and this only roughly, because of the faintness of the comet."

I have not minded gathering these testimonies of Tycho himself into one place, so that it might be plainly established that Tycho entered in the catalogue not only certain but doubtful observations, and not only those obtained with the radius and sextant together, but also those obtained somehow with the radius alone, and indeed by mere estimation by eye. It follows that Kepler — with a new lie, if he noticed this, or with a careless fiction rather than a contrivance — tried in vain to defend Tycho's lie or fiction; and that while we were chasing a single little fox, two were caught in almost the same snare. But see how quickly Tycho incurred the penalty for violating astronomical good faith (for there is no greater punishment for a sin than the sin that follows it). For between those very pages 124 and 127, on which he invented the comet as observed by himself on November 16 and 24, he fell into that pseudographic figure we mentioned above, whose diagram you will see in Book 10, in the section on parallaxes, chapter 12, number 3, and its fallacy shown in the same place, number 5. In it he supposes two parallel straight lines falling perpendicularly on the convexity of the Earth, and invents angles such that, if they were true, the distance of the bright star of the Vulture from the zenith of Uraniborg would be many degrees smaller than its declination, as asserted by Tycho himself, requires. For this he was rightly thrashed by Galileo on page 22 of the *Trutinator*, and by Chiaramonti in the *Antitycho*, Book 2, chapters 12 and 13. Thus, from a disturbance either of conscience or of memory and imagination, he slid at once from pseudology into pseudography. [Margin: Tycho, from one falsehood, at once slid into another.]

XI. Let what has been said so far serve to prepare the reader's mind, free of all prejudice, for the naked truth, all authority, whether of the Peripatetic school or of the Tychonic sect, being set aside for the present. I should not at all wish anyone to suspect that I meant to detract from Tycho's authority and to vote for Chiaramonti's name because I wished to favour the one rather than the other, or that I was led to it by some greater affection toward Don Scipione Chiaramonti — as being an Italian and a Catholic, afterwards a priest of wonderful integrity, a very great friend of our Society, and finally the uncle of Father Girolamo Chiaramonti of the same Society, who was once most closely joined to me in literary fellowship and in the study of mathematics. All these reasons, which are not otherwise to be disapproved when other things are equal, I passed by as though with a deaf ear of the heart; and having entered this controversy out of the simple love of truth, I have weighed the arguments of both sides to the end in an even balance.

I confess, however, that out of zeal for my Institute and for the religious life I profess, I have more than once grieved deeply that Tycho, in volume 1, page 712, poured himself out so lavishly in praise of Philipp Melanchthon and David Chytraeus, men of most corrupt faith and most bitter enemies of the Catholic Church. But I grieve still more deeply that the same man, in the same volume 1 of the *Progymnasmata*, pages 776 and 777, follows Luther with such devotion as to brand Theodorus Graminaeus [?] with the mark of iniquity and malice because he thought ill of Luther's heresy. And lest he seem to want to pronounce on religion, Tycho says that he appeals to the judgment of God, and that God alone can judge and decide infallibly on these things — a saying by which, under the appearance of piety, he shows clearly enough how little piously, and how much less catholicly, he thinks of the authority of the Roman Pontiff in settling controversies of religion. [Margin: Tycho suspected of heresy.]

XII. *Fourth* and lastly, I wish the readers to be asked not to require of me in this place all the theorems and problems of parallaxes, but to consult my Book 10, in its penultimate section, which is entirely on parallaxes; for I hope they will be abundantly satisfied there. Since that doctrine is common not only to comets but also to new stars, and indeed to all phenomena old and new, I had to reserve it for that book which treats of, and is entitled, the Common Problems. Besides, that treatise would have been tiresome to some, out of place here, and would have interrupted the course of this dissertation too much. To that section, therefore, I shall myself refer where there is need, and I shall send the readers there — not unwillingly, I believe. Some things from it, however, that are most necessary for parallactic subtlety and for this controversy, I shall select and give a foretaste of in the following chapter, gathering into a summary, as it were, what is set out more fully there. [Margin: Postulate 4.]

CAPVT XVII.

Chapter XVII.

In quo Definitiones, & Axiomata ad Parallaxes earumque proprietates magis neceſſaria.

In which: the definitions and axioms more necessary for parallaxes and their properties.

I. In my Book 10, in its penultimate section, I treat parallaxes at length, and give selected and necessary — or more useful — diagrams suited to illustrating the parallactic theorems and problems; to these I shall refer the reader from time to time. But I cannot pass over the first diagram here, in which, from the Earth's cen- tre A, let there be described a semicircle ZBY of the terrestrial hemisphere, beneath a semicircle HVR of the supreme heaven of visible things described from the same centre A. Let this semicircle be part of a circle of altitude, or vertical circle. (Among the vertical circles — that is, the great circles of the sphere drawn through the zenith or vertex of the inhabitant — any meridian is also counted; and in the right sphere the equator, and in the Torrid Zone the ecliptic, coincides for some people with a vertical circle.) Let the semicircles already mentioned be bounded by the straight line HAR drawn through the centre A, which is called the true, or astronomical, or rational horizon.

[Margin: Delineation of the primary diagram for parallaxes.]

Diagram. A semicircle on the diameter H–A–R, set in the left column, with three smaller concentric arcs about the centre A. The vertical A–B–V rises from the centre to the apex; a horizontal O–B–N crosses it at B; straight lines radiate from A and from B to the outer arc. A small semicircle about A bears Z and Y.

- V (apex of the outer semicircle): the vertex or zenith
- ε, P (on the vertical, below V): the Sun and the Moon at the zenith
- D, E, F (outer arc, upper right): ends of the lines ACD, BGE, BCF
- G (inner arc, right of the vertical): the Sun on the line ACD
- C (inner arc, right of the vertical): the Moon on the line ACD
- Q, T, X (outer arc, upper left): ends of the lines ADQ, AIT, BDX
- I (inner arc, left): the Sun on the line BDX
- D (second D, inner arc, left): the Moon on the line BDX
- B (on the vertical): the observer's eye on the Earth's surface
- K, M, N (outer arc, right, above the diameter): ends of the lines ALK, ASM and the horizontal OBN
- L, S (inner arcs, right): the Moon and the Sun on the physical horizon
- O (left end of the horizontal through B)
- H, R (ends of the diameter)
- Z, Y (small terrestrial semicircle about A)
- A (centre, foot of the vertical)

Upon this line, from A, let the perpendicular ABV be erected. It will be the vertical line with respect to an eye placed at B, a point on the Earth's surface,

and V will be its vertex or zenith, which Regiomontanus, with the more ancient writers, calls "the summit of the heads" [ſummitatem capitum]. The straight line OBN drawn through B parallel to HAR, or orthogonal to AV, is called the apparent, or physical, or sensible horizon with respect to the eye B. Now from the centre A, beneath the vertical HVR, let there be described a semicircle SGεI etc. for the higher phenomenon and LCPD etc. for the lower; for clarity let the former be the Sun and the latter the Moon. First, let both appear together on the physical horizon, the Sun at S and the Moon at L, and through the centres of each let the straight lines ASM and ALK be drawn from the centre of the Earth up to the supreme sphere. Next, let both appear above the physical horizon, but lie on the same line drawn from the centre of the Earth through their centres up to the supreme heaven — such as the line ACD — so that the Sun is at G and the Moon at C; and through their centres let different lines, BGE and BCF, pass from the eye B as far as the fixed stars. Finally, let both appear above the physical horizon, but on the same line BDX, from the eye B through their centres to the supreme heaven — namely the Sun at I and the Moon at D; and through their centres let different lines pass from the centre of the Earth to the supreme heaven, AIT through the Sun and ADQ through the Moon. With this laid out, you will understand the following Definitions and Propositions very easily; in them, what I say of a heavenly body holds for any lofty phenomenon.

DEFINITIONES.

Definitions.

II. The true place of a heavenly body, taken absolutely, is the point in which the centre of its body actually is; but relative to the supreme heaven of visible things, beneath which it is considered, it is the point of the supreme heaven at which the straight line drawn from the centre of the Earth or universe through the centre of the body terminates. And so the *line of the true place* is the straight line drawn out from the centre of the Earth or universe, through the centre of the body, up to the supreme heaven. Thus if the Moon is at L, its true place is absolutely the point L, but relatively the point K, and the line of the true place is ALK. Hence the *true distance from the vertex* is the arc of the supreme heaven intercepted between the vertex and the true place, and the *true altitude* is the arc intercepted between the true horizon and the true place.

[Margin: True place, and line of the true place.]

[Margin: True distance from the vertex, and true altitude.]

The *seen* or apparent place [Viſus locus ſeu apparens] is the point of the supreme heaven beneath which the centre of the body is seen to be, or at which the straight line drawn out from the eye through the centre of the body terminates; and so the *line of the apparent place* is the straight line drawn from the eye through the centre of the body to the supreme heaven. If, for example, the Moon is at L, beneath K, but, seen from B along the line BLN, appears

beneath the point N, its apparent place will be the point N, and the line of the apparent place will be BLN. If, however, it is at C, beneath D, but appears beneath F, the Moon's apparent place will be the point F, and the line of the apparent place BCF. Hence the *apparent distance from the vertex*, or the *altitude from the horizon*, is the arc of the supreme heaven between the apparent place of the body and the vertex, or the sensible horizon.

[Margin: Apparent place, and line of the apparent place.]

[Margin: Apparent distance from the vertex, and apparent altitude.]

The reason why the one is called apparent and the other true is that the true place of a single, unreplicated body is single, from whatever place on Earth it is viewed, and common to all who view it at the same moment; and it cannot be such unless it is considered from the common centre of the Earth or universe. The apparent place, by contrast, is as varied and manifold as the position of the eye from which the body is seen. The reason why the lines of the true and apparent place are drawn out all the way to the supreme heaven — when otherwise, for any body taken separately, any heaven above it would suffice — is that this heaven is the universal place of all visible things, and suited to setting out the parallaxes not only of all the planets but even of the fixed stars themselves, however slight those parallaxes may be.

[Margin: Why is the one called the true place, the other the apparent?]

[Margin: Why is the supreme heaven used for both places?]

Identity of aspect [Identitas aſpectûs] is when the true and the apparent place are the same, and the lines of the true and apparent place consequently coincide in one line. This happens either because the eye (if this were possible) is transferred to, or is at, the centre of the Earth or universe; or because (as actually happens) it is indeed on the Earth's surface, but the body is beneath the vertical point. So if the Moon is at P and the Sun at ε, they will be, and will appear, together beneath the zenith V, and the line AV of the true place will coincide with the line BPεV of the apparent place, granted that one is shorter than the other.

[Margin: Identity of aspect.]

Variation of view [Diuerſitas aſpectûs] is the difference between the true and the apparent place of a body. This aberration, or hallucination, or deviation of the apparent place from the true, the Greeks name *parallaxis* [Greek: παράλλαξιν (parallaxin, "parallax")], from the verb [Greek: παραλλάσσω (parallassō, "to deviate")], which means to deviate, or to go off in different directions. This difference, taken formally, is the arc of the supreme heaven intercepted between the true and apparent place of the body. Thus, with the Moon at L, the true place is K but the apparent N, and its parallax is the arc KN; with respect to the Sun, placed at S, the parallax is the arc MN. But if the Moon is at C and the Sun at G, the Moon's parallax is the arc DF and the Sun's DE; and if, finally, the Moon (on the left side of the diagram) is at D and the Sun at I, the Moon's parallax is the arc QX and the Sun's TX.

[Margin: What variation of view, or parallax, is.]

[Margin: Parallax taken formally.]

Taken mensuratively, however, or equivalently, parallax is the angle formed at the centre of the body by the lines of the true place on the one side and of the apparent place on the other: if the Moon is at L, the angle ALB; if the Sun is at S, the angle ASB; if the Moon is at C, the angle ACB; and so for the rest. This is not because the angle vertical to it — say the angle KLN — is the measure of the parallactic arc KN; for an arc of this kind is not described from the angle's point L as centre, since it is described from A. It is because, by Euclid I.32, ALB is the interior angle by which the other interior angle BAL — that is, VAK, which measures the arc VK of the true distance from the vertex — is exceeded by, and differs from, the exterior angle VBN, which measures at B, the centre of the instrument (the natural one, the eye, or an artificial one), the apparent distance VN of the body from the vertex. Accordingly it shows indirectly how great the parallactic arc KN is, by which the true distance from the vertex VK differs from the apparent distance VN.

[Margin: Parallax taken equivalently in two ways.]

I know, indeed, that Regiomontanus and some others draw from the centre of the Earth a line parallel to the line of the apparent place — so that, with the Moon at C, a line AK is drawn parallel to the line BCF — in order to measure the parallactic arc from the centre of the universe, from which the supreme heaven is described, and not from a foreign centre. For in this way the angle VAK will be as great as VBF, by Euclid I.29, and the angle DAK is that by which VAK exceeds the angle VAD of the true distance. But these do not take the parallactic arc formally either: the arc DK, enclosed between those two parallels, is not the actual difference between the true place D and the apparent place F, since we suppose the Moon at C to be seen beneath F, not beneath K; it is that difference only equivalently. As to the measuring angle, however, it comes to the same thing: because the lines BCF and AK are parallel, the angle BCA is equal to the alternate angle DAK, by Euclid I.29, and each is the measure of the parallax. That parallel line is therefore superfluous; indeed, it seems contrary to the nature of parallax — which arises from the difference of the centres, of the world and of the eye — to try to measure it from the same centre from which the true place is measured.

Parallax of altitude [Parallaxis Altitudinis] is the difference between the apparent and the true altitude; or it is the arc of the circle of altitude intercepted between the true and the apparent place of the body. In substance and in magnitude it is the same as the parallax of distance from the vertex, which some call the vertical parallax: for that is the difference between the true and the apparent distance from the vertex, or the arc of the vertical circle intercepted between the true and the apparent place. The vertical circle and the circle of altitude are the same, and do not differ except in name, or formally by relation to different terms: the vertical circle is referred to the vertex, whereas the circle, or the parallax, of altitude is referred to the horizon and reckoned from it. So if the Sun is at G, the same arc DE is the parallax of altitude with respect to

the horizon, since it is the amount by which the true altitude RD differs from the apparent altitude NE; and it is the vertical parallax, since it is the amount by which the true distance VD from the vertex V differs from the apparent distance VE. The latter, however, is simpler than the former, because the term V from which they are reckoned is the same, whereas the horizons from which the true and apparent altitudes are counted are different.

[Margin: Parallax of altitude, and of distance from the vertex, or vertical parallax: what they are, and whether they are the same.]

[Margin: Vertical parallax is simpler than parallax of altitude.]

Horizontal parallax [Parallaxis Horizontalis] is the parallax of a body appearing on the physical horizon — that is, when it appears in such a way that it seems to be no distance at all from the sensible horizon, but at the greatest distance, a full quadrant of a circle, from the vertex. It therefore is, and is called, the greatest parallax of all for a body that keeps the same distance from the centre of the Earth. So if the Moon appears at L, the arc KN, or the equivalent angle ALB, is the horizontal parallax, and the greatest of all that the Moon can undergo so long as it keeps the same distance AL from the Earth's centre. If, for instance, it rises from L to C, but AC is equal to AL, ALB will be greater than ACB; and so for the rest.

[Margin: Horizontal and greatest parallax.]

SPECIES PARALLAXIVM.

Kinds of parallax.

III. Of parallaxes, one is true, and another false, or merely apparent. The true is the difference between the true and the apparent place, arising from the distance both of the centre of the eye from the centre of the Earth or universe and of the body from each of these centres; it therefore varies when either of them varies, whether the variation is due to the motion of the body or to the motion of the eye. This parallax, considered causally or radically, we may call *parallax from the interval* [?]. False or apparent parallax is the difference not between the true and the apparent place, but one that is thought to lie between the true and the apparent place of the body: either because it is the difference between two places seen by the same eye at different times, or by different eyes at the same time; or because it is the difference between two true places arising from the true motion of the body, and gives the inexperienced occasion to think that it arises from the interval. This could be called parallax from mere motion. If, however, the place seen by one of the eyes were beneath the vertex, and so the same as the true place, while the place seen by the other observer is far from the vertex, the difference between the seen places will be a true parallax.

[Margin: True parallax, or parallax from the interval.]

Of true parallaxes, one is sensible in itself, another insensible in itself. Sensible in itself is the one that can be discerned with some instruments by some observer

on the Earth's surface, even if, by accident, some observer could discern it with none of his instruments. Insensible, by contrast, is the one that can be perceived by no observer on the Earth's surface, however great the instruments and however fine the sights [dioptrarum]. As the smallest of the sensible parallaxes some set 10′ or 12″[16], others a greater or a smaller value; we set 5″ or 6″, in seconds. In that case the lines of true and apparent motion are judged to be not so much parallel as coincident to sense, and to make no angle at the centre of the body; and the distance of the body from the Earth is judged to have no sensible proportion to the Earth's semidiameter, or to the distance between the Earth and the eye; and so the body is seen just as if the eye were at the centre of the Earth — or, in other words, the globe of the Earth is judged to be like a point with respect to the heaven in which that body is.

[Margin: Parallax sensible or insensible in itself.]

Of true and in-itself sensible parallaxes there are, moreover, many kinds. The first, and the root of all the others, is the parallax of altitude, or vertical parallax, which was discussed in number 2. For as many as are the great circles of the sphere in which the body is, or to which it is referred by reason of its place or motion, so many kinds of parallax sprout from the one and same parallax of altitude; but the chief ones are those written below.

Parallax of depth [Parallaxis Profunditatis] is the difference between the true and the apparent depth. For the eye can be raised above the convexity of the land and the sea, so that a body which is truly either above the true horizon, or on the horizon, or a little below it, appears to the eye below the horizon already mentioned, or lower than it is; on this see more in Book 10, penultimate section, chapter 3. This parallax is either the difference between the true and the apparent depth, or the aggregate of the true altitude and the apparent depth of the body; and it is considered in the vertical circle continued below the horizon.

[Margin: Parallax of depth.]

Parallax of declination is the difference between the true and the apparent declination; or it is the arc by which the declination in the circle drawn through the true place differs from the declination taken in the circle drawn through the apparent place of the body; and this is its measure.

[Margin: Parallax of declination.]

Parallax of right ascension is the difference between the true and the apparent right ascension; or it is the arc of the equator, less than a quadrant, intercepted by two circles of declination, one of which is drawn through the true place and the other through the apparent place of the body. The angle made at the pole of the world by these circles is the measure of this parallax. Consider the figures of both kinds in Book 10, penultimate section, chapter 6.

[Margin: Parallax of right ascension.]

[16]the first value is printed with a single prime, the others with double primes; kept as printed

Parallax of latitude, or in latitude, is the difference between the true and the apparent latitude of the body; or it is the arc by which the circle of latitude drawn through the true place differs from the circle of latitude; and the same arc is its measure.

[Margin: Parallax of latitude.]

Parallax of longitude, or in longitude, is the difference between the true and the apparent longitude of the body; or it is the arc of the ecliptic, less than a quadrant, between two circles of latitude, one of which is drawn through the true place and the other through the apparent place of the body. The measure of this parallax is the angle made at the pole of the ecliptic by the two circles already mentioned. For diagrams of these two kinds see Book 10, penultimate section, chapter 7.

[Margin: Parallax of longitude.]

Parallax of distance — not from the vertex, but from another body — is the difference between the true and the apparent distance of two bodies, a distance measured in a great circle of the sphere. The parallax of distance is therefore the arc of a great circle by which the true distance differs from the apparent either in quantity, or at least in position; for it can differ in position alone while being equal in quantity. On these, more in Book 10, penultimate section, chapter 5.

[Margin: Parallax of distance.]

Parallax of the annual orb [Parallaxis Orbis Annui], taken inadequately, is the difference between the true place of a star, considered from the centre of the universe as distinct from the centre of the Earth, and its place seen from the Earth; it arises from the annual motion of the Earth about the Sun, according to the Samian and Copernican school, for which the centre of the universe is either the Sun or a point as far from the Sun as the Sun's eccentricity is for other authors. Taken adequately, however, it is the difference between the place of a star seen from the Earth occupying one point of the annual orb, and another place of the same star — motionless, or taken as motionless — seen from the Earth occupying the point diametrically opposite the first: as if an inhabitant of the Earth, when it stands beneath Cancer, sees the Pole Star, and the same person sees it again after the Earth has been carried beneath Capricorn. A parallax of this kind does not arise from the parallax of altitude, granted that it can be reduced to it; nor is it sensible unless the diameter of the annual orb is supposed to have a sensible ratio to the distance of the star from the centre of the Earth or universe; otherwise it is not sensible. But on this, more in Book 10, penultimate section, chapter 4.

[Margin: Parallax of the annual orb.]

Parallax of motion is the difference between the true and the apparent motion of a body; or it is the arc, or time, by which the true motion of the body differs from its apparent motion; and it is of as many sorts as there are kinds of motion of the body. See the figure and examples in Book 10, penultimate section, chapter 9.

Difference of parallaxes is the difference between two or more parallaxes of the same kind. It is neither parallax itself, nor the difference between two seen places, as some who otherwise think rightly speak wrongly — except in the case of the parallax of the annual orb, or in the case in which the place seen by one observer is also the true place. See more on this in Book 10, penultimate section, chapter 9.

AXIOMATA PARALLAXIVM.

Axioms of parallaxes.

IV. *A body beneath the vertex, or seen from the centre of the Earth, has no parallax*; its apparent and true place are the same — at least outside the case of the parallax of the annual orb.

[Margin: Axiom 1.]

A body appearing on the sensible horizon has the greatest parallax of all: by the definition of horizontal parallax. Understand this other things being equal, and with the same distance of the body and of the eye from the centre of the Earth preserved.

[Margin: Axiom 2.]

For the same body at the same distance from the centre of the Earth, the greater the distance from the vertex, the greater the parallax; and the smaller that distance, the smaller the parallax too: as in the figure of number 1,

[Margin: Axiom 3.]

the parallax KN of the Moon at L is greater than the parallax DF of the Moon at C.

Of any two bodies having an equal apparent, or an equal true, distance from the vertex, the parallax of the one that is less distant from the centre of the Earth is greater, and that of the one more distant is smaller. As in the figure of number 1: the parallax DF of the Moon at C is greater than the parallax DE of the Sun at G; and, on the left, the parallax QX of the Moon at D is greater than the parallax TX of the Sun at D.

[Margin: Axiom 4.]

As great as the horizontal parallax doubled, so great is the portion of the semicircle of that hemisphere, in whose heaven the body moves, that lies hidden beneath the physical horizon. If, for example, the Sun's horizontal parallax were 3′, then of the semicircle of the solar heaven standing above the true horizon, three minutes on this side and three on that would lie hidden beneath the apparent horizon — 6 minutes in all; and the apparent semicircle is only 179° 54′.

[Margin: Axiom 5.]

As great as the horizontal parallax of a body, so great is the apparent semidiameter of the Earth seen from the centre of that body. For the angle that measures the one and the other is the same, or equal to it.

[Margin: Axiom 6.]

As great as the greatest parallax of the annual orb, taken inadequately, with respect to some star, so great is the apparent semidiameter of the Earth's annual orb seen from that star. For in this hypothesis it stands exactly as the Earth's semidiameter stands to the horizontal parallax.

[Margin: Axiom 7.]

The parallax of altitude and of depth always, in itself, depresses the body apparently; and so it diminishes the true altitude from the horizon but increases the distance from the vertex — not truly, but apparently. Hence, if a true altitude is to be converted into an apparent one, the parallax belonging to the given true altitude must be subtracted from the true altitude; if an apparent altitude is to be converted into a true one, the parallax belonging to the given apparent altitude must be added to the apparent altitude. The contrary must be done in each case if a distance from the vertex is to be converted, true into apparent or apparent into true.

[Margin: Axiom 8.]

The true and the apparent altitude of a body undergoing parallax cannot be the same at the same moment of time: otherwise, if they were the same, there would be no difference between them, and consequently no parallax. Hence it follows that there cannot be the same, or an equal, parallax fitting two equal altitudes, one apparent and the other true. Those who use the same table for both therefore err. But see what I shall say in Book 10, penultimate section, chapter 2, number 18.

[Margin: Axiom 9.]

Refraction raises the body apparently. It is therefore opposed to parallax, and the refraction can be so great as only to diminish the parallax; or so great as to equal it, and so cancel it; or so great as to exceed it. If it equals it, the true and the apparent place of the body are the same. Hence, likewise, for converting a true altitude into an apparent one, or the latter into the former, rules opposite to those indicated in Axiom 8 must be observed as regards the correction for refraction.

[Margin: Axiom 10.]

A body has no parallax, or refraction, in azimuth: for each produces its effect in the same circle of altitude, and azimuth is considered by the arc of the horizon between the vertical in which the body is and the meridian — not in the arc of some determinate circle parallel to the horizon, drawn through the body's true or apparent place.

[Margin: Axiom 11.]

A body appearing, or truly standing, in the meridian has no parallax of right ascension: for the meridian is then a circle both of altitude and of declination. A body therefore cannot appear in the meridian and be outside the meridian, or be in the meridian and appear outside it.

[Margin: Axiom 12.]

A body standing, or appearing, in the ninetieth degree of the ecliptic has no parallax of longitude: for in that case the circle of latitude is the same as the circle of

altitude, and determines the place in the ecliptic through which it is drawn; the true and the apparent ecliptic place are therefore the same. The ninetieth degree of the ecliptic is the one that stands ninety degrees from the horizon on either side.

[Margin: Axiom 13.]

A body standing, or appearing, in the ninetieth degree of the equator has no parallax of right ascension; for it cannot be in the ninetieth degree of the equator reckoned from the horizon without being in the meridian. Axiom 12 therefore holds here.

[Margin: Axiom 14.]

The parallaxes of right ascension and of longitude in themselves increase, in the eastern quadrant of the equator or of the ecliptic, and in the western, in themselves or for the most part, diminish — the former the right ascension, the latter the longitude of the body: for there parallax depresses the body apparently in the order of the signs, here against the order of the signs. Rarely, however, or by accident, it can happen that in the eastern quadrant they place the body visibly at the beginning of Aries, or beyond, and so either cancel the whole longitude reckonable from the beginning of Aries, or show a smaller one from a new beginning of reckoning: as if a body is truly at the end of Pisces and appears in the first degree of Aries. And conversely, in the western quadrant parallax can by accident increase it: as if a body is at the beginning of Aries but is depressed so that it appears at the end of Pisces.

[Margin: Axiom 15.]

The parallaxes of declination and of latitude — the former the declination, the latter the latitude — apparently either increase it, or diminish it, or generate the whole of it, or cancel the whole of it, or change it from one region, or kind, into the other.

[Margin: Axiom 16.]

For this, see the figures and expositions in Book 10, penultimate section, chapter 6, number 2, and chapter 7, number 2. There are, indeed, many theorems of parallaxes that bear on this subject, and ones unknown to the more ancient astronomers; but so as not to be too long, I ask the reader at least to run through those I shall give in Book 10, penultimate section, chapter 9.

CAPVT XVIII.

Chapter XVIII.

An Cometa Anni 1577. Demonſtratus ſit ſupra Lunam an infra : ſeu Vtrùm oſtenſus ſit minorem, an maiorem habere Parallaxin Lunari?

Whether the comet of the year 1577 was demonstrated to be above the Moon or below it; that is, whether it was shown to have a smaller or a greater parallax than the Moon's?

I. Tycho Brahe, in volume 2, chapter 7, affirms that the comet of the year 1577 was in the ethereal region of the world and not in the elementary region — that is, that it was higher than the Moon — and that he demonstrated this

by five arguments. Although we have already adduced some of these, as general arguments, in chapter 11, they must nevertheless be repeated briefly here, because they bear indirectly on the comet's parallax: for if they establish that it was above the Moon, it follows also that it had a smaller parallax than the Moon. We shall reduce his arguments to syllogistic form, but with the conditions added which Tycho has scattered about.

PRIMUM ARGUMENTUM TYCHONIS À MOTU PER CIRCULUM MAXIMUM.

Tycho's first argument, from motion along a great circle.

II. The first argument is of this kind: *The comet of the year 1577, by its motion, marked out with the utmost exactness, to sense, a portion of a great circle in the sphere, no less than the Sun, the Moon and the other wandering stars. But if it had been a fiery meteor blazing in the elementary region, as the Peripatetics hold, it could not by its motion have marked out with the utmost exactness, to sense, a portion of a great circle in the sphere. Therefore it was necessarily in the highest aether, and completed its course there.* The major premise is proved because, from the comet's longitude and latitude, observed by distances from the fixed stars, it is established that from the beginning to the end of its motion it always kept the same angle of inclination to the ecliptic. The minor is shown from this: if it had been a fiery meteor, it would have been carried with a wandering motion wherever the matter it needed for fuel had drawn it, or wherever the force of the winds had violently driven it. And even if it were said to be swept along by the force of some wandering star, still, since the planets themselves do not by their sensible motion describe an exactly great circle, much less could they have imparted one to a comet compacted of such fluid matter. And the non-wandering stars, since they have no sensible proper motion within a few days, could much less have communicated such a motion to a body so foreign to them.

III. I reply, first, by granting for the moment the major and minor premises and denying the consequence, for many reasons. For first, it is established from Tycho himself that this conclu-

[Margin: First reply, denying the consequence.]

sion is not necessary, or demonstrative. For although on pages 91 and 105 he uses the word *demonstrandi* ("of demonstrating"), yet on pages 92 and 93, speaking of this very argument, he says: *It is proved with sufficient probability*; and a little later: *It remains, therefore, that we conclude reasonably.* And Kepler himself, in the *Hyperaspistes*, admits that this argument does not exceed the limits of probability and likelihood. For he says on page 5: *But it is likely, if indeed these endowments are taken to have been given to the comet's body itself, that this body is in a place higher, etc., than this elementary region of ours. The authority, etc., increases the likelihood of the opinion.* And on page 18, again speaking of this argument: *I reply that the probability of Tycho's argument rests on its own degrees: so that it holds for the Moon nonetheless, even though not even this celestial planet, as Tycho has expressly admitted, appears to proceed exactly under the same great circle — as much because of its rather large parallax as for other reasons. The closer,*

therefore, the comet keeps to the path of a great circle, the greater is the probability of its celestial nature; and if only a twentieth part of the Moon's deviation is found to exceed the bounds of the great circle, it is believed twenty times more probably to be in the heavens than the Moon itself — by this argument, at least. And finally on page 19: *Let the assertion stand unshaken, that the comet proceeded under a great circle, and on that account appears to have been above the Moon*; where the word *videri* ("to appear") sounds of mere probability. Tycho, however, wrongly confuses probability with demonstration, or opinion with knowledge; we, for our part, are meanwhile disputing about demonstration and the necessary condition. What is to be said about probability we shall settle elsewhere, below.

[Margin: For the consequence is only probable, not necessary, by the admission of Tycho and Kepler.]

Secondly, because the syllogism has four terms, and more is inferred in the conclusion than is contained in the premises. For it infers not only that the comet was not a fiery meteor blazing in the elementary region — which alone ought to have been inferred by force of the syllogistic form — but also that it was in the highest aether. Yet there are not a few who think that comets shine by the Sun rather than blaze and feed on elementary matter as fuel, and who nevertheless place them below the ☾.

[Margin: 2. Reason for denying the consequence: because Tycho's syllogism is faulty and formless.]

Thirdly, because to conclude that this comet was in the aether, the comet's true motion — that is, the motion distinguished from the seen motion — would have had to be along a great circle. For the planets are not recognized as celestial from the fact that by their seen motion they describe the same circle, great to sense, since all those that have a sensible parallax, or a change of latitude, or both — the Moon especially — are carried by their seen or apparent motion along the same great circle; but because by their true, or rather mean, motion they are carried along the same orbit of a great circle. Therefore Tycho ought to have deduced from the seen motion along a great circle the true motion along a great circle, as Chiaramonti rightly observes in the *Antitycho*, Book 1, chapter 11, in the corollary to proposition 2, and in Book 2, page 119. But from seen motion along a great circle, true motion along a great circle is not necessarily inferred unless the moving body lacks sensible parallax. For if it has a sensible parallax, then if one of these motions is along a great circle, the other is not, from what will be said in Book 10, penultimate section, chapter 9 — and Chiaramonti and Cabeo, adduced there, agree. Therefore, before it is known whether there is any parallax at all, and whether it is sensible or insensible, the kind of circle of the one motion cannot be known from the circle of the other motion, as we shall say there with Chiaramonti, in the *Apologia* for the *Antitycho*, page 53, and the *Antitycho*, Book 1, chapter 11, proposition 10.

From this it is clear that Kepler erred in three ways in the *Hyperaspistes*, page 12. For he thought, first, that by the very fact that a moving body is carried by its seen motion along the same great circle, it lacks sensible parallax; second,

that it therefore necessarily follows that it also moves by its true motion along a great circle; and finally, that the kind of circle marked out by the seen motion must be investigated first, so that the parallax may be determined from it, rather than that the parallax must be known beforehand, so that the circle of each motion may be determined from it. For he says in the *Hyperaspistes*, page 12, against Chiaramonti: *Hear me, Peripatetic: we attend to whether the comet proceeds on a great circle precisely so that we may determine the parallax; we seek the parallax so that from it we may also learn its place along the diameter of the world. In this inquiry the kind of circle comes first; it does not follow. The closer one keeps to a great circle, the less the comet is understood to change its place through the different positions in the first motion.* Then, on page 18, he says: *For it is true that if the co-*

[Margin: Kepler's threefold error in the method of parallax.]

met by its true motion held the path of a great circle, it did not hold it by its seen motion, since it produced a parallax. But, with less circumlocution, this too is true — which Scipio [Scipione Chiaramonti] has not yet refuted — that if by its seen motion it marked out an arc of a great circle, it also marked one out by its true motion, because in that way sensible parallax is taken away from it. But we, in Book 10 of this work, penultimate section, chapter 9, have demonstrated much more clearly than Chiaramonti that a phenomenon can have a very large and sensible parallax and yet be carried by its seen motion along the same great circle, and consequently not describe a great circle by its true motion. This confirms what Chiaramonti rightly taught in Book 1 of the *Antitycho*, chapter 11, proposition 10: that before deciding the kind of circle along which the comet proceeds by its true motion, one must decide about the parallax — whether it is sensible or not. And indeed, even without drawing any figure, who would not understand that, if parallax always depresses a phenomenon below its true place, it cannot happen — if the circle of the seen motion is distinct from the vertical circle — that the circle of the true motion is not always above the circle of the seen motion, and that the one never cuts the other? And if it does not cut it, it is certain that both cannot be great circles, by proposition 11 of Book 1 of Theodosius's *Spherics*. Therefore, if the parallax is sensible, who would not understand that the circle of the seen motion deviates sensibly from the circle of the true motion?

Finally, Tycho, in volume 2, page 207, grants this comet a parallax of 19′ in its first days, and for almost the whole time of its duration one greater than 3′ 7″; but in volume 1, page 80, he does not grant the Sun a parallax greater than 3′ 7″. Therefore this comet's parallax was almost always greater than the Sun's parallax, let alone than Jupiter's and Saturn's; and yet, on Tycho's assertion, it described a portion of a great circle by its seen motion. And so Kepler, while defending Tycho, contradicts Tycho: for he affirms that by the very fact that the comet describes a great circle by its seen motion, it lacks sensible parallax.

[Margin: Kepler contrary to Tycho in his very defence of Tycho.]

IV. Chiaramonti, however, replies secondly, in Book 2 of the *Antitycho*, chapter 4, by denying the major premise and its proof. First, because if we wish to follow full rigour, it does not follow that, if the comet kept a constant angle

to the ecliptic, it described a great circle: for all the parallels along which the Sun proceeds are circles that are not great, and yet they keep the same constant angle to the ecliptic. Next, because in chapter 6 he shows from the data given by Tycho that the comet's seen path departed from the same point of intersection with the ecliptic not only by 5′ at a time — which Tycho acknowledged and disregarded — but also by 19′, and sometimes by 55′, as I shall say below at number 17. Finally, on the ground of parallax: because he thinks that Tycho spoke, or ought to have spoken, of the true motion; but if by its true motion the comet described a great circle, and had a parallax not only of 3 minutes but sometimes greater, up to 19′, it could not have described a great circle by its seen motion.

[Margin: Chiaramonti's objection against the major premise of the syllogism set out in number 2.]

But this last reason is invalid, because Tycho spoke of the motion observed by himself, the seen motion. Granted that, for the conclusion lifting the comet into the heavens to be valid from a seen motion made along a great circle, he ought to have deduced from it a true motion along a great circle — which he could not do, given a parallax so sensible. The second reason, however, does hold against Tycho, insofar as, with excessive exaggeration [?], he will have it that the comet described a great circle with the utmost exactness, and no less than the Sun. For the Sun never deviates by its seen motion, by reason of parallax alone, from the track of a great circle by 5 minutes, let alone by 19, as much as this comet deviated (for we are not considering here the refractions near the horizon common to the Sun and the comet). But it does not hold for the comet compared with the Moon, which, because of a parallax sometimes of 60′ and more, and because of the variation of its latitude, departs from a great circle more than this comet does. And it is enough for Tycho, and for Kepler — as is clear from his words adduced in number 3 — if the comet described a portion of a great circle more exactly than the Moon. Nor does Chiaramonti win on this part, but on the other, just mentioned. The fourth reason, on the rectilinear motion which Kepler attributes to this comet, does no harm to Tycho, because it is enough for Tycho that the comet was in the same plane of a great circle, even if it did not describe the circumference of the circle.

[Margin: Chiaramonti's reasoning against Tycho, partly valid, partly invalid.]

V. The third reply is to deny the minor premise. For nothing prevents some elementary body from being carried along a great circle, even if it is fiery or blazing, since

the very matter of its fuel can be so disposed along that circle. And that there are elementary bodies which move naturally along the plane of a great circle, I have already taught in chapter 11, number 9.

Secundum, Tertium, & Quartum Argumentum Tychonis.

Tycho's second, third and fourth arguments.

VI. Tycho's three following proofs, in volume 2 from page 103 to 105, reduced to the form of a single syllogism, run as follows: *Every body that moves with a regular and ordered motion — that is, either uniform or uniformly difform — and that is slower than the Moon in its own proper motion from west to east, is celestial and above the Moon, especially if, beginning at one tropic, it ends at the other. But the proper motion of the comet of the year 1577 was regular, etc.* For at the beginning it was seen to complete about 4 degrees daily, then 3½, afterwards 3, next 2, afterwards 1, and finally, towards the end, not even one. From this it is also clear that it was slower than the Moon's motion, which is never less than 10 degrees. Finally, the beginning of this motion was from the tropic of Capricorn above the head of Sagittarius, and its end at the tropic of Cancer near Scheat of Pegasus, a quadrant of a circle having been completed both with respect to the ecliptic and with respect to its own track — which savours of the nature of a celestial body. Therefore that comet was above the Moon.

But this argument was sufficiently answered in chapter 11, from number 9 to 12, and there is no need to repeat the reply, since Tycho and Kepler at length acknowledged that, even if the minor premise were granted, the major is nevertheless not necessarily but only probably true. Indeed, from what was said in chapter 11, number 10, it is probable in such a way that its opposite is nevertheless equally probable, because of the many other disagreements which the motion of this comet had with the motions of the celestial bodies.

Quintum Argumentum Tychonis ex differentia Diſtantiarum Cometæ ab eadem ſtella Fixa diuerſis locis obſeruatarum, orta ex Parallaxi.

Tycho's fifth argument, from the difference, arising from parallax, between the comet's distances from the same fixed star observed in different positions.

VII. For the force of the argument that Tycho uses in volume 2, chapter 6, from page 106 to 123, to be understood, certain things must be presupposed which he himself either demonstrated from his observations or seemed, to himself and to others, to have demonstrated. Thus in chapter 1 he reports all the observations of the comet, made on clear nights as well as on nights that were not clear — that is, the certain as well as the doubtful — namely the distances from fixed stars obtained with the radius and the old sextant. Then, in chapter 2, he corrects the places of the fixed stars that were corrupt in Alfonso X and Copernicus, from their declinations and right ascensions, observed by himself with the help of the azimuthal quadrant, through altitudes, azimuths and definite moments of time; for he admits that he did not then have the armillae. Afterwards, on page 31, he admits that not only the radius but that sextant too was liable to some error, and that later, equipped with larger and more accurate

instruments and with a knowledge of refractions, he obtained a more exact obliquity of the ecliptic and altitude of the pole, and more correct places of the fixed stars; and therefore he corrects, for the time of the comet, the places of the stars he had used in observing the comet. Yet because their places did not differ from the earlier ones by more than six minutes, and often by less, he chose to correct neither the distances from the fixed stars taken with the radius and the old sextant nor the innumerable calculations built upon them, judging that no evident difference could arise from this. For when he recognized the fault of the earlier instruments and obtained more correct places of the fixed stars, he had already finished almost the whole second volume — granted that, by remaking or reprinting folios 31 to 34, he inserted this acknowledgement and addition. Moreover, since he always used the same places of the stars, uncorrected though they were — not sometimes corrected and sometimes uncorrected — he judged that, for the sake of coherence, the differences of the parallaxes would come out the same from the corrected places as those he had gathered from the uncorrected ones. And accordingly, on page 34, he says: *Therefore, since there is no difference of any evident moment between the places of the stars which I used in this book from the earlier observations and those which we afterwards noticed, more exactly, that they actually hold in the heavens, I did not wish, on account of*

so few minutes as are lacking, to call back to the anvil the entire calculation founded on their places throughout this book, with a labour tedious and troublesome rather than useful or necessary, etc. Thus Tycho in chapter 3, from the uncorrected places of the fixed stars and the uncorrected distances of this comet from the fixed stars, gathers by the analysis of triangles the comet's seen longitude and latitude for each day of observation; in chapter 4, the comet's right ascensions and declinations; and in chapter 5, the portion of the circle which the comet described by its motion, with its inclination to the ecliptic and the equator, and the point at which the comet's path cut both the ecliptic and the equator.

VIII. After this, in chapter 6, having first set out the four arguments discussed above, he proceeds to the 5th argument, which, reduced to form by me, runs as follows: *If the comet of the year 1577 had been below the Moon, even if it had been in the very concave of the lunar heaven, it would have had to undergo so great a parallax, and no smaller, that on November 23 its own proper motion eastward over three hours would be retarded by 15 minutes and more, and that after the three hours it would appear as far from the mouth of Pegasus as at their beginning, or farther. But it did not undergo so great a parallax* [?]*, nor was its motion retarded in those three hours by 15′, but only by three. Therefore the comet of the year 1577 was not below the Moon.*

[Margin: Tycho's 5th argument, gathered into a few words.]

He attempts to show the minor premise thus. On November 23, at $5^{h}\ 30^{m}$ after noon, at Uraniborg, the comet's seen distance from the mouth of Pegasus was 21° 8′; then, at $8^{h}\ 35^{m}$, the comet's seen distance from the same mouth was 20° 56′. Therefore in $3^{h}\ 5^{m}$ the comet approached the mouth of Pegasus (for that mouth was more easterly than the comet) by 12′. But from the comet's

proper motion eastward, taken from the 21st and the 25th, from which the 23rd is equally distant on either side, the comet ought to have approached the mouth of Pegasus by 15′: for its daily motion on those days was exactly 2 degrees, or 120′, which, divided by 24 hours, gives 5′ to each hour and 15′ to every three hours. Hence, since at the second observation it was nearer the horizon, and parallax depressed it towards the west, retarding its visible motion eastward, it is concluded that the three minutes by which the comet's approach to the mouth of Pegasus was retarded were due to parallax.

[Margin: Proof of the minor premise.]

Moreover, on the same night, at $5^h\ 45^m$, the comet was seen to be 4° 38′ from the star in the left hand of Antinous, and at $6½^h$ to be 4° 40′ from it, this star being more westerly than [?] the comet. But from the hourly motion of 5 minutes, 3′ 45″ were owed to three quarters of an hour; therefore, had the comet had no parallax, it ought to have receded from that star by 3′ 45″ at the second observation; but it receded only 2′. The remainder, therefore, 1′ 45″, was due to parallax depressing the comet towards the west. Now let us come to the proof of the major premise, which he reaches gradually, through many steps, up to number 15.

[Margin: 1st step, for the difference of the distances observed from the same fixed star.]

[Margin: The proof of the major premise begins.]

IX. *Secondly*, since he did not observe the comet's altitudes at the hours mentioned, he investigates them on page 109 by spherical triangles. In this analysis he assumes the distance of the pole of the world from the vertex, that is AB, to be 34° 7′; the place of the Sun at $5^h\ 30^m$ in the afternoon of November 23 to be ♐ 11° 8′; and its right ascension 249° 55′. If to this are added 82° 30′ of the equator, which correspond to $5^h\ 30^m$, the right ascension of mid-heaven becomes 332° 25′. If from this is subtracted the comet's right ascension already found by him on page 70, which was 301° 7′ — though here, on page 109, it is set at 301° 5′ — there remain 31° 20′: that is, ME, or the angle ABD which the meridian HAC makes at the pole of the world B with the quadrant BE of the circle of declination drawn through the comet D as far as the equator ML. And the declination DE of the comet D, found on page 70, was 51′ to the north, and its complement BD 89° 9′, although Tycho here sets 89° 10′. Therefore, by the analysis of triangle ABD, AD comes out at 60° 35½′, and so the altitude ID at 29° 24½′. Similarly, at the second observation, with the comet at F, at $8^h\ 35^m$, the Sun's place for Tycho was ♐ 11°

[Margin: 2nd step, for each seen altitude of the comet.]

Diagram. A semicircle standing on its diameter HC, set at the right of the right column beside the computation of §IX. From A at the top of the arc and from B on the upper right of the arc, straight and curved lines descend to the diameter; arcs cross the interior through D, F, E and G; M stands on the left of the arc; I, K and L stand on the diameter. The text makes HAC the meridian, B

the pole of the world, D the comet at the first observation and F at the second, BE a quadrant of a circle of declination, ML the equator, ME the hour angle, and ID the comet's altitude; these roles are taken from the text, not printed on the block.

- A (top of the arc)
- B (upper right on the arc)
- M (left on the arc)
- D (interior, below and right of A)
- F (interior, below D)
- E (interior, left, below M)
- G (interior, below E)
- H (left end of the diameter)
- I (on the diameter, left of centre)
- K (on the diameter, beside I)
- L (on the diameter, right of K)
- C (right end of the diameter)

36′, and its right ascension 250° 4′. To this he adds 128° 45′, corresponding to 8^{h} 35^{m}, and the right ascension of mid-heaven (together with a whole circle) becomes 378° 49′. And since the comet's right ascension for that time, verified proportionally, was 301° 18′, when this is taken from 378° 49′ there remains MG, or the angle ABF, 77° 31′. The declination FG, verified for that time, was 1°, and its complement BF 89°. Therefore in triangle ABF, from AB 34° 7′, ABF 77° 31′ and BF 89°, AF comes out at 82° 12′, and the altitude KF at 7° 48′ — the altitudes that had to be found.

X. *Thirdly*, from page 110 he investigates the lunar parallaxes that the Moon at perigee would undergo at the two altitudes of the comet found just before, namely at the altitude ID, 29° 24½′, and KF, 7° 48′. He assumes, from Copernicus, the distance of the Moon at perigee as 52 semidiameters of the Earth; but, to work more finely, he converts it to 5,200,000 parts, of which the Earth's semidiameter is 100,000. With these assumed, in the following figure let there be described from the Earth's centre A the Earth's quadrant BH, and that of the concave of the lunar heaven, KG, enclosed by the vertical line AK and the horizontal AG. And let the Moon first be at D, from which let DBF be drawn through the eye B until the perpendicular AF falls on it at F; then, with the Moon placed at C, let CBE be drawn, and the perpendicular AE to it at E; and let D and C be joined to the Earth's centre by the straight lines AD and AC.

[Margin: 3rd step, for the parallaxes corresponding to each altitude, if the comet had been in the concave of the Moon [?].]

Diagram. A quadrant of a circle set at the right of the left column, its vertical side AK and horizontal side AG meeting at A at the foot. An inner arc runs through B on the vertical; straight lines run from A and B out to the outer arc and beyond it to the right, where E and F stand outside the quadrant and I between them and A. In the text A is the Earth's centre, BH the Earth's quadrant, KG the concave of the lunar heaven, B the eye, D and C the Moon's

two positions, and F and E the feet of the perpendiculars from A; these roles are taken from the text, not printed on the block.

- D (top of the outer arc, left of K)
- K (top of the vertical side)
- C (on the outer arc, left of D)
- L (on the outer arc, left)
- B (on the vertical side, at the inner arc)
- E (outside the quadrant, right of B)
- I (between A and E)
- F (outside the quadrant, right, below E)
- G (left end of the horizontal side)
- H (on the horizontal side, between G and A)
- A (corner at the foot of the vertical)

First, in triangle ABF, right-angled at F, the angle ABF is given, 60° 35½′, since it is equal to the angle KBD, that is, to the complement of the comet's first altitude; the base AB is also given, of 100,000 parts; therefore, by the rules of triangles, the side AF is found, of 87,114 parts. *Secondly*, in triangle ADF, right-angled at F, AF 87,114 and AD 5,200,000 are given; therefore the parallactic angle ADF is 57′ 36″. *Thirdly*, in triangle ABE the angle ABE is given, 82° 12′, since it is equal to the angle KBC, which is the complement of the comet's second altitude, and the base AB, 100,000; therefore AE is found, of 99,075 parts. *Fourthly* and lastly, in triangle ACE, right-angled at E, AE 99,075 and AC 5,200,000 are given; therefore the parallactic angle ACE is 1° 5½′. So the parallax of altitude of the Moon at perigee would have been 57′ 36″ at the comet's first altitude and 65′ 30″ at the second, and the difference of the parallaxes 7′ 54″.

[Margin: By Euclid I.15.]

XI. *Fourthly*, from page 112 he investigates the angle which the vertical circle makes with the comet's path at each time of observation. For this, in the semicircle of the meridian HAR, let A be the vertex and B the pole of the equator EQ; let the comet be at C, and its path FCL; and through the comet let there be drawn the quadrants ACK, of a circle of altitude, and BCG, of a circle of declination. With these described, the angle ACF is sought.

[Margin: 4th step, for the angles of the comet's path with the vertical.]

Diagram. A semicircle on the diameter HR, set across the left column below the statement of §XI. Arcs from A at the top and from B on the upper right of the arc pass through C in the interior; a dotted line runs from A to O; below C stand G, M, D and V, and on the diameter K, L and Q. In the text HAR is the meridian, A the vertex, B the pole of the equator EQ, C the comet, FCL its path, ACK a circle of altitude and BCG a circle of declination; these roles are taken from the text, not printed on the block.

- F (top of the arc, left of A)
- A (top of the arc)
- O (interior, at the end of the dotted line from A)

- B (upper right on the arc)
- E (left on the arc)
- C (interior, centre)
- G (interior, below and left of C)
- M (interior, below C)
- D (interior, below G)
- V (interior, below M)
- H (left end of the diameter)
- K (on the diameter, left of centre)
- L (on the diameter, centre)
- Q (on the diameter, right of L)
- R (right end of the diameter)

First, then, in triangle ACB, AB is given, the complement of the altitude of the pole, 34° 7′; BC, the complement of the comet's declination at the first observation, 89° 10′; and AC, the complement of the altitude then found, 60° 35½′. From these the angle ACB is gathered, 19° 34′. *Secondly*, in triangle CGV, right-angled at G,

the angle CVG is given, found by Tycho on page 85 — that is, the inclination of the comet's path to the equator, 33° 45′; and the side GV is known from the difference between the comet's right ascension and the point of the equator at which the comet's path cut the ecliptic, which point Tycho found on page 81 at 299° 50′. Hence from these data he finds the angle GCV — that is, FCB, vertical to it — 56° 15½′; and the angle ACB, 19° 34′, subtracted from this, leaves the angle sought, ACF, about 36° 42′. By a wholly similar method he finds at the second observation, that is for 8^{h} 35^{m}, the angle ACF, 22° 42½′.

XII. *Fifthly*, on page 114 he investigates the comet's parallax of longitude and latitude, not with respect to the ecliptic but with respect to the arc which the comet described by its own proper motion — in the preceding figure the arc FL — which he conceives as described from its own proper pole, for which B may now serve, although in reality that pole was off the meridian. And so from the comet's pole B let the arc BC be drawn through C, the comet's true place, and another arc BD to the seen place D. For since the arc FL is described from the pole B, it follows that the arcs BC and BM fall on the arc FL at right angles. Hence the triangle DCM is right-angled at M, and in it the base DC is given, namely the parallax of altitude from the 3rd step: 57′ 36″ at the first observation and 65′ 30″ at the second. And by the 4th step the angle ACF is given, that is, its vertical angle DCM: 36° 42′ at the first observation and 22° 42½′ at the second. He therefore finds the side DM, that is, the parallax of latitude, 34′ 25″, and CM, that is, the parallax of longitude, 46′ 42″, at the first observation; and at the second, DM 25′ 17″ and CM 60′ 14″.

[Margin: 5th step, for the parallax in longitude and latitude with respect to the comet's path.]

XIII. *Sixthly*, on page 115 he assumes, from what he set out in the table of the comet's motion found on page 86, that on the 23rd at $5\frac{1}{2}^{h}$ the comet stood

distant from the point V by the arc CV, 46° 30′. Subtracting, then, the first parallax of longitude, 46′ 42″, there remains the comet's seen longitude MV from the point of intersection V, 45° 43′ 18. But since from 5^h 30^m to 8^h 35^m the comet completed by its daily motion, as Tycho says, exactly 15′ (from what was said in the 1st step), and was moving eastward, that is from C towards F (for FL is the western arc), the comet's true elongation CV at 8^h 35^m was therefore 46° 45′; and when the parallax of longitude, 60′ 14″, is subtracted from it, the true elongation 45° 44′ 46″ is left.

[Margin: 6th step, for the comet's seen longitude from the intersection V.]

XIV. *Seventhly*, again by spherical triangles, on page 116, he determines the position of the star in the mouth of Pegasus with respect to the comet's path, from the longitude and latitude of the mouth of Pegasus, from the comet's parallax of latitude, and from the comet's longitude from its intersection with the ecliptic, already found in chapter 5 together with the angle of inclination of the comet's path to the ecliptic. From these, I say, he finds the seen longitude of the mouth of Pegasus with respect to the comet's path, 67° 4′, with a seen southern latitude, with respect to the comet's track, of 4° 44′.

[Margin: 7th step, for the position of the mouth of Pegasus referred to the comet's path.]

XV. *Eighthly*, and finally, on page 117, through many windings and the analysis of other triangles — whose diagrams are not at all necessary to us; see them in his book if you wish — he investigates, from what was found above, the seen distance which the comet ought to have had from the mouth of Pegasus at each observation if it had been in the concave of the Moon. At the earlier he finds a distance of 21° 44′ 16″, at the later 21° 44′ 44″, and so the later greater than the earlier by 29″, or almost half a minute. Therefore the major premise of the argument set out in number 8 seems proved — which, however, we shall presently repeat and explain.

[Margin: 8th step, for the distances at which the comet should be seen from the mouth of Pegasus.]

[Margin: Proof of the major premise.]

For with these things laid down, Tycho, on page 118 — rather obscurely and with a very involved line of reasoning, but here reduced by us to a better form — argues thus. The comet by its proper motion moved in three hours eastward, and at the same time towards the mouth of Pegasus, by 15′ in the space of 3 hours. Therefore, had no parallax intervened, after 3 hours it ought to have approached the mouth of Pegasus by 15 minutes, that is, to be less distant from it than before by a quarter of a degree. But if a parallax intervened, depressing the comet towards the west and apparently increasing its distance from that more easterly star, its motion at the later observation ought to have been visibly retarded, so that it would seem to have approached the mouth of Pegasus by less than 15 minutes — and by so much the less, the greater the parallax, or the greater its nearness to the Earth. So that, if we suppose the comet to have been in the concave of the lunar heaven, it follows from the other circumstances of

the comet, by geometrical calculation, that its motion toward the east — its approach to the mouth of Pegasus — ought to have been retarded not merely by 15 minutes, so that its whole proper motion would apparently have been consumed, but that it ought even to have been carried back farther toward the west. For in the earlier observation it ought to have stood 21° 44′ 16″ from the mouth of Pegasus, and in the later one, when it was nearer the horizon, 21° 44′ 44″ — that is, almost half a minute farther — as is clear from the 8th step. But according to the observed distances it approached the mouth of Pegasus by 11½ minutes; that is, its motion, which in itself was of 15 minutes, was retarded by only 3′ 12″. Therefore that supposed seat of the comet in the concave of the lunar heaven is false, and the comet's distance from the Earth must have been much greater than the distance of the Moon at perigee, that is, of the Moon placed in the concave of its own heaven.

[Margin: Tycho's argument.]

[Margin: The argument of number 8 is repeated.]

XVI. Let the argument set out in number 8, then, be repeated, but gathered into fewer points and somewhat differently, as follows. *If the comet of the year 1577 had not been above the Moon but below it — however close to it, and in the concave of the lunar heaven — then on the 23rd, at 8^h 35^m after noon, it would have had to stand, by force of parallax, as far from the mouth of Pegasus as it had stood at 5^h 30^m, or indeed farther, as regards the seen distance. But at 8^h 35^m it did not, by force of parallax, stand as far from the mouth of Pegasus as it had stood at 5^h 30^m, or farther, as regards the seen distance; for it stood less far, and indeed less by 12 minutes. THEREFORE the comet of the year 1577 was above the Moon.*

[Margin: Understand the hours as reckoned for Uraniborg.]

And lest you say that this proves at most the comet's position on November 23, he confirms the same thing by a similar method for November 29 and 30, and for December 1, 13 and 31. For on those days, although it had come nearer the horizon in the hours that elapsed between the paired observations, it nevertheless underwent so small a parallax that its motion toward the east was hardly retarded at all, but it approached the same fixed star very nearly as much as its proper motion, corresponding to those hours, required. He confirms these things from the distances taken with the radius, pages 120 to 123. See the summary of these confirmations in the following table.

Day of the month	Hour and minute after noon, at Uraniborg	Seen distance of the comet from the fixed star, by the radius	Fixed star from which it stood distant	Proper motion of the comet due in the interval of hours	Seen motion by which the comet approached the fixed star	Difference
(days)	(hours, minutes)	(degrees, minutes)	(the more easterly)	(minutes, seconds)	(minutes, seconds)	(minutes, seconds)
Novem~~6~~ber 29	6^h 40^m; 9^h 10^m	35° 45′; 35° 36′	Scheat of Pegasus	8′ 20″	9′ 0″	0′ 40″

Day of the month	Hour and minute after noon, at Uraniborg	Seen distance of the comet from the fixed star, by the radius	Fixed star from which it stood distant	Proper motion of the comet due in the interval of hours	Seen motion by which the comet approached the fixed star	Difference
November 30	$6^h\ 0^m$; $9^h\ 15^m$	10° 25′; 10° 14′	Mouth of Pegasus	9′ 30″	11′ 0″	1′ 30″
December 1	$7^h\ 10^m$; $9^h\ 30^m$	9° 17′; 9° 11′	Mouth of Pegasus	6′ 0″	6′ 0″	0′ 0″
December 13	$7^h\ 40^m$; $9^h\ 30^m$	22° 18′; 22° 14′	Scheat of Pegasus	3′ 30″	4′ 0″	0′ 30″
December 31	$6^h\ 0^m$; $9^h\ 0^m$	12° 0′; 11° 56′	Scheat of Pegasus	3′ 45″	4′ 0″	0′ 15″

From this it is clear, if Tycho's observations are to be relied on, that the comet — when it was in a position lower down on account of the daily motion of the primum mobile — should, if it is supposed to have had a sensible parallax, have approached that same fixed star visibly less than its own proper motion of approach toward that more easterly star required; and yet it approached it as much as that motion required, or indeed somewhat more. And so its approach was not retarded at all by parallax. From this he concludes that it underwent scarcely any sensible parallax, and was therefore far above the Moon.

Deſtructio Argumenti Quinti Tychonici per Inſtantias Scipionis Claramontij.

The demolition of Tycho's fifth argument by the objections of Scipione Chiaramonti.

[Margin: 1st objection of Chiaramonti against Tycho.]

XVII. But Chiaramonti, not at all moved by the machinery already mentioned, tries in Book 2 of the *Antitycho*, chapter 11, to destroy the force of Tycho's argument just set out by five objections [instantiae], to use his own word. The first of them is this. In the steps already mentioned Tycho supposes that the comet moved along the same great circle, and with a motion so regular that its hourly motion could be determined from its daily motion — for example, on November 23 an hourly motion of 5 minutes and a three-hour motion of 15 minutes — and that the comet's path kept the same constant angle to the ecliptic and the equator, and cut those circles at the same point. But Chiaramonti, in Book 2 of the *Antitycho*, chapter 6, demonstrated from the data supplied by Tycho that the comet did not move along the same circle but described a winding path, with a varying angle to the ecliptic and the equator, intersecting those circles at one point and then another; so much so that the point of the ecliptic at which it cut the comet's path differed not only by 5 minutes, which Tycho acknowledged and disregarded, but by 19′ and

sometimes by 55′. But whether the comet's motion in the intervening hours was uniform and proportional to its daily motion, or grossly non-uniform, cannot be established with certainty — and much less so if the kind of circle along which the comet moved is not established.

I said that Chiaramonti demonstrated this because, having examined his calculations as he sets them out in Book 2, chapter 6, I found in them no discrepancy except in a few seconds, which is entirely negligible.

[Margin: Kepler approves Chiaramonti's demonstration.]

Nor does Kepler object, in the *Hyperaspistes*, page 24; on the contrary, he reduces to a summary the calculations given by Chiaramonti in Book 2, chapter 6, and approves them in these words: *Chiaramonti is a good calculator; but the use of his calculation he either, through want of skill, does not know, or, ill-disposed toward his adversary, maliciously conceals.*

[Margin: But rejects the use made of it.]

Let us look at the sum of his seven operations: this is what he finds, this is what he concludes.

Degree and minute of ♐ toward which the comet's arc tends	From November day	to day
20° 19′	13	14
21° 14′	14	15
21° 0′	15	20
20° 58′	20	21
20° 34′	21	23
20° 51′	23	25
20° 20′	25	29

Therefore they do not tend toward the same point, but toward wandering points between ♐ 20° 19′ and ♐ 21° 14′, which are separated from one another by a space of 55 minutes, and are not one point. I concede the whole argument, even without examining this calculation. Tycho himself grants this very thing when, taking the point ♐ 20° 55′ — which came out for him more often, or lay midway among the principal results — he computes how far the places differ from those he had previously computed from the observations. And a little later he says that if the points of intersection of the comet's path and the ecliptic differ by no more than one degree or 55′, the comet's path from a great circle by no more than one minute — which is negligible in this astronomical business, and in a hurried observation of a comet.

[Margin: Kepler thinks Tycho's argument only probable.]

And he immediately adds: *Nor is the probability of his assertion, that comets are above the Moon, overturned by these minutiae.* Afterwards he says that Chiaramonti is looking for a knot in a bulrush, *and that the imperfections of the motions in figure and time are so slight that we are compelled to tolerate greater ones in astronomy itself, that most divine science.*

[Margin: Chiaramonti's reply to Kepler.]

To this Chiaramonti replies, in the *Apologia* for the *Antitycho*, pages 6 and 75, that in the matter of parallax — especially a small one, on which hangs the

decision whether a comet is above the Moon, or the Sun, or Saturn, as some contend — the geometrical calculation must be more accurate than in some part of astronomy, though not in every part. And he shows, from Tycho himself, that disregarding a few minutiae can produce a great error in this matter; he quotes Tycho's words from volume 2 of the *Progymnasmata*, page 220, which are these: *In which, unless the most exact precision is applied, an easy slip creeps in over certain very small things, which afterwards, when one comes to geometrical practice, grows into an intolerable deviation.*

[Margin: Chiaramonti undeservedly censured here by Kepler.]

For although this comet described a less winding path by its motion than the Moon does, and, considered strictly in this respect, it would seem more probable that the comet was more celestial than the Moon, as we said in chapter 11, number 9, and chapter 18, number 2, nevertheless, if in Tycho's steps 4, 5, 6 and 7 there was an error of some minutes in the angle of the comet's path with the ecliptic and the equator, there could have been an error of as many minutes and more in deriving the comet's distance from the mouth of Pegasus. And these minutes are not negligible, since the dispute was whether the comet's motion on November 23 was retarded by 3′ or by 11′ ½. Therefore Chiaramonti's diligence in this matter deserved praise rather than Kepler's carelessness and complacency; nor ought he on that account to have been branded with lack of skill in the use of calculation, or with malicious ill will against Tycho.

[Margin: 2nd objection of Chiaramonti.]

XVIII. Chiaramonti's *second* objection, on page 166 of the *Antitycho*, is this. Tycho, he says, could not know the parallax before he distinguished the true place and motion from the seen place and motion; but he either confused these or tried unsuccessfully to distinguish them, and he supposed as true the comet's distance from the point where the ecliptic intersects the comet's path, which was nevertheless a seen distance, since it was derived from the seen distances of the comet from the fixed stars. Recall the figure set out at number 11, and then step 6: there Tycho says that the distance of the comet C from the intersection V had previously been gathered by him as 46° 30′, and, subtracting the parallax CM, he converts it to the seen distance MV, 45° 43′ 18″. And indeed Tycho's words in volume 2, page 115, are these: *Therefore, since the comet's true longitude from the point of intersection is presupposed from the foregoing to have been 46° 30′ at the first observation, made at 5½^{h}, then, subtracting the parallax of longitude just found for this time, the seen longitude comes out as 45° 43′ 18″.*

But Tycho called the former distance true not absolutely — for he knew he had derived it from seen distances — but comparatively, with respect to the comet's other, visible elongation: the one that would have been seen if the comet had been in the concave of the Moon and had undergone, at each seen altitude, the parallaxes we recorded in step 3, that is, in number 10. Nor did he investigate the parallax of longitude and latitude with respect to the comet's path absolutely, but from a feigned hypothesis of the comet's distance from the

Earth, and from the parallax of altitude derived from it. Tycho therefore uses two kinds of seen places, which Chiaramonti did not distinguish, attending here to Tycho's words rather than to his meaning: one, which he called true — understand, comparatively, with respect to the other, which is more "seen", that is, would have had a greater difference of appearance if the comet had been below the Moon.

[Margin: Chiaramonti's slip in attacking Tycho.]

Therefore, when Chiaramonti, on page 168 of the *Antitycho*, reproaches Tycho for not having used the earlier places seen through the observations in order to investigate the comet's seen distances from the mouth of Pegasus, he is mistaken. For in step 8 Tycho was not seeking these distances — he already had them, known from the observation cited in number 8 — but the visible distances there would have been if the comet had been below the concave of the Moon; and for these he had to use other seen places, to which the comet would have been carried from its earlier seen path *by force of the parallax* of longitude and latitude. So Tycho supposed the comet's earlier path, which he knew to be apparent, as if it were true, in order to see what kind of seen path, and how great, there would have been if the comet had been below the Moon — as Kepler points out, in rather obscure words, in the *Hyperaspistes*, page 37.

[Margin: 2nd part of the 2nd objection, or 3rd objection of Chiaramonti.]

XIX. From the preceding objection arose the *third*, which Chiaramonti accordingly merges with it into one, on page 168 of the *Antitycho*; and it runs as follows. In the step we numbered 8 above, Tycho, from places on the comet's path which he thought true, deduced that the comet's earlier distance from the mouth of Pegasus was smaller than the later one — namely, the former 21° 44′ 16″, the latter 21° 44′ 44″. But Chiaramonti, from the same data given by Tycho, gathers the earlier distance as 21° 5′ and the later as 20° 50′, and so the former greater than the latter by 15′, contrary to what Tycho deduced. From this he gathers, on page 171, that the comet had as great a parallax as would suffice for Tycho to place it below the Moon; for a parallax that great would retard the comet's proper motion by the full 15′, as is clear from what was said at number 15.

[Margin: A second slip of Chiaramonti, rightly reproved by Kepler.]

But Chiaramonti does not prevail in this either. For he investigates the seen distances of the comet from the mouth of Pegasus which it actually had, without supposing the parallaxes that Tycho deduced from the hypothesis of a comet feigned below the concave of the Moon; whereas Tycho, in that step 8, inquires into the seen distances of the comet from the mouth of Pegasus — or rather, those it would have been seen at, had the comet been below the concave of the Moon — applying the parallaxes of longitude and latitude with respect to the comet's earlier path. It is no wonder, then, that Chiaramonti finds distances different from Tycho's; and so Kepler rightly reproves him on this point in the *Hyperaspistes*, page 40, nor did Scipione clear himself sufficiently of these charges in the *Apologia*.

[Margin: 4th objection of Chiaramonti.]

XX. The *fourth* objection, which Chiaramonti counts as the third, in Book 2 of the *Antitycho*, page 172, arises from what Tycho said and we reported at number 8. For Tycho said that in the later observation the comet, on account of its proper motion toward the east of 15 minutes, which corresponded to three hours, ought to have been nearer the mouth of Pegasus — that is, the more easterly star — nearer, I say, than before by the full 15′; but that, since the parallax depressed it visibly toward the west more than in the first observation (for in the second it was far less high above the horizon than in the first), it approached the mouth of Pegasus by only 12′; and so he attributed this difference of three minutes to parallax. Chiaramonti, however, denies that this difference was due to parallax, and says it was due rather to refraction raising the comet.

[Margin: Chiaramonti's blunder.]

But Chiaramonti is deceived on this point, because he thinks Tycho said that the seen distance of the comet from the mouth of Pegasus — the more easterly star, and the one nearer the vertex — was diminished by parallax. Had Tycho said that, this effect would rightly be attributed to refraction rather than to parallax, since it belongs to refraction to diminish the distances of a phenomenon from the vertex, or from a point nearer the vertex, and to parallax to increase them. But Tycho did not say this. He said that the comet's motion, which ought to have been seen as 15 minutes, and by which the comet should have approached the mouth of Pegasus, was retarded by parallax, so that it was seen to move only 12 minutes. Therefore, since the comet was seen farther west and nearer the horizon in the second observation than, considering its motion, it otherwise should have been, that effect could rightly be attributed to parallax rather than to refraction.

I am truly astonished that Chiaramonti, a man otherwise of the sharpest intellect, was so plainly deceived, and gave Kepler an occasion to rebuke him in the *Hyperaspistes*, pages 41 to 44. There, however, Kepler acknowledges that the comet at an altitude of 7° 48′ — that is, in the 2nd observation — was subject to a refraction of no more than 7′ in altitude, and of at most 4′ in its distance from the mouth of Pegasus; with these removed, the later distance would turn out smaller than the earlier by only 7′ or 8′. This does Tycho no harm, since for the comet to be sublunary he required it to be 15 minutes less distant from the mouth of Pegasus in the later observation than in the earlier. But Chiaramonti says, in the *Apologia*, page 114, that he had understood from Tycho that the refractions of phenomena lower than the Sun are greater than the solar ones, or not less, and hence 11′ 30″ at that altitude of 7° 48′. But even this does not suffice to make the comet sublunary: for that refraction would lie in the circle of altitude, but in the arc of distance from the mouth of Pegasus it would come out smaller; so the retardation of the motion of approach toward the star would not reach 15 minutes in the arc of distance itself.

Noſtra Reſponſio ad Quintum Argumentum Tychonis.

Our reply to Tycho's fifth argument.

XXI. Tycho's argument at numbers 8 and 16 was this: *If the comet of the year 1577 had not been above the Moon but below it — however close to it — and in the concave of the lunar heaven, then on November 23 at 8^h 35^m after noon, at Uraniborg, it would have had to stand, by force of parallax, as far from the mouth of Pegasus as it had stood at 5^h 30^m, or indeed farther, as regards the seen distance. But at 8^h 35^m it did not, by force of parallax, stand as far from the mouth of Pegasus as it had stood at 5^h 30^m, or farther, as regards the seen distance; for it stood less far, and indeed less by 12 minutes. Therefore this comet was not below the Moon, but above it.*

[Margin: 1st reason for denying the certainty of the major premise.]

I reply: if the major premise is asserted as probable, it can be admitted; but if as certain and evident, it can be denied, for two reasons. *First*, because it supposes that the comet's proper motion toward the east, corresponding to three hours of the 23rd, was of 15 minutes, which is very uncertain. For this motion had to be extracted from the daily motion of November 23 compared with the motion of the 22nd or the 24th; but on the 22nd and the 24th the comet was not observed by Tycho, as he himself admits in the catalogue of observation, pages 3 and 5 — and perhaps on those days it had some irregularity unknown to us. And although from 6^h on the 21st to 6^h on the 25th the comet completed 8° 12′ on its own course, it does not follow that in one day, and that the 23rd, it completed exactly two degrees, as Tycho puts it on pages 86 and 107. For on that day it could have been much faster, and so in those three hours could have completed more than 15 minutes — so many more that by its speed toward the east it would have absorbed all that difference of distance from the mouth of Pegasus which would otherwise have appeared on account of a large parallax, greater than the Moon's.

[Margin: 2nd reason for denying the certainty of the major premise.]

Second, I say that this major assertion is not certain and evident, because Tycho's proofs of it, reported above from number 9 to number 15, rest on suppositions that are either erroneous or uncertain. They do so on account of many errors, each small taken singly, but which, heaped together by their number, could either have grown into a large error or at least have left uncertain and doubtful the conclusion derived from them.

[Margin: Tycho's errors in the foundation of his calculations.]

To make this plain, the certain errors, or strong suspicions of errors, must be reviewed one by one.

[Margin: 1st error.]

The *first* error was in the altitude of the equator at Uraniborg. Throughout volume 2, dealing with this and other comets, he uses 34° 7′ — especially on pages 109, 113, 135, 148, 152, 153, 154, and here and there elsewhere — but later, with larger instruments and more accurate observation, he found it to be 34° 5′

30″, or 5′ 20″, or 5′ 15″, as is clear from his volume 1, pages 28 and 218. Hence an error of a minute and a half.

[Margin: 2nd error.]

The *second* error was in the obliquity of the ecliptic, which in volume 2 he takes as 23° 27′, as he himself admits on page 74, when he investigates both the places of the fixed stars he used for investigating the comet's places, and the places of the comet. But later he arrived at 23° 31′ ½, as is established from his volume 1, pages 66, 70 and 90. Hence follows an error of 4′ ½ or 3′ ½, which in some places alters the longitude by nearly 10′.

[Margin: 3rd error.]

The *third* error was in the comet's distances taken with the radius and the old sextant. It is manifest from Tycho's own admission, in volume 2, pages 31 to 34, that their unreliability was later recognized, and yet that he did not correct these intervals, as we said in chapter 16, number 9.

[Margin: 4th error.]

The *fourth* error is in the angle of the ecliptic with the comet's path, and in the point of the ecliptic at which it cut the comet's path. He treated each as always the same and unvarying, although there was variation in both, as Chiaramonti demonstrated and Kepler conceded — variation, I say, of up to 55′ in the place of the point already mentioned, as we said at number 17.

[Margin: 5th error.]

The *fifth* error is in the comet's right ascension. On page 86 he puts it at 301° 3′ for 6^h on November 23, but on page 109 at 301° 5′ for $5½^h$, whereas the latter ought rather to have been smaller.

[Margin: 6th error.]

The *sixth* error is in the comet's distance from the mouth of Pegasus on November 23 at $5½^h$: on page 4 he puts it at 21° 8′, but on page 51 at 21° 5′.

[Margin: 7th error.]

The *seventh* error was the omission of refraction, whose use, he himself confesses in volume 2, on the reprinted leaves, page 31, was unknown to him when he was writing about this comet. Now to the seen altitude of the comet, which on the 23rd at $8^h\ 35^m$ was for Tycho 7° 48′, as he himself has it in volume 2, page 110, there corresponds a refraction of at least 11′ 33″ — as much as corresponds to the Sun at such an altitude, from volume 1 of Tycho, page 79, where the table of solar refractions is given; since, according to page 280 of the same volume, things nearer the Earth have a greater refraction, and the comet was then nearer the Earth than the Sun.

With all the errors already mentioned taken together, then, it is readily clear that in the end an error of 15 minutes and more could have been committed in the comet's distance from [?] the mouth of Pegasus. And since, as Tycho himself demands (as I said at number 17), the most exact precision is required in this business, and the dispute is over a retarded motion of 15′ — for if it had been retarded by 15′ or 16′, Tycho concedes that the comet would have been sublunary — it follows that the major premise built on this foundation is either

erroneous or uncertain. As for correcting the errors already mentioned: neither Tycho himself, out of weariness and because of the multitude of triangles to be solved, nor Kepler was willing to do it, although it was very much in their interest to do so; nor have we cared to, since we do not know how great an error was admitted in using the radius and the old sextant, and since we are always pressed by that uncertainty of the proper motion, which could have been swift enough to make good a very large parallax of the comet, or the effect of parallax.

Sextum Argumentum Tychonis, ex Diſtantijs Cometæ à Fixis in diuerſis Orbis terreni locis habitis, & Solutio eius expeditiſſima.

Tycho's sixth argument, from the distances of the comet from the fixed stars taken in different places of the terrestrial globe, and its most ready solution.

XXII. There follows Tycho's third proof (for he includes the first three arguments under the heading of one proof, the first), in volume 2, from page 123. There he takes the comet's distance from the bright star of the Vulture, observed on November 16 at 6^h after noon at Prague by Tadeáš Hájek with the aid of an astronomical radius, which was seen as 17° 52′; and to this he adds: *But we here, with a similar instrument, on the same day, about six in the evening, found 17° 50′ ½.* And he says that the comet, together with the bright star of the Vulture, was virtually under the same vertical circle common to Prague and Uraniborg, and that Prague is east of Uraniborg by a quarter of an hour; from which he tries to show that the comet was above the Moon — but in vain.

[Margin: Tycho guilty of violating astronomical good faith.]

For, *first*, Tycho invented a spurious observation of his own, so that he could compare it with Hájek's. For from the history of the observations of this comet, and from the complete catalogue of them that Tycho gives in volume 2, pages 2 to 13, it is plainly evident that he reports not only the more certain observations of distances, or those taken with the radius jointly with the sextant — even granting that in the preface he had promised only these, and that Kepler, in the *Hyperaspistes*, page 47, thinks that only these are recounted — but absolutely all of them, distinguishing the less exact ones, owing to passing clouds or impurity of the air, from the exact ones. You will see this done on pages 2 and 3 twice, on page 4 once, on page 5 three times, on page 7 twice, on page 9 twice, and on page 12 once; and I have already quoted his words in chapter 16, number 10. So too, on pages 4 and 9 he reports two observations taken with the radius alone. Then, in the same catalogue, page 3, after reporting the observation of November 15 at about 6^h, he adds: *On the following four days the air with us was filled with dense obscurity, which shut off the sight of the comet: the 18th being not only dark but also very foggy, and the 19th raging fiercely with storms of wind and rain; so the observation of the comet was put off until the 20th.* It is false, therefore, that the comet was observed by Tycho on the night following the 16th; and it is no less false that he observed it on November 24, the day on which it was observed by Hájek — even though Tycho, of doubtful good faith, shamefully

invented that observation in volume 1, page 127, in order to have a second little observation to compare with Hájek's, when he had nevertheless formerly said in the catalogue, page 5: *On the following day, the 24th, no clear sky shone on our horizon.*

[Margin: Tycho rightly condemned by Chiaramonti for a feigned observation.]

So Chiaramonti, in the *Antitycho*, Book 2, chapter 14, was entirely right to call these two observations into question and to hold them fictitious; and Kepler, in the *Hyperaspistes*, pages 45 to 47, could not cover up their falsity by any evasion whatever. Indeed, striving to protect one fiction with a new fiction — pretending that Tycho entered in the catalogue only the more certain and select observations — he deserved to be turned from Tycho's advocate into a defendant charged with violating astronomical good faith.

[Margin: Kepler protects Tycho's fiction with a new fiction.]

But let us grant that this observation was left out of the catalogue because it was even more uncertain than some uncertain ones: even from this it follows that whatever is deduced from it is uncertain, and by that very fiction the sinews of Tycho's argument are cut.

Secondly, even if we granted that Tycho observed the comet on November 16 and 24 (which we nonetheless flatly deny), the scheme he uses to demonstrate the comet's parallax is thoroughly faulty, as will be clear from what is to be said in Book 10, the penultimate section, chapter 11, number 5. There we shall show its faults, detected by Galileo and Chiaramonti, and confirmed not only by us but by Kepler's own admission. Here it is enough to say that Tycho, in a great circle of the Earth drawn through Uraniborg and Prague, draws the chord from Uraniborg to Prague, requires at its ends two parallel lines, each making a right angle with that chord, and then supposes that they fall perpendicularly on the convex surface of the Earth. This is both false in itself and, in the case proposed, at odds — by many degrees, not minutes — with the declination of the bright star of the Vulture that Tycho himself gives in his tables for that time.

[Margin: Tycho pays the penalty for violating astronomical good faith, and falls into a false figure.]

So, no doubt by the just judgement of God, he at once incurred this penalty of his lie as well: from a falsely feigned observation he slid into a false and distorted form of demonstration.

Septimum Argumentum Tychonis ex Diſtantijs Cometæ à Stellis Fixis, quas obſeruauit Cornelius Gemma, collatis cum diſtantijs ab ipſo Tychone obſeruatis.

Tycho's seventh argument, from the distances of the comet from the fixed stars observed by Cornelius Gemma, compared with the distances observed by Tycho himself.

XXIII. From Hájek's observations Tycho passes, in volume 2, page 131, to the observations of Cornelius Gemma made with the astronomical radius at

Louvain, whose polar altitude he takes as 50° 50′ from the universal astrolabe [Astrolabium catholicum] of Gemma Frisius, Cornelius's father. The comet's distances from the fixed stars observed by Cornelius on the same days as by Tycho are set out below.

Distances of the comet observed from the bright star of Aquila, or from the mouth of Pegasus, in the year 1577.

No.	November	Star	Tycho	Cornelius Gemma
1	16	Aquila	18° 0′	17° 50½′
2	21	Aquila	10° 34′	10° 40′
3	28	Pegasus	12° 40′	12° 45′
4	30	Pegasus	10° 20′	10° 25′
	December			
5	1	Pegasus	9° 14′	9° 15′
6	31	Pegasus	13° 48′	14° 0′

From their difference he tries to persuade us (for he offers no demonstration) that the comet was above the Moon: otherwise, he says, a greater difference would have appeared between his own distances and Cornelius's. But, *first*, it is false that the comet was observed by Tycho on November 16, as I have already shown at number 22 and in chapter 16, number 10. *Secondly*, Cornelius's distances were taken with the astronomical radius, that is, with a very deceptive instrument — so much so that Tycho says of the first observation: *He seems not to have taken account of the utmost exactness*; of the 2nd: *Something is lacking in the observation*; and of the 4th: *I judge that some error crept into this observation of Gemma's.* And of others, not reported here but found in Gemma, Tycho says on page 133: *For the intermediate distances in Gemma are less certain and do not agree with one another*; and on 134: *There were also some of Cornelius's observations that were not exact enough.* To what end, then, does he defend his opinion with such deceptive observations in a matter so exacting? *Thirdly*, Cornelius Gemma did not record the hour of observation: *which I greatly miss both in him and in Tadeáš Hájek, especially when the comet was swifter in its daily motion*, says Tycho on page 133. Yet if anything certain were to be gathered from this, the observations in both places ought to have been made at the same moment of time, or at least at similar hours, or else these should be derivable from a recorded hour of observation. Wrongly, therefore, did Tycho say on page 134, from these and from Hájek's observations: *It can be clearly established that this comet was far above the Moon and completed its course in the aether itself; which we proposed to demonstrate from distances taken in remote parts of the globe by different observers.*

Octauum Argumentum Tychonis, ex Azimuthis & Altitudinibus Cometæ Vraniburgi diuerſis horis obſeruatis.

Tycho's eighth argument, from the azimuths and altitudes of the comet observed at Uraniborg at different hours.

XXIV. Let the figure set out at number 9 be placed here again, for Tycho uses a similar one in volume 2, page 136.

[Margin: 1st step.]

First, he brings in the azimuths and altitudes of the comet that he observed, for a definite moment of the day, though at different hours of the same night.

[Margin: 2nd step.]

Secondly, from these azimuths, from the declinations of the comet that he found in chapter 4, and from the complement of the polar altitude, he seeks each altitude as seen, or visible. For in the first observation, when the comet appeared higher above the horizon, he uses the triangle ADB, in which are given AB, the complement of the polar altitude; BD, the complement of the declination; and the angle BAD, the complement of the observed azimuth. So by the laws of triangles he gathers AD, the complement of the altitude, whose complement to 90° is the altitude ID. In the same way, in the second observation, using the triangle AFB — with the arc AB given as above, BF the complement of the declination, and the angle FAB the complement of the observed azimuth — he seeks AF, and from it the comet's altitude KF; and finally the differences of the altitudes.

Diagram. Set into the right column beside the text of number XXIV: a semicircle standing on its diameter, with several arcs drawn from the top of the semicircle down to the base and two arcs crossing from the right-hand point on the circumference towards the left. Labels:

- A (top of the semicircle)
- B (on the circumference, upper right)
- M (on the circumference, upper left)
- D (inside the figure, below and left of A, where arcs cross)
- F (inside the figure, below D)
- E (inside the figure, left, below M)
- G (inside the figure, below E)
- H (left end of the diameter)
- I (on the diameter, left of centre)
- K (on the diameter, beside I)
- L (on the diameter, right of K)
- C (right end of the diameter)

EXEMPLVM TYCHONICVM.

Tycho's example.

On November 30 at $5^{h}\ 26^{m}$, the complement of the azimuth, DAB, observed by Tycho, was 143° 40′, and the complement of the declination DE, namely DB, was 82° 52′. From this, and from AB, 34° 7′, as the complement of the polar altitude, Tycho gathers the arc AD, 53° 49′, and the altitude ID, 36° 11′ — whereas he had observed that altitude at the time as 36° 10′. Again at $7^{h}\ 54^{m}$, when the comet was at F, the complement of the azimuth, that is the angle FAB, observed by Tycho, was 105° 50′, and the complement of the declination

GF, namely FB, was 82° 48′. From this, with the arc AB, 34° 7′, he gathers AF, 70° 58′, and the altitude KF, 19° 2′, which nevertheless he says was observed as 19° 4′. Therefore the difference between the observed altitudes was 17° 6′, but between the altitudes derived trigonometrically 17° 9′.

XXV. With these premises, Tycho argues on page 137 roughly as follows. At different hours, in different azimuths, the comet showed almost the same altitude as it would have shown if it had been at an immense distance from the Earth, or at one so great that the Earth's semidiameter compared with it was scarcely sensible; for the difference between the observed altitudes is 17° 6′, and between those derived by calculation 17° 9′, that is, differing by only three minutes. Therefore this comet was far above the Moon.

[Margin: 3rd step.]

This he tries to confirm by another step. For, *thirdly*, taking the least distance of the Moon as 52 semidiameters of the Earth, by exactly the same method we set out at number 10, he gathers from two seen altitudes of the comet the comet's parallaxes for those altitudes: from the earlier seen altitude, 36° 10′, a parallax of 53′ 22″, and from the later altitude, 19° 4′, a parallax of 62′ 30″; and so the true altitudes, as seen from the centre of the Earth, would have been 37° 3′ 20″ in the first case and 20° 6′ 30″ in the second. Hence the difference of the visible altitudes, had the comet been in the concave of the lunar heaven, would have been 17° 6′, but that of the true altitudes 16° 57′; and so the difference of the parallaxes of altitude would have been 9′ 8″, whereas from observation it was no more than 3′ — which, on page 139, he thinks almost negligible, or else to be attributed to refraction. By a similar method he tries to confirm the same thing from the observations of azimuths and altitudes of December 13 and of January 11.

Diſſoluitur Argumentum Octauum Tychonis.

Tycho's eighth argument refuted.

XXVI. Chiaramonti, in Book 2 of the *Antitycho*, chapter 14, set out at greater length and in another form Tycho's reasons, which we have reported under the heading of the eighth argument, and then refuted them in chapter 15 — and soundly. For (as I noticed at once on reading Tycho, and as anyone even moderately versed in optics and geometry will be able to notice) Tycho supposes that the altitudes derived trigonometrically from the azimuths, the complement of the polar altitude and the declinations are true, and correspond to the comet's true place. But this is plainly false. The declinations Tycho uses here are those he had derived in volume 2, chapter 4, from the comet's distances from the fixed stars, observed and seen with the radius and the sextant; and so the declinations derived from them are likewise seen, not true, and correspond to the comet's seen place; nor could he distinguish them from the true ones while the parallax was unknown. It is no wonder, then, if he found the trigonometrically derived altitudes to differ from the observed ones by only one minute or two; indeed, they ought to have differed from each other by

no minute at all; and much less ought the true altitude, as he supposed, to be exceeded by the seen one by 2′ — unless we have recourse to refraction, which at an altitude of 19° is about 6′. But I do not dwell on correcting these things and examining them minutely, because Tycho's calculations are built on an erroneous foundation: namely, an erroneous polar altitude, an erroneous obliquity of the ecliptic, distances taken with a deceptive instrument, and the other things discussed at number 21 — besides the fact that he admitted that the azimuths and altitudes he uses here are subject to some deception, as we shall show presently, towards the end of number 27.

[Margin: Kepler's fictions in protecting Tycho.]

It is wearisome now — indeed shameful — to report here the fictions and evasions with which Kepler, in the *Hyperaspistes*, page 55, labours to protect Tycho; nor can I wonder enough at how much he falsely attributes not only to Chiaramonti but to Tycho as well. One thing, however, I cannot pass over in silence, which he has on page 59. There he says that the comet's altitudes and declinations were not observed by Tycho at the same moment, for the altitudes were observed, one at $5^{h}\ 26^{m}$, the other at $7^{h}\ 54^{m}$: *Since the declination was observed at the 6th hour*, he says — adding that the declination was adjusted to those two moments of the altitudes by keeping to the proportion of the comet's motion. But it is false that the comet's declination was observed by Tycho. He did not yet have the equatorial armillae when he was observing the comet, since he says in volume 2, page 31, that at that time he had at Uraniborg nothing besides the radius and the sextant except the azimuthal quadrant; and in chapter 4 he derives the declinations from the comet's longitude and latitude, which in chapter 3 he had derived trigonometrically from the observed distances between the comet and the fixed stars. Nor does Tycho anywhere mention declinations of this comet observed by himself with any instrument. And those that he entered in the table on page 86, adjusted to the 6th hour from noon, are the very ones he had derived geometrically from the comet's observed distances from the fixed stars, as is clear from the preface before that table, which stands in volume 2, page 85. But let us grant that the declinations were observed: it follows, then, that they were seen, not true, and so the comet's altitudes gathered from them were seen, not true — which is what I contend, and Chiaramonti before me, rightly blunting Tycho's arguments on this point.

[Margin: Chiaramonti refutes Tycho partly rightly, partly not rightly.]

Yet Chiaramonti wrongly condemns Tycho, on page 201 of the *Antitycho*, for having extended the calculation beyond the parallaxes to the difference of the parallaxes and of the altitudes. For if Tycho had not erred in other respects, he would have skilfully compared with each other the differences of the parallaxes corresponding to the two altitudes — namely, the one that had resulted from the observations, and the one that would have resulted from a sublunary position of the comet — showing that the latter ought to have been greater; so that, since the observations exhibited the former as smaller, he would rightly have concluded, as far as this goes, that the comet was not sublunary.

For a smaller difference of parallaxes, derived from the same altitudes above the horizon, also shows smaller parallaxes and a greater distance from the Earth. It should be noted, however, from what will be said in Book 10, the penultimate section, chapter 8, proposition 7, that if one takes on the one hand the difference between two seen altitudes, and on the other the difference between the two true altitudes corresponding to those seen ones, or differing from them only by parallax, and then derives the difference of those two differences, this is equal to the difference of the two parallaxes by which, of course, the true altitudes differ from the seen.

Nonum Argumentum Tychonis ex Methodo Regiomontani ſuis obſervationibus accommodata, exponitur & expungitur.

Tycho's ninth argument, from the method of Regiomontanus adapted to his own observations, set out and struck down.

XXVII. Johannes Regiomontanus, in his little work on comets, had devised several problems for investigating the parallaxes of comets. All of them suppose that the comet either moves with no motion other than that of the primum mobile, or with a proper motion indeed, but one so regular that its hourly motion can be known from its daily motion by the golden rule of proportions, or can be neglected without notable error because of the shortness of the time, as is clear from what he says in Problems 2, 3 and 4. Tycho therefore chose Problem 2, and so, in volume 2, from page 145 to 158, he tries to raise this comet above the Moon on Regiomontanus's ladders. That problem rests on two observed altitudes with their azimuths, both before or both after noon, with the moment of each observation known, together with the declination and, finally, the polar altitude — a problem we shall set out more fully in Book 10, the penultimate section, chapter 10, problems 8 and 9, with the aid by which Tycho taught that it could be used as if the comet were carried only by the motion of the primum mobile. And since by this method he found the parallax of this comet to be either nil or insensible, he affirmed that it was carried beyond the Moon.

[Margin: 1st objection against Tycho.]

But Tycho's argument totters on two counts. *First*, it rests on the comet's proper motion, whose measure was known only by probable conjecture; on an erroneous polar altitude; on deceptive distances of the comet from the fixed stars, with a very sensible refraction neglected; and on seen declinations taken for true ones.

[Margin: 2nd objection.]

Secondly, it rests on altitudes, azimuths and moments of time which, unless they are most accurate, are enough to sniff out parallaxes in a rough way, but not those parallaxes whose slight difference can call the comet down from the heavens into the air, or call it up from the air into the heavens. Yet Tycho observed neither the altitudes of this comet, nor its azimuths, nor the moments of time as accurately as was needed. I shall show both points from Tycho

himself. For in volume 2, page 145, speaking of Regiomontanus's problem, he says: *By two altitudes taken before or after the meridian in different azimuths, with the time elapsed between those two observations also known, it makes each parallax in the circle of altitude known — a subtle and quite ingenious speculation indeed, but one that by no means deserves a place in those smaller parallaxes such as occur in the aether. For it builds the greatest things out of the smallest, so that an error of one or two minutes in the time, which can easily creep in, grows into an excessive deviation; and then too, unless the azimuths and altitudes are obtained so scrupulously that nothing is lacking, you will have wasted, as the saying goes, your oil and your labour.*

[Margin: The reckoning by azimuths with the moments of time is slippery.]

For a slip of a few barely sensible minutes in the time and in the other data easily brings about a departure of several degrees from the mark of truth. But since Regiomontanus, led by the arguments and authority of the Peripatetics, believed rather that comets were sublunary and were generated in the upper region of the air, where they would produce a parallax of many degrees, he did not hesitate to put this method forward, however little suited to practice in a subtler business, and useful at least for these larger parallaxes. And on pages 151 and 157 he twice admits, from experience of the calculation, which led him to it, that this way of Regiomontanus is *less suited to this business*; and so he halts and breaks off the calculation he had begun, seeing that what he had hoped for did not follow from it. And in volume 1, the *Progymnasmata*, page 604, hear what he wrote about this way of observing: *But since he examined these things mechanically on a certain bronze globe three feet in diameter, it was not possible to reach exact precision. In the very times, too, of the azimuths and altitudes taken (for at that time he proceeded by this all too slippery way of investigation), some slight discrepancy could sensibly alter the place of the star*; he is speaking there of the Landgrave's observations. Again, in the *Epistolae Astronomicae*, page 295, refuting the objections of a certain physician, he writes as follows: *He further infers that the comet's parallax should have been sought not from distances but only from altitudes and azimuths — both of which, however, we carried out. But even if he does not know it and is purblind to it, the method by distances, duly applied, is more certain than the one taken from altitudes and azimuths, in which a barely sensible error turns out to be very prolific: as these things are well known to you, who have handled them; and you know for certain how easily one errs in altitudes and azimuths, but not likewise in distances.*

Let this suffice for the first part of our assertion. For the second part, take an open admission from Tycho himself, who, after writing almost the whole of volume 2 on this and other comets, nevertheless inserted the following on folio 31 and the two following, which were reprinted: *When this comet shone, I had, besides the astronomical radius and the sextant — more convenient than the radius itself for measuring the intervals between stars — only a single quadrant, made skilfully of solid brass and finely subdivided by transversal points in our customary way; but it was not fully two cubits, and it turned standing on a steel azimuthal horizon no more than three cubits in diameter, and so it did not give a large enough size to the single minutes. Since, then, in the following years I had much larger and*

more precious astronomical instruments made, I did not trust that quadrant I was then using safely enough where a matter had to be handled very scrupulously; and so it has long since been retired by us in those observations that require the utmost precision. He repeats this on page 465; and on page 32 he admits that at that time he could scarcely obtain the moments of time by the clock precisely enough.

From this we may now turn the following syllogism back against Tycho himself. In investigating those parallaxes on which the solution of the question depends — whether the comet is below or above the Moon — the comet's altitudes, azimuths and moments of time must be observed so scrupulously that nothing is lacking in them, and exact precision must be applied; otherwise an error of a few minutes grows into a large error. But the altitudes, azimuths and moments of time that Tycho uses in applying Regiomontanus's problem were not observed in this way, but with instruments that did not attain the utmost precision, and of such a kind that it had to be retired because of its uncertainty. Therefore they are not so certain that a certain and evident conclusion about this comet's parallax can be drawn from them. Tycho's argument, then, stands sufficiently refuted.

[Margin: Another way in which Chiaramonti breaks Tycho's argument.]

XXVIII. Chiaramonti, however, in Book 2 of the *Antitycho*, chapter 17, met Tycho's argument in another way. By the force of refraction, which Tycho omitted in correcting the altitudes, he tries to break Tycho's argument and calculations — and certainly not without effect. For I note that Tycho, in reducing Regiomontanus's problem to practice, used on page 150 a seen altitude of 28° 56′ in the first observation and 12° 12′ in the second; that then, on page 151, having used the altitudes 33° 7′ and 19° 19′, he found from them and from the azimuths and moments of time no parallax, but rather a greater altitude of the comet in the second observation, when he ought to have found a smaller one; and that on page 155 he attributed this raising to refraction, whose effect he then knew after a fashion, but whose measure he did not yet know. Now, from Tycho himself, about 10′ of refraction are due to an altitude of 12°. Their omission could have introduced no small error into Tycho's computation.

But what does Kepler, Tycho's *Hyperaspistes*, say to this? From page 69 to 81, of course, he entangles himself and Tycho in many evasions, and concedes more to Chiaramonti and to us than one could have hoped.

[Margin: Kepler, by his very advocacy, harms Tycho's cause.]

For on page 72 he says that the ordinary refraction belonging, from Tycho's table, to an altitude of 12⅕° is 4⅖′. From this, and from the other things Tycho laid down, he continues the procedure in Regiomontanus's problem that Tycho had broken off, and by trigonometric calculation gathers, for the first altitude of the comet, 28° 56′, a parallax of 3° 50′, and for the second, which was 12⅕°, a parallax of 3° 54′. Then he adds: *I continued this procedure so that it might appear that what Tycho wrote of it is true, that the greatest things are built out of the smallest*; and a little later: *So not only does this demonstration have no place in the smallest parallaxes, as Tycho said; not even in the large ones, which Tycho*

was ready to concede to Regiomontanus, can any security be hoped for. In short, so great an agreement of the time interval with the azimuths cannot be hoped for from an observer's diligence that the two can be combined in the same demonstration, the one being derived from the other by reasoning, as the method of the demonstration requires. He therefore grants what we want: namely, that whatever Tycho deduced from that method of Regiomontanus, and from moments of time and azimuths that were not of the utmost exactness, is uncertain; or else that this comet's parallaxes, had Tycho's assumptions been sound, were greater than the Moon's, amounting as they do to several degrees.

As for the claim of the *Hyperaspistes*, on pages 72, 75 and 76, that from Tycho's table no more than 4⅖′ of refraction corresponds to 12⅕°: this would indeed be true if the refraction to be ascribed to the comet were the one appropriate to the fixed stars, as is clear from Tycho's table in volume 1 of the *Progymnasmata*, page 280; but it is false if the refraction to be attributed to it is the one appropriate to the Moon and the Sun. For from Tycho's tables in volume 1, pages 73 and 124, a refraction of about 12′ is due to 12⅕°. Moreover, to lower phenomena, other things being equal, a greater refraction is due, in Tycho's opinion (volume 1 of the *Progymnasmata*, page 280); and this comet, according to Tycho, volume 2, page 197, was lower than the Sun for many days; so a refraction no smaller than the Sun's must be granted to it. Now, if a refraction of 4⅕′ is granted, Kepler by his calculations from the rest of Tycho's data gathers a parallax of the comet of almost 4°; much more, then, would he have gathered had he applied a refraction of 12′. Hence in this part of the defence he harms Tycho's cause by his advocacy more than Chiaramonti would have wished. For one of these two follows: either the method of Regiomontanus that Tycho used to establish this comet's position above the Moon is most uncertain; or, if it is applied and Tycho's data are accepted, but with a correction for refraction of at least 4′ applied, the comet had a parallax of nearly 4° and was far below the Moon. Either of these overturns the foundations of Tycho's argument set out last.

Decimum Argumentum Tychonis ex Aliorum obſeruationibus ſumptum, eiuſque Solutio.

Tycho's tenth argument, taken from the observations of others, and its solution.

XXIX. Tycho had finished nine chapters of volume 2 in the year 1578, towards the end of whose January the comet ceased to be seen. Then, nine years later, when the leaves had already been printed, in reworking, that is, inserting a new leaf — the one we have from page 31 to 34 of volume 2 — he himself relates this: *What is contained in this second book I had written immediately after this comet's disappearance, nine years ago, except only the last chapter, in which, after more writings published by others on this very matter had come in, I made most things fuller. But what is contained both in the earlier book and in the following one was written by us not long ago, after the places of the stars had been restored more precisely with new instruments, and the polar altitude and the greatest declination had been more thoroughly explored.* And in chapter 10, page 268, he says: *As also the*

comet seen in the year 85 just past, etc. From this it appears that the last chapter, that is the 10th of volume 2, was written by Tycho long after the first 9, when he had become more learned — namely in the year 1586. So it is no wonder if he often mentions refraction in it, and seems to have known its determinate quantity. In chapter 10, moreover, he reports the observations and opinions of others about this comet that we are now discussing; yet nowhere in this chapter does he deduce the parallax of this comet from two observations made at different places on the Earth, by the means we shall teach in Book 10, the penultimate section, chapter 11, or by similar problems. Instead he uses the observations of others, made at a single place on the Earth, each set separately, in the same way as he had used his own observations made at Uraniborg to investigate the comet's parallax — because, I believe, he did not find two places on the Earth that had been under the same vertical circle as the comet and had observed it at the same moment of time. He begins, moreover, with the observations of Wilhelm, Landgrave of Hesse, which he considers the more exquisite.

Parallaxes Cometæ ex Lantgrauij obſeruationibus à Tychone inueſtigatæ.

The parallaxes of the comet investigated by Tycho from the Landgrave's observations.

XXX. Tycho's method is as follows. First, from page 217 on, he takes the moments of time, the altitudes and the azimuths of the comet observed by the Landgrave of Hesse; assuming the polar altitude at Kassel to be 51° 18′, the obliquity of the ecliptic 23° 31′, and a place of the Sun more correct than before, he gathers by the analysis of triangles the comet's declination, right ascension, latitude and longitude. Then he selects two seen longitudes of the comet on the same night at different hours and, from the analogy of the comet's proper motion, considers how much that motion was retarded by the force of parallax. This will be better understood by an example.

[Margin: An example of the parallax investigated.]

On November 16, at 4^h $59\frac{1}{2}^m$, the comet's seen altitude was 24°, and its seen place in ♑ 16° 20′; but at 7^h 16^m it was in 16° 35′ — that is, after 2¼ hours. On the 17th, at 24^h 36^m, its seen altitude was 25°, and its seen place ♑ 19° 21′. From this Tycho gathers a daily motion in longitude of 3° 1′. So in those 2¼ hours of the 16th that elapsed between the first and the last observation a motion of 17′ was due, yet the comet was not seen to advance more than 15′, namely from 16° 20′ to 16° 35′ of Capricorn. Therefore, says Tycho, the parallax that retarded the comet's proper motion was only 2′, whereas it would have been much greater if the comet had been in the concave of the lunar heaven. In this way, from four similar pairs of longitudes, he contends that the comet was above the Moon. Lastly, from azimuths, altitudes and moments of time observed by the Landgrave, he hunts for the parallaxes by Regiomontanus's problem, discussed in number 27, and finds them either insensible, or else some arcs that came out larger, although as parts they ought to have been smaller than their whole.

From this he confirms that neither were all the observations so accurate, nor is Regiomontanus's method useful for discerning very small parallaxes. Yet since he gathers from it insensible parallaxes, or an effect contrary to parallax — namely, the comet advanced at the lower altitude towards the vertex, when it ought to have been moved away by the parallax — he at least persists, on this ground, in his opinion that the seat of this comet was above the Moon.

[Margin: The non-evidence of Tycho's argument.]

XXXI. But the method just described, although it presents no small probability, is nevertheless not evident. For whatever was said against Regiomontanus's method in number 27 holds equally here, since it requires the utmost precision, so that nothing is lacking in the azimuths, altitudes and moments of time, as we made plain from Tycho himself in the same number 27. But such precision was not present in the Landgrave's observations, of which the same Tycho says, in volume 2, page 212: *Yet in these very observations a deviation of a few minutes could easily have occurred, especially since His Highness at that time was using instruments that were not so exact and corrected*; and on page 226: *It may indeed seem strange that the longitude from these observations, on some preceding days, came out everywhere somewhat greater than our findings, but is now, from this record, found to be smaller — which is an indication that these determinations of the azimuths and altitudes, or even of the time taken together with them, are not exact in every respect*; and on page 227: *It seems strange that, whereas the longitude from these observations, found earlier after the middle of our sixth hour, exceeded by only 10′, now, near the ninth hour, it comes out more than half a degree further off. This must be imputed to these less exquisite observations.* Whether, then, this is to be attributed to the fallacy of the observations or to the irregularity of the comet's motion, it is clear that the conclusions drawn from them labour under some uncertainty.

The earlier method too — by which Tycho, comparing longitudes of the same night with one another, hunts down how much the parallax retarded the comet's proper motion — besides resting on the observations already mentioned, which are not entirely exact, or at least not free of suspicion, also supposes that the comet's daily motion was not only regular but uniform, so that if it advanced 3° 1′ in one day, it follows that in 2¼ hours it advanced 17′. But if that motion, gathered from various observations, is weighed, either it is shown to be very inconstant and unequal, or the observations are found not to agree with one another. For, as Tycho admits on pages 219 and 220, the motion gathered from the altitudes and azimuths on November 27 from 4^h $59½^m$ to 7^h 16^m was 15′, and yet from 4^h 56^m to 7^h 16^m it was only 10′, when it ought to have been greater than 15′. And since in this second case Tycho admits that the comet's motion seems to have been retarded by 7′ because of parallax, if you add to these the 11′ of refraction that are due to an altitude of 8°, the whole parallax will come to 18′. But all these things are uncertain.

Mœſtlini, Gemmæ, & Rœslini Opiniones. de loco & Parallaxi Cometæ huius.

The opinions of Mästlin, Gemma and Röslin on the place and parallax of this comet.

[Margin: Mästlin's opinion.]

XXXII. What Michael Mästlin wrote about this comet in ten chapters, Tycho condensed into fewer, in volume 2, from page 245 to 288. Mästlin had pronounced, in chapter 3, that this comet was above the Moon, because its difference of parallax at different altitudes was barely sensible, especially on December 11. But that this was not demonstrated by Mästlin you will gather from the following: first, that he used places of the stars taken from the Prutenic table, which sometimes differ by a whole degree from the places corrected by Tycho, as Tycho himself testifies on page 261; second, that he considered the comet's motion in the circle of altitude, when it should have been considered in its own track, which was different from the vertical circle, as Tycho points out against him on page 251; and finally, because of the various disagreements between his observations and those of Tycho and of the Landgrave, which Tycho detects again and again. For, given these, his demonstrations remain uncertain.

[Margin: Cornelius Gemma's opinion.]

Tycho presents Cornelius Gemma's observations in volume 2, from page 288 to 305. Among them the most notable for our purpose is the comet's distance, taken with the radius, from the star in the hand of Antinous when it stood 22° 4′ high on November 20; this distance was seen almost unchanged when the comet was near its setting, and from this Gemma gathers that the parallax was small, and smaller than the Moon's. However, as Tycho says on page 291: *This is merely asserted, baldly, by Gemma himself, without any demonstration; nor is it expressly indicated how great a distance the comet had from that star near its setting, and the assignment of both the time and the altitude — the two things most required — is neglected as well.* Gemma, moreover, held that the comet moved in the orb of Mercury.

[Margin: Röslin's opinion.]

Lastly, among others who placed this comet above the Moon was Helisaeus Röslin, about whom Tycho has no little to say in volume 2, from page 306 to 316; for he too thought that this comet had its seat or course in the orb of Mercury. But anyone who reads through what Tycho reports about him will see that this was not shown by Röslin by a conclusive demonstration. For among other things Tycho says of Röslin on page 314: *But his placing the comet in the orb of ☿, acquiescing in the views of Cornelius Gemma, while he tries to prove from the analogy of its motion that this is consistent, lacks foundation: for Gemma's parallaxes are not exact, nor did he demonstrate them mathematically from certain observations, as he ought to have done, but simply asserted that they were so. And Röslin's own opinion, that this comet imitated the motion of ☿ as closely as possible in speed, slowness, stations and retrogradations, is utterly wide of the mark.* Finally, Tycho, about to report the opinion of both men, had said on page 288: *Since*

they do not treat the matter itself mathematically enough, I will be briefer and dwell on them less.

[Margin: Squarcialupi's opinion.]

Nor did Marcello Squarcialupi, as Tycho testifies on page 450, show by any demonstrations what he asserted: that comets move in the aether above the Moon.

Antonij Santutij Argumentum pro Cometæ huius loco ſupra Lunam.

The argument of Antonio Santucci for this comet's place above the Moon.

XXXIII. This comet, says Santucci in chapter 10 of *De Cometis*, was on November 11 in a southern parallel declining from the equator by 22° 20′, and on that day it stayed above the physical horizon for $8^h\ 56^m$; but to that parallel is due a stay of $8^h\ 56^m$ above the astronomical horizon; therefore it had no parallax, or else it was above Venus and about as far from the Earth as the Sun, since otherwise it could not have been seen for so many hours. The reply is, first, to deny that it was in such a parallel on that day, since Tycho says that its declination then was 18° 50′. Secondly, the argument from the visible stay to the distance from the Earth is not valid so long as the parallax is unknown, as we said in chapter 15, in Corollary 1 of Problems 7 and 8.

An Claramontius ex obſeruationibus Tychonis, Lantgrauij, Mœſtlini, Cornelij Gemmæ & Rœslini demonſtrarit Cometam Anni 1577. fuiſſe Sublunarem.

Whether Chiaramonti demonstrated, from the observations of Tycho, the Landgrave, Mästlin, Cornelius Gemma and Röslin, that the comet of the year 1577 was sublunar.

XXXIV. Chiaramonti certainly promised this in Book 3 of the *Antitycho*, pages 261 and 269, and affirms that he demonstrated it on pages 289, 319 and 321, and in the *Apologia* for the *Antitycho* from page 255. To this end, *first*, he himself candidly admits, in Book 3 of the *Antitycho*, chapter 3, that among the other problems he had proposed in Book 1 he chose Problem 1 of chapter 7, because he had newly devised it himself. The problem runs as follows: *Given the seen latitudes and longitudes of some phenomenon at the same time, and hence given the difference of the parallaxes relative to the ecliptic with respect to two places on the Earth differing in latitude alone, or in longitude alone, or in both, provided their difference is given, and given the point of the ecliptic then standing on the meridian: to investigate the parallax of the phenomenon in the vertical circle, or circle of altitude, appropriate to each place on the Earth.* This problem is solved by solving no fewer than 16 spherical triangles, which Scipione laboured through, most patiently, more than once; and we shall give a specimen of this most ingenious problem below, in chapter 19, numbers 11 and 12. *Secondly*, from the record of the Landgrave's observations, which Tycho reports in volume 2 from page 211, and from the observations of Tycho himself, he assumes: that in the year 1577, on the first day of December, at $6^h\ 45^m$ after noon at Kassel, the comet's azimuth was observed to be 59° 25′ and its seen altitude 31° 0′; that it was then $7^h\ 10^m$ at Uraniborg,

this place being more easterly than Kassel by 25^m of time; that therefore the two observations fell at the same moment of time; that the difference of the observed longitudes was 10′ 15″, and the difference of the seen latitudes 24′; and finally that the complement of the polar altitude is 34° 7′ at Uraniborg, as Tycho puts it throughout volume 2, and 38° 41′ at Kassel.

[Margin: The sum of Chiaramonti's calculation.]

Thirdly, from the data or assumptions just mentioned, after the analysis of 16 triangles, he concludes on page 289 that the comet, seen from Kassel, had a parallax of 12° 27′ 47″, and from Uraniborg one of 12° 29′ 38″. From this, and from the Earth's semidiameter of 3035 miles, he gathers on the following page the comet's distance from the centre of the Earth as 12,657 miles at Uraniborg, but 12,059 at Kassel.

XXXV. However, in the assumptions just mentioned, not everything seems to have been taken precisely from Tycho himself. For Tycho, in volume 2, page 87, gives for the first day of December the comet's seen longitude in Aquarius 16° 21′ and its northern latitude 24° 47′, and for December 2 longitude ♒ 17° 38′ and latitude 25° 6′, both for 6^h after noon. Hence, keeping the proportion, the longitude for $7^h\ 10^m$ on the 1st would have been 16° 24′ of Aquarius, and the latitude 24° 48′. Then Tycho, on page 224, from the Landgrave's observations of December 1, deduces for $6^h\ 34^m$ at Kassel a longitude of the comet in Aquarius of 16° 38′ and a latitude of 24° 20′, and for $7^h\ 49^m$ longitude ♒ 16° 49′ and latitude 24° 33′; hence at $6^h\ 45^m$ the longitude would have been ♒ 16° 40′ and the latitude 24° 22′. So, for Tycho, the difference of the longitudes was 16′ and that of the latitude 26′. Yet from these very figures Scipione could have gathered a very large parallax of altitude. Nor was the difference of the meridians, which Chiaramonti puts at 25^m in time, taken from Tycho: for Tycho, in the *Epistolae Astronomicae*, pages 58 and 72, puts the difference between Uraniborg and Kassel at 12^m or 13^m in time, or a fifth part of an hour — as much as both Longomontanus and Kepler in their catalogues, and we from eclipses, have gathered, although Wendelen thinks it is only 5^m. So, on Tycho's data, that observation was not made at the same moment in both places; it was adapted by Chiaramonti, from the proportion of the motions, to suit his calculation and the example of the problem he had devised. Moreover, if they had observed at the same moment, and the parallax had been so great, then at Kassel, the less northerly place, the comet would certainly have been seen more northerly than at Uraniborg, the more northerly place, since the parallax depresses the comet towards the horizon more with respect to Uraniborg than with respect to Kassel. But the opposite is found from the observations: the seen latitude was 24° 22′ at Kassel and 24° 48′ at Uraniborg. I pass over other points that Kepler, in the *Hyperaspistes* from page 129 to 136, objects against Chiaramonti — above all this one: that from the Landgrave's azimuths, altitudes and times neither correct places of the comet nor correct parallaxes are elicited.

[Margin: Chiaramonti's second example.]

XXXVI. But Chiaramonti, in Book 3 of the *Antitycho*, chapter 5, saw most shrewdly that the former example was not adequate for his purpose, because in it the comet's northern latitude was seen smaller at Kassel than at Uraniborg, when the opposite ought to have been seen. He therefore chose two other observations, of November 16: on that day at Kassel, at $7^h\ 16^m$, the seen longitude was ♍ 16° 35′ and the latitude 13° 59′; at Uraniborg it was then $7^h\ 41^m$, and the comet's seen longitude was then ♍ 16° 50′ and its latitude 13° 45′, as is gathered from Tycho's ephemeris and from the comet's daily motion in longitude laid down by Tycho himself. Accordingly, although Tycho did not observe at the same moment, his observation is nevertheless reduced to the same moment by keeping the proportion of the motion, in the way Tycho himself often uses. The difference was therefore 15′ in longitude and 14′ in latitude; and indeed the seen latitude was greater at Kassel than at Uraniborg, as the parallax in latitude required. From this difference of 15′ and 14′, then, repeating the calculation by the problem already mentioned, he gathers, correctly and without any error of calculation, a parallax of the comet of 7° 29′ in the circle of altitude with respect to Uraniborg, and a distance from the Earth of 24,276 miles; with respect to Kassel, the parallax is 7° 28′ 24″ and the distance 24,113 miles. But here too, in reducing the seen longitudes and latitudes to the same moment, Chiaramonti supposes a difference of time of 25^m between Kassel and Uraniborg; yet it is not greater than 13^m, from which there would follow, between the Landgrave and Tycho, a difference of longitude of only 8′ and of latitude of 7′. And yet even from this a parallax of altitude greater than the Moon's is gathered. But if the difference of the longitudes had been 15′ and of the latitude 14′, Chiaramonti's demonstration would hold.

[Margin: Mästlin's observation compared with Tycho's.]

XXXVII. Using, further, the same method and the same problem, Chiaramonti, in Book 3, chapter 8, gathers the difference of longitude and latitude from certain of Tycho's observations compared with Mästlin's and reduced to the same moment by keeping the analogy of the motion; and whenever he finds it equal to 15′ in longitude and 14′ in latitude, or greater, he at once asserts a parallax greater than 7° at the least, and a distance of the comet from the Earth not greater than 24,278 miles. For example, in chapter 8 Chiaramonti considers the observations of November 12, on which day Tycho, from Mästlin's data, in volume 2, page 261, though using corrected places of the fixed stars, deduces for 6^h the comet's place at 4° 2′ of Capricorn and its northern latitude at 6° 34′. But from Tycho's ephemeris, in volume 2, page 86, the comet's longitude for the 6th hour of that day is given in Capricorn 3° 27′ 20″ and its northern latitude 6° 56′, and so a difference of longitude of 35′ and of latitude of 22′. Tycho, however, reckons that the place where Mästlin observed lies further west than Uraniborg by the space of half an hour, a time to which, keeping the analogy of the motion as Tycho usually does, about 5′ correspond. So when it was $6\frac{1}{2}^h$ at Uraniborg, it was 6^h at Mästlin's place; or, when it was 6^h at Uraniborg,

it was 5½^{h} at Mästlin's place. In either case, it follows that the difference of longitude cannot be cut down by more than 5′, nor that of latitude by more than 2′. From these data, therefore, the difference of longitude was 30′ and that of latitude 20′. Therefore, says Chiaramonti, if a difference of only 15′ in longitude and 14′ in latitude between the Landgrave and Tycho yielded a parallax of either 12°, or at least 7°, how much more will a difference of 30′ in longitude and 20′ in latitude yield it — and so a distance from the Earth not greater than 24,278 miles? And how much more does this very thing follow if at some time the difference of the longitudes grew to as much as a degree and a half, as Tycho admits that it did? Moreover, to say that Mästlin's observations are imperfect because they disagree with Tycho's is not to use the observations as they lie, nor to keep to Chiaramonti's hypothesis: for he does not affirm that so great a nearness of the comet is demonstrated absolutely from them, but only if some observations of both men are accepted, however much they were corrected in some respect by Tycho.

[Margin: From this comparison a parallax of the comet greater than the Moon's is deduced.]

XXXVIII. If you have understood Chiaramonti's reasoning set out in the preceding number, you will easily understand also the reasoning by which, in Book 3 of the *Antitycho*, he gathers the difference of the longitudes and latitudes — in chapter 9 from the observations of Tycho and Cornelius Gemma, and in chapter 10 from those of Tycho and Röslin — and, wherever it is greater than 15′, confirms from this, not absolutely but on a hypothesis (that is, if those observations are accepted as they lie), that a parallax of the comet of more than 7° follows. Here, then, are the differences of longitude and latitude, from Tycho himself, volume 2, from page 290:

On November 16, the comet's longitude greater for Gemma than for Tycho by 40′, and the latitude by 20′.

On the 19th, the longitude smaller for Gemma than for Tycho by 1½°; the latitude greater by 15′.

On the 25th, the longitude smaller for Gemma than for Tycho by 2½°; the latitude likewise greater by 15′.

On the 26th and 27th, Gemma's longitude smaller than Tycho's by more than a degree, and the latitude greater by a whole degree.

On the 29th, the longitude smaller for Gemma than for Tycho by 1° 45′.

On the 30th, the longitude smaller for Gemma by 1° 33′, and the latitude greater by 1° 34′.

On the 30th, the longitude smaller for Röslin than for Tycho by 2°, and the latitude greater by 1° 30′.

On January 12, the comet's longitude smaller for Röslin than for Tycho by 4½°, and the latitude greater by almost as much, again for Röslin.

Nor is the difference between the meridians of Uraniborg, where Tycho observed, of Louvain, where Gemma observed, and of Zabern in Alsace, where Röslin observed, so great that, by reducing the observed longitudes and latitudes

to the same moment of time by the proportional part of the motion, a difference of longitude and latitude smaller than those 15′ could be obtained. Nor, again, is the difference in the polar altitudes so great that the demonstration which held for the Landgrave's observations compared with Tycho's would not hold for these as well. Nor can Tycho reject the analogy of the motion in longitude, since he himself uses it very often, and gathers by the proportional part, from the comet's daily motion, how much motion belongs to each hour.

[Margin: Kepler's reply insufficient.]

Nor, finally, does Kepler answer this sufficiently in the *Hyperaspistes*, page 138, by reproaching Chiaramonti for having fished out from the more imperfect observations of Mästlin and Gemma parallaxes of the comet greater than the Moon's, while leaving aside and passing over in silence the more perfect ones, from which Tycho elicited parallaxes smaller than the Moon's. For Chiaramonti does not proceed absolutely, but on a hypothesis — namely, if certain of their observations are accepted; just as he says in the *Apologia* for the *Antitycho*, in part 5 of the preface, that there are certain observations of Tycho and the Landgrave which, if they are accepted, show the comets of the years 1577 and 1580 to be sublunar, and certain others which show them to be above the Moon. Further, if it is not established on other grounds, rather than from an opinion already prejudged about the place of comets, whether observations are imperfect, they are not to be condemned merely because they disagree with Tycho's opinion and parallaxes. The rest that Chiaramonti says in Book 3, chapters 12 and 13, about the refraction of this comet, so as to increase the comet's total parallax, we pass over as less necessary for us and less certain. Let those who care to pursue these matters at greater length look into them.

Reliquæ Opiniones de Parallaxi & Loco huius Cometæ infra Lunam.

The remaining opinions on the parallax and place of this comet below the Moon.

XXXIX. Among the many who, from their own observations, hold that the comet of the year 1577 was sublunar, Tycho counts, in volume 2 of the *Progymnasmata*, page 318, Tadeáš Hájek ab Haych, who observed it at Prague and, at an altitude of 38°, assigned the comet a parallax of 5° and some minutes; but after seeing Mästlin's writings he changed his opinion and conceded that this comet was above the Moon, as Tycho relates on page 366.

[Margin: The parallaxes of this comet according to some.]

Bartholomäus Scultetus of Görlitz, by contrast, gave this comet a parallax of 5° 22′ at an altitude of 29°; Andreas Nolthius of Einbeck a parallax of 5° 32′ at an altitude of 33°; and Nikolaus Winckler, who observed at Schwäbisch Hall, assigned the same comet a parallax of 6° 50′ at an altitude of 46° — on the testimony of the same Tycho, page 318, who afterwards disapproved of them because of these authors' imperfect instruments, or other signs of imperfect observations. Finally, in volume 2, from page 449, he lists several others who placed this comet below the Moon without mathematical proof. Such were Johannes Praetorius, the astronomer of Nuremberg; Thomas Erastus; Simon

Grinaeus; Conrad Dasypodius of Strasbourg; Georg Henisch of Augsburg; Nicolaus Bazelius, a Batavian; Valentin Steinmetz of Gersbach, professor at Leipzig; Ioannes Huernius of Utrecht; Theodor Graminaeus of Cologne; and Georg Busch of Erfurt, a painter rather than a mathematician, who attributed to this comet a parallax of 2° 21′ and, from inexperience, thought that the seen azimuth differed from the true by as many degrees and minutes — whereas, however great the parallax of altitude may be, the true and the seen place of any phenomenon lie in the same vertical circle, and so in the same azimuth, as Tycho rightly points out on this occasion in volume 2, page 456.

Concluſiones ex dictis, ac Noſtra Opinio.

Conclusions from what has been said, and our own opinion.

Conclusion I. *Neither by Tycho nor by anyone else, so far as I know, has it so far been demonstrated absolutely that the comet of the year 1577 was above the Moon.* This is clear from what was said from number 1 to 34 — even though Magini, in his letter to Tycho, Froidmont, in Book 3 of the *Meteorologica*, chapter 1, article 1, and very many others believed that Tycho had demonstrated it, as did Cysat too, on page 33.

Conclusion II. *Yet, if some hypothesis is made and some observations are accepted, it is demonstrated that the comet of the year 1577 was above the Moon; while, if certain other observations are accepted, it is demonstrated that it was below the Moon.* The first part is established by the many arguments of Tycho already adduced above — namely, if it is admitted that the comet travelled along a great circle and, within a few hours of the same night, advanced with a proper motion uniform and proportional to the motion of one whole day, and that the observations of Tycho and the Landgrave, though made with smaller instruments and not emended by the correction for refraction, could not have produced a very sensible difference; which the more skilled astronomers will scarcely concede. The second part is certain from what was said from number 34 to 39 — namely, if certain other observations are accepted as they lie, or even as corrected by Tycho, and the comet's proper motion within a few hours is likewise accepted as uniform.

Conclusion III. *Although it is not improbable that the comet of the year 1577 was below the Moon, and indeed very near the Earth, though higher than the twilight vapours and exhalations, it is nevertheless more probable that it was above the Moon.*

That this comet was not lower but higher than the vapours and exhalations that make the twilight appears clearly enough, first from their altitude, which we showed in chapter 14 does not exceed 100 Italian miles and is indeed much less; and then from the altitude assigned to the comet even by those who pressed it down furthest below the Moon. For Chiaramonti, who of all of them strove most to bring it near the Earth, taking account of parallax and refraction, in Book 3 of the *Antitycho*, chapter 13, assigns to this comet, at an altitude of 4°, a parallax of 19° 35′ and a distance of 8333 or 9025 Italian miles, of which the Earth's semidiameter has 3035. Scultetus, on the other hand, as Tycho reports in

volume 2, page 409, says that it was 8047 miles and 1754 paces from the centre of the Earth; but he is speaking of German miles.

That it is not improbable that this comet was below the Moon is clear both from the hypothetical demonstrations discussed in Conclusion 2, and from the opinions of many authors discussed in number 39; these will keep their probability for as long as the opposite has not been absolutely demonstrated.

But that it is more probable that it was above the Moon follows not only from the authority of the most eminent mathematicians — such as Tycho, Mästlin, the Landgrave of Hesse with his men, Hájek, Cornelius Gemma and Röslin, besides those who held that all comets, or many, and this one among them, were celestial, whom I have already listed in chapter 6 — but above all from Tycho's arguments. These are so many, and established by so great a variety of confirmations, that they fall little short of exact mathematical demonstrations. For many of those arguments rest on the measure of the comet's proper motion decreasing in an orderly way, which is more probably granted than denied, since the way of gathering the quantity of that motion is very like the way in which, in the planets, the motion of the intermediate days is gathered from the motion of a few days.

CAPVTXIX.

Chapter 19.

De Cometarum reliquorum ab Anno 1577. ad Annum 1590. Parallaxi & Altitudine.

On the parallax and altitude of the remaining comets from the year 1577 to the year 1590.

I. In the year 1580, from the beginning of October to the middle of December, a comet was seen, as Tycho says in volume 2, page 267. Mästlin, Rothmann, Hájek and Röslin wrote about it, affirming that it was above the Moon, which Tycho, on that page 267, promises to demonstrate in volume 3 of the *Progymnasmata* [?]. Mästlin, indeed, did not hesitate to raise it as far as the sphere of Saturn, and Tycho, on page 442, even beyond the eighth sphere. Froidmont subscribed to these views in book 3 of the *Meteorologica*, chapter 1, article 1. But Chiaramonti opposes them in book 3 of the *Antitycho*, chapter 18, on account of the difference of 18′. About these minutes Tycho himself, in a letter to the Landgrave of Hesse dated 1592 February 20, old style — in which, on page 267 of my copy, these words of Tycho's stand — wrote: *I have written, moreover, to Your Highness's mathematician about those eighteen minutes that are everywhere lacking in the observations of the comet of 1580 communicated to me. For whenever this comet crossed the meridian, I found that exactly 18 minutes less than was right had been observed at Kassel, whereas my observations made at the same time always have just as many minutes more. From this I conjecture that such a defect was committed because the quadrant, through a fault of the plumb-line, was not correctly*

set by so many minutes. I also conferred about this matter with Rothmann while he was here, and demonstrated it by a comparison of your observations and mine.

Chiaramonti, however, both above and in the *Apologia* for the *Antitycho*, pages 279 and 289, thinks it improbable that an error of so many minutes was committed by the Landgrave's mathematician, since elsewhere, in the *Epistolae Astronomicae*, page 39, Tycho wrote that the error due to the plumb-line was one or two minutes in the Landgrave's observations. Instead he judges that the discrepancy came from parallax, because of which the comet was seen to stand farther from the vertex of Kassel than Tycho would otherwise have it; and from this he draws out a parallax much greater than the Moon's. To do so he takes from Tycho that this comet was hidden from a great part of Germany in the lower part of the meridian, and from this he gathers that it could not have been less than 81° from the vertex of Uraniborg. Otherwise — if less, or indeed if it had been only 81° away — then, subtracting 34° 7′, that is, the complement of the pole's altitude at Uraniborg, from 81°, there remain 46° 53′, that is,

the comet's distance from the pole, which is the geographical latitude at which Germany begins. But if the comet had been 86° from the vertex of Uraniborg, it would not have been visible at Kassel, which lies 4° 34′ farther south than Uraniborg; for with these added to the 86°, the comet's meridian distance from the vertex of Kassel would come to 90° 34′, and so, unless the refraction had been enormous, it would then have lain hidden below the horizon. He therefore assumes what is, as it were, an intermediate distance between 81 and 86, namely 84, so that from this it may appear what is to be judged of the intermediate distances.

Problema Claramontij.

Chiaramonti's problem.

[Margin: Step 1.]

II. With these assumptions: first, in the following figure, let the place of Kassel be at A and that of Uraniborg at I, through which let the vertical lines TAR and TIQ be drawn from the centre of the Earth, and let those places be joined by the chord AI. Let the comet be at L, and through it let the lines of the seen place, ALP and ILO, be drawn, and also the line of the true place, TLM. For the seen place of the comet at Kassel will be P, and at Uraniborg O, but its true place M; hence the parallax at Kassel will be the arc PM, which the angle ALT measures, and at Uraniborg the arc OM, which the angle TLI measures; hence the difference of these angles, that is, the angle ALI, will be the difference of the parallaxes. Now let the Earth's semidiameter AT be given, which Chiaramonti assumes

Diagram. A woodcut set in the right column: a large semicircle on the base S–T–Z, a concentric middle arc from V to X, and a full small circle about T (the Earth) reaching down to u; a horizontal H–T–N across the small circle; a vertical from T up to R; straight lines from T and from points on the small circle out to the arcs.

- R (top of the outer semicircle, on the vertical from T)
- D. (on the outer arc, just right of R; printed with a following dot)
- D (on the outer arc, farther right)
- Q (upper left of the outer arc)
- M, O, P (left of the outer arc, from top to bottom)
- L (on the middle arc, left)
- A (above T, near the centre)
- G, C (right of A, on the inner lines and middle arc)
- E, F (right of the outer arc)
- m (small letter at the right end of a horizontal line)
- I, B (on the small circle, left and right of the vertical)
- H, N (ends of the horizontal across the small circle)
- S, V, T, Z, X (along the base, from left to right; Z is a Z-shaped sort with a descending tail)
- u (small letter at the foot of the small circle)

to be 3035 Italian miles. Let this be, under another ratio of parts, the whole sine, or radius, of 100,000 parts. Let the arc AI be 4° 34′, the amount of the difference in the pole's altitude between Uraniborg and Kassel, and its chord 7968 of the parts of which AT is 100,000; therefore, of the parts of which AT is 3035, AI is 241 miles — a figure to be kept in reserve.

[Margin: Step 2.]

Second, let the comet's seen distance from the vertex of Uraniborg, that is, the angle LIQ, be 84°. The angle ATI, moreover, is 4° 34′ in the isosceles triangle ATI; therefore the sum of the angles at the base, by I.32 of Euclid, is 175° 26′, and each angle separately, namely TAI as well as TIA, is 87° 43′, by I.5. Hence the adjacent angle, by I.13 — namely IAR, as also QIA — will be 92° 17′. Adding, then, QIA and LIQ, the whole angle LIA comes to 176° 17′. Now let the difference of the parallaxes, that is, the angle ALI, be given as 17′. For in the triangle AIL, from the two angles AIL and ALI and the side AI of 241 miles, the comet's distance from the Earth's surface, that is, IL, is gathered by the rules of triangles to be 2921 Italian miles.

[Margin: Step 3.]

Third, in the triangle TIL there are given TI, 3035 miles, IL, 2921, and the angle TIL, 96°; for it is the supplement of the angle LIQ to two right angles. Therefore, by solving this triangle, the distance TL is found to be 4452 miles, and the parallax with respect to Uraniborg, namely the angle TLI, 42° 59′; adding to this ILA, 17′, the parallax TLA with respect to Kassel comes to 43° 16′.

[Margin: Chiaramonti's ingenuity in hunting down parallaxes.]

III. But since that difference in the comet's distance from the vertex of Kassel could have appeared greater than it should because of some larger error in the observation, and the difference of the parallaxes might not reach 18′ or 17′, and the comet's seen distance from the vertex might be some other value between 81° and 86°, what did the most ingenious Chiaramonti do? He assumes a

difference of the parallaxes, that is, an angle ALI, of at least one minute, or even half a minute, and a seen distance from the vertex now of 84°, now of 86°, and by the same method described in number 2, with calculations that are truly exact and checked by me, he gathers the distance of the comet from the Earth, and the parallaxes belonging to Uraniborg and to Kassel. I have decided to bring all of these together into a single synopsis; you should not be surprised if it lacks things that are not found worked out in the author himself.

Given: difference of the parallaxes	Given: seen distance of the comet from the vertex of Uraniborg	Resulting distance of the comet from the centre of the Earth, less, in Italian miles	Parallax of altitude: at Uraniborg	Parallax of altitude: at Kassel
17′	84°	4452	42° 59′	43° 16′
17′	86°		64° 43′	65° 0′
1′	84°	56696		
1′	86°	27691		
½′	84°	89554		
½′	86°	54368		

But who would not grant that the difference of the parallaxes, free of refraction, was at least half a minute? Therefore, from the observations of the Landgrave and of Tycho, if they are taken as they stand in the authors and are not corrected on the presumed opinion that comets are to be carried up into the heaven, it follows that this comet was below the Moon — not in the sphere of Saturn or of the fixed stars — and was not more than three semidiameters of the Earth away from the Earth. Tycho, moreover, could not spurn the Landgrave's observations made in 1580, since he had already accepted the observations of 1577 and had tried to confirm his opinion from them, as we said in the preceding chapter.

[Margin: Kepler substitutes insults for replies.]

But Kepler, in the *Hyperaspistes*, from page 165 to 171, leaves this problem untouched and unexamined; he meets Chiaramonti with nothing but insults and his usual subterfuges, and looks down on him as "trampled underfoot", as he himself puts it. This is quite undeserved: such a thing was not to be expected from an astronomer, let alone from a Christian man — a thing that Ptolemy, pagan though he was, would certainly not have dared. Kepler erred, moreover, in holding that the comet was seen towards the south; for if that were so, it would have been seen in Italy, where it was nevertheless not seen, as is gathered from Santucci, who by order of Cosimo, Grand Duke of Tuscany — as is clear from his dedicatory letter to Cosimo II — observed and described the comets of these years, and makes no mention of this one.

De Cometa Anni 1582.

On the comet of the year 1582.

IV. Kepler mentions this comet in the *Phisiologia Cometarum*, saying that it turned retrograde at the beginning of Sagittarius and nearer the ecliptic; but

he has nothing about its seat or its parallax. Antonio Santucci, in chapter 13 of his work on comets, says that it rose about the beginning of March and ceased to be seen around the middle of April. Now on March 10 the comet's stay above the natural horizon of Rome was observed to be $14^h\ 10^m$, when it was in a northern parallel declining 17° from the equinoctial. For the Sun, which was in ♓ 20°, set at $5^h\ 48^m$ after noon, while the comet was on the meridian at $2^h\ 50^m$ after noon and set at $9^h\ 55^m$; its semidiurnal arc was therefore $7^h\ 5^m$, and its diurnal arc $14^h\ 10^m$. In that parallel, moreover, the Sun's true diurnal arc is $14^h\ 10^m$, so that there was no sensible difference between the true and the apparent diurnal arc. Since this is so, Santucci concludes that the comet was above the Moon, and at least in the sphere of the Sun.

But Chiaramonti, in the supplement to the *Antitycho*, part 2, chapter 16, says that Santucci could not have observed the comet's arrival at the meridian, because the Sun was then above the horizon, and that this was invented from Santucci's own hypothesis and imagination. Next, he says that with the parallax unknown, the true parallel in which the comet stood cannot be known from its seen stay above the horizon; and with that parallel unknown, the comet's distance from the Earth cannot be demonstrated from that stay. That this is true you will learn from what was said in chapter 15, problems 7 and 8, corollary 1. So it has not yet been demonstrated to me that this comet was above the Moon, although that is not without probability, if what Santucci relates is true.

De Cometa Anni 1585.

On the comet of the year 1585.

[Margin: The opinion of Tycho and of Rothmann on the parallax of this comet.]

V. Tycho treats this comet in volume 2, chapter 10, where on page 268 he has this: *Just as the comet seen in the year '85, just past, clearly testified the same thing; for by my most accurate observations it was found to admit a parallax of scarcely one minute; as also the mathematician of the most illustrious Prince Wilhelm, Landgrave of Hesse, Christoph Rothmann, a most learned man and excellently skilled in astronomical matters, demonstrated from its apparent motion that this comet had no parallax at all.* But he treats this very matter at greater length in the *Epistolae Astronomicae*, from which we shall select what bears on our subject. Thus on page 4 he reports these words from a letter of the Landgrave, written at Rotenburg to Tycho, 1585 October 20, old style: *Our mathematician Christoph Rothmann has recently written to us that on the 8th of this month, at 9^h in the evening, he observed the comet in ♓ 23° 15′ with a southern latitude of 14° 0′, and on the 9th of the same month in ♓ 25° 50′ with a southern latitude of 13° 6′. We ourselves noted it yesterday, the 19th, in the evening — observed not with any instrument but only by straight lines on our globe — and found it in ♈ 21° with a latitude of 4° south. It is small, and hairy on every side, so that we judge it to be of the kind of comets they call circaean [circæos], which usually appear at the time of the greatest conjunctions. What it portends, especially since it is Saturnine and conjoined with Saturn, time will tell.*

[Margin: A circaean comet, and Saturn conjoined.]

To this Tycho replies, on page 6, that because of clouds and storms he could observe this comet only ten days after Rothmann, that is, from October 18. He narrates his observations at length from page 13 to page 20; in them he records the comet as observed on October 18, 20 and 22, and on November 4, 5, 6, 7, 9 and 12. Of the remaining days he says: *The sky was so covered with clouds that the comet could not be observed with any instruments during all that time* — granted that he wove the continuous ephemeris I mentioned in chapter 3 out of conjecture from the other days.

He affirms, moreover, that its motion was along a great circle, though with its inclination to the ecliptic varying by 45′ from beginning to end, and that it decreased regularly; and he adds: *So that from the 18th to the 19th, about the time of the first observation we made, it was 2° 18′; and on the following days it became successively slower, so that from the 4th to the 5th of November it advanced only 53½′, and from the 12th to the 13th of the same month only 34′.* From this he gathers that it was not a fiery meteor generated in the elementary region, but in the heaven. This, however, he tries to confirm with stronger arguments taken from parallax, which are as follows.

[Margin: Tycho's first argument.]

VI. From October 18 at $10^h\ 15^m$ to $13^h\ 30^m$, that is, over 3¼ hours, the comet's apparent motion along its own path is gathered, from its observed declinations and right ascensions, to have been 17½′. *If with this*, says Tycho, *one compares the daily course — found from some definite position until, after one revolution of the primum mobile, it returns to a like one (for parallax, if there were any, introduces no difference from the true motion in this way) — that course is found, taking account of the observations made on the two following days, to be 2° 18′. Therefore, according to this daily motion, the comet ought truly to have advanced 18⅔′ in the stated interval of time, the motion by the apparent observation falling short by not much more than a single minute, by which, at least, the parallax anticipated the true course.* But if the comet had been in the concave of the lunar heaven, Tycho says likewise, at a distance from the Earth of only 52 semidiameters of the Earth and 17′, it would have induced a parallax of 27′ in its proper motion, and between the first observation and the second there would have been a difference of almost 26′, which could have been perceived even with a very small instrument.

[Margin: Tycho's second argument.]

In the same way, on October 22, from $13^h\ 15^m$ to $16^h\ 10^m$, that is, over $2^h\ 55^m$, the comet advanced along its [?] arc by 12¾′, from the declinations and right ascensions observed; whereas, at the rate of its daily motion, which was 1° 53′, it ought in the meantime to have completed 13⅚′. And so here too the apparent motion differs from the true motion by not much more than a single minute; but if the comet had been near the confines of the Moon, it would have produced a far greater discrepancy in its motion.

[Margin: Tycho's third argument.]

Again, on November 5, observing in the same way, from $7^h\ 50^m$ to 13^h

30^m, the comet was found to have covered 11⅓′ along its own path in the space of 5^h 40^m, whereas with respect to its daily motion (which, by comparison with the following day, was 50′) it ought in the meantime to have covered 11⅚′. The observed motion thus fell short of the true motion by only half a minute, and so the parallax turns out almost insensible. But if the comet had been in the concave of the Moon, it would have had a parallax in its proper motion of 47⅔′, as is clear from the computation of triangles.

[Margin: Tycho's fourth argument.]

But also, on the 6th, from 6^h 5^m to 14^h 55^m, that is, over 8^h 50^m, the comet's apparent motion along its path was 16½′; but its daily motion was 46′, so that in 8^h 50^m it ought to have been 16′ 56″. Hence, on account of parallax, the apparent motion fell short of the true by not even half a minute; and yet over so long an interval of time, if the comet had been in the concave of the Moon, it would have had a parallax of 1° 1′ — a discrepancy that could have been detected without instruments, by sight alone, against the neighbouring fixed stars.

[Margin: The suspicion of refraction is removed.]

And lest anyone say that the parallax was diminished by refraction, he says that on October 18 the comet was 37½° high at the earlier observation and 31⅙° at the later; on November 5, 39¾° high at the earlier observation and 48⅓° at the later; and on the 6th, 26° high at the earlier observation and 38° at the later — altitudes at which there is almost no refraction.

[Margin: Tycho's fifth argument.]

Finally, he says that this comet, observed at different hours in a higher and a lower position, kept the same distance from Capella, towards which it was directing its course, with no other difference besides the one its daily motion required. From this, on page 18, he concludes that this comet was in the highest aether, above the Sun, or not much below it. He was greatly confirmed in this opinion by the agreement of his own observations with the Hessian ones obtained by Rothmann, and by the opinion of Rothmann himself and of Prince Wilhelm, who said that no parallax, or an insensible one, had been detected in this comet, as Tycho testifies in the *Epistolae Astronomicae*, pages 37, 57 and 58. There, however, he admits that in the longitude of this comet there was at times a discrepancy of 6′ between himself and Rothmann, and of 2′ in latitude, which he thinks arose from uncorrected places of the fixed stars. It is no wonder, then, that Froidmont, subscribing to Tycho and Rothmann in book 3 of the *Meteorologica*, chapter 1, articles 1 and 2, taught that the comet of 1585 was above the Moon.

Solutio Argumentorum Tychonicorum ex Claramontio, & Kepleri Reſponſio.

The solution of Tycho's arguments, from Chiaramonti, and Kepler's reply.

VII. I have reported the arguments and their foundations from Tycho himself; you will find them set out afterwards, in a somewhat different form and more briefly, by Chiaramonti in book 2 of the *Antitycho*, chapter 21, and their solution

in chapter 22. There, first, he denies that the comet's motion was along a great circle, since, as Tycho himself grants, it changed its inclination to the ecliptic by almost a whole degree. Second, he denies that the motion was exquisitely regular. Third, he points out that Tycho calls the daily motion true, although it was only the seen motion, deduced from observations, and with the parallax unknown could not be distinguished from the true motion; and since the comet's motion was not along a vertical circle, it is wrongly denied that any sensible difference between the true and the seen daily motion arises from parallax. Fourth, he affirms that a great refraction could have occurred even at an altitude of 31°; for in book 3, chapter 13, he promises to demonstrate that the comet of 1577 suffered at Kassel a refraction of 11° 7′ at an altitude of 31° — which, however, he shows not absolutely but on a hypothesis. Fifth, he denies that from the persisting equality of the comet's distance from Capella, observed at different hours of the same night, an evident argument is gathered for no parallax, or an insensible one; for in book 1 of the *Antitycho*, chapter 10, he says he has demonstrated that a case occurs in which a phenomenon has a large parallax and yet this is tempered from another source, by reason of the angles; and he notes there, on pages 93 and 233, that this very case occurred in this comet. Sixth, he denies that from the agreement between Tycho and Rothmann, with no difference exceeding one minute, it follows that the comet lacked parallax; for he had demonstrated, in book 2, chapter 20, pages 223 and 227, that there are many cases in which two observers differ by a single minute in the seen place of a phenomenon even though it has a large parallax — which we too shall show in Book 10, the penultimate section, chapter 11, numbers 11 and 12.

Kepler, however, in the *Hyperaspistes*, from page 106 to 112, replies that in a comet a motion along a great circle is not to be required more exquisitely than in the Moon, nor a motion regular according to a continuous proportion in its increase or decrease, since not even the motion of the planets is regular in this way, and yet it is considered ordered and worthy of the heaven. Next, he replies that although the termini of the seen and the true place differ, the spaces lying between the true places are equal to the spaces lying between the seen places, because after exactly 24 hours the same position and the same parallax return; and so the true daily motion is rightly gathered from the seen one, from the comet's return to the same position after 24 hours. Afterwards he says that Chiaramonti's propositions — by which he tries to demonstrate that a phenomenon, notwithstanding a large parallax, can keep the same visible distance from the same fixed star at different hours — are wrapped in darkness, partly through the fault of the printer, partly of the engraver, partly of the author. He does not, however, deny Chiaramonti's demonstration, but says that it is not rightly applied to this comet, because from the ephemeris of its motions and from inspection of the globe alone it is clear enough that Capella was always nearer the vertex than the comet, especially in the western quadrant

of the world; and so, if the comet had had a quite sensible parallax, its seen distance from Capella would have become ever greater and greater.

[Margin: Kepler convicted of falsity by Chiaramonti.]

Yet Kepler demonstrates nothing but is content with bare assertions, and for that reason he is deservedly reproached by Chiaramonti in the *Apologia* for the *Antitycho*, from page 204 to 212, where Chiaramonti convicts certain propositions of Kepler's of falsity — and does so by bringing geometrical demonstrations, as any geometer reading Chiaramonti will easily see.

Noſtra Opinio de Argumentis Tychonicis.

Our opinion on Tycho's arguments.

VIII. For my part, I see that not a few objections can be made to Tycho which render the conclusion about the comet's place uncertain. First, in the first and second arguments, the comet's proper and daily motion — from the 18th to the 19th 2° 18′, and from the 22nd to the 23rd 1° 53′ — is posited not from observation on the 19th and the 23rd, but only from observation on the 18th, 20th and 22nd. For Tycho affirms in the *Epistolae Astronomicae*, page 14, that he observed the comet on these days only (speaking of October), and that on the others it went unobserved because of clouds. Hence, when he says on page 18 that the comet's motion was gathered *taking account of the observations made on the two following days*, this must be understood of the 20th and the 22nd, lest Tycho be accused of falsehood. Nor, again, is any observation set down there from October 22 to November 4, because, as is said on page 14, through the 13 whole days that elapsed no observation could be made with instruments for lack of clear weather. Since, then, he found the motion from the 18th to the 20th to be 4° 29′, from the 20th to the 22nd 4° 3′, and from the 18th to the 22nd 8° 32′, he concluded that from the 18th to the 19th it was 2° 18′ — probably enough, but not evidently. For from the 18th to the 19th the comet could have been faster and covered almost three degrees, and then, having become slower from the 19th and 20th, covered a degree and a half, so that from the 18th to the 20th it completed 4° 29′. The motion from the 22nd to the 23rd is much less evident still; for what happened from October 22 to November 4 is not established by any observation, and from the 22nd to the 23rd the comet could have completed more than 1° 53′.

Second, as I have already said in chapter 17, number 5, proposition 19: from the fact that a phenomenon observed from a single place on the Earth at different seen altitudes appears to undergo a smaller difference of altitudes or of parallaxes than the Moon would undergo at the same altitudes, it is not evident that it has a parallax smaller than the Moon's. The reason is that the comet could, by reason of its motion in height, or in longitude, or in latitude, or of a mixture of all of these, be presented in such a position that the whole, or almost the whole, parallax was compensated by motion in the contrary direction. It would therefore be necessary either that the true motion be known beforehand, separately from the seen motion, or that the parallax be known;

but in a phenomenon whose revolutions do not recur, and which never passes through the vertex, this cannot be known from the seen motion through observations made at the same place on the Earth, as I said in the same chapter 17, number 5, propositions 20 and 21. Third, besides what Chiaramonti has demonstrated, I shall show in Book 10, the penultimate section, chapter 9, theorem 16, that from the equal distance of a phenomenon from the same fixed star, seen at different hours of the same night, the absence of a sensible parallax is not evidently inferred (through observations, that is, made at one place on the Earth). Therefore, although Tycho's arguments are very probable, they have not yet removed all misgiving, nor have they reached mathematical evidence.

Argumenta Rothmanni pro Cometa Anni 1585. eorumque Solutiones.

Rothmann's arguments for the comet of 1585, and their solutions.

IX. What Rothmann thought about the almost insensible parallax of this comet we have already learned from Tycho's letters, in number 5. But Rothmann himself published his opinion in writing, together with his observations, and it was published with Snel's dissertation. In the first chapter Rothmann treats the history of the observations; in the second chapter, the comet's longitude and latitude; in the third, its parallax. Chiaramonti, by more exact calculations and diagrams, detected his various errors in geometrical calculation, as well as his disagreements with Tycho, in the supplement to the *Antitycho*, part 2, from chapter 20 to 24, and proved himself to us the better geometer, as will be plainly clear to anyone who considers his demonstrations. He also refuted, and excellently, the method by which Rothmann boasted of having demonstrated the insensibility of the parallax from observations of the comet near the nonagesimal degree of the ecliptic from the horizon.

[Margin: Chiaramonti a better geometer than Rothmann.]

[Margin: Summary of Rothmann's argument.]

Rothmann's argument, drawn together in brief, was of this kind. "On October 21, at 9^h after noon," says Rothmann, "I observed the comet in 25° 27′ 40″ of Aries, with the 20th degree of Cancer rising; the comet was therefore only 5° 27′ 40″ from the nonagesimal. Again, the same night, at 15^h 6^m after noon, I observed the comet in 25° 56′ of Aries. Then, the following night, because vapours were in the way, I could not observe the comet near the nonagesimal; but I did observe it when it reached the same western altitude at which it had been the night before, namely at 15^h 6^m, and I found it in Aries, at degree 27° 43′." *Subtracting the preceding observation from this one, there remains the comet's true daily motion*, 1° 47′. Hence, for the 6^h 6^m that elapsed between the earlier and the later observation of the 21st, 27′ 12″ are due, keeping the proportion. Added to the place found near the nonagesimal, namely 25° 27′ 40″ of Aries, these give the comet's true place at the later observation as 25° 54′ 52″ of Aries. But by observation the comet's apparent place was found at 25° 56′, greater by about one minute. Yet if it had had a sensible parallax, the apparent place ought rather to have been smaller; for at 15^h 6^m the comet was in the

western quadrant of the ecliptic, where parallax diminishes the true longitude. This, in summary, is Rothmann's argument, which he tries to confirm by another, similar observation near the nonagesimal. He affirms that in both observations the comet, because of its nearness to the nonagesimal, lacked a sensible parallax in longitude.

[Margin: First refutation of Rothmann's argument.]

X. In the preceding argumentation, however, a manifold fallacy lies hidden. First, Rothmann himself, in that chapter 3, holds this view: *Without separating out the parallaxes, the true motion can in no way be established.* How, then, from comparing the places observed at $15^h\ 6^m$ on the 21st and the 22nd — which were certainly seen places, being found by observing — does he gather the true motion, so as to discern from it, compared with the seen motion, the parallax previously unknown? Is this not to contradict himself, or to seek the unknown through the unknown?

[Margin: Second refutation.]

Second, the insensibility of the parallax in longitude is not rightly concluded from a distance from the nonagesimal of less than 6 degrees. For if the parallax of altitude were 15° or 14°, the parallax of longitude could, at the polar altitude of Kassel, be greater than 69 minutes, as Chiaramonti demonstrates in the supplement already mentioned, part 2, chapter 24, problem 4. So long, then, as the parallax of altitude is unknown, the insensibility of the parallax in longitude cannot be concluded from a few degrees of distance of the comet from the nonagesimal, and consequently the true motion cannot be distinguished from the seen motion on the strength of such a position.

[Margin: Third refutation.]

Third, even if, as to longitude, it would have had no sensible parallax had it been in the ecliptic, this nevertheless holds of the comet's own arc, which was different from the ecliptic and inclined to it at an inconstant angle, as Rothmann himself admits in chapter 2.

[Margin: Fourth refutation.]

Fourth, the longitudes of this comet observed on November 4 at the same hours of the same nights, at Kassel by Rothmann and at Uraniborg by Tycho, differ so much that from the difference of longitude there follows a parallax of many degrees in the circle of altitude, as Chiaramonti showed above, in chapters 20 and 23. For, from Tycho's letters, page 15: on November 4, at $7^h\ 5^m$, the comet was seen by Tycho in 13° 12⅔′ of Taurus, and at $10^h\ 35^m$ it was seen in 13° 16⅓′ of Taurus. Therefore, keeping the analogy of motion that Tycho and Rorhmann [?] frequently use, with the motion due for a few hours, the place seen by Tycho at $7^h\ 37^m$ was 13° 13′ 13″ of Taurus. But at that same hour, $7^h\ 37^m$, Rothmann observed it in 15° 20′ 49″ of Taurus. The difference of longitude is therefore 2° 7′ 36″, if they had been under the same meridian. But since Chiaramonti holds that Uraniborg is east of Kassel by 25 minutes of an hour, then, taking account of the comet's motion in longitude due for

these 25 minutes, the difference of longitude will have been 2° 8′ 9″; or, if we put Uraniborg east of Kassel, with Tycho, by only a fifth part of an hour, as he often supposes in the letters, that difference was 2° 7′ 50″. The latitude observed at that time was 6° 18′ 26″ for Tyhco [?] and 6° 18′ 49″ for Rothmann, to the north. Now from this difference of the observed longitudes it follows that this comet had a parallax of altitude not less than 15 degrees, as Chiaramonti demonstrates in the supplement already mentioned, with calculations — and by no means erroneous ones — supposing, however, certain things: namely, that on November 4 of the year 1585, Old Style, at 7^{h} 37^{m}, the Sun was at Kassel very nearly in 21° 3′ of Scorpio; that on the meridian of Kassel the 10th degree of Pisces culminated, but on that of Uraniborg degree 11° 47′ of Pisces, because the 25 minutes of an hour by which he puts Uraniborg further east correspond to 1° 40′ on the equator, and the right ascension at Uraniborg was greater by so much; that the complement of the polar altitude is 37° 4′ at Uraniborg and 38° 41′ at Kassel; and that the distance between the poles of the equator and of the ecliptic is 23° 30′. But since the problem is very ingenious, I have decided to insert it here in clearer words.

Problema Claramontij.

Chiaramonti's problem.

Given the latitude and longitude of a phenomenon observed at the same moment at two places on the Earth whose polar altitude and distance between meridians are known, and given the moment of the observation, the point of the ecliptic culminating on each meridian, and the obliquity of the ecliptic: to find the parallax of altitude.

[Margin: Construction of the diagram.]

XI. In the following diagram, let AHPKL be the solstitial colure, in which A is the pole of the equator and H that of the ecliptic, from which the arc of the ecliptic PML is described. Let AC be a portion of the meridian of Uraniborg, in which the vertex of the place is B; and let AO be a portion of the meridian of Kassel, in which the vertex is X, and the culminating point of the ecliptic is O with respect to Kassel, but C with respect to Uraniborg. Let the beginning of Capricorn be at P, and of Cancer at L. Let the comet's ecliptic place observed at Uraniborg be at Q, marked off by the latitude quadrant HQ; but let the place observed at Kassel be S (because it was greater), marked off by the quadrant HS; on these quadrants let the seen northern latitude be IQ as observed by Tycho, and RS as observed by Rothmann. Let the comet's place seen by Tycho be I, and that seen by Rothmann R. Finally, from the vertices of the places let arcs of altitude be drawn through the seen places, namely BI and XR. These will necessarily intersect at F, since B is further east than X, and conversely S, the comet's ecliptic place seen from X, was further east, and Q, seen from B, further west. Therefore the comet's true place was F, by Lemma 1 of book 1 of *De tribus novis stellis*, chapter 27, demonstrated by the same Chiaramonti. And this is easily seen: because the true place of a phenomenon is always at some point of the vertical circle on which the seen place lies, and at one and the

same moment it is single, it follows that if at the same moment two different observers observe a phenomenon, the vertical cir- cles of each have one point in common, in which the true place lies; and this is none other than the point in which they intersect. The parallax of altitude, therefore, will be FI with respect to place B, and FR with respect to place X.

Diagram. The figure for Chiaramonti's problem, set in the left column. A large circle, the solstitial colure AHPKL, with H (the pole of the ecliptic) at the top and K at the bottom; A (the pole of the equator) on the circumference to the upper right. The arc of the ecliptic runs across the lower half of the circle from P at the left to L at the right, with O, C, M, N, Q and S marked along it from left to right. Arcs descend from H through X and B towards the ecliptic, and arcs from A descend to the left; the lines cross at F, inside the circle, below X and B. R stands above S, and a small I just above and to the left of Q.

- H (top of the circle): pole of the ecliptic
- A (upper right, on the circle): pole of the equator
- X (left of centre, inside): vertex of Kassel
- B (right of X): vertex of Uraniborg
- F (below B): the comet's true place, where the arcs of altitude intersect
- R (right, above S): the comet's place seen by Rothmann
- I (just above and left of Q): the comet's place seen by Tycho
- P (left, on the circle): beginning of Capricorn
- L (right, on the circle): beginning of Cancer
- O (on the ecliptic, left): culminating point for Kassel
- C (on the ecliptic, right of O): culminating point for Uraniborg
- M (on the ecliptic, bottom): foot of the arc HXM
- N (on the ecliptic, right of M): foot of the arc HBN
- Q (on the ecliptic): the comet's ecliptic place observed at Uraniborg
- S (on the ecliptic, right of Q): the comet's ecliptic place observed at Kassel
- K (bottom of the circle): a point of the colure AHPKL

Further, let the seen places be joined by the arc IR, and from the pole of the ecliptic H, through the vertices B and X, let the arcs HBN and HXM be drawn down to the ecliptic. With these laid down, we shall arrive in several steps at knowledge of the parallaxes FI and FR.

[Margin: Step 1.]

First, in the triangle HIR, the complements of the seen latitudes, HI and HR, are given, and the angle IHR, which is the difference of the seen longitudes. In it, therefore, seek both the arc IR and the angles HRI and HIR.

[Margin: Step 2.]

Second, in the triangle ABH, there are given AH, the distance of the poles, or the obliquity of the ecliptic; AB, the complement of the polar altitude of place B; and the angle HAB, which measures on the equator the difference of right ascension between the beginning of Capricorn and the culminating point of the ecliptic, C. In that triangle, therefore, find the arc HB and the angle AHB, the measure of the arc NL. From this subtract the arc of the ecliptic QL

— since L is the beginning of Cancer, and Q the point of the ecliptic known from the comet's longitude as seen by observer B — for there will then remain known the angle BHI and the arc of the ecliptic NQ.

[Margin: Step 3.]

Third, in the triangle BHI, from what has just been said, there are now given the side HB, the angle BHI, and HI, the complement of the latitude seen by observer B. Seek, therefore, the arc BI and the angle HIB; add this to the angle HIR, and the angle FIR will result.

[Margin: Step 4.]

Fourth, in the triangle AXH, there are given AH, the distance of the poles; AX, the complement of the polar altitude of place X; and the angle HAX, which is the difference of right ascension between the beginning of Capricorn, P, and the point O of the ecliptic culminating on the meridian of place X. In that triangle, therefore, find both the arc HX and the angle AHX, the measure of the arc ML. From this subtract the arc of the ecliptic SL, and there will remain MS, that is, the angle XHR.

[Margin: Step 5.]

Fifth, then, in the triangle XHR, from the arc HX and the angle XHR just found, and HR, the complement of the latitude seen at place X, find the arc RX and the angle HRX. Take this from the angle HRI, found by step 1, and the angle FRI will remain known.

[Margin: Step 6.]

Sixth and finally, in the triangle FIR, with the side IR now known by step 1, the angle FIR by step 3, and the angle FRI by step 5, find the arc FI, or the parallax of altitude with respect to place B, and the arc FR, that is, the parallax of altitude with respect to place X. Which was to be done.

EXEMPLVM Calculi Claramontani

Example of Chiaramonti's calculation.

	Value
XII. Q, longitude seen from B	♉ 13° 13′ 13″
S, longitude seen from X	♉ 15° 20′ 49″
QS, difference of longitude	0ˢ 2° 7′ 36″
QI, latitude seen from B	0ˢ 6° 18′ 26″
SR, latitude seen from X	0ˢ 6° 18′ 49″
HI, complement of latitude	0ˢ 83° 41′ 34″
HR, complement of latitude	0ˢ 83° 41′ 11″

[Margin: Data for step 1.]

	Value
Therefore the arc IR	0ˢ 2° 7′ 23″
And the angle HRI	0ˢ 90° 9′ 18″

	Value
And the angle HIR	0ˢ 89° 38′ 31″
AH, distance of the poles	0ˢ 23° 30′ 0″
AB, complement of the polar altitude	0ˢ 34° 7′ 0″
Right ascension of the beginning of ♎, P	0ˢ 270° 0′ 0″
C is the culminating point	♓ 11° 47′ 0″
Its right ascension is	0ˢ 343° 13′ 0″
Difference of the right ascensions, or BAH	0ˢ 73° 13′ 0″
Therefore the arc HB	0ˢ 34° 32′ 0″
And the angle AHB, or NL	0ˢ 71° 19′ 0″
But at L is the beginning of ♋	
Therefore the point N is	♈ 18° 41′ 0″
And Q is	♉ 13° 13′ 13″
Therefore NQ, or the angle BHI	0ˢ 24° 32′ 13″
And there are given HB	0ˢ 34° 32′ 0″
And the arc HI	0ˢ 83° 41′ 34″
Therefore the arc BI	0ˢ 52° 55′ 0″
And the angle HIB	0ˢ 17° 10′ 0″
But the angle HIR was	0ˢ 89° 38′ 31″
Therefore the angle FIR	0ˢ 106° 48′ 31″
Again AH, distance of the poles	0ˢ 23° 30′ 0″
AX, complement of the polar altitude	0ˢ 38° 41′ 0″
Right ascension of the beginning of ♎, P	0ˢ 270° 0′ 0″
O, culminating point of the ecliptic	♓ 10° 0′ 0″
Its right ascension is	0ˢ 341° 33′ 0″
Difference of the right ascensions, or HAX	0ˢ 71° 33′ 0″
Therefore the arc HX	0ˢ 37° 22′ 0″
And the angle AHX, or ML	0ˢ 77° 39′ 0″
But at L is the beginning of ♋	
Therefore the point M is	♈ 12° 21′ 0″
But S was	♉ 15° 20′ 49″
Therefore MS, or the angle XHR	0ˢ 32° 59′ 49″
But there are given HX	0ˢ 37° 22′ 0″
And the arc HR	0ˢ 83° 41′ 11″
Therefore the arc XR	0ˢ 53° 36′ 0″
And the angle HRX	0ˢ 24° 14′ 0″
But HRI was	0ˢ 90° 9′ 18″
Therefore XRI, or FRI	0ˢ 65° 55′ 18″
But FIR was	0ˢ 106° 48′ 31″
And the arc IR	0ˢ 2° 7′ 23″
THEREFORE the parallax FR	0ˢ 15° 47′ 51″
And the parallax FI	0ˢ 15° 3′ 0″

[Margin: The comet's distance from the Earth.]

XIII. With the parallaxes of altitude of the comet of 1585 now obtained — 15° 3′ as seen at Uraniborg and 15° 47′ 51″ at Kassel — the distance of the comet from the centre of the Earth is easily gathered, by the problem set out in book 3, chapter 7, number 3: 9324 miles from the former parallax and 8973 from the latter, provided that the Earth's semidiameter is, as Chiaramonti assumes, 3035 Italian miles. Hence the distance did not reach 4 semidiameters of the Earth, and the comet was far below the Moon, let alone below Saturn — if, that is, those observations of Tycho and Rothmann are accepted. For Tycho is accustomed, when he thinks they support him, to accept and commend the observations of the Landgrave and of Rothmann, and to disregard a difference of a few minutes between them and his own, as is clear from Tycho's letters, pages 37 and 38. Now the complement of the polar altitude at Kassel, as corrected in Tycho's letters, page 39, is 38° 41′, and at Uraniborg 34° 7′, or 34° 5′ 30″. And although the distance between the meridians is not 25 minutes of an hour, as Chiaramonti puts it, but 13, yet from these values the parallaxes FI and FR will still always come out at very nearly 15°; and there is no danger about its always being greater than 2 degrees, which is enough for it to be greater than any lunar parallax. Granted, then, that from other observations, whether taken separately or comparing Tycho's with Rothmann's, the parallax of this comet would be gathered to be smaller than the Moon's, while yet from others it is gathered to be greater, we are still uncertain which we ought rather to prefer; and consequently it has not yet been evidently demonstrated from these that this comet was either above or below the Moon, but only that on one hypothesis it was above the Moon, and on another below it.

Concluſiones ex Prædictis Deductæ.

Conclusions drawn from what has been said.

I. CONCLUSION. *It has not yet been demonstrated, so far as I know, that the comets of the years 1580, 1582 and 1585 were either above or below the Moon.*

This is clear from what has been said in [?] 1 to 13. For since each of the two opposites has been demonstrated on some hypothesis, but not absolutely, and it is not evidently established which hypothesis is to be preferred to the other, neither remains absolutely demonstrated. This I say of the comets of 1580 and 1585. For as to the comet of 1582, although it has not been demonstrated to have been above the Moon except on some uncertain hypothesis, it has nevertheless not been demonstrated on the other hypothesis, so far as I know, that it was below the Moon.

II. CONCLUSION. *It is nevertheless very probable that the comet of 1585 was above the Moon, and not improbable of the rest.*

For there are many more arguments of Tycho and Rothmann — besides the authority of very many who have subscribed to them — by which it is made persuasive that it was above the Moon; and the same is gathered from comparing several observations; and the measure of the proper motion gathered by Tycho, which measure is one of the principal foundations of his own arguments and of Rothmann's, is very probable.

CAPVT XX.

Chapter 20.

De Cometarum ab Anno 1590. ad Annum 1600. Parallaxi & Altitudine.

On the parallax and altitude of the comets from the year 1590 to the year 1600.

I. In the year of the Lord 1590 Tycho began to observe a certain comet, from the day[17] of February until March 6. It began from the northern Fish, at longitude 18° 27′ of Aries and northern latitude 18° 14′, and ceased to be seen on March 6 at longitude 3° 15′ of Gemini and northern latitude 20° 46′. Its motion was quicker at the beginning, since it then completed almost 8 degrees in its daily motion. The tail was at first thin but long, 10 degrees, directed opposite the Sun towards the zenith; the head at first barely 3′. Tycho wrote about it in the *Epistolae Astronomicae*, pages 173 and 174, but more fully from page 176 to 181, where he says that it described a great circle which, if produced as far as the equator, would have cut it at degree 339° 45′, with a constant inclination to it of 42°; from this intersection it was distant about 37 degrees when it first appeared to Tycho, and almost 80° at the end. We have already given its ephemeris, from Tycho himself, in chapter 3, for this year. From the observations of the 12 days he selects those made on March 1 and 2, on which the comet moved about the pole of the world without setting, and from them he tried to derive the parallaxes by a twofold experiment, or argument.

[Margin: Tycho's argument for the insensible parallax of this comet.]

First, on March 1, at 7^h 19^m after noon, the comet appeared 47° 35′ high, and its azimuth was distant from the meridian by almost 92 degrees; and then, with the ten-foot armillary [Armillam Decempedalem], its distance from the pole was taken as 51° 22½′, or its declination as 38° 37½′. Then, at 15^h 25^m, when it passed the meridian below the pole, its seen altitude, with refraction subtracted, was 4° 49½′; subtracted from the polar altitude of Uraniborg, 55° 54¾′, this leaves its distance from the pole of the world as 51° 5¼′. So in 8^h 6^m it approached the pole by 17′. On March 2, when it again appeared 47° 35′ high, at 7^h 34^m, he observed its declination as 39° 22′ and its distance from the pole as 50° 37½′. Its seen declination therefore increased in $24¼^h$ by 45 minutes; and so, if this motion had been uniform, 15 minutes would be due

[17]no numeral is printed

for 8^h 6^m. But since this change was greater at the beginning of the day than at the end, it is nearer the truth that 17′ are due for those first 8^h 6^m. The true change of declination was therefore as great as the seen one, and no other change of declination was seen after so many hours than that which the comet's own proper motion required. Therefore the parallax was nil, or insensible, and so this comet completed its course in the highest aether. But had it been on the border of the Moon, and distant from the Earth by at least 52° 15′, it ought to have been seen, at its lowest altitude, distant from the pole of the world by 15′ more than when it was 47° 35′ high; and that difference anyone would have observed with any instrument, however crude. And he confirms this very point from another, similar observation. He adds, on page 180, that he attributed to this comet the same refraction as to the fixed stars. Many, moreover, subscribed to Tycho's opinion, especially Froidmont, *Meteorologica* book 3, chapter 1, article 1, and placed this comet far above the Moon.

[Margin: Froidmont's opinion on the place of this comet.]

II. But the *Antitycho* — that is, Chiaramonti, book 2, reporting Tycho's arguments in chapter 23 and refuting them in chapter 24 — stands against Tycho.

[Margin: Chiaramonti's first objection against Tycho.]

First, he says that a refraction equal to that of the fixed stars ought not to have been attributed to this comet, since it is certain from Tycho himself and from the laws of optics that things nearer the Earth undergo a greater refraction; and, with the parallax unknown, it cannot be known whether this comet was as distant from the Earth as the fixed stars, for to suppose that would be to suppose the very point in dispute. The refraction could, moreover, have been great enough to correct that parallax of declination of 15′, which is sufficient to place the comet beneath the concave of the Moon, and indeed even a greater parallax; but that it was not so great cannot be known as long as the parallax is unknown.

[Margin: Second objection, Chiaramonti's and ours.]

Second, he denies that the regularity or measure of the motion estimated by Tycho is certain. And I add that this motion, taken from the observations, was the seen and not the true motion, and that by reason of its proper motion the comet could have been so presented as to keep apparently the same distance from the pole of the world, or to change its seen declination by only 17′ after 8^h 6^m, even though it had a large parallax; and that this cannot be known certainly and evidently as long as the parallax, or the true motion, is unknown.

[Margin: Chiaramonti's third objection.]

Third, he points out that one must not, in Tycho's manner, confuse the difference of the parallaxes of declination with the parallax of declination; and that at a great nearness to the Earth, such as this comet's was when it stood 4° 49′ high on the meridian, a large parallax of altitude can be gathered from a small difference of parallaxes. Therefore, although Tycho's argument carries

great likelihood, it does not yet seem to me to have attained mathematical evidence.

De Cometa Anni 1593. & 1596.

On the comet of 1593 and 1596.

III. Further, about the comet of 1590 and 1593 — and indeed not even about those of 1580 and 1585 — Antonio Santucci has nothing; and yet he observed, by order of Cosimo II, Grand Duke of Tuscany, as many comets as he could. This is a sign either that they were very low, towards the centre of the Earth, as Chiaramonti judges in the *Apologia* for the *Antitycho*, page 292; or that they were within the circle of perpetual occultation with respect to Tuscany; or that, because of cloudy nights, they could not be watched by Santucci. But it does not follow determinately that they could not be seen in Italy because of excessive nearness to the Earth. Therefore neither from this nor from anywhere else has Chiaramonti or anyone else, so far as I know, demonstrated that the comet of 1590, or of 1593, or of 1596 was below the Moon — just as no one has demonstrated that it was above the Moon; or, if anyone has tried to demonstrate it, his writings have not yet reached my hands. Granted that Froidmont, *Meteorologica* book 3, chapter 1, article 1, drew from Tycho — from where, I do not know — that the comet of 1593 was above the Moon.

[Margin: Froidmont's opinion on the comets of 1590 and 1593.]

An Cometa Anni 1597.

Whether the comet of 1597.

IV. Antonio Santucci, in his treatise on comets, from chapter 16, relates that in the year 1597 a comet appeared from July 16 to August 9, that it was observed by him diligently, and that at first it had a declination of 50° 30′. To show that it was in the heaven of the Sun, he adduces the following figure, in which, from D, the centre of the Earth, he describes the Earth's quadrant AP, and the quadrant of the heaven XE. Having drawn DE, the rational horizon, and AF, the natural horizon, and the vertical line DAX, perpendicular to the horizontal lines, he draws the straight line DG, cutting off the arc EG of 4 degrees — as large as he says the comet's least meridian altitude, observed on July 16, was. He further draws the straight line DK, cutting off the arc KX of 7 degrees, because he says the comet's highest altitude observed on the meridian was 83°. He then bisects the arc KG at S, and draws the straight line DS as though it were the axis of the world. Again, he takes the arc FH as 4 degrees, and draws to H the straight line AH, cutting DS at the point C; from this point he draws the straight line CL, parallel to the straight line DK. Then, taking DM as the Moon's least distance from the centre of the Earth, which for Ptolemy is 33⅓ semidiameters of the Earth, he describes the arc MO, cutting the straight line CL at B; and through the point B he draws the straight line ABN, and supposes the altitude of the pole at Florence to be 43° 30′. With these laid down, he tries to demonstrate that the comet, had it been so near the Earth, would have had

to be seen under N, since it would then have been on the line CL; and that, if it were placed in the lunar orb, for example at L, the arc KL would be 1° 58′, so that the comet would have appeared raised 81° 2′, and not 83° as was observed; whereas if it were in the sphere of Mercury it would have appeared 81° 58′ high, in the sphere of Venus 82° 33′, but in the sphere of the Sun 82° 57′; and hence that it was at least as high as the Sun.

Diagram. Santucci's construction for the comet of 1597, set in the left column beside the opening of paragraph V. A quadrant with its centre D at the lower left corner: the base DE runs to the right, the vertical DX rises at the left, and the arc of the heaven runs from X at the top through K, L, S, N, H, G and F down to E. A stands on the vertical between M above and D below; a second, smaller arc runs from M down through B to O on the base, with P on the base between D and O. Straight lines radiate from D and from A to points on the outer arc; a small lower-case c marks an intersection to the right of A and below B.

- X (top of the vertical): the end of the quadrant of the heaven XE
- K (on the outer arc, just right of X)
- L (on the outer arc, right of K)
- S (on the outer arc)
- N (on the outer arc, just right of S)
- H (on the outer arc, right side)
- G (on the outer arc, below H)
- F (on the outer arc, below G)
- E (right end of the base)
- M (on the vertical, upper)
- A (on the vertical, below M)
- D (lower left corner, the centre of the Earth)
- B (on the inner arc MO)
- c (lower case, at an intersection right of A)
- P (on the base, between D and O)
- O (on the base, where the inner arc ends)

V. But Chiaramonti, in book 2 of *De novis stellis*, chapter 5, and in the Supplement to the *Antitycho*, page 2, chapter 17, detected many errors in this method. First, the comet could not have been on the line CL, but on the line DK, for this is the line of the true place — granted that LC is drawn parallel to it. Second, the line of the seen place is not to be drawn from A to some point of the line CL, but to a point of the line DK: so that if the comet is at K, the line AK should have been drawn. Hence the comet's parallax will be the angle AKD, and not the arc KL; which is the third error. Fourth, the angle of 7 degrees of the observed distance from the vertex is not, as Santucci puts it, the angle XDK, but XAK, since the comet was seen with the instrument at the surface of the Earth; just as the angle of the least observed altitude is HAF, not GDE. Consequently the arc KH lay between the seen places of the comet, not between the true places — unless these are supposed to differ insensibly from

the true ones, which is, however, under dispute. Hence, once the arc KH is bisected at S, it is not rightly supposed that K and H are equally distant from the pole of the world, or that DS is the axis of the world. Finally, it is false that the comet could not have been seen 7° from the vertex, or 83° high, had it been at a smaller distance from the centre of the Earth than the Sun; for it could have been seen on the line AK however near the Earth it was, the angle XAK always remaining the same, of 7 degrees. But I am ashamed to detain the learned reader any longer with false demonstrations [Pſeudogramatiſmis] of this kind.

[Margin: Santucci's various errors, excised by Chiaramonti.]

VI. Further, I have so far found the place of no other comet, from this year 1597 to 1600, demonstrated. The present chapter is therefore to be concluded, in our usual manner, with the following theses.

Concluſiones ex Prædictis.

Conclusions from what has been said.

I. CONCLUSION. *It has not yet been demonstrated, so far as I know, that the comets of the years 1590, 1593, 1596 and 1597 were either above or below the Moon.*

II. CONCLUSION. *It is nevertheless probable that the comet of the year 1590, at least, was above the Moon.* This I concede to Tycho's authority and arguments, since it is probable that the motion by which that comet changed its declination was such as Tycho laid down, and that the refraction at an altitude of about 5° was not much greater than the solar refraction, which there is 14′, and was insufficient for inferring a parallax greater than the Moon's.

CAPVT XXI.

Chapter 21.

De Cometa Anni 1607.

On the comet of the year 1607.

I. Observations of this comet made by themselves are reported by Kepler, book 1 of *De cometis*, from page 25 to 36; by Longomontanus [?] in the Appendix to the *Astronomia Danica*, chapter 9; and by Antonio Santucci, *De cometis*, chapter 21. I have already presented the ephemeris of the comet's motion, from Kepler and Longomontanus, in the history of comets under this year. Now, since these three authors contend that the comet was above the Moon, and strive to show this chiefly from its parallaxes, we need examine only what pertains to those parallaxes.

Kepleri Obſeruationes pro Parallaxi Cometæ.

Kepler's observations for the comet's parallax.

II. On page 25 Kepler admits that on September 26, at Prague, the comet was seen by him with the help of telescopes [perſpicillorum ope], larger than the other stars but without a tail — which others nevertheless affirmed was seen;

and that his observations were not exact but rough. For he says: *"I noted the place as best I could"*; and soon after: *"We shall leave very little in doubt if, trusting our eyes, we place the comet at latitude 35° 30′"*; and on page 28: *"the comet, with the diagram compared mechanically with the sky, would have fallen at 29½° of Leo"*; and on page 30: *"For there is no need of subtlety, since the observation is rough. For Tycho's instruments require a platform, a free horizon, a skilled observer as companion, and keen eyes — all of which I lacked at the beginning"*; and a little below: *"From the daily and hourly motion, in passing, though from not very fine observations, it is nevertheless easy to show some parallax greater than the one the comet had, if it had any."*

So then, by the bare estimate of the eye, on September 26 at $8\frac{1}{2}^{h}$ after noon, he saw the comet as though on the line joining the knees of Ursa Major, but nearer the hind knee by about 3 degrees, and nearer the wheels than the knee itself is, and higher than the line already mentioned. Hence, from the longitude and latitude of those fixed stars, a diagram having been drawn roughly: the comet's longitude 18° 30′ in Leo, and its latitude 35° 30′, approximately. At 9^{h}, from its position with respect to the fixed stars as noted by eye, he deduced by trigonometry the longitude 18° 50′ in Leo. And the following morning, at 3^{h} after midnight, when the tail appeared clearly, fairly long and turned upward, he saw the comet distant from the left knee of the Bear's hind leg much less than it had been at $8\frac{1}{2}^{h}$ and at 9^{h}; and from its position drawn on paper, by the solution of triangles, he deduced the comet's longitude 21° 20′ in Leo and its latitude 35° 34′, approximately. From this he gathers that the comet, from 9^{h} after noon to 3^{h} after midnight — that is, in 6 hours — advanced from 18° 30′ of Leo to 21° 20′, and completed 2° 50′.

From here he proceeds to the 27th, at 9^{h} of which, he says, the longitude, observed as before, was seen at about 29° 30′ of Leo; from this he gathers a daily motion of 11 degrees. And on the 28th, at the same hour, at about 12° 0′ of Virgo, with latitude 40° 4′; from this he gathers a daily motion of 12½°. The 29th was empty of observations because of the cloudy air; and on the 30th, at $9\frac{1}{2}^{h}$, *through gaps in the clouds, by mechanical estimation*, the comet was seen at 7½ degrees of Libra, with latitude 38⅔°; and therefore from the 28th to the 30th it completed 25½ degrees, that is 12¾° a day.

Kepleri Argumenta pro Parallaxi Cometæ.

Kepler's arguments for the comet's parallax.

III. From the observations set out above, although they were taken rather roughly, he nevertheless hopes it can be shown that the comet was not even in the concave of the lunar heaven, but above the Moon. For from the moment of time he derives the right ascension of the midheaven; and from this, and from the altitude of the equator at Prague, 39° 54′, and the distance between the poles of the ecliptic and of the equator, 23° 31½′, he derives for the 9th hour of the 26th the comet's altitude, 9° 48′. And at this altitude above the

horizon — that is, in round figures, at an altitude of 10 degrees — the comet, had it been on the border of the Moon, that is, at a distance from the Earth of 60 semidiameters of the Earth, would have undergone a parallax of altitude of 59′. From this he gathers a parallax of latitude of 57′ and of longitude of 19′; and therefore the comet's true longitude would have been 18° 11′ of Leo, and its true latitude 36° 27′, since the seen longitude was 18° 30′ of Leo and the seen latitude 35° 30′. Then, by the same method, he investigates the comet's altitude at 15^h after noon on the 26th, and gathers it as 23° 30′; at this altitude, with the comet supposed on the border of the Moon, the parallax of altitude would have been 55′, of latitude 20′, and of longitude 63′. Hence the true longitude at 15^h would have been 20° 17′ of Leo, and the true latitude 36° 20′. In 6 hours, therefore, it would have completed by its true motion only 2° 6′ — as many as there are from 18° 11′ to 20° 17′ of Leo — and it would have completed much less had it been below the borders of the Moon. But if it had been higher than the Moon, it would have completed in 6 hours 2° 50′, or at least 2° 32′, as he gathers from the daily motion from 9^h on the 26th to 9^h on the 27th, which he says was 11 degrees: for a quarter of this is 2° 45′. Or else, because the daily motion from the 27th to the 28th grew by a twelfth of itself: if a twelfth part is taken from 2° 45′, 2° 32′ will remain. Otherwise, if you would have it complete 2° 6′ in those first hours and afterwards 11° in one day, *the comet would have been very slow in its true motion; then, from 3^h in the morning to 9^h the following evening, it would suddenly have become very fast, and on the next day slower again — which conflicts with the analogy of motions, even violent and sublunary ones.* And this is the first argument, from the motion in longitude.

[Margin: 1. Argument from the motion in longitude.]

The second is from the motion in latitude, and is as follows. If the comet had been on the border of the Moon, its true latitude at hour 9′ [?] on the 26th would have been 36° 27′, but at 15^h 36° 20′, and at 9^h on the 27th, because of an equal parallax of 57′, 38° 27′. Therefore the comet's true path — that is, as seen from the centre of the Earth — would have been tortuous, and the latitude in the morning smaller than on the preceding evening. If, by contrast, we consider the seen latitudes without parallax, the series of latitudes will be orderly, as you see in the following little table.

[Margin: 2. Argument from the motion in latitude.]

September	Hour	Seen latitude
26	9	35° 30′
26	15	36° 0′
27	9	37° 30′
28	9	40° 4′

He says this argument is firmer than the former. In the former, which was taken from the longitude and founded on a time determined from the town clock, someone could raise a dispute as to whether the clock ran regularly;

whereas in this argument, taken from the latitude, *nothing has been forced by me, or accommodated to my purpose by prosthaphaereses; but everything, even in a rough observation, comes of its own accord as one would wish: a proof of truth.* He therefore concludes, on page 33, in these words: *"Since, then, the Moon is distant sixty semidiameters of the Earth, that is, more than fifty thousand German miles, the comet was certainly higher; by no means, therefore, in any region of the air. For the region of the air ends at once with the extreme summits of the mountains, so that already on Olympus in Asia, and now on the snowy summits of Peru, one can no longer live, for want of that breath which we call air, and whose inhalation we cannot do without. And this, in passing, on the daily parallaxes of the comet."*

[Margin: Kepler's conclusion on the place of the comet.]

Afterwards, however, he constructed a table in which he gives the comet's distances from the Earth in parts of which the Sun's distance from the Earth is 100,000. He puts the comet's least distance, on September 28, at 13,135 such parts, and its greatest, on October 26, at 134,561 parts. But the Sun's mean distance, according to Kepler in the *Rudolphine Tables* and in the *Epitome Astronomiae*, was nearly 3410 semidiameters of the Earth. Therefore, for Kepler, the comet's least distance from the Earth was 449 semidiameters of the Earth, and its greatest 4588½.

Noſtra Solutio Argumentorum Kepleri.

Our resolution of Kepler's arguments.

IV. Although Kepler's arguments seem very involved, we shall nevertheless unfold them by reducing them to form. The first argument, then, taken from the motion in longitude, is this: *If the comet had been below the Moon or on the border of the Moon, it would have completed, on September 26, from 9^h after noon to 15^h, only 2° 6′ in longitude; but if it had been above the Moon it would have completed 2° 50′. But in that space of time it completed not only 2° 6′, but much more. Therefore the comet was not below the Moon, nor on the border of the Moon.*

[Margin: 1. Kepler's argument reduced to form.]

The major proposition is proved from the parallaxes of longitude due to the comet placed on the border of the Moon and having, at 9^h and at 15^h, those altitudes which the observations show it had. For at 9^h it was seen at 18° 30′ of Leo, nearly 10 degrees high; at a distance equal to the Moon's, a parallax of longitude of 19′ answers to that altitude, to be subtracted from the seen place, and so the true longitude remains 18° 11′ of Leo. And at 15^h it was seen at 21° 20′ of Leo, 23° 30′ high; at a distance equal to the lunar distance, a parallax of longitude of 63′ answers to that altitude, likewise to be subtracted from the seen place, and so the true longitude remains 20° 17′ of Leo. And from 18° 11′ to 20° 17′ there are only 2° 6′.

[Margin: 2. Proof of the major proposition.]

The minor proposition, or assumption, is proved, first, from the analogy of the daily motion. For from 9^h on the 26th to 9^h on the 27th the comet

completed 11 degrees, since at 9^h on the 26th it was at 18° 30′ of Leo, and at 9^h on the 27th at 29° 30′ of Leo. A quarter of 11 degrees is 2° 45′, and 6 hours are a quarter of the natural day; therefore, in the 6 hours that passed from 9^h to 15^h, the true motion ought to have been 2° 45′. And if you say that the comet was slower from the 26th to the 27th than from the 27th to the 28th by a twelfth part, because the former motion was 11 degrees and the latter 12, or 12½, then, when a twelfth part — which is about 14′ — is taken from 2° 45′, there remain 2° 31′. So great, then, and no smaller, ought the comet's motion in those 6 hours to have been. Second: if in those 6 hours the comet's motion had been only 2° 6′, its true motion would have kept a smaller analogy than violent and sublunary motions keep, whereas, being natural and supralunar, it ought to have kept a greater, or at least an equal one. For from 9^h to 15^h it would have been very slow, completing less than a quarter of the daily motion; and from then until the 9th hour of the following night, that is, through three quarters of the day, it would have completed more than three quarters of the daily motion — namely the remainder from 2° 6′ up to 11 degrees, which is 8° 54′ — whereas three quarters of 11 degrees are only 8° 15′. So, on the following day, because of equal parallaxes at an equal altitude, it would have been slow in the first 6 hours and then fast. Therefore this is Kepler's consequence: *it would have been very slow in its true motion, then suddenly very fast, and on the following day slower again.*

[Margin: First proof of the minor.]

[Margin: Second proof of the minor.]

I reply, however — granting, but not yet conceding, the major — by denying the minor proposition. To its first reason, I deny that the comet ought, by its true motion, to have completed 2° 45′, or 2° 31′, in 6 hours. For this is not proved from the true daily motion, since the daily motion of 11 degrees was gathered from two longitudes observed before the investigation of the parallax. Nor can Kepler say that, because of the revolution made in 24 hours back to the same point, the true motion was as great as the seen one; for, because of its proper motion in the order of the signs, the comet at 9^h on the 27th could not have been at the same altitude at which it was at 9^h on the 26th. To the second proof of the minor, I deny, first, that it did not keep the analogy; I likewise deny that it was first very slow, then suddenly very fast, and again slower. For it has not been shown that that change from slowness to speed was sudden, since it could have come about gradually, by increments, so that at the end of the 12th hour the comet had completed 4° 35′, at the end of the 18th hour 7° 30′, and at the end of the 24th hour 11°. Nor could it, or ought it to, have been shown from the seen motion what that daily motion of 11 degrees, and then of 12½ degrees, was; and from the true motion itself it could not have been shown except by supposing that motion regular, which can nevertheless be disputed. Next, the comet is supposed to move naturally, whereas it could have been moved by an Intelligence at will, or at the nod of divine Providence. It is likewise supposed to be supralunar, since the argument is *a fortiori* from sublunary things; but this

very point is still in question. Finally, if some violent or sublunary motions are so ordered as to keep an analogy in a perpetual decrease of speed, it does not necessarily follow that the same is owed to all comets, or to this particular comet — granted that this is not improbable.

[Margin: 1. Negative reply to the minor.]

Otherwise it would also have to be judged necessary — if some sublunary motions are uniform, as many certainly are — that the motions of the celestial planets, as seen from the centre of the Earth, must be uniform too, which is false. And he ought to have remembered the comet of 1472, observed by Regiomontanus, which was at first slow, then became so fast that it ran through 40 degrees in one day, and afterwards was slower again, as I said in the history of comets under that year.

I reply, second, that the first part of the major can be denied: both because that motion was derived from very rough observations, whereas in the matter of parallaxes very exquisite observations and computations are required, as we learned from Tycho in chapter 16, number 8; and because it is quite incongruous that the comet, at an altitude of 10 degrees, should have had a parallax of longitude of only 19′, and at an altitude of 23° 30′ a parallax of longitude of 63′, greater than the parallax of altitude. And Kepler himself does not deny that in this argument some things were forced and accommodated to his purpose.

[Margin: 2. Negative reply to the major, as to its first part.]

I reply, third, by denying the second part of the major, in which it was said that, had the comet been above the Moon, its motion in those first 6 hours would have been 2° 50′. First, that immediate jump from 2° 6′ to 2° 50′ is too great. For if, from its being on the border of the Moon, it made only 2° 6′, then, had it made not merely 26′ [?] but more — say 2° 30′ — it would have been above the border of the Moon; therefore it does not follow that, if it was above the Moon, it made 2° 50′. Second, this quantity of motion is proved only from the seen motion, namely because it is said to have been seen at 9^h at 18° 30′ of Leo and at 15^h at 21° 20′ of Leo; but this ought to have been shown of the true motion. For that Kepler is speaking of the true motion when he compares the motion the comet would have had on the border of the Moon with its motion had it been above the Moon is clear from these words of his on page 32: *"Therefore, by its true motion, freed from the parallax (which we attributed to it, referring it to the borders of the Moon), it would have completed 2° 6′ in six hours. But if it did not have so great a parallax, that is, if it was higher than the abodes of the Moon, then it completed 2° 50′ in 6 hours. Which of the two is true, the portion of the daily motion shows."* Third, because, even speaking of the seen motion, it is false that it completed 2° 50′ in 6 hours: it completed them in 6½ hours. For Kepler says in express and explicit terms, on page 25, that the first observation was made at $8½^h$; and from it he gathers the comet's motion on page 26, saying: *"It is nearest the truth that it was seen at 18° 30′ of Leo"*; and at once, examining the second consideration, on page 27, he says it was seen at 18° 50′ of Leo, adding: *"This last consideration, however, was made about half*

an hour after the earlier ones, at 9½ʰ." Then, speaking of the place observed at 15ʰ, on page 28, he says: *"the comet would have been seen beyond this line: in the morning, therefore, at 3ʰ, the comet was at about 21° 20′ of Leo, etc. The comet therefore advanced in six hours from 18° 30′ of Leo to 21° 20′ of Leo, at most 2° 50′."* That motion of 2° 50′, therefore, was not made from 9ʰ to 15ʰ, nor in precisely 6 hours, as he sets it down in contradiction with himself, but from 8½ʰ to 15ʰ, that is, in 6½ hours. From 9ʰ to 15ʰ, on the other hand, it went from 18° 50′ to 21° 20′, and so was 2° 30′; and this is the seen motion which, from his own observations, he ought to have assigned to the 6 hours. Fourth, because the true motion in those 6 hours, gathered from the daily motion, as Kepler thinks, ought to have been 2° 45′, or rather less, 2° 32′, as we saw above. Therefore it does not follow that, if it was above the Moon, the motion must have been 2° 50′. Hence, fifth, I turn the argument back thus: If it had been above the Moon it would have completed, on your own account, 2° 50′; but it completed only 2° 45′, indeed only 2° 32′; therefore it was not above the Moon.

[Margin: 3. Reply to the second part of the major.]

V. The other argument was from the motion in latitude, which Kepler calls much firmer; reduced to a syllogism, it runs as follows: *If the comet had been on the border of the Moon, or below it, its true path would have been tortuous, and its latitude in the morning smaller than on the preceding evening; but if it had been above the Moon, without parallax, the path would not have been tortuous, nor the latitude smaller in the morning than on the preceding evening. But the comet's true path was not tortuous, nor was its latitude smaller in the morning than on the preceding evening. Therefore the comet was above the Moon.* The major is proved from the parallaxes of latitude applied to convert the observed latitudes into true ones; for from these it follows that on the evening of the 26th, at 9ʰ, the true latitude was 36° 27′; in the morning, that is, at 3ʰ after midnight, the true latitude was 36° 20′; and on the evening of the 27th, at 9ʰ, the true latitude was 38° 27′. The minor, as to its second part, is proved because the latitudes without parallax were found in this order: namely 35° 30′, then 36° 0′, then 37° 30′, then 40° 4′.

[Margin: 2. Kepler's argument reduced to form.]

I reply [?], first — granting, as above, the first part of the major (which could nevertheless be denied by one who holds to astronomical rigour, since it was derived from rough observations in so slippery a matter) — by denying the second part of the major proposition. For the comet could have been above the Moon and yet its path have been tortuous because of some very sensible parallax, though one smaller than the Moon's.

[Margin: 1. Negative reply to the second part of the major.]

I reply, second, by denying the minor proposition, which is proved not of the true motion and from the true latitude, but of the seen motion and from the seen latitudes, taken as observed and reduced to true ones by no parallax. Even granting these, it is not proved that the comet's path was not tortuous; for the latitude could have increased continually and yet the path have been

tortuous, and bent now and again towards the same quarter, without being twisted by alternating bends towards opposite quarters of the world.

Solutio Argumentorum Kepleri & Santutij ex Claramontio.

The resolution of the arguments of Kepler and Santucci, from Chiaramonti.

VI. In the Supplement to the *Antitycho*, part 2, chapters 18, 26 and 27, Chiaramonti resolves the arguments brought both by Antonio Santucci and by Kepler for this comet's seat above the Moon: Kepler's, indeed, alone in chapter 26 — he too noticing the perpetual fallacy of arguing from the seen motion to the true, that is, of confusing these motions equivocally, and that the comet's motion could have been first slow, then very fast, and again slow, as happened in the comet observed by Regiomontanus. Santucci's argument alone, given by him in chapter 21, was taken from the stay of this comet above the natural horizon for $14^h\ 28^m$, in a northern parallel declining from the equator by 18° 20′, and this on October 8; to this parallel answers a diurnal arc of 217 degrees, that is, of $14^h\ 28^m$. From this he gathers that the comet's apparent stay was as long as its true stay above the true horizon ought to have been, and so that it had no sensible parallax.

[Margin: Santucci's argument.]

Chiaramonti, however, replies, first, in chapter 18, that this argument is not valid so long as the parallax is unknown. See what we said in chapter 15, problems 7 and 8, corollary 1.

[Margin: 1. Chiaramonti's reply.]

He replies, second, that the declination of this comet on October 8 asserted by Santucci disagrees by many degrees with the declination deduced from the longitude and latitude observed by Kepler on the same day, namely October 8. For Kepler says, in his book *De cometis*, page 34, that he saw the comet at 21⅙ degrees of Scorpio, with northern latitude 21⅚°. From this, by the usual problems of the primum mobile, with the obliquity of the ecliptic put at 23° 30′, the comet's declination is gathered as 3° 1′ 24″, differing, that is, from Santucci's by 15° 18′ 36″. And to a parallel declining 3 degrees answers a diurnal arc of 186° 14′, or $12^h\ 25^m$. Moreover, if, as Santucci affirms, on October 8 the comet's altitude at Pisa was 37° at $\frac{1}{2}^h$ of the night, and at $2^h\ 43^m$ before sunset the comet was on the meridian, Chiaramonti shows, and geometrically, that its declination was 10° 39′. Either way, then, it disagrees greatly with the declination of 18° 20′ asserted by Santucci himself. Therefore either both are false, or only one is true; and so we are still in uncertainty, since neither were Kepler's observations of this comet very accurate, nor are Santucci's consistent with themselves.

[Margin: 2. Chiaramonti's reply.]

But if anyone insists that the observations of both be admitted, Chiaramonti readily accepts this condition in chapter 27. From the difference of the comet's declinations on this eighth day — which difference was 15° 18′ 36″, as we have already said — and supposing the altitude of the pole at Prague, where Kepler

then was, to be 50° 6′, and at Pisa, where Santucci was, 43° 30′, he shows, by the problem set out by us in chapter 19, number 2, that this comet's distance from the centre of the Earth was less than 4276 Italian miles, of which 3035 make up one semidiameter of the Earth. Nor will there be any great disagreement from this if the altitude of the pole at Pisa is chosen as 43° 27′, as

[Margin: 3. Chiaramonti's reply.]

observed there, Dr Vincentius Reinerus [Vincenzo Renieri]. Therefore, if we are willing to admit some of the observations of both Santucci and Kepler, it follows necessarily that this comet was far nearer the Earth than the Moon is. For we have inspected Chiaramonti's calculations and found no error of great moment, except that he puts the difference of the declinations as 14° 18′ 36″ instead of 15° 18′ 36″.

Argumenta Longomontani pro Parallaxi Cometæ huius.

Longomontanus's arguments for the parallax of this comet.

VII. After some observations of this comet, made partly by estimation with the eye and partly by the sextant and by distances taken from the fixed stars, and reported by Longomontanus in the Appendix to the *Astronomia Danica*, chapter 9, we have these words of Longomontanus: *"Although in this comet it did not fall to us to have, in order, such observations as would let us extract its parallaxes, if it had any, with sufficient subtlety — according, that is, to what was taught in the doctrine of the sphere — nevertheless, among other things, even that single observation of the comet's position which we made on September 28 in the evening at 7¼^{h}, jointly as it were with Dr Johannes Kepler, who was then at Prague in Bohemia, will suffice for the one thing we aim at here."* He adds afterwards that the comet then appeared to him to be distant scarcely one diameter of the Moon, or 34′, below and to the east of the small unformed star placed behind the Bear; from which he gathers the comet's seen longitude as 11° 57′ of Virgo, with latitude 40° 5′. But Kepler too, for that evening, reports as follows in his little book *De cometis*, page 29: *"For on September 28 the comet was seen to stand below the small unformed star, the companion of the large unformed one, between the tails of the Bear and of the Lion: it is at 12° 16′ of Virgo, latitude 40° 30′. It was distant by a diameter of the Moon on the line that runs along the last star of the Bear's tail through the hand of Arcturus. The comet was therefore at 12° 0′ of Virgo, latitude 40° 4′."* From this Longomontanus supposes that in the vertical circle there was scarcely a difference of 3′ between the place seen by himself and that seen by Kepler. He likewise supposes that there was no sensible difference between the time at which the said observation was made by Kepler at Prague and that at which it was made by himself at Copenhagen, which he conjectures from its daily motion; that Prague is not more easterly than Copenhagen by more than 6 minutes of time; and that the altitude of the pole is 50° 6′ at Prague and 55° 43′ at Copenhagen, and therefore the difference 5° 37′. From this he gathers that these two places, as if on the same circle of altitude, are 5½° apart, and that the comet's altitude was then 20° at Prague and 25½° at Copenhagen. *"All*

things considered broadly," he says; for he thinks this latitude, and a somewhat rough construction from the data, suffice to convince the Peripatetics and to raise this comet above the Moon.

[Margin: In the new style the day was the 28th, but in the old style the 18th.]

With these things prepared, let the figure set out in chapter 19, number 2, be repeated here. In it let AT be the semidiameter of the Earth, of 860 German miles, and TL the altitude of the vapours, or of the highest region of the air, which is to be 873 German miles; let Prague be at A and Copenhagen at I, and let the arc of the vertical circle between them, AI, be 5½°; and let the distance of the comet, seen at L, from the zenith of Prague be LAR, of 70°, since its seen altitude there is put at 20°. Then the angle LAT, its supplement to two right angles, will be 110°. Therefore in the triangle TAL, given that angle and the sides AT 860 and TL 873, the parallactic angle ALT with respect to Prague is gathered, with trigonometry as guide, as 67° 46′.

[Margin: 1. Step.]

Diagram. Set in the left column below the paragraph above: a large semicircle on a base line, with a smaller concentric semicircular arc inside it and a small full circle centred on the base line at T, its lower half hanging below the base. A vertical rises from T to the top of the outer arc; straight lines run from points on the inner arc and the small circle out to points on the outer arc, and a horizontal line crosses through the inner arc to the right.

- R (top of the vertical through T): label
- D (just right of R, close against it): label
- Q (upper left, on the outer arc): label
- D (upper right, on the outer arc): label — a second D, as printed
- E, F (right, lower on the outer arc): labels
- m (lower-case, right end of the horizontal line): label
- M, O, P (left, on the outer arc, top to bottom): labels
- L, A, G, C (along the inner arc, left to right): labels
- I, B (on the small circle): labels
- H, N (where the inner arcs meet the base region): labels
- S, V, T, X, Z (along the base line, left to right): labels; Z is a Z-shaped sort with a curled foot
- u (lower-case, foot of the small circle): label

Second, in the triangle TIL are given TI 860 and TL 873, and the angle TIL, 115½°. For the comet's distance from the zenith of Copenhagen I, LIQ, was put smaller than at Prague by 5½°: it was put at 64½°; therefore its supplement to two right angles, that is TIL, is 115½°. Therefore by trigonometry the parallactic angle TLI with respect to Copenhagen comes out 62° 46′, and so the difference of the parallaxes, that is the angle ALI, or the arc PO, is 5°. So great, then, would have been the difference between the comet's distance from the unformed star of the Bear — say from the star Q — as seen by Kepler at A, and its distance from the same star as seen by Longomontanus at I, on this supposition. But the difference in the distances from the fixed star, placed

as if on the same vertical, was not greater than the Moon's diameter; indeed, probably it was not greater than 3′. Therefore the comet was not a mere 873 German miles high above the Earth, nor in the highest region of the vapours, as the Peripatetics would have it, but much higher.

[Margin: 2. Step.]

Having demonstrated these things — though with another diagram, which is corrupt in my copy — Longomontanus appends these words: *"Moreover, from the proportionate change of this comet's proper motion and latitude, and likewise from its constant progress under a great circle almost to the last days before it disappeared, we can gather, indeed plainly establish, that this comet was celestial; although the observations of it, taken less precisely and less timely, scarcely permit us to reason how far it climbed aloft through the aether. Therefore, breaking off the web here, we shall hasten on to the phenomena of the comet of the year 1618."* He admits, therefore, that the parallax or distance of this comet was not demonstrated and determined by him.

Solutio Argumentorum Longomontani.

Resolution of Longomontanus's arguments.

VIII. First, in the apparatus for the demonstration already mentioned, Longomontanus admits many errors not to be despised, but two above all. For he wrongly supposes that the observation was made by himself and by Kepler with the insensible difference of time already mentioned. He himself testifies that his own was made at $7\frac{1}{4}^{h}$ after noon, whereas Kepler records his observations of the 27th and 28th at 9^{h} after noon, and from them gathers the comet's daily motion at that time as 12 or 12½°. Therefore if Prague, as Longomontanus himself concedes, is more easterly than Copenhagen by only 6 minutes of time, when it was 9^{h} at Prague it was $8^{h}\ 54^{m}$ after noon at Copenhagen, and not $7\frac{1}{4}^{h}$. The difference of time between the one observation and the other was therefore $1^{h}\ 39^{m}$, which is very sensible; and to it there correspond, from the comet's daily motion in longitude observed by Kepler, about 50′, and not merely 3′, as Longomontanus supposed.

[Margin: 1. Error of Longomontanus.]

Second, from the fact that Prague is more easterly than Copenhagen by only 6^{m} of time, and from the difference of pole altitude of 5° 37′, he wrongly concludes that those places are apart on the same great circle — that is, on the vertical drawn through them — by an arc of only 5° 30′; for this distance had to be greater than the difference of the pole altitudes. For in the diagram below let AGQ be a portion of the equator, to which let quadrantal arcs be drawn from the pole of the world P: PBG, passing through B, Prague in Bohemia, and PKA, through Copenhagen, K; and let K and B be joined by KB, an arc of a vertical circle. Since, then, the altitude of the pole is given as 55° 43′ at Copenhagen and 50° 6′ at Prague, their complements will be PK, 34° 17′, and PB, 39° 54′; and the angle BPK is given as 1° 30′. Therefore by trigonometric calculation the arc KB comes out 5° 51′ 30″, and not 5° 30′, as Longomontanus

put it. But notwithstanding these errors, it is still gathered that the comet was above the altitude of the vapours.

[Margin: 2. Error of Longomontanus.]

Diagram. Set in the right column beside the lines describing it: a spherical triangle with its apex at P and its base an arc of the equator running from A through G to Q. From P two arcs descend, one through K to A and one through B to G; K is joined to B, and further lines run from K and B to a point C on the right-hand side.

- P (apex): the pole of the world
- K (upper left): Copenhagen
- C (right): label, not cited in the text of this page
- B (lower centre): Prague
- A (lower left): end of the arc of the equator
- G (base): on the arc of the equator
- Q (lower right): end of the arc of the equator

Third, however, I deny that the comet must plainly be established as celestial from the fact that it was seen to describe a great circle, and with a regular motion at that; for we have often taught already that both can belong to sublunary moving bodies. And I deny that this argument is evident: at most it is probable, for a place or motion above the Moon. Indeed, if Longomontanus's and

Kepler's observations are admitted, but reduced to the same moment of time, as is fitting, it can be demonstrated from the remaining data given by Longomontanus that the comet was below the Moon. For since the difference of longitude observed by himself and by Kepler (at the same moment of time, as he thought) was 3′, he inferred that the difference in the circle of altitude was about 3′. Therefore, since in reality it was 50′, he ought to have admitted a difference of the parallaxes of about 50′ in the circle of altitude as well. This being posited:

OSTENDITUR COMETAM ANNI 1607. EX DATIS À LONGOMONTANO & KEPLERO SED CORRECTIS, FUISSE INFRA LUNAM.

It is shown, from the data of Longomontanus and Kepler, but corrected, that the comet of 1607 was below the Moon.

IX. Go back to the figure shown here at number 7, and in chapter 19, number 2, in which let AT be 860 German miles, which are 3440 Italian; or, to be generous, let AT be 4139 Italian miles, according to our view shown in book 2, chapter 7. And let the arc AI between Prague and Copenhagen be 5° 51′ 30″, as stated under Longomontanus's second error. Then the chord AI will be 10,220 parts, of which the whole sine AT is 100,000; therefore, in units of which AT is 4139, AI is 423 Italian miles. The angle ATI, which measures the arc AI, is given as 5° 51′ 30″; therefore, by propositions 5 and 32 of the first book of Euclid taken together, each angle at the base of the isosceles triangle, that is both TAI and TIA, is 87° 4′ 15″. But the seen distance of the comet from the zenith of Prague, A, that is the angle RAL, is put at 70°; joined to the angle TAI of 87° 4′

15″, it makes a sum of 157° 4′ 15″. Therefore its supplement to two right angles, by proposition 13 of the first book of Euclid, that is the angle LAI, is 22° 55′ 45″. This angle is given in the same triangle LAI; but there are also given the difference of the parallaxes, that is the angle ALI, 50′, and the side AI, 423 Italian miles. Therefore the comet's distance from Copenhagen, that is the side IL, is by geometric necessity 11,332 Italian miles, in which AT, the semidiameter of the Earth (which we put at 4139), is contained 2 3054/4139 times. But let us put IL at 3 terrestrial semidiameters: with TI added to IL, TL, the comet's distance from the centre of the Earth, would come out at most 4 semidiameters of the Earth — much less, therefore, than the distance of the Moon at perigee, which in the Ptolemaic hypothesis is more than 33 semidiameters of the Earth from the Earth, and in Longomontanus's more than 51 terrestrial semidiameters, from what was said in book 4, chapter 14. But Longomontanus will perhaps object, and will not be willing to admit so great a difference of the parallaxes, namely 50′, which he nevertheless ought to admit. Since, then, he will not yield to us, let us yield to him in this and assume the difference of the parallaxes in the circle of altitude that he admitted, 3′. For from this too we shall forthwith demonstrate that this comet was still below the Moon. Let this, then, be a proposition most worthy of note in this matter.

Data differentia Parallaxium in circulo altitudinis 3′. tantummodo minutorum, & altitudine Cometæ viſa Pragæ Gr. 20. & arcu circuli maximi inter Pragam & Hafniam Graduum 5. Min. 51 1/2. Demonſtratur Cometæ Diſtantia à terris minor quàm Lunæ, & Parallaxis maior.

Given a difference of the parallaxes in the circle of altitude of only 3′, a seen altitude of the comet at Prague of 20°, and an arc of a great circle between Prague and Copenhagen of 5° 51½′, the comet's distance from the Earth is demonstrated to be less than the Moon's, and its parallax greater.

X. Keep everything else in the triangle ALI that was stated at the preceding number — namely the angle IAL, 22° 55′ 45″, and the side AI, 423 Italian miles in units of which AT is 4139 — but assume the angle ALI, that is the difference of the parallaxes, to be 3′. Then by the laws of trigonometry the comet's distance from the surface of the Earth, namely IL, is gathered as 188,848 Italian miles. Divided by 4139, the terrestrial semidiameter, these leave IL as 45 26/41 terrestrial semidiameters. If you add one semidiameter to these, that is, if you join the lines TI and IL, the comet's distance from the centre of the Earth, that is TL, would be at most 46 26/41 terrestrial semidiameters. But TL is less than the sum of the two sides TI and IL, by proposition 20 of the first book of Euclid; therefore the comet's distance from the centre of the Earth was less than 46 26/41 terrestrial semidiameters. It was therefore also less than the lunar distance, which for Longomontanus is at least 51 semidiameters 57′ of the Earth, from what was said in book 4, chapter 14. And, the Ptolemaic hypothesis excepted — which on this point, from what was said in the same place, is false

— there is no astronomer who does not put the Moon, however far at perigee, beyond 47 semidiameters of the Earth.

Corollarium Insigne in hac materia.

A notable corollary in this matter.

Gather from this that if the comet is distant from the zenith of each observer by 70° or more, and the places of the two observers are not more than 6° apart from each other, then even if the observed difference of the parallaxes is of a few minutes, say 3 or 4, the comet can nevertheless be below the Moon; indeed, this can sometimes happen even if the difference is of one minute. Chiaramonti showed this too in the *Antitycho*, book 3, chapters 19 and 20, and we with him in book 10, the penultimate section, chapter 11, problem 3, and in this very book, chapter 19, number 3; and finally we have thought it right to drive the point home with the example just given, so that it is not pronounced so readily, as most have done until now, that comets are above the Moon because of a slight difference of the parallaxes.

Conclusiones ex Prædictis.

Conclusions from what has been said.

I. CONCLUSION: *It has not so far been demonstrated that the comet of the year 1607 was above the Moon.* For none of the three authors who tried to demonstrate this has in fact demonstrated it: not Kepler, as is clear from what was said from number 4 to 6; not Santucci, as is clear from what was said at number 6; nor, finally, Longomontanus, as is evident from what was said from number 8 to 10.

II. CONCLUSION: *Although it is not improbable that the comet of the year 1607 was above the Moon, it is nevertheless more probable that it was below the Moon.*

The first part is established not only by the authority of Kepler, Santucci and Longomontanus, who assert it, but also by their arguments. The second, however, is clear from the observations made at two places on the Earth, which, other things being equal, prevail in this business over observations made at a single place on the Earth, as can be established from what has been said so far and will be shown in book 10, the penultimate section, chapter 9. And from the observations either of Kepler and Santucci, or of Kepler and Longomontanus, compared with each other, it follows that this comet was sublunary, as is clear from what was said at numbers 6, 9 and 10. It is more probable, moreover, that those observations — at least those of Kepler and Longomontanus, whatever they were like — are to be accepted rather than rejected; therefore it is also more probable that this comet was below the Moon, though far above the vapours and the twilight exhalations, as is certain from the distances of this comet deduced at numbers 6, 9 and 10, if they are compared with the altitude of the vapours and exhalations given at the end of chapter 14.

CAPVT XXII.

De Cometis Anni 1618. Diſtantia & Parallaxi.

Chapter 22. On the distance and parallax of the comets of the year 1618.

I. We come at last to the last comets seen, in our own time at least, since from the year 1618 down to this year in which we are writing no comet has shone upon our regions. Since, however, no comet of all those before had more observers skilled in mathematics, in different parts of the globe, than the last of this year; since none drew more votes for its celestial nature and place; and since none, finally, was made more famous by more booklets published, whether of the Peripatetics, who contend that it was born and died in the elementary region, or of the Tychonians (for so it pleases me to distinguish the sect of astronomers on this question from the Peripatetics, even granting that Tycho did not see this comet), who strive with all the engines of geometry and optics to carry it beyond the confines of the Moon — we too must discuss this comet more accurately. For if not even this one has been demonstrated to be above the Moon, there will be no reason for the astronomers, in this respect, to look down on the Peripatetics with such haughtiness.

Now, among those who raised this year's comet into the heavens, there are some who tried to show it by geometrical reasons: first of all Father Johann Baptist Cysat of our Society, professor of mathematics at Ingolstadt, in the *Mathemata Astronomica*, which he composed in 7 chapters on the one comet of this year; Kepler, in his book *De cometis*, from page 47; Longomontanus, in the Appendix to the *Astronomia Danica*, chapter 10; Snel, in his book on the comet of the year 1618, consisting of ten chapters; Father Orazio Grassi, both in the disputation on these comets held in our Roman College and in the *Libra Astronomica*, published under the name of Lotharius Sarsius; and Biancani, in the *Sphaera*, book 16, chapter 5. There are others who, drawing conclusions from the authors already mentioned that they think demonstrated, and adorning them with probable reasons, raised the comets of this year — but one above all — into the heavens. Chief among these were Thomas Fienus, Erycius Puteanus, Libert Froidmont and Descartes.

[Margin: Authors of different classes.]

On the other side, some have tried by mathematical demonstrations to keep these comets too below the Moon: first of all Scipione Chiaramonti, in his *Antitycho*, book 2, chapter 26, and book 3, chapters 20 and 21; in the *Apologia* for the *Antitycho*, book 2, chapters 11 to 13; and in the supplement to the *Antitycho*, part 2, from chapter 28 to the very end.

Others, again, did strive to draw them back below the Moon, but partly by using mathematical reasonings foreign to the matter, partly by merely probable reasons taken either from physics or from astronomy — above all Cottunius, on Aristotle's *Meteorology*, book 1, lecture 31.

II. We have already set out the history of these three comets in chapter 3. The first of them, which arose in the month of August, is said to have been very

faint through September, so that it could scarcely be made out by astronomers; and so Kepler says of it, on page 47: *"But since no proper observations of it exist, nothing can be brought forward to demonstrate its altitude and motions."* The second comet, for its part, was so confused by several observers with the third, or with the fiery beams seen in October and November, that we can have nothing certain from it as regards parallaxes.

[Margin: The first comet of the year 1618.]

[Margin: 2. Comet.]

The third comet was not observed in Europe, but in Persia and in the East Indies, and yet without any marks suited to extracting its parallaxes, or even to attempting them by conjecture; nor did it shine for more than 10 days, as I said in the History.

[Margin: 3. Comet.]

The fourth comet, then, which European writers call the third, is that most celebrated one which was observed by Father Giacomo Rho of the Society of Jesus at Goa; Father Antonio Rubino of the Society of Jesus at Cochin; the Fathers of the College at Rome; Father Biancani at Parma; Schickard in Württemberg; Chiaramonti at Cesena; Antonius Lucianus at Valencia in Spain; Gallus Prouenzalis at Paris; Gassendi at Aix; Snel in Holland; our Fathers at Antwerp; Father Cysat of the Society of Jesus at Ingolstadt; Dr Habrecht at Strasbourg; Gaspar Herspachius at Cologne; Froidmont at Louvain; Philippus Millerus [Philipp Müller] at Leipzig; Ambrosius Rhodius at Wittenberg; Benjamin Ursinus at Frankfurt an der Oder; Johannes Remus Quietanus at Rastadium and at Innsbruck; Longomontanus at Copenhagen; Kepler at Linz; Vuelperus at Lora and at Worms; Gotthard Arthus at Danzig; Herlicius in Pomerania; Nagellius at Magdeburg; and many others, most of whom raised this comet beyond the Moon. And so we must treat of it more accurately.

[Margin: 4. Comet.]

ARGUMENTA LEVIORA PRO CÆLESTI NATURA & LOCO COMETÆ ANNI 1618. ADDUCTA, & REIECTA INTER MERÈ PROBABILIA AUT INSUFFICIENTIA.

Lighter arguments for the celestial nature and place of the comet of the year 1618, adduced and rejected as merely probable or insufficient.

III. The first argument is from its motion, regularly unequal and along the same circle, sensibly a great circle — a motion such as seems to suit celestial rather than elementary phenomena. So it is used by Cysat, page 35; by the author of the *Libra Astronomica*, page 9; by Biancani, on the mathematical passages of Aristotle, page 93; by Froidmont, *Meteorology* book 3, chapter 1, article 3; by Cabeo, *Meteorology* book 1, text 37, question 1; by Franciscus Resta, treatise 1 on the *Meteorology*, chapter 2; and by Snel, in his first reason. But we have clearly taught, in chapter 11 from number 7 to 12, and in chapter 18 from number 2 to 4, that this argument is not evident and necessary for proving that the origin and place of the phenomenon are celestial rather than elementary,

and that in the end Tycho himself and Kepler, in other comets, acknowledged it as merely probable.

[Margin: 1. Argument, from the regular motion along the same great circle.]

The second argument is from the comet's proper motion towards the east, slower than the motion of the Moon: for, says Snel, it completed not a full three degrees. But this argument cannot properly be adapted to this comet we are dealing with, because its proper motion was not towards the east but towards the west, against the order of the signs, namely from the end of Libra to Virgo; and besides, it is not an evident argument, but at most a probable one, as we showed at length in chapter 11, numbers 5 and 6. Snel nevertheless uses it.

[Margin: 2. Argument, from a motion slower than the Moon's.]

The third argument is from the daily motion imitating the motion of the primum mobile, from which a celestial nature seems to be gathered; Biancani touches on this argument in the *Sphaera*, book 16, chapter 5. But this argument is not evident, because even the element of air and of fire may imitate this motion. See what I said in chapter 11, number 3.

[Margin: 3. Argument, from the imitation of the motion of the primum mobile.]

The fourth argument is from the comet's stay above the natural horizon being as great as the stay of the Sun, placed in the same parallel, above the rational horizon; from which it seems to be gathered that the comet's parallax is no greater than the Sun's; or at any rate, if the stay is not so great but is still of several hours, the comet's altitude seems to be gathered to be far greater than that of the vapours and of the highest region of the air. But the first part of the argument cannot evidently be fitted to this comet, because it was not seen to move within the torrid zone in such a way as to be visible all night from rising to setting. Besides, its true declination would have to be distinguished from the seen one, and the true parallel from the seen one, so that it could be known how great a stay above the rational horizon suited it, and how that stay differed from the stay above the sensible horizon; but this cannot be known so long as the comet's parallax is unknown, and it is still supposed unknown. On this see what we said in chapter 11, number 4, but especially in chapter 15, problems 7 and 8, corollary 1. Cysat, nevertheless, in chapter 3, proposition 2, shows from the stay of this comet above the horizon that it must have been higher than 2580 German miles, indeed than 8600, or 10 semidiameters of the Earth; and this, granting it to him, does not avail to advance the comet as far as the Moon.

[Margin: 4. Argument, from the stay of the comet above the horizon.]

As to the latter part of the argument, I admit that from the many hours during which the comet appears above the horizon its altitude is gathered to be greater than the altitude of the vapours, but not that it is concluded from this to be above the Moon, as I said in chapter 11, number 4. I therefore freely grant Father Cysat what he himself taught in chapter 3 in his first three propositions, of which the first is that the comet was above the highest region of the air, or higher than 13 German miles, because it was seen for more than two hours in

the morning above the horizon before it reached the meridian. This could not have been so had it not been higher than 13 German miles, or 52 Italian; for within two hours it would have flown from rising to setting — and all the more so, the more certain it is that this comet did not resist the motion of the primum mobile but rather complied with it, by its own proper motion towards the west. See on this matter the diagrams and problems 7 and 8 of chapter 15. But neither Cysat there, nor Froidmont, *Meteorology* book 3, chapter 1, article 4, contends anything else by this argument than that comets were above the vapours.

The fifth argument is from the comet's duration through a whole month and more, and the sixth from the comet's bulk, especially counting the tail; for neither of these does elementary matter, of itself fluid and ill-suited to so great a bulk, seem sufficient. But from this it is at most proved that the comet was not generated from a mere hot and fatty exhalation by ignition, etc.; and not even this is evidently shown, but is only urged by probable reasons, as may be seen from what was said in chapter 11, from number 13 to 18, where we weighed what Snel adduces for this comet.

[Margin: 5th and 6th arguments, from duration and bulk.]

The seventh argument is from the transparency of the tail, and the eighth from its being turned away from the Sun. But not even by these is it evidently shown that the comet was above the Moon; but if

[Margin: 7th and 8th arguments, from the transparency of the tail and its turning away from the Sun.]

anything is shown, this alone is shown: that it is not a meteor generated by mere ignition, but that its head is transparent and pervious to the rays of the Sun, which pass right through it and, in place of a shadow, paint a luminous tail on the comet. See more on these matters in chapter 11, numbers 1, 2 and 19, and below, in chapter 23.

The ninth argument is from the property of the telescope, which usually enlarges notably the objects that are below the Sun, and indeed the Sun itself, but usually does not enlarge the fixed stars, because of their immense distance. Yet the comet of the year 1618, viewed through excellent telescopes, gained no sensible increase; therefore it seems to have been far higher than the Sun, and near the sphere of the fixed stars. But we have already said more on this argument in chapter 11, from number 20 to 23, teaching that the telescope shows an increase even in the fixed stars, and that it showed in this comet as much increase as the real size of its apparent disc, shorn of adventitious rays, required.

[Margin: 9. Argument, from the almost null increase taken on through the telescope.]

The tenth argument is from the altitude this comet needed in order that it and its tail, which derive from the Sun's illumination, could be seen for many hours by night and not lie hidden within the Earth's shadow. But I reply to this that it is not necessary for the comet to be higher than the whole axis of

the Earth's shadow; it suffices that it be outside the shadow, to the sides, by reason of its latitude or declination from the ecliptic, along which that shadow is carried — in the way the Moon mostly is at full moon. For this, an altitude much smaller than the Moon's suffices, provided the latitude, or deviation from the ecliptic, is greater; and this argument proves no more than an altitude greater than the altitude of the vapours. See problem 9 of chapter 15.

[Margin: 10. Argument, from the altitude outside the Earth's shadow.]

The eleventh argument is from the altitude required for the comet to be seen at once from many places on Earth very distant from one another, or, in one place, very distant from the comet's parallel; and the twelfth is from parallax. Because these arguments carry greater weight in this matter, they must be discussed separately.

[Margin: 11. and 12., from the distance of the observers and from parallax.]

1. Argumentum ex Loci, in quo viſus eſt Cometes diſtantia à Parallelo, in quo verſabatur Cometa. Quod Argumentum eſt P. Cyſati.

1. The argument from the distance of the place in which the comet was seen from the parallel in which the comet was moving. This argument is Father Cysat's.

IV. This comet was seen here at Frankfurt an der Oder on November 19, and somewhat earlier at Danzig in Prussia; on that day it had a southern declination of at least 23°. But the latitude, or northern declination from the equator, of Frankfurt is at least 52°, and of Danzig 54°. When these are joined with the comet's southern declination, the result is an arc of 75° between Frankfurt and the comet, but of 77° between Danzig and the comet. Therefore, taking the Earth's semidiameter as 860 German miles, and the comet in the physical horizon, it follows, by problem 3 of chapter 15 of this section and its corollary 3, that the comet must have been 3322 German miles distant from the centre of the Earth, or, with respect to Danzig, 3823 miles — and much more, if the comet was seen above the horizon in both places. So Father Cysat on this comet, chapter 3, proposition 2.

[Margin: Argument of Father Cysat.]

But this argument supposes the true declination, which, so long as the comet's distance from the Earth and its parallax are unknown, cannot be distinguished from the apparent declination — such as was the one which Cysat, or others, had gathered from the observations. Moreover the apparent declination, when it is southern, appears greater to a northern observer, because of parallax, than it really is; and therefore the distance mentioned above ought to have been smaller. Next, from this it is shown only that the comet was much higher than the vapours and the boundary of the highest region of the air — namely, about 4 or 5 semidiameters of the Earth; but from there to the Moon a great deal still remains. Nor does Cysat wish to show from this that the comet was above the Moon, but rather by the following argument.

2. Argumentum ex Diſtantia duorum Locorum terræ, ex quibus eodem tempore obſeruatus eſt Cometa.

2. The argument from the distance between two places on Earth from which the comet was observed at the same time.

V. If any places were suited to this, they were surely Goa and Cochin, where Fathers of our Society — namely Father Giacomo Rho and Father Antonio Rubino — observed this comet on the same days on which it was also observed by our men at Rome, Parma and Innsbruck, and by others at Antwerp, Linz, Ingolstadt, Cesena, Valencia and elsewhere. But, as is clear from our problem 6 of chapter 15, the comet would have had to be observed at the same moment of the same day; or at least it would have had to be possible, from the hour exactly noted in each place and from the comet's true motion, to reduce the observation to the same moment. Further, the comet's distance would be needed, exactly observed from the zenith of each place, or from the same fixed star, first corrected for refractions; and finally the exact distance of the two places along the arc of a great circle drawn through both would have to be known, or knowable from an accurate polar altitude and the distance of the meridians. But in this case we lack all of these. For neither the true motion can be distinguished from the apparent, nor refraction from parallax, if one supposes, as is supposed here, that the comet's distance and parallax are still unknown. Nor is the polar altitude of Goa or of Cochin yet exactly known; nor is the distance of those meridians from the meridians of Europe determined, except only ὁλοσχερῶς [Greek: holoscherōs, "in the gross"], or roughly; nor the size of the arc of the great circle drawn through Goa and some place in Europe. Finally, in many of the European observations, and in all the Indian ones, the hour of observation is missing and only the day is noted, and the distances from fixed stars are not accurate throughout. So it is rightly said in the disputation on the three comets of this year held in our Roman College: *"I know that account should have been taken of the hours at which observations of this kind were made in different places, even though they were made on the same day; and besides of the refractions and other matters, whose investigation required far more diligent observers."*

Moreover, the Fathers already mentioned, in the letters they sent from Italy to Europe, in which they recorded their observations of this comet, excuse themselves in the very preface of those letters: through haste, and the lack of better instruments, they could not obtain more accurate observations. And one of them says, in the name of all: *"We had scarcely entered port, and were unprepared for this kind of observation, when it happened that the sky was suddenly seen to blaze with two comets in the morning hours. Among the Moors and the heathen, astonished by the novelty of the thing, this stirred up various rumours. Our baggage was still stuck in the ship; there were no instruments to hand [?] we could trust; to seek them elsewhere was not possible, since there were none there; and we ourselves were forced to move off, one here, another there. So we seized what was to hand — only the astrolabe and the astronomical radius of the College of Goa — and girded ourselves for the*

observations, as far as our other business allowed. Often with broken sleep, often on journeys by land and sea, often in places ill-suited to observing. These, nevertheless, such as they are, hastily copied, I send to the Europeans, meaning to satisfy everyone in the name of all; and since it could scarcely be done otherwise, it seemed good to commit them to print. I hope they will be welcome on this account, that they were sent from the East Indies. For I by no means offer them as exact. The instruments, the place and our occupations did not allow that: we gave what effort we could. We do not strive for a scrupulous count of minutes. If we do not err in whole degrees, that is enough." So he — or rather they — with the sincerity and candour that befit religious men.

[Margin: Excuse of the Fathers in India for their observations of the comets.]

Let our good Biancani go now and say, in the *Sphaera*, book 16, chapter 5: *"The observations made at Goa of the beam and of the comet of the year 1618 agree entirely with ours carried out at Rome, Parma and Antwerp — that is, both were seen by them near the same stars at the same time, etc. From which it may be affirmed with the utmost certainty that they showed no parallax, since from places separated by so great an interval of lands and seas they obtained the same apparent place in the firmament."* Had the observations been accurate, had they been made at the same moment of time, and had the comet's apparent place been the same in both places, Biancani would be arguing rightly; otherwise, not rightly.

[Margin: Biancani's excessive credulity about the diligence of the Indian observations.]

An Potuerit eodem momento temporis videri Cometa Goæ & Ingolſtadij; & ſi potuit aliquo die,quanta fuerit Diſtantia Cometæ.

Whether the comet could have been seen at the same moment of time at Goa and at Ingolstadt; and, if it could on some day, how great the comet's distance was.

VI. Therefore, since we cannot attain evidence from this, I wish, for the sake of conjecture, to investigate whether this comet could have been seen at the same moment of some day in the places of Europe and of India already mentioned; and, if it could, how great both the least and the greatest altitude of the comet must have been, or could have been, for it to have been visible above the horizon in both places while keeping to the observations. I choose Ingolstadt, because Cysat noted there carefully both the hour and the altitude of the comet. We shall take the difference of geographical longitude between Goa and Ingolstadt, established by many investigations in our geographical book, as 70°, that is, $4^{h}\ 40^{m}$; and the polar altitude of Goa as 16°, and of Ingolstadt as 48° 40′. Further, in the year 1618, on November 24, when the comet was first seen in both places, the Sun's place by Magini's Tychonic tables was at Sagittarius 2° 27′ at noon at Rome; but at the end of December, where the Indian observations stop, it was at Capricorn 9° 51′. From these places, from the declination of the parallels in which the Sun was moving, and from the polar altitudes already mentioned, the seminocturnal time set out below is gathered

by the usual problems of the primum mobile, or by the table of semidiurnal arcs published in our *Crux Geographica*.

Seminocturnal time [Seminocturnum Tempus]

Days	Ingolstadt	Goa	Sun's place
November 24	$7^h\ 42^m$	$6^h\ 25^m$	♐ 2° 27′
December 31	$7^h\ 56^m$	$6^h\ 28^m$	♑ 9° 51′

Now the comet is reported, at Rome and throughout Europe as well as at Goa, to have been seen from the beginning — that is, on November 24 and the days immediately following — in the morning hours, namely between midnight and sunrise. Now the difference of longitude, $4^h\ 40^m$, is smaller than the seminocturnal time in both places; so nothing, as far as this goes, prevents the comet from having been seen in both places in the morning hours, or between midnight and sunrise. Let us now examine the possible extremes, and suppose the comet seen at Rome at midnight itself, namely at $7^h\ 42^m$ or $7^h\ 56^m$ before sunrise. For, once $4^h\ 40^m$ are taken away, there remain for Goa, which lies further east, $3^h\ 2^m$ or $3^h\ 16^m$ before sunrise, at which time — and not before — it could first be seen there, if it was seen in the morning in both places. But if we suppose it seen much later at Ingolstadt — yet in such a way that it could not have been seen earlier — there would be a danger that at Goa, with the Sun already rising, the comet could not be seen: if, that is, on November 24 it began to be seen on the horizon of Ingolstadt only $4^h\ 40^m$ before sunrise, or $3^h\ 2^m$ after midnight; or if on December 31 it began to be seen $3^h\ 16^m$ after midnight at Ingolstadt, for then the Sun was rising at Goa. It could therefore be observed, but not later than $3^h\ 2^m$ or $3^h\ 16^m$ after midnight, and not at these very hours unless it was very close to the Ingolstadt horizon; and this was much less possible in the more westerly places of Europe. But if it were established from the record of observations that it was observed later than $3^h\ 2^m$ or $3^h\ 16^m$ after midnight at Ingolstadt, but very low and near the horizon, that would be proof that it could not have been observed at the same moment at Goa, or at any rate was not observed. Take now, for the conjecture, the hours of the Ingolstadt observations and the apparent altitudes of the comet; to these we shall add the hours before or after sunrise at Goa.

Hours before sunrise at Ingolstadt, but at Goa before or after sunrise [Horæ ante Ortum Solis Ingolſtadij, ſed Goę ante vel poſt ortum Solis.]

December, day	Ingol-stadt	Goa	Apparent altitude of the comet at Ingolstadt
1	$2^h\ 6^m$	$2^h\ 34^m$ after	12° 20′
2	$3^h\ 2^m$	$1^h\ 38^m$ after	5° 40′

December, day	Ingol-stadt	Goa	Apparent altitude of the comet at Ingolstadt
4	$3^h\ 42^m$	$0^h\ 58^m$ after	✠ ✠
4	$1^h\ 0^m$	$3^h\ 40^m$ after	28° 20′
7	$2^h\ 24^m$	$2^h\ 16^m$ after	32° 50′
7	$0^h\ 54^m$	$3^h\ 46^m$ after	44° 0′
8	$4^h\ 55^m$	$0^h\ 15^m$ before	12° 30′
Remainder of the preceding table [Reſiduum Tabulæ Præcedentis.]			
9	$6^h\ 10^m$	$1^h\ 30^m$ before	1° 0′
9	$5^h\ 9^m$	$0^h\ 29^m$ before	10° 12′
9	$1^h\ 33^m$	$3^h\ 7^m$ after	48° 58′
10	$1^h\ 30^m$	$3^h\ 10^m$ after	47° 30′
17	$7^h\ 39^m$	$3^h\ 0^m$ before	10° 45′
17	$4^h\ 0^m$	$0^h\ 40^m$ after	47° 25′
18	$5^h\ 0^m$	$0^h\ 20^m$ before	39° 40′
18	$1^h\ 0^m$	$3^h\ 40^m$ after	76° 56′
20	$4^h\ 6^m$	$0^h\ 36^m$ after	48° 30′
20	$1^h\ 21^m$	$3^h\ 19^m$ after	75° 20′
24	$1^h\ 41^m$	$2^h\ 59^m$ after	80° 45′
28	$2^h\ 56^m$	$1^h\ 44^m$ after	69° 30′
29	$3^h\ 30^m$	$1^h\ 10^m$ after	66° 20′
29	$1^h\ 24^m$	$3^h\ 16^m$ after	79° 30′
30	$1^h\ 54^m$	$2^h\ 46^m$ after	76° 25′

From what has been said so far it is clear that there were very few days on which the morning observations made at Ingolstadt could coincide at the same moment with the morning observations at Goa, since for the most part the Sun had already risen at Goa. Let us now choose December 9, when, $5^h\ 9^m$ before sunrise, Father Cysat saw the comet, as he himself reports in chapter 1, 6° 42′ distant from Arcturus and 10° 12′ high. On the same day the comet's

apparent distance from Arcturus at Goa is reported as 6° 46′. Let us suppose the comet seen at Goa at the same moment, namely 29^{m} before sunrise. With these posited, the task is to investigate, if the comet had been on the same great circle under which Ingolstadt and Goa lie, its least and greatest distance from the centre of the Earth, while keeping to the altitude of the comet then seen at Ingolstadt.

VII. First, by the problem and diagram given in chapter 21, number 8, let Ingolstadt be at K and Goa at B; let the complement of the polar altitude, PK, be 41° 21′, and PB 74° (since the distance from the equator is as great as the polar altitude, so that AK is 48° 40′ and GB 16°); and let the angle KPB be the difference of longitude assumed above, AG, 70°. From these the arc KB comes out as 64° 55′.

Diagram. A spherical triangle set in the right column beside the text of §VII: two arcs descend from the pole P at the apex to a base arc AQ; an arc runs from P down to G on the base; lines join K to C, K to B and B to C.

- P (apex): the pole
- K (left arc, upper): Ingolstadt
- C (right arc, middle): no reference in the text of this page
- B (inside, low): Goa
- A (lower left): end of the base arc
- G (base, between A and Q): foot of the arc through B
- Q (lower right): end of the base arc

Secondly, look at the other diagram, in which likewise Ingolstadt is I and Goa B, between which lies the arc IB already found, 64° 55′, which measures the angle IAB. Now let the straight line BV be drawn, touching the Earth at B, to be the physical horizon of Goa; and from the centre of the Earth, A, let the straight line AV be produced through I; and let VIC be the angle of the comet's apparent distance from the zenith of the place I. For the comet's distance will be least if it appears at C, a point of the sensible horizon of Goa — namely the distance AC. If, indeed, it is within CI, it will not appear, as being below the horizon BV; but if beyond, as at M, its distance from the centre of the Earth will increase. Let there therefore be sought in the triangle ABC, right-angled at B, the base AV, in parts of which AB, the Earth's semidiameter, is 4139, since the angle VAB, 64° 55′, is given in it; and AV will be found to be 9763 miles. Taking away AI, 4139, there will remain IV, 5624. With this seek IC in the triangle IVC: for in it, besides IV, every angle is given — namely AVB, the complement of the angle VAB to a right angle, 25° 5′, and VIC, the apparent distance of the comet from the zenith of Ingolstadt, 79° 48′; and therefore ICV, 75° 7′. There will

Diagram. A semicircle (the Earth's section) on the base line LG, set in the right column beside the second construction of §VII. From the centre A lines run to K, through O, and through I to V; the tangent at B rises to V; a line runs from V through C and M to G; further lines join L to the region of I and C, and R to O.

- K (on the arc, upper left): no reference in the text of this page
- V (above, right of centre): end of the line AV and of the tangent BV
- C (below V, right): point of the sensible horizon of Goa
- O (left of centre): no reference in the text of this page
- I (near the arc, left of C): Ingolstadt
- M (on the line toward G): a point beyond C
- L (left end of the base): no reference in the text of this page
- R (base, between L and A): no reference in the text of this page
- A (base): centre of the Earth
- B (base, right of A): Goa
- G (right end of the base): no reference in the text of this page

therefore be IC, 2466 miles. Third, in the triangle AIC, with the sides IC, 2466, and AI, 4139, given, and the angle AIC, 100° 12′, as the complement of the angle VIC, which is 79° 48′, you will find the least distance AC, 4872 Italian miles. Fourth, in the triangle IGA, in which AI, 4139, is given, with the angle IAG, 64° 55′, and AIG, 100° 12′, you will find AG, 15,860 Italian miles. This is less than 4 semidiameters of the Earth; and this is the greatest distance of the comet from the Earth that there could have been under the hypothesis already mentioned — namely, if it had appeared to the people of Goa at the zenith — when at Ingolstadt it appeared 10° 12′ high above the horizon, on December 9. But we have played enough at conjectures for indicating the comet's distance — not uselessly, however.

3. Argumentum, quod eſt Kepleri, ex obſeruationibus Romæ & Lincij factis.

3. The argument which is Kepler's, from observations made at Rome and at Linz.

VIII. Before Kepler brought out this argument, he set before it, on page 73, an excuse in these words: *"Here I ask the astronomers to forgive me if, for the sake of those who have learned to judge of the heavens in a popular way, I shall have used a demonstration that is popular too, not necessary to the astronomers themselves, and for that reason ridiculous."* Then, having brought forward many examples, he shows that most of the observations of this comet made in different places on Earth are rather coarse, indeed conflict with one another; and at last he lays it down thus, on page 75: *"I conclude therefore, on the whole, that no suitable suspicion of any sensible parallax can be elicited from the discrepancy of the observations. On the contrary, the observations of different places frequently agree very nearly, and furnish an argument that there is no parallax caused by the distance of the places; from which we are made somewhat more certain about the altitude of the comet from the centre of the Earth."* This mere probability, as you see, he tries to show from three pairs of observations; but he judges this one the most select, and so we put it forward, although in the end it will turn out a ridiculous demonstration.

[Margin: Kepler's excuse for the levity of the demonstration to be offered.]

He says that on November 29 the comet was observed at Rome a degree and a half from the northern Scale [Lanx Borealis], but by himself at Linz three

Moons, which he says is the same as 1½°; that the comet's distance from the Scale was then almost parallel to the horizon, and the comet very far down towards the horizon, yet with some altitude; and that the azimuth, or vertical circle, in which the comet appeared inclined towards the wind midway between Solanus and Auster, namely towards Notapeliotes, as the Roman observation has it. With these posited, let Rome be at A, says Kepler, and Linz at L, under very nearly the same meridian LG; and since Linz is more northerly, let the straight line AL point to the north; and, a semicircle LKB having been described from A, as of the eastern horizon, let there be cut off from it the arc LKI of 135°, the number of degrees by which Notapeliotes is distant from the north; and let the straight lines AV and LV be drawn to the comet V, raised a little above the horizon. For there will be formed the triangle ALV, in which AL is 100 German miles, because the difference of the polar altitudes of Rome and Linz is 6½°. The angle LAV, of 135°, is also given; and the angle LVA was very small, because in both places the comet was seen to stand equally distant from the Scale, to sense. Yet let the angle LVA be supposed, because of some error, to have been 15′, and the parallax of the apparent distance from the Scale to have been as great; for from these three givens it follows by trigonometric calculation that LV, that is, the comet's distance from Linz, is 16,000 German miles (of which, namely, he supposes 860 to be contained in the Earth's semidiameter). It was therefore the farther off, the smaller the angle LVA was than 15′. From this he at once boldly concludes: *"And beyond doubt not even one minute; so that this number of miles must be taken at least fifteen times over, so that by these observations we may raise the comet even up under the fixed stars: but we may not lower it below 16000 German miles."* Now if you take 16,000 fifteen times, you get 240,000 German miles, that is, almost 291 semidiameters of the Earth. From where, then, that leap all the way to the fixed stars?

Solutio Argument. 3.

Solution of argument 3.

IX. Having received Kepler's own admission, I could have spared myself this labour; for he calls the demonstrations of parallax to be drawn from the observations of different places ridiculous and popular, not worthy of astronomers; and by the very fact that he convicts some of them of grossness and uncertainty, he has no reason to be certain of the others — for they do not deserve certainty merely because they favour his opinion. Yet some things must be noted against this very kind of demonstration. First, on page 58, he had said of this observation of his of November 29: *"The comet's distance from the Scale, about three Moons. When I recorded this from memory of what I had seen in the same quarter of an hour, I began to doubt somewhat whether I had seen the comet above or below the Scale. But the Roman observer frees me from doubt, who gives its distance on this very day from the northern Scale as a degree and a half, towards the Sirocco wind, which are precisely my three Moons."* But how "about three Moons", and afterwards "three Moons exactly"? Next, if three Moons, from where "precisely one degree and

a half"? Was the Moon's apparent diameter then precisely thirty minutes? I do not think so: for it was to be at perigee on December 1, that is, the third day after quadrature; and yet, mind you, from what I said in book 4, chapter 16, the Moon at perigee in the quadratures, just as at full moons, is 32′ 44″, but at apogee 30′; at that time, therefore, at least 32′, so that three Moons were 1° 36′. How slippery that estimation of distances by Moons is, and how easily the eyes are deceived by several minutes, anyone can learn by experience if he asks several people at once, even experts, how many Moons two stars are distant from each other: from their disagreement, which has happened to us more than once, he will recognize the fallacy of this estimation. It was with excessive confidence, therefore, that you said that beyond doubt not even one minute's error or difference had entered your observation or the Roman one.

[Margin: Kepler's excessive confidence.]

Moreover, Chiaramonti, in the supplement to the *Antitycho*, page 149, denies that in the record of the Roman observation (which I do not now have to hand) the comet's distance from the northern Scale is set down for November 29 as 1½°, either in the writing or in the table, which begins from December 1; and he asserts that in the diagram for the 29th a distance of 2½° from the Scale rather appears, if you measure it carefully with compasses. Yet Chiaramonti errs in the same place when he thinks that in the preceding figure the angle LVA was posited by Kepler for the vertical parallax, since Kepler says expressly that it is the parallax of the distance from the Scale. But again, this diagram contains a false construction [pseudographia]: for since the plane of the triangle LAV would not be wholly parallel to both horizons — the Roman, that is, and that of Linz — but would be raised as much as the comet V, the distance from the Scale could not be seen on the same arc by both. Besides, in the Rudolphine Tables Linz is placed 10^{m} of time further east than Rome, that is, 2° 30′, by which the angle LAV must be diminished; nor is that turning of the comet towards Notolybicus to be taken so strictly that the comet strayed nothing this way or that from 135°. Finally, it is not established that the observation was made at the same moment of time; and that equal distance could have been seen at different times — a distance which, had it been seen at the same moment, would have turned out unequal because of the comet's motion. All these things considered, we may lower the comet below 16,000 German miles, which Kepler denies. Chiaramonti adds, moreover, that notwithstanding a large parallax the same distance from the same fixed star may be seen in different places — which he did in fact demonstrate in book 1 of the *Antitycho*, chapter 8.

[Margin: Chiaramonti's slip.]

4. Argumentum, quod eſt Kepleri, ex obſeruationibus in eodem loco terræ factis.

4. The argument which is Kepler's, from observations made at the same place on Earth.

X. After the kind of popular demonstration already mentioned, as he himself calls it, Kepler at once passes, on page 77, to another, saying: *"A demonstration becomes much more evident from observations made at one place but at different hours: for not all of them are untrustworthy; we have some placed beyond the hazard of error."* Having premised this, he lays down the following axiom: *"It is a well-worn axiom, and not to be demonstrated for the first time in this place (although earlier, in the example of the comet of the year 1607, already sufficiently declared in a diagram), that if any heavenly body [Sidus] whose two diurnal motions, following each other most closely, are equal, has in its whole diurnal revolution a motion corresponding proportionally to the number of hours elapsed, that body lacks parallax."* He shows that this happened with this comet from two comparisons of observations. The first is of the Ingolstadt observations, namely those of Father Cysat. For in the middle of the night preceding December 17, the distance from the extreme star of the Bear's tail, which the comet approached almost in a straight line, was 12° 30′; but at the following hour after midnight, $4\frac{1}{2}^{h}$, it became 12° 3′, so that the difference was 27′; and on the following morning, at the same hour, $4\frac{1}{2}^{h}$, that distance was 9° 54′. The diurnal motion was therefore 2° 9′, of which 24′ are due to 4½ hours; but because the diurnal motion was decreasing, it was rightly faster in those first 4½ hours of the preceding day, about 27′. No disproportionate inequality arising from parallax was therefore noticed — and yet one ought to have been noticed if the comet had had a very sensible parallax, both because within those 4½ hours the comet rose a good deal from the horizon, and because in the last observation it cut the vertical circle with its path at an angle nearer to a right angle. For these two reasons, then, its distance from that star ought to have appeared greater within 4½ hours than the diurnal measure gives; and since this did not happen, the comet therefore lacked sensible parallax.

[Margin: Kepler's axiom.]

[Margin: 1. Comparison of the Ingolstadt observations.]

The second comparison of observations, on page 78, is of those made by Schickard, from which he gathers that within three hours the comet increased in longitude by 20′ and in latitude by 21′, *"so that on the same great circle on which it was ascending from day to day it was also ascending from hour to hour, and was not moved off it to any extent that could be perceived: for about two or three minutes the observer himself does not wish to contend with anyone."* Then he concludes in these words: *"Let these things, then, suffice us thus far for this purpose: that the common people may be taught of some comprehensible sum of German miles by which the comet was certainly higher."*

[Margin: 2. Comparison of observations.]

Solutio Argumenti 4.

Solution of argument 4.

XI. Here again I could rest content with the last words of Kepler, who calls this not an absolute demonstration, but one by which the common people

may be taught of some sum of miles that must at the least be conceded to this comet's distance from the Earth. Yet a little earlier he called this very demonstration more evident, resting on observations not at all erroneous and on a well-worn axiom, and from it he twice pronounces that the comet lacked sensible parallax. With the greatest cunning, moreover, he wishes to insinuate it to the astronomers as a demonstration in such a way that, if they do not examine it, they accept it as beyond doubt; but if they call it back to geometrical examination and detect some defect in it, he can withdraw, as into a place of refuge, to his protestation that the demonstration was merely popular. It must therefore beyond doubt be examined by us, who are not pursuing mere probability in this place, but asking whether it has been evidently demonstrated that this comet was above the Moon. We shall weigh his propositions in the order in which he himself wove them together.

First, then, I deny that in the matter of parallaxes a demonstration from observations made at one place at different hours is more evident than one from observations made at the same moment at different places on Earth; for we shall show the opposite to be truer in book 10, the penultimate section, chapter 9, theorem 22. For by the very fact that the observations are made at the same moment of time, the demonstration does not depend on the comet's motion: the comet is considered as unmoved. And if the distance of those places from each other on a great circle is known, together with the comet's apparent distance from the zenith of each place, or from the same fixed star, or both, then from these alone the comet's distance from the Earth can be gathered most evidently, in parts of which the Earth's semidiameter is known — as can be gathered from what was said in chapter 19, number 2, and chapter 21, number 7, and from what is to be said in book 10, penultimate section, chapter 8. We are speaking, however, with other things equal, that is, given equal certainty in the observations. But Kepler has admitted that the observations of this comet were often coarse and uncertain. Why, then, did he hold as certain those from which no sensible parallax is gathered, rather than those from which a very sensible one is gathered? Surely because the former supported his opinion and the latter opposed it. Or at any rate, why did he not choose at least two observations, made in different places, that were trustworthy and not erroneous?

[Margin: 1. Refutation of Kepler's argument.]

Second, I say that these very Ingolstadt observations of the 17th, which he preferred to all others, are uncertain by his own judgement. For he had said on page 65: *"On the same day, the 16th of December, but at the 11th and 12th hours after noon, the distances taken at Ingolstadt from two stars of Draco were 28° 18′ and 35° 30′; from the extreme star of the Bear's tail, 12° 30′ and 12° 46′."* And a little after: *"On the following morning, December 17, at 4^h, distances were taken at Ingolstadt and in Alsace from a number of stars; but they do not agree with one another — not even the Ingolstadt ones — unless you add one degree to the one and subtract it from the other. The observation by straight lines [Rectarum] is therefore more certain; for the comet was seen at Ingolstadt at $6½^h$ between the hindmost stars of the Bear's tail and*

the hip of Boötes, etc." With what inconstancy, then — not to say effrontery — does he call the Ingolstadt observations of the 16th and 17th, by distances from the extreme star of the Bear's tail, *"trustworthy and beyond the hazard of error"* on page 77, if they do not agree with one another but disagree by a whole degree, and if the observation at $6\frac{1}{2}^{h}$, by straight lines drawn between the hindmost stars of the Bear's tail and the hip of Boötes, was more certain than the observation made at 4^{h} or $4\frac{1}{2}^{h}$ by distances from the fixed stars?

[Margin: 2. Refutation.]

Third, I say that the observations already mentioned, granted that they were conceded to be trustworthy, were nevertheless reported and used by Kepler in an untrustworthy way. For the comet's distance from the last star of the Bear's tail on the 16th, at 11^{h} after noon, was seen at Ingolstadt as 12° 30′, and at 12^{h}, that is, at midnight, it was seen as 12° 46′, as we saw from his own page 65. But on page 77 it is said: *"For at midnight preceding the 17th, the distance from the extreme star of the Bear's tail, which it approached almost in a straight line, was 12° 30′; at the following hour, $4\frac{1}{2}^{h}$, it became 12° 3′, a difference of 27′."* Here there is a twofold contradiction and untrustworthiness. First, the midnight observation ought to have been assigned the distance not of the 11th hour but of the 12th, namely 12° 46′; and, this done, if at $4\frac{1}{2}^{h}$ it became 12° 3′, the difference would have been 43′. But this was too damaging to Kepler, who, from the proportion of the diurnal motion, needed a difference exceeding 24′ by very few minutes. The other is that on page 77 the comet is said to have approached straight towards the star *with proportional inequality*, and yet on page 65 it is said to have receded from the 11th hour to the 12th, since the distance at the 11th hour was 12° 30′ and at the 12th 12° 46′.

[Margin: 3. Refutation of Kepler's argument.]

Fourth, therefore, from what has just been said, I turn the argument back against Kepler in this way. From $4\frac{1}{2}^{h}$ after midnight on the 17th to $4\frac{1}{2}^{h}$ after midnight on the 18th, the comet's motion was 2° 9′; and so, by your account, the motion of 4½ hours was 24′, or 27′ because of the somewhat greater speed at the start. Therefore, if at $4\frac{1}{2}^{h}$ on the 17th the comet stood 12° 3′ from the star of the Bear, it ought, those 4½ hours earlier, that is, at midnight, to have been distant from the same star only 12° 27′, or 12° 30′ at most — provided, of course, that the measure and proportion of the diurnal motion is kept and no parallax intervened. But at 12^{h} it stood 12° 46′ off, when the comet was lower, as Kepler admits. Therefore, by Kepler's own way of arguing, there follows a parallax of distance of 19′, or at least 16′, by which the comet, depressed towards the horizon, appeared to stand farther from the star of the Bear [vrſina ſtella] than it should have.

[Margin: 4. Refutation and retortion of the argument.]

[Margin: A parallax of distance of 16 or 19 minutes.]

Fifth, I say that the Ingolstadt observations which Kepler used are not those which Cysat later committed to the press after selecting the more certain

ones, but those which Io. Georgius Heruuartus [Johann Georg Herwart von Hohenburg], Councillor of the Duke of Bavaria and Chancellor of the Estates, had sent to Kepler before any selection — as is clear to anyone who reads Kepler on page 59 on the one hand, and Cysat on page 10 on the other, where in the Appendix Cysat testifies that his observations published by Kepler were mixed with uncertain and less accurate ones. This will be established even from his observations of this very day. For as Cysat himself relates on page 3: *"On December 16, about 9^h in the evening, the tail [Coma] of the comet was seen to pass through the middle of the quadrilateral of the Great Bear, the head lying hidden either below the horizon or in a cloud that lay close upon the horizon. It began to appear"* — that is, the head — *"at an altitude of 3° 23′, about 11^h of the night; at which time also the comet's distance from the extreme star of the tail of the Great Bear, or Benenaz, was 12° 36′."* Then, for December 17, thus: *"At 0^h 21^m, about the midnight that followed the 16th day, the comet's altitude was 10° 45′; it was 12° 30′ from Benenaz. At 4^h 7^m it was 12° 3′ from Benenaz, and the comet's altitude was then 44° 30′. On December 18, at 4^h 46^m, the comet's altitude was 49° 0′; it was 9° 54′, or 56′, from Benenaz."* But Kepler, in reporting the minutes of the hours, does not agree at all with this narrative, trusting an uncorrected writing, or

[Margin: 5. Refutation, and Kepler's disagreement with Cysat in reporting Cysat's observations.]

his own customary complacency: for 12^h 21^m he puts 12^h, that is, midnight itself; for 4^h 7^m he puts $4½^h$; and for 4^h 46^m of the following day he puts $4½^h$. But he needed precisely one diurnal revolution, and so the observation had to be drawn to $4½^h$ at both ends.

Sixth, as Chiaramonti also noticed in the supplement to the *Antitycho*, page 150, Kepler treats the comet's proper motion as if it had been made on the circle of distance from the Bear's tail, when in fact it was made on a different arc, since the comet approached that star not wholly in a straight line but nearly so. And what is worse, he takes this motion, which was of course the apparent motion, caught by immediate observation, for the true one. For his argument runs on this supposition: that if in 4½ hours the comet approached the star of the Bear by as much as the account of its motion required, there was no sensible parallax. Otherwise, if he were speaking of the apparent motion, there would be no argument at all; for it could be said that the apparent motion towards the star at midnight had been notably faster than at $4½^h$, and so had prevented a parallax that would otherwise have appeared from being seen. From here we step to the seventh refutation.

[Margin: 6. Refutation of Kepler's argument.]

Seventh, I deny that the axiom on which Kepler relies is true of the true motion taken by itself, or of the apparent motion taken by itself; it holds only, and at most, of the true motion compared with the apparent. For the true diurnal motion of two days can be equal, so that it keeps the proportion of equality even in any part of the day, and yet, because of a sensible parallax,

appear unequal — either the whole diurnal motion compared with the other diurnal motion, or a part of it with a part. Conversely, the true motion can be unequal, but so tempered by parallax alone, or by parallax mixed with refraction, that either the whole diurnal motion appears equal to the other diurnal motion, or one part appears equal, or proportional in that part to the whole diurnal motion. But if the measure of the true diurnal motion is established, and its equality, or the proportion due to a certain number of hours — say 4½ hours — and the apparent motion in those hours was also as great, and the comet did not stand farther from the same fixed star at those different hours than the true motion requires, then indeed it is a sign that the comet lacks sensible parallax, or, if it has one, that this was corrected by refraction. But Kepler, with the parallax still unknown, could not distinguish the true motion from the apparent; and the apparent motion of 4½ hours was compared with the motion due to the same time, gathered from the proportion to the apparent diurnal motion and from mere observation. This argument is therefore full of fallacy, and unworthy of Kepler's intellect.

[Margin: 7. Refutation of Kepler's argument.]

Eighth: the same axiom requires that two diurnal motions following each other most closely be equal. And yet Kepler gathers the quantity of the diurnal motion from the revolution of a single day; and that very motion is said to have been so much faster at the beginning that in the first 4½ hours it made 27′ instead of the 24′ it would have completed had it been equal. So it is being used as unequal.

[Margin: 8. Refutation of the same argument.]

Ninth: on the 16th, at 11^h after noon, the comet's apparent altitude was 3° 23′, and at 12^h 21^m its apparent altitude was 10° 45′, on Cysat's testimony, page 3. At 12^h, therefore, its apparent altitude was about 8°; and at that altitude the lunar refraction [Refractio Lunaris] is 12′, which could have contracted the comet's distance from the star of the Bear and so diminished the parallax. It is not rightly concluded, then, even if the rest were granted, that the comet lacked sensible parallax.

[Margin: 9. Refutation of the same.]

Tenth: there are many other observations of this comet, made at Ingolstadt and elsewhere, from which, by Kepler's method, a very sensible parallax is gathered. Therefore, even if some did not indicate one, it cannot be affirmed with certainty that this comet lacked sensible parallax. An example from the Ingolstadt observations, for a sensible parallax of distance of 19′ or 16′, we have already brought forward in the 4th refutation. Let another example be taken from Father Cysat, page 4, where he says that on December 20, at 4^h 40^m in the morning, the comet, at an altitude of 55° 42′, stood 26° 21′ from Arcturus, and at 6^h 39^m, at an altitude of 75° 20′, stood 26° 42′ from Arcturus; at 5^h 44^m, therefore, it stood very nearly 26° 33′ away. And on the 21st, at 5^h 44^m in the morning, at an altitude of 67° 10′, it stood 28° 18′ from Arcturus. The diurnal

motion was therefore 1° 45′, of which 9′ are due to the two hours between 4^h 40^m and 6^h 39^m. Subtract these from the apparent distance at 6^h 39^m, and there will remain a distance of 26° 33′ — the distance the comet ought to have stood from Arcturus, which lay lower than the comet, at 4^h 40^m. But it was seen to stand only 26° 21′ away. Therefore the parallax of distance, depressing the comet towards Arcturus, was 12′, which is very sensible, and is an argument for a much greater parallax of altitude, corresponding to an altitude of 56°.

[Margin: 10. Refutation, and an argument for a very sensible parallax.]

5. Argumentum Item Kepleri ex Motu per rectam lineam Traiectoriam.

5. An argument, likewise Kepler's, from the motion along a straight trajectory line.

To be done with Kepler, I note that on page 92, with no demonstration set out beforehand, he asserts that this comet at the beginning of its appearance was thirty times higher than the Moon and had a parallax of 2′, and at the end was between Jupiter and Mars. He takes the foundations of these altitudes from the annual motion of the Earth and from the comet's motion upwards along a straight line — neither of which, we shall show below, has been demonstrated or can be; and therefore this view about the comet's altitude is mere opinion, not demonstration.

6. Argumentum, Longomontani, ex proprijs Obſeruationibus Hafniæ habitis, diuerſis horis eiuſdem noctis.

6. The argument of Longomontanus, from his own observations made at Copenhagen at different hours of the same night.

XII. In place of the Tychonizing Kepler we put the Tychonic follower Longomontanus, who in the Appendix to the *Astronomia Danica*, chapter 10, page 35 in my copy, admits that observations of cometary parallaxes are the most subtle of all in astronomy, and are to be obtained not with childish instruments but with such as show aliquot parts of single minutes — as he professes his own to have been. On December 16, then, which was the 26th in the Gregorian style, in the evening at $7\frac{1}{3}^h$ after noon, when the comet was seen below the pole very nearly at its lowest altitude, from the comet's observed longitude, ♏ 12° 58′, and northern latitude, 60° 18⅙′, its northern declination is gathered by spherical triangles as 58° 41½′. Then, the same night, at $6\frac{1}{12}^h$ after midnight, when the comet appeared in the morning not far from the zenith above the pole, from the longitude then observed, ♏ 11° 9¾′, and the latitude, 60° 39⅔′, the comet's declination is gathered as 59° 35⅓′. In the space of 10^h 45^m, therefore, the declination advanced towards the north by 53⅚′. Now from the table he himself drew up, the motion in declination from December 26 to 27 was 1° 25′ or 26′, of which the proportional part due to 10^h 45^m is 38⅙′. *"Therefore the difference between the true and the apparent declination was 15⅔′,"* says Longomontanus. For between the observed declinations, 58° 41½′ and 59° 35⅓′, the difference was 53′ 50″; but between the true ones, gathered from the diurnal motion, it should have been 38′ 10″; the difference between these

was therefore 15′ 40″, or 15⅔′. With these preparations made, he girds himself to demonstrate the parallax by means of the following diagram, which, being mutilated in his work, we shall complete.

Diagram. A geometric figure for Longomontanus's demonstration of the comet's parallax from observations at two hours of one night, set in the right column. A large circle stands on a horizontal diameter R … L drawn through the centre A; a vertical line runs from A up to C at the top of the circle; two smaller semicircles stand on the diameter about A; straight lines run from A and from O to points on the arcs, and short arcs are drawn near the upper right. The text below names the meridian RCL, the semicircle IDS for the comet's places, TBV for the terrestrial meridian, the rational horizon RAL, the vertical ABC, the north pole of the equator P, and the equator ZAO with its axis AP.

- C (top of the circle): the upper end of the vertical ABC
- F, G (together near the top, right of C): not yet referred to on this page
- P (upper right): the north pole of the equator
- Q, H, K (down the upper right): not yet referred to on this page
- D (left of the vertical): on the semicircle IDS
- E, N (right of the vertical): not yet referred to on this page
- O (on the circle at the left): an end of the equator ZAO
- M (inside the circle at the right): not yet referred to on this page
- B (on the vertical, low): on the semicircle TBV and the vertical ABC
- R, L (ends of the horizontal diameter): the meridian RCL and the rational horizon RAL
- I, S (on the diameter, inner): ends of the semicircle IDS
- T, V (on the diameter, either side of A): ends of the semicircle TBV
- A (centre, on the diameter): the Earth's centre
- Z (on the circle at the lower right): an end of the equator ZAO

From the Earth's centre A, describe the meridian RCL, and under it the semicircle IDS for the places of the comet, and TBV for the terrestrial meridian; and let RAL be the rational horizon, and ABC the vertical line standing perpendicular to it. Let the north pole of the equator be P, and the equator ZAO, whose axis is AP. And let the comet be observed at its lowest meridian altitude at M, and at its highest at E. Through the comet, placed at each of these places, let there be drawn from A, the centre of the Earth, the lines of the true place, AMH and AEF; but from B, the eye placed on the surface of the Earth, let there be drawn the lines of the apparent place, BMK and BEG. Finally, from the pole P let the arc GNQ be described, touching the comet's path at N. With these marked out, the true declination in the first observation, when the comet was at M, was the arc HLZ, and the apparent declination KLZ; hence HK is the parallax of altitude, whose measure is the angle AMB. But in the other observation, when the comet was at E, the true declination was the arc OCF, the apparent OG, and the parallax of altitude FG, whose measure is AEB. Longomontanus says, moreover, that the arc QH is equal to the parallax FG, and that the arc KQ is equal to the sum of the parallaxes, and as great as

the difference between the apparent and the true declinations, that is, 15⅔′. From here he investigates the comet's apparent altitudes in this way. Since the apparent declination KZ of the comet at M was 58° 42′, its complement KP to the quadrant ZP was 31° 18′. Subtracting this from the altitude of the pole at Copenhagen, PL, which is 55° 43′, there remains the apparent altitude KL, 24° 25′; and so the angle CBK is 65° 35′, and ABM 114° 25′. Next, since for the comet placed at E the latitude was 60° 40′ and the declination 59° 35′, he gathers from these the comet's right ascension as 203° 40′, and its altitude at $6\frac{1}{12}^{h}$ as 80° 6′, which he says would have been 80° 8′ on the meridian; from this he gathers the arc FG, 2′, for the parallax. When this is subtracted from 15′, there remains the parallax HK on its own, that is, the angle AMB, 13′, in the triangle AMB, in which the angle ABM is also given — the complement, which was 114° 25′ — and AB, 1 semidiameter of the Earth. Hence AM, by the rules of triangles, comes out at 240 semidiameters of the Earth, or 206,400 German miles, of which there are 860 in AB.

Solutio Argumenti 6. ex Declinationibus in Altitudine Maxima & Minima Meridiana.

Solution of argument 6, from the declinations at the greatest and least meridian altitude.

XIII. First, Longomontanus supposes that the declinations of the comet that he drew up in his table are true, whereas they are apparent, being derived from the comet's apparent distances from the fixed stars. Thus he says, on page 34 of my copy, that on the 16th, or the 26th new style, at $7\frac{1}{3}^{h}$, he observed the comet's distance from Dubhe as 21° 28′, and from the antepenultimate star of the bend of the Serpent as 19° 45½′; and from the longitude and latitude of these fixed stars he gathers the comet's longitude at that time as ♏ 12° 58′, its northern latitude as 60° 18⅙′ [?], and from this its declination as 58° 41½′. But at $6\frac{1}{12}^{h}$ in the morning after midnight, he says, he observed the distance from Dubhe as 20° 42′, and from the same star of the bend of the Serpent as 19° 39′; from which he gathers the comet's longitude as ♏ 11° 9¾′, its latitude as 60° 39⅔′, and from this its declination as 59° 35⅓′. All these must certainly be understood of apparent, not true, values; nor does he set down any other observation for that day. From where, then, does he put in the table, for the 26th, a declination of the comet of 58° 10′, and for the 27th a declination of 59° 35′? Not from the apparent declinations: for if in 10¾ hours the declination increased by 53⅚′, then in 24 hours it ought surely to have advanced 2 degrees, and not only 1° 25′. Nor did he know it beforehand from the parallax of declination, since he seeks that parallax through these very declinations, as an unknown. That table, therefore, is fallacious and merely arbitrary, made from conjectures taken broadly — the table before which he himself, as if excusing himself, had said: *"There follows a synopsis of the motions of this comet, assigned from all the observations set out above, as in the earlier one, broadly, and as far as could be done and was needed."* Since, therefore, the whole structure of the problem

already mentioned rests on comparing the motion of the true declination with the apparent, and the true motion was not known beforehand, nor could it be known beforehand while the parallax and the comet's distance from the Earth were unknown, it follows that the conclusion of the problem is fallacious and uncertain.

Second: although he had said that this business is most subtle, so much so that not only one minute but not even aliquot parts of a minute are to be disregarded, he himself afterwards uses two altitudes outside the meridian as if they had been on the meridian itself — which could nonetheless introduce a discrepancy greater than one minute.

7. Argumentum, P. Cyſati, ex Differentia Parallaxium Cometæ in arcu proprij motus, collata cum differentia Parallaxium Lunarium in ijſdem altitudinibus.

7. The argument of Father Cysat, from the difference of the comet's parallaxes on the arc of its proper motion, compared with the difference of the lunar parallaxes at the same altitudes.

XIV. To unweave the web of this argument in order, let us first set down, from the *Mathemata Astronomica* that Father Io. Baptista Cysatus published on this comet — namely from chapter 2, problem 4, in which he teaches how to find the comet's diurnal and hourly motions — these words: *"We call the diurnal motion of our comet the arc of its path which it has advanced, from some one altitude of its own above the horizon, by the time it has returned to the same altitude, carried round in the revolution of the primum mobile; and this return of the comet happened in about 24 hours. And this is the comet's true motion for 24 hours, because, even if the comet had suffered the greatest parallax, yet since its altitude from the horizon is supposed to be the same, everything that follows from the parallax was the same as well. However apparent the endpoints may be, therefore, the motion intercepted between them is true; because by however much, and in whatever direction, the comet was pushed by the parallax at the earlier endpoint, by just as much and in the same direction it was pressed at the later endpoint also — by the same parallax, of course."* He then teaches, on page 17, how to find this motion, and indeed the apparent one as well, by the following method. Let the ecliptic be GEK, and its pole A, on its colure; from A let two quadrants, AF and AE, descend to the ecliptic; let the comet's path be DBC, etc.; and on the earlier day or hour let the comet be at B, whose longitude, and latitude BE, are known at that time through distances from the fixed stars. Then, on the following day or hour, let the comet be at C, whose latitude CF and longitude are known in the same way. For in the triangle BAC there will be given the sides AB and AC, which are the complements of the latitudes, and the included angle BAC, which is the difference of the longitudes. Therefore, he says, the arc BC will not be hidden — that is, the comet's motion completed either in one whole day or in some hours of the same day. And if it was completed in one day, it will be the diurnal motion, *which will indeed be true if, on the next day,*

while the comet is at C, its altitude from the horizon is the same as it had been on the earlier day, when the comet was at B; otherwise the motion will be apparent, if the comet's altitude was different when it was at B at the earlier hour from when it is at C at the later hour. On this foundation, from the observed longitudes and latitudes, he wove a table containing the diurnal motions of this comet, which we have already reported, from Cysat's ephemeris, in the history of the comets of this year. Afterwards, in chapter 3, lemma 8, he teaches that if the comet's true motion is subtracted from the apparent, there remains the difference of the comet's parallaxes belonging to its different altitudes from the horizon.

Diagram. Cysat's figure for finding the comet's motion BC from two observed longitudes and latitudes, set into the right half of the right column. A circle with a horizontal line G … K drawn across it below the centre, representing the ecliptic GEK; from the pole A at the top, a curved arc runs down to F and a straight line down to E (the quadrants AF and AE); a slanting line passes through C and B towards D (the comet's path DBC).

- A (top of the circle): the pole of the ecliptic
- C (left of centre): the comet's place on the following day or hour
- B (centre): the comet's place on the earlier day or hour
- G (left end of the horizontal line): on the ecliptic GEK
- F (on the horizontal line, left): foot of the quadrant AF; CF is the latitude at C
- E (on the horizontal line, middle): foot of the quadrant AE; BE is the latitude at B
- D (on the horizontal line, right): on the comet's path DBC
- K (right end of the horizontal line): on the ecliptic GEK

With these supposed, he now tries, in the same chapter 3, page 49, to demonstrate that the comet of the year 1618 was above the Moon from its parallax, which is smaller than the lunar parallax, by this method. On December 1, he says, the comet was observed at $5^{h}\ 45^{m}$ in the morning at an apparent altitude of 12° 30′, and at $6^{h}\ 56^{m}$ at an altitude of 22° 20′. The interval was $1^{h}\ 11^{m}$. The true diurnal motion from the ephemeris for that day was 3° 14′, of which 9. 34′ [?] are due to $1^{h}\ 11^{m}$. But the apparent motion in the same interval of time, gathered from the observed longitudes and latitudes by the preceding problem — that is, the arc CB — was 12′. Therefore, when the true motion is subtracted from the apparent by Cysat's lemma 8, there remains a difference of parallaxes of 2′ 26″ — namely of those two of which one belongs to the comet at an altitude of 12° 30′, the other at an altitude of 22° 20′. Now if, for Copernicus and Tycho, the greatest parallax of the Moon at perigee is 66′, the parallax due to an altitude of 12° 30′ will be 64′ 48″, and that of an altitude of 22° 20′ will be 61′ 36″; so the difference of parallax will be 3′ 12″, greater than 2′ 26″. Therefore the comet was above the Moon. The argument reduced to form, then, is of this kind: *That phenomenon is higher than another which, from one altitude to another on the same day, has a smaller difference of parallaxes.*

[Margin: Father Cysat's argument 7 in the form of a syllogism.]

But the comet of the year 1618, on December 1, had a smaller difference of parallaxes than the Moon from one altitude to another. Therefore the comet of the year 1618, on December 1, was higher than the Moon. The major premiss is certain, and was demonstrated by Father Cysat himself, chapter 3, proposition 4, lemma 3. The minor was proved from what was said just now, at number 14.

Solutio Argumenti 7.

Solution of argument 7.

[Margin: First refutation of argument 7.]

XV. The major proposition of argument 7 is granted; the minor is denied, because in its proofs some [?] things are supposed that are false, and some that are uncertain. First, it is supposed that the comet's true proper diurnal motion can be known before the parallax is known, from the comet's return to the same altitude. But this is false. For if a comet, besides the common diurnal motion of the primum mobile, has a peculiar motion in longitude that is sensible in one day — as this comet had, which within two months advanced against the order of the signs from the last degrees of Scorpio to about the 20th degree of Cancer — it is impossible that, when 24 hours have elapsed, or one revolution of the primum mobile has been completed, the comet should return to the same apparent altitude, whether it has a sensible parallax or not (except in the case in which the comet's path is parallel to the horizon). Rather, it will come back to the same altitude on the rising side later if it moves in the order of the signs, and earlier if it moves against the order of the signs. The first of these is evident in the Moon; the second in the five lesser planets when they become retrograde, especially in Mars, Mercury and Venus. Hence, when a revolution of 24 hours has been completed, the comet's altitude will be different from its altitude on the preceding day; and in that case Father Cysat grants that the motion gathered from two observations is apparent. But the motion of this comet was against the order of the signs: for according to his ephemeris, page 20, the comet on December 1 at $5^h\ 45^m$ in the morning was seen at 9° 24′ of Scorpio, but on December 2 at $4^h\ 48^m$ in the morning it was observed at 7° 56′ of Scorpio. Nor was its path parallel to the horizon, since at $5^h\ 45^m$ in the morning its apparent altitude was 12° 20′, as is said on page 2, or 12° 30′, as is supposed on page 49; and at $6^h\ 56^m$ its altitude, from the same pages, was 22° 20′; and on the following day, at $4^h\ 49^m$ in the morning, the apparent altitude was 5° 40′.

Moreover, even if the comet's apparent path were parallel to the horizon, though above the horizon, so that after 24 hours it returned to the same apparent altitude, the comet's true motion still could not be gathered from the difference of the longitudes and the complements of the apparent latitudes — nor indeed the apparent motion — because in such a case the arc of the comet's motion would be an arc of a circle in the sphere that is not a great circle; whereas in the problem already mentioned the arc BC is supposed to be an arc of a great circle, since otherwise it would run contrary to the laws of trigonometry that

Cysat applies here. It could not, I say, except in the case in which the ecliptic coincided with the horizon, and so the altitude of the pole was 66° 30′; for then after 24 hours the comet could return to the same apparent altitude, and the complements of the altitudes and of the latitudes would be the same. Likewise, if the equator coincided with the horizon, the true and the apparent motion could be gathered from the difference of right ascension and the complements of the declinations — which would be the same as the complements of the altitudes — because the comet's progress would be parallel to the horizon; and in either case the two motions would be equal, and so there would be no difference of parallax, however great the parallax might be — provided that in this case there is no proper motion oblique to the equator.

[Margin: Second refutation of argument 7.]

Second, even if we were to grant that the true diurnal motion could be known while the parallax is unknown (which nevertheless cannot be known except in the case just mentioned, in which the ecliptic coincides with the horizon and the comet's proper motion is parallel to the horizon, and so to the ecliptic), it still could not in fact be known by Father Cysat, as I shall show from his observations recorded for December 1 and 2, which are set out below from his pages 2 and 20.

December: day, time	Apparent altitude	Apparent distance from Arcturus	Apparent distance from Spica	Apparent longitude	Apparent northern latitude
1, 5^h 45^m morning	12° 20′	27° 6′	24° 48′	9° 24′ ♏	11° 37′
1, 6^h 56^m morning	22° 20′	26° 56′	24° 54′	9° 12′ ♏	11° 50′
2, 4^h 48^m morning	5° 40′	24° 0′	25° 20′	7° 56′ ♏	14° 31′
2, 6^h 52^m morning	✠	✠	✠	4° 56′ ♏	19° 18′

For 6^h 52^m of day 2 no altitude or distance from the fixed stars is given, because after the observation at 4^h 48^m it is said: *"When the observation was finished, the sky was covered with clouds."*

From these it is clear that Father Cysat could not have known the comet's true diurnal motion for certain, because between the first two observations, of the 1st and the 2nd day, not 24 hours elapsed but 23^h 3^m. And in the second observation of day 2 the observation of altitude and distances was either not made or doubtful — otherwise they would have been recorded — and the huge jump itself in the motion in latitude, from 14° 31′ to 19° 18′, makes the observation suspect. Further, from 5^h 45^m to 6^h 56^m of the first day there are 1^h 11^m, and in that space the apparent motion in longitude was 12′, as you see in the little table above; yet on page 49 he says that in 1^h 11^m the comet's apparent proper motion was 12′. He therefore takes the comet's motion just as though the motion were in the ecliptic, or in a parallel of the ecliptic. If so, then just

as in 1^h 11^m it completed 12′, so from 5^h 45^m of the first day to 4^h 48^m of the second day, that is, in 23^h 3^m, it completed 1° 28′, if you subtract 7° 56′ from 9° 24′ of Scorpio. But if this motion was gathered by proportion — whether one puts it: as 1^h 11^m to a motion of 12′, so 24 hours to 4° 35′; or: as 24 hours to 1° 28′, so 1^h 11^m to 4′ 20″ — you will never gather that diurnal motion of 3° 14′ that Father Cysat sets down; and the motion he gathered from the longitudes was not of 24 hours but of 23^h 3^m.

Third, the difference of the lunar parallaxes that Father Cysat considers at the altitudes already mentioned is the one gathered from parallaxes in circles of altitude; but the difference of the comet's parallaxes is not a difference of parallaxes in a circle of altitude but on the arc of the comet's path, which was indeed not parallel to the horizon, yet came nearer to a parallel than to a vertical circle. Now the difference of parallaxes on the phenomenon's own arc can be smaller than the difference of parallaxes in its circle of altitude, and so the latter larger; and the latter could have been larger than the difference of the lunar parallaxes of altitude. The major premiss of the argument therefore had to be distinguished: granted if the comparison is made within the same kind of parallax, denied if in a different kind.

[Margin: Two other examples of Father Cysat are refuted.]

From what has been said, the same argument, which Father Cysat confirms with two other examples on pages 50 and 51, remains refuted. For in these he errs in the same two ways. He supposes, namely, that the true motion is known distinctly from the apparent motion, without prior knowledge of the parallax, and from mere observed places, yet not at the same altitudes, as was required after a revolution of 24 hours. Then he compares the difference of the parallaxes of the arc that the comet described by its own progress with the difference of the lunar parallaxes viewed in a circle of altitude. For he says that on December 9, between the first observation, when the comet was seen at an altitude of 10° 12′, and the second, when its altitude was 44° 10′, the apparent motion was 39′ 30″, corresponding to 3^h 56^m, but the true motion 30′, because the diurnal motion was 2° 59′ 50″; and that the difference of parallaxes [?] was therefore 9′ 30″. But at the same altitudes the difference of the parallaxes of the Moon at perigee was 17′ 39″, much greater than the difference of the comet's parallaxes. He himself, however, on page 3, had said that the comet was seen at an altitude of 10° 12′ at 2^h 46^m, and at an altitude of 48° 58′ at 6^h 22^m; between these hours there are 3^h 36^m, not 3^h 56^m.

8. Argumentum,P. Cyſati, ex Differentia Parallaxium in diſtantijs ab eadem Fixa ſtella, Collata cum differentia parallaxium Lunarium.

8. The argument of Father Cysat, from the difference of parallaxes in the distances from the same fixed star, compared with the difference of the lunar parallaxes.

XVI. This argument is the same as the 7th, but the proof of the minor is different. Father Cysat's argument on page 49, then, runs as follows: *That star*

is higher than another which changes its parallax less from one altitude to another. But the comet of the year 1618 changed its parallax less than the Moon from one altitude to another; therefore it was higher than the Moon. He supposes the major as proved from his lemma 3 of chapter 3.

[Margin: First example of Father Cysat.]

The minor he tries to prove by two examples. For on December 1, at $5^h\ 45^m$ in the morning, the comet appeared at an altitude of 12° 30′ and at a distance from Arcturus of 27° 6′, or, on account of [?] refraction, 27° 9′; but at $6^h\ 56^m$ in the morning, at an altitude of 22° 20′, it appeared at a distance from Arcturus of 26° 56′. Therefore in the space of $1^h\ 11^m$ the apparent approach to the star was 13′. But the true motion, gathered from the comet's diurnal proper motion, was 9′ 34″ in that space, as was said in the proof of argument 7; therefore the difference of these, and so the difference of the parallaxes, was 3′ 26″. But the difference of the lunar parallaxes of altitude at the same apparent altitudes is 3′ 30″; therefore the comet's difference is smaller than the Moon's. Again, on the 9th, at $2^h\ 46^m$ in the morning, the comet appeared at an altitude of 10° 12′ and at a distance from Benenaz of 33° 36′; but at $6^h\ 22^m$, at an altitude of 48° 58′, at a distance from Benenaz of 32° 54′. Therefore within $3^h\ 56^m$ the apparent approach to the star was 42′, but the true approach, from the true motion, ought to have been 30′; hence the difference of the parallaxes was 12′. But at the same altitudes the difference of the parallaxes of the Moon at perigee is 17′ 39″; therefore the former is smaller than the latter. By a similar method he investigates the difference of parallaxes for December 1, 9, 17, 20 and 29; and from these, by his lemmas 5 and 6 (on which, our Book 10, penultimate section, chapter 2, problems 7 and 8), he investigates the comet's horizontal parallax; and finally from this, by the problem I have already given in Book 3, chapter 7, number 3, he seeks the comet's distance from the centre of the Earth, and finds it as in the table below.

December, day	Horizontal parallax	Distance of the comet from the centre of the Earth, in semidiameters of the Earth	Distance of the comet from the centre of the Earth, in German miles
1	47′ 34″	72	62139
9	35′ 33″	96	83172
17	26′ 3″	132	113456
20	22′ 15″	154	132921
29	13′ 39″	252	216625

Solutio Argumenti 8.

Solution of argument 8.

XVII. We reply by distinguishing the major proposition: granting it if the comparison of the differences is made within parallax of the same kind, and denying it if within parallax of a different kind; and so denying the minor, understood — as is fitting — of the difference of parallaxes of the same kind.

For the comet's parallaxes that Father Cysat uses are on the arc of distance, which was different not only from the circle of altitude but also from the circle of the comet's proper motion (and in this very point there is a flaw, nor is the approach to the star properly compared with the proper motion); whereas the lunar parallaxes and their difference are viewed in two circles of altitude. Moreover, the comet's true proper motion is supposed to be known distinctly from the apparent one before the parallax is known, which we have already shown to be false in the first refutation of argument 7. Finally, Father Cysat frankly admits, on page 10, that he used a wooden sextant: *"With this instrument,"* he says himself, *"we measured the comet's distances from the fixed stars, with an error, as is clear from the size and dimensions of the instrument, not greater than 6′."*

9. Argumentum, Villebrordi Snellij, ex Differentia Parallaxium Cometæ in diſtantia ab eadem Fixa, Collata cum differentia Parallaxium Lunarium in circulo Altitudinis.

9. The argument of Willebrord Snel, from the difference of the comet's parallaxes in its distance from the same fixed star, compared with the difference of the lunar parallaxes in a circle of altitude.

[Margin: Argument 9 in syllogistic form.]

XVIII. Snel's argument, from chapter 4 of his work published on this comet, extracted like marrow from the bone, is of this kind: *If the comet of the year 1618 had not been higher than the Moon from the centre of the Earth, then between the observation of the 13th day at 4½ʰ and that at 6½ʰ there would have been a difference of parallaxes equal to the difference of the lunar parallaxes, or smaller, or at least 23′ 37″. But no such difference occurred; therefore it was higher than the Moon from the centre of the Earth.* He proves the minor from the distances from the adjacent stars on the back of Boötes. But we reply in the same way as to argument 8. For here too, all things considered, Snel compares the difference of the comet's parallaxes on arcs of distance from the fixed stars (which nevertheless were different from the arc of the comet's path) with the difference of the lunar parallaxes in a circle of altitude. Chiaramonti also noted this in the supplement to the *Antitycho*, page 176, where he adds that a phenomenon can keep, at different altitudes, the same apparent distance from a given fixed star as its true one, and yet have a large parallax in the vertical circle — which he had demonstrated in the *Antitycho*, Book 1, chapter 8, proposition 1. Chiaramonti indeed detected many errors in Snel, but two above all. The first lies in his using Tycho's longitude of the fixed stars for the year 1600 as though nothing had changed by the year of this comet, 1618, although by Tycho's reckoning they advance 15′ 18″ in 18 years; on this error see Chiaramonti there, page 164. The second is that, from a disturbed order of the arcs in his trigonometric analysis, he gathers the comet's latitude towards the end of December as 72° 44′ 45″, whereas Chiaramonti, from the same data, gathers the latitude as 58° 33′ 37″. There is no need to unweave the calculations of either of them here;

but a sign of Snel's error can be the comet's greatest latitude, which the other observers — Kepler, Longomontanus, Cysat — put at no more than about 59°.

10. Argumentum, P. Blancani & commune Multorum, ex Aequali diſtantia Cometæ ab ijſdem Fixis viſa in locis Terræ valde diſtantibus eodem tempore.

10. The argument of Father Biancani, shared by many, from the equal distance of the comet from the same fixed stars, seen at the same time from places on Earth very far apart.

XIX. These, of course, are the feathers and wings with which the comet of this year 1618 tried to fly out beyond the bounds of the Moon and the Sun — wings that a truly Daedalian Rumour fitted to it, when, that is, the report spread from various regions of the world that this comet had been observed at the same time under the same fixed stars, or at a nearly equal distance from the same fixed stars; and astronomers hold it for certain that this could by no means happen if it had had a very sensible parallax. And the comet was observed not only at places in Europe very far apart — at Antwerp, Danzig, Linz, Strasbourg, Cologne, Leipzig, Wittenberg, Frankfurt, Ingolstadt, Innsbruck, Rome, Parma, Cesena, Paris, Aix, and Valencia in Spain — but also at Goa and Cochin, by Fathers of our Society in the East Indies. Why, then, should so great a distance between the places not supply an argument for the comet's distance from the Earth, splendid in appearance and celebrated with the applause of all? But if, by melting the waxen wings of this Icarus too, we show them to be too weak for so great a height of motion, I believe we shall obtain pardon from lovers of the truth — not to say no small gratitude. Further, this argument too, contracted into syllogistic form, is as follows:

[Margin: Argument 10 in syllogistic form.]

A phenomenon which, seen at the same time from places on the globe very far apart, appears equally distant from the same fixed star — or with a smaller difference of distance than the Moon would show, viewed from the same places on Earth — is above the Moon. But the comet of the year 1618 appeared, at the same time, from places on Earth very far apart, equally distant from the same fixed star, or with a smaller difference of distance than the Moon would show viewed from the same places on Earth. Therefore the comet of the year 1618 was above the Moon. Biancani uses a similar argument, though not framed in this way, in the *Sphaera*, Book 16, chapter 5. The major proposition is proved, first, because if the comet had a sensible parallax greater than the Moon's, it would appear unequally distant from the same fixed star from different parts of the Earth, as the Moon now appears — and indeed with a greater inequality; and second, because parallax is denied to the fixed stars precisely because, at any altitude above the horizon whatever, viewed from any place on Earth whatever, they appear to keep the same distance from the other fixed stars around them. The minor is proved from the history of the observations: for this comet was observed at distances from Arcturus, from Spica, and from certain stars of Ursa Major or of Draco,

and the difference seen between the distances was either none or of very few minutes.

Solutio Argumenti 10.

Solution of argument 10.

[Margin: First reply, distinguishing the major.]

XX. First, the major proposition must be distinguished. It is to be granted as to its second part — provided, that is, that the difference between the observed distances from the fixed stars was smaller than the one that belongs to the Moon. As to its first part, however, it must be subdistinguished: it is to be granted if the places on Earth, the phenomenon and that fixed star were under the same great circle, and the phenomenon is not within the zeniths of the two places on Earth but outside the arc enclosed between the zeniths, and if with exact instruments and observations the distance from the same fixed star was found equal. Otherwise it must be denied, because it is not true in itself, or universally, even if the instruments and observations are exact — namely, if the phenomenon, or the fixed star, or both, are outside the great circle under which the two places on Earth lie, or are indeed under that circle but on the arc enclosed between their zeniths. For in these cases the distance from the same fixed star can appear equal from both places, however near the Earth the phenomenon may be, as will shortly be shown; and so even though it has a parallax greater than the Moon's.

[Margin: Second reply, denying the minor.]

Second, the minor must be denied in the sense in which the major was granted. For from the history of the observations — those, at least, that are available to us — it is not established that this comet was observed at different places on Earth at the same moment of time (granted, on the same days), or in such a way that the phenomenon and the fixed star were with those places in the same great circle and outside the arc enclosed by the zeniths, or without any difference of distance at all. For it is not enough that the difference was small, since it can be of a single minute and the phenomenon nevertheless have a parallax much greater than the Moon's, as has already been shown in chapter 19, number 3, and will be shown again in Book 10, penultimate section, chapter 11, numbers 11 and 12, together with Chiaramonti, Book 2 of the *Antitycho*, chapter 20, and Book 3, chapter 19, theorem 1. Now, so that what we said in distinguishing the major proposition may be clear, the following figure must be inspected first. In it, from the Earth's centre A, let there be described the quadrant BC of a great terrestrial circle, beneath the celestial quadrant DS; under this let there also be the comet's circle VT; and let the two places on Earth be B and G, and their lines drawn from the centre of the Earth to their zeniths ABD and AGL. With these laid down, two cases bear on our matter.

Diagram. Riccioli's figure for the two cases of the solution of argument 10, set across the left column. A horizontal base line runs from S at the left through T, C and A to E at the right. From the Earth's centre A a vertical line rises

through B and V to D. An outer arc, the celestial quadrant DS, runs from D down to S; a middle arc, the comet's circle VT, runs from V down to T; an inner arc, the terrestrial quadrant BC, runs from B down to C through G. A further arc runs from B down to E. Straight lines from the two places B and G run to the comet's places K and R and on to the outer arc, and a line runs from A through G towards L. Star symbols mark points on the outer arc.

- D (top of the vertical): the zenith of B, on the line ABD; an end of the celestial quadrant DS
- Z (beside a star symbol near the top of the outer arc): not referred to on this page
- H (on the outer arc): the apparent place of the comet K seen from B, by the line BKH
- F (on the outer arc, beside H): the fixed star in the first case
- I (on the outer arc, beside F): the apparent place of the comet K seen from G, by the line GKI
- V (on the vertical, below D): an end of the comet's circle VT and of the arc QV
- K (on the middle arc): the comet in the first case
- L (on the outer arc): the zenith of G, on the line AGL
- M (on the outer arc, below L): not referred to on this page
- Q (on the middle arc): an end of the arc QV
- X (beside a star symbol on the outer arc): not referred to on this page
- N (on the outer arc): the fixed star in the second case
- O (on the outer arc, below N): the apparent place of the comet R seen from G, by the line GRO
- P (on the outer arc, below O): the apparent place of the comet R seen from B, by the line BRP
- R (on the middle arc): the comet in the second case
- B (on the vertical): the first place on Earth; an end of the terrestrial quadrant BC
- m (italic, to the right of B): not referred to on this page
- Y (beside a star symbol low on the outer arc): not referred to on this page
- G (on the inner arc): the second place on Earth
- S (left end of the base): an end of the celestial quadrant DS
- T (on the base): an end of the comet's circle VT
- C (on the base): an end of the terrestrial quadrant BC
- A (on the base, foot of the vertical): the Earth's centre
- E (right end of the base): not referred to on this page

[Margin: First case, for the negative part of the major.]

The first: if the comet is at K, a place enclosed within the vertical lines AD and AL (the sign of which is that for one observer it lies towards one region of the world, and for the other towards the opposite region), it can be equidistant from both zeniths as to both its true and its apparent place. The fixed star can be at F, and the comet's true place, marked by the line AKF, under it; while

its apparent place seen from B, by the line BKH, is under H, and seen from the place G, by the line GKI, under I; so that the arc HF, of apparent distance from F, is equal to the arc IF, likewise of apparent distance from the star F, and so the parallactic angles GKA and BKA are equal to each other. In that case, then, however great the parallaxes may be, the apparent distance of the comet K from the same fixed star F will nevertheless be equal, and the sum of the distances equal to the sum of the parallaxes.

[Margin: Second case.]

The second case is if the comet is outside the arc QV enclosed by the vertical lines AD and AL — for instance if it is at R, that is, towards the same region for both observers B and G. In this case, if the fixed star is at N and the comet R under it, the line of the true place being ARN, but the apparent place seen from B, by the line BRP, is under P, and the visible distance from the fixed star is PN, while the apparent place seen from G, by the line GRO, is under O, and the visible distance ON, then the difference of the distances, and likewise of the parallaxes — namely the angle BRG — will be equal to the angle PRO. But this difference can be of one minute, indeed less than one minute, even if the parallaxes ARB and ARG are very large, as was shown in chapter 19, number 3, and will be shown in Book 10, penultimate section, chapter 11, numbers 11 and 12.

XXI. From this you will understand that it can also happen outside the same arc that, however great the parallax of a phenomenon may be, it nevertheless appears equally distant from the same fixed star from different places on Earth. This may be explained, in more evident cases, by the following diagram. In it, A and B are two places on Earth under the same meridian ACB, equally distant from the equator GD, one towards the north and the other towards the south, and the comet D, with the fixed star E, is under the equator. Or the two places on Earth A, B are under the equator AB, and the comet D, with the fixed star E, under the same meridian GD, which lies equally between those places. Or, finally, the two places A, B are under some other vertical AB, and the comet D, with the fixed star E, under the same other vertical GD, which cuts at right angles the vertical AB — the circle of those places — and bisects at C the arc of the vertical AB intercepted between the two places; this can happen in countless verticals. With these laid down, the distance of the comet from the same fixed star could appear equal to both places and observers at the same moment, however near the Earth the comet might be. But besides these there are also other cases of this equality in the apparent distance from the same fixed star, even though the parallax is of several degrees. And let this be said for the negative part of the major proposition. And so that you do not doubt that in these cases the comet can be near the Earth, suppose that at D there is the top of a tower, lit by some lantern, so that at night, by some instrument, from the places A and B, equally distant from the vertical GD that cuts the vertical AB at right angles, the distance of that top from the star E, situated in the same

vertical, can be taken. It will be found equal from both, if they work exactly, and yet the top D will be very near the Earth.

Diagram. Riccioli's figure for the cases of §XXI, set in the right column beside the short lines of the text. A rhombus with A at the top, B at the bottom, G at the left and D at the right. A horizontal line G … D passes through F, C and E; a vertical line A … B crosses it at C. Straight lines run from A and from B to each of G, F, E and D. Star symbols mark G, F, E and D.

- A (top): one of the two places on Earth
- G (left end of the horizontal): an end of the circle GD (the equator, meridian or vertical of the three cases)
- F (on the horizontal, left of C): not referred to on this page
- C (centre, above the crossing): the point bisecting the arc AB
- E (on the horizontal, right of C): the fixed star
- D (right end of the horizontal): the comet, or the lit top of the tower; an end of the circle GD
- B (bottom): the other place on Earth

XXII. Now, so that it may be clear that we have denied the minor proposition of the argument put forward neither gratuitously nor without consulting the history of this comet, it has seemed good to gather faithfully into one synopsis this comet's distances from the same fixed star, taken at different places on Earth but on the same day, with the hour added if the observers noted it, or the comet's altitude. But if other booklets of observations are extant of this kind that have not come into our hands, from which the contrary may be clearly gathered, our negative reply to the minor is not to be understood of them: in that case we are ready to grant it. But so long as that is not established, it can rightly be denied, and the burden of proving the opposite falls on our opponents. Note, moreover, that several observers excuse themselves and do not present their observations as exact, since they say that, especially at the beginning, these were rough: so Kepler, Habrecht, Rhodius and Chiaramonti; nor would Cysat deny that an error of 6 minutes could have lain hidden in the distances. And Kepler said of these and similar observations, on page 61: *"These observations are not of the highest accuracy, nor is there any need to treat them by laborious calculation; a pair of compasses with a globe is enough, for nothing is to be suspected about parallax in so short a span of hours."*

[Margin: Kepler's excessive confidence in pronouncing.]

This last remark was made with Kepler's usual confidence — as though he himself and others had not used observations of the same night, taken a few hours apart, to investigate parallax.

Obſeruationes Diſtantiarum Cometæ Anni 1618. & 1619. à Stellis Fixis. Diebus Stylo Gregoriano notatis.

Observations of the distances of the comet of the years 1618 and 1619 from the fixed stars, the days given in the Gregorian style.

[Margin: Observations of November. Days 27 and 29. Day 30.]

XXIII. On November 27 the comet was seen by our men at Rome a little less than 4 degrees from the northern Scale. On the 29th it was seen at the same place 1½° from the same Scale. But at Goa Father Giacomo Rho saw it 34° 5′ from Arcturus and 25° 40′ from Spica. Finally, on the 30th, at Parma, Father Giuseppe Biancani saw the comet, at 14^h Italian civil time, 30° from Arcturus and 25° from Spica.

[Margin: Observations of December. Day 1.]

On December 1 Father Johann Baptist Cysat at Ingolstadt, at 5^h 45^m in the morning, saw the comet at an altitude of 12° 20′, 27° 6′ from Arcturus and 24° 48′ from Spica; and at 6^h 56^m in the morning at an altitude of 22° 20′, 26° 56′ from Arcturus and 24° 54′ from Spica. But Longomontanus at Copenhagen, at 5^h 45^m, saw it at an altitude of 18°, 24° 56′ from Spica and 32° 41½′ from the bright star of the Crown.

[Margin: Day 2.]

December 2. Cysat at Ingolstadt, at 4^h 49^m in the morning, saw the comet at an altitude of 5° 40′, 24° 0′ from Arcturus and 25° 20′ from Spica. But Biancani at Parma, at $13¾^h$ Italian civil time, saw it 24° from Arcturus and 25° from Spica.

[Margin: Day 3.]

December 3. At Rome it was seen 21° 0′ from Arcturus and 25° 25′ from Spica. But at Goa Father Rho saw it 21° 38′ from Arcturus and 25° 54′ from Spica; and at Parma Biancani, at $13½^h$ civil time, 21° 10′ from Arcturus and 26° 30′ from Spica. Longomontanus at Copenhagen, at $6½^h$ in the morning, saw it 25° 52′ from Spica and 27° 28′ from the bright star of the Crown.

[Margin: Day 4.]

December 4. At Rome it was seen 17° 40′ from Arcturus and 26° 33′ from Spica. At Goa Father Rho saw it 19° 0′ from Arcturus and 26° 50′ from Spica. At Parma Biancani, at 14^h civil time, saw it 18° from Arcturus. Chiaramonti at Cesena, at 12^h 40^m Italian solar time, saw it 17° 11′ from Arcturus and 27° 45′ from Spica. But Longomontanus at Copenhagen, at $6½^h$ in the morning, saw the comet at an altitude of 21°, 26° 52′ from Spica and 24° 54′ from the bright star of the Crown; then, when it appeared at an altitude of 24° 50′, he saw it 18° 13⅔′ from Arcturus. But Dr Habrecht at Strasbourg saw it 17° 0′ from Arcturus, and Ambrosius Rhodius at Wittenberg saw it 25° 21′ from Spica.

[Margin: Day 5.]

December 5. Our men at Rome saw the comet 23° 26′ from Arcturus; at Antwerp, however, 25° 10′.

[Margin: Day 6.]

December 6. At 13^h Italian civil time Biancani at Parma saw it 12° from Arcturus, 17° from the hip of Boötes and 27½° from Spica.

[Margin: Day 7.]

December 7. By Cysat at Ingolstadt, at $6⅛^h$ in the morning, it was seen at an altitude of 38°, 9° 48′ from Arcturus and 17° 46′ from the bright star of

the Crown; and at 7^h at an altitude of 44°, 1° 58′ from the star of the third magnitude in the leg of Boötes. But Habrecht at Strasbourg saw it 9° 20′ from Arcturus and 38° 30′ from the last star of the tail of Ursa Major. And Vuelperus at Lora in Alsace saw it 10° 30′ from Arcturus, 18° 30′ from the bright star of the Crown, and 39° 30′ from the last star of the tail of Ursa Major.

[Margin: Day 8.]

December 8. Cysat at Ingolstadt, at 3^h 0^m in the morning, saw the comet at an altitude of 12° 30′, 7° 57′ from Arcturus and 11° 42′ from the star of the third magnitude in the right elbow of Boötes. But Longomontanus at Copenhagen, at $5½^h$, saw it about 2° from the bright star in the knee of Boötes, and higher than that star, towards the west.

[Margin: Day 9.]

December 9. Cysat at Ingolstadt saw the comet rise in the morning at 1^h 45^m; at 2^h 46^m it stood at an altitude of 10° 12′, 6° 42′ from Arcturus, but 33° 36′ from Benenaz, the end star of the tail of Ursa Major; then at 6^h 22^m at an altitude of 48° 58′, 32° 54′ from Benenaz and 14° 30′ from the bright star of the Crown. At Rome it was seen 6° 25′ from Arcturus; at Goa Father Rho saw it 6° 46′ from Arcturus; and Johannes Remus Quietanus at St Johann in Tirol saw it about 6° from Arcturus, but a little less — and that at 5^h.

[Margin: Day 10.]

December 10. At Ingolstadt Cysat, at 6^h 25^m in the morning, saw it at an altitude of 47° 30′, 29° 26′ from Benenaz and 13° 44′ from the bright star of the Crown. At Goa Father Rho saw it 6° 5′ from Arcturus; he then saw that between the comet, at an altitude of 20° 24′, and Spica, at an altitude of 33° 10′, there lay an azimuthal arc of 34° 30′, from which Chiaramonti infers the comet's distance from Spica to be 33°.

[Margin: Day 12.]

December 12. At $5½^h$ in the morning Remus at Innsbruck saw it 1° 45′ from the belt, or hip, of Boötes. At Parma Biancani, at 13^h civil time, saw it 8½° from Arcturus and 3° from the hip of Arcturus.

[Margin: Day 13.]

December 13. At Antwerp our men saw it 11° 20′ from Arcturus, but in the Roman College 10° 55′; and Remus at Innsbruck 10° 53′ from Arcturus. Snel, at Leiden I believe, at $4½^h$ in the morning saw it 10° 47′ from Arcturus, 14° 3′ from the bright star of the Crown, 52′ 23″ from the upper of the adjoining stars on the back of Boötes, and 34′ from the lower. On the same day the comet covered, for the observers at Rome, the tenth star of Boötes, which it also partly covered for those at Cologne.

[Margin: Day 14.]

December 14. At Goa Father Rho saw it 12° 40′ from Arcturus; but at Parma Biancani, at 13^h civil time, 13° from Arcturus and 16° from the bright star of the Crown; while Willebrord Snel, at $5½^h$, saw it 13° 6′ from Arcturus and 15° 1′ from the Crown; and Remus at Innsbruck 13° 10′ from Arcturus.

[Margin: Day 15.]

December 15. Longomontanus at Copenhagen, at 5^h, saw it 43° 43′ from the bright star in the southern wing of ♍ [Virgo] and 48° 2′ [?] from Spica.

[Margin: Day 16.]

December 16. At Ingolstadt Cysat saw that around 9^h the head of the comet was still hidden, either in the vapours or below the horizon, but that it emerged around 11^h, when it appeared at an altitude of 3°; at that time it was seen 12° 36′ from Benenaz. But Remus at Innsbruck saw it 1° from the left shoulder of Boötes, while from the same star it was seen by Benjamin Ursinus at Frankfurt an der Oder to be one and a half diameters of the Sun away.

[Margin: Day 17.]

December 17. At Ingolstadt Father Cysat, at 0^h 21^m — almost in the middle of the night between the 16th and the 17th — saw the comet at an altitude of 10° 45′, 12° 30′ from Benenaz, and 16° 2′ from the unformed star of the second magnitude under the tail of Ursa Major; then at 4^h 7^m at an altitude of 44° 30′, 12° 3′ from Benenaz; and at 4^h 43^m at an altitude of 47° 55′, 19° 48′ from Arcturus and 19° 42′ from the bright star of the Crown; and at 5^h 30^m at an altitude of 57° 10′. Vuelperus at Lora saw it 19° 48′ from Arcturus, 19° 42′ from the bright star of the Crown, and 11° 3′ from the first star of the tail of Ursa Major; but Millerus at Leipzig saw it 20° 50′ from Arcturus, 18° 30′ from the bright star of the Crown, and 11° 30′ from the first star of the tail of the Bear.

[Margin: Days 18 and 20.]

December 18. At Ingolstadt Cysat, at 4^h 46^m, saw it at an altitude of 49° 0′, 21° 26′ from the bright star of the Crown and 9° 55′ from Benenaz. And on the 20th, at 3^h 54^m in the morning, he saw it at an altitude of 48° 30′, 26° 18′ from Arcturus, and 24° 42′ — or 48′ — from the bright star of the Crown; at 4^h 40^m at an altitude of 55° 42′, 26° 21′ from Arcturus and 24° 51′ from the bright star of the Crown; and at 6^h 39^m at an altitude of 75° 20′, 26° 42′ from Arcturus. From this day to the end, he says, the comet never set, but moved among the stars that are always visible.

[Margin: Day 21.]

December 21. At 5^h 44^m in the morning, at Ingolstadt, Cysat saw it at an altitude of 67° 10′, 28° 18′ from Arcturus and 26° 42′ from the bright star of the Crown. Remus at Innsbruck saw it 4° 20′ from the last star of the tail of Ursa Major and 2° from the wrist of Boötes; but Kepler at Linz, 4° 30′ from the last star of the tail and 50′ from the wrist of Boötes.

[Margin: Day 24.]

December 24. At Ingolstadt, at 6^h 19^m in the morning, Cysat saw the comet at an altitude of 80° 45′, 33° 30′ from Arcturus and 31° 6′ from the bright star of the Crown. But Ambrosius Rhodius at Wittenberg, at 6^h, saw it 46° 40′ from the tail of Ursa Major and 33° 50′ from Arcturus. Snel: distance from the last star of the tail of Ursa Minor 22° 3′, and 4° 9′ from the uppermost star of the quadrilateral of Ursa Major.

[Margin: Days 26 and 27.]

December 26. Longomontanus at Copenhagen, at 7^h 20^m in the morning, saw it 21° 28′ from Dubhe and 19° 45½′ from the third-from-last star of the coil of the Serpent; and on the 27th, at 6^h 5^m in the morning, 20° 42′ from Dubhe and 19° 39′ from the third-from-last star of the coil of the Serpent.

[Margin: Day 28.]

December 28. At Ingolstadt, at 5^h 4^m in the morning, Cysat saw it at an altitude of 69° 30′, 16° 39′ from the bright star of the quadrilateral of Ursa Minor, and 11° 42′ from the northern star among the front wheels of the Wain of Ursa Major. At Parma Biancani, at $12½^h$ civil time, saw it 5° from the second star of the tail of Ursa Major and 6½° from the third star of the tail of the Serpent. On this day Longomontanus stopped observing.

[Margin: Day 29.]

December 29. At 4^h 28^m, at Ingolstadt, Cysat saw it at an altitude of 66° 20′, 18° 49′ from the northern star among the posteribus [?] wheels of the greater Wain, and 15° 9′ from the bright star of the quadrilateral of Ursa Minor; and at 6^h 34^m in the morning at an altitude of 79° 30′, 18° 45′ from the already mentioned northern star of the Wain, and 15° 6′ from the bright star of the quadrilateral of Ursa Minor [?]. At Parma, however, Biancani, at $12½^h$ civil time, saw it 5½° from the second star of the tail of Ursa Major and 5½° from the third star of the tail of the Serpent.

[Margin: Days 30 and 31.]

December 30. At Ingolstadt, at 6^h 2^m, Cysat saw the comet at an altitude of 76° 25′, 17° 45′ from the northern star among the rear wheels of the greater Wain, and 13° 56′ from the bright star of the quadrilateral of Ursa Minor. Biancani at Parma, at $12½^h$, saw it 7° from the third star of the tail of Ursa Major and 5¼° from the third star of the tail of the Serpent; and on the 31st, scarcely able to make it out, he stopped observing.

[Margin: January. Day 3.]

January 3. At 7^h 30^m in the evening the comet stood in almost the same vertical as Benenaz, near the meridian of Ingolstadt; and Cysat saw the comet at an altitude of 28° 50′, but Benenaz at an altitude of 10° 50′. The comet was 10° 51′ from the first star of the tail of Ursa Major and 14° 15′ from the northern star among the rear wheels of the greater Wain.

[Margin: Day 7.]

January 7. At 8^h in the evening the comet was in conjunction with the penultimate star in the tail of Draco: its altitude was 35° 12′, while the star appeared at an altitude of 35° 31′. So Cysat at Ingolstadt. On this day Kepler stopped seeing the comet.

[Margin: Day 12.]

January 12. At 8^h 3^m in the evening, at Ingolstadt, Cysat saw it at an altitude of 40° 41′, 18° 12′ from the first star of the tail of Ursa Major and 12° 21′ from the bright star of the quadrilateral of Ursa Minor.

[Margin: Day 13.]

And on the 13th, at $3^h\ 45^m$ in the morning, he saw the comet almost on the meridian, at an altitude of 63° 33′; but at $7^h\ 51^m$ in the evening at an altitude of 41° 33′, 12° 45′ from the bright star of the quadrilateral of Ursa Minor and 18° 42′ from the first star of the tail of Ursa Major.

[Margin: Day 14.]

January 14. At $3½^h$ in the morning, at Ingolstadt, Cysat saw the comet at an altitude of 62° 57′, and in the same vertical the brighter star of the left foot of Cepheus at an altitude of 34° 36′; at $4^h\ 25^m$ the comet at an altitude of 61° 55′, 18° 57′ from the first star of the tail of Ursa Major and 12° 56′ from the bright star of the quadrilateral of Ursa Minor; at $5^h\ 56^m$ in the evening the comet at an altitude of 37° 40′, 19° 27′ from the first star of the tail of Ursa Major and 13° 20′ from the bright star of the quadrilateral of Ursa Minor; and at $9^h\ 15^m$, when its altitude was 48° 20′, 13° 25′ from the bright star of the lesser quadrilateral and 19° 31′ from the first star of the tail of Ursa Major.

[Margin: Day 15.]

January 15. At $8^h\ 3^m$ in the evening, at Ingolstadt, Cysat saw it at an altitude of 45° 20′, 19° 54′ from the first star of the tail of Ursa Major and about 13° 42′ from the bright star of the lesser quadrilateral. But at about 9^h the comet, at an altitude of 46° 53′, and the third-from-last star of the tail of Draco, at an altitude of 31° 31′, were in the same vertical.

[Margin: Day 16.]

January 16. At $6½^h$ in the evening, at Ingolstadt, Cysat saw it at an altitude of 39° 55′, 20° 28′ from the first star of the tail of Ursa Major and 14° 41′ from the bright star of the quadrilateral of Ursa Minor; and at $8½^h$ in the evening at an altitude of 46° 22′, 20° 30′ from the first star of the tail of Ursa Major and 14° 42′ from the bright star of the lesser quadrilateral.

[Margin: Day 17.]

January 17. At Ingolstadt, at $8^h\ 29^m$ in the evening, Cysat saw it at an altitude of 45° 50′, 21° 10′ from the first star of the tail of Ursa Major, 15° 24′ from the bright star of the lesser quadrilateral, and 54° 30′ from the left arm of Boötes.

[Margin: Day 18.]

January 18. At Ingolstadt Cysat, at $2^h\ 45^m$ in the morning, saw in the same vertical the comet at an altitude of 62° 36′ and the star of the 4th magnitude in the left shoulder of Cepheus at an altitude of 23° 9′; and at $6^h\ 44^m$ in the evening the comet at an altitude of 41° 31′, 16° 12′ from the bright star of the quadrilateral of Ursa Minor and 22° 0′ from the first star of the tail of Ursa Major.

[Margin: Day 22.]

January 22. At $4^h\ 30^m$ in the morning, at Ingolstadt, Cysat saw the comet at an altitude of 55° 59′, 16° 44′ from the bright star of the quadrilateral of Ursa Minor, 23° 40′ from the first star of the tail of Ursa Major, and 37° 55′ from the

left arm of Boötes — but this last with the radius. Eight cloudy days followed, after which the comet appeared no more.

These are the observations of this comet of the year 1618, which were spread abroad among the public with such fame and gathered by us with no less fidelity and diligence, so that we might at last extract some kernel or pith from so thick a rind, or so branching a trunk. If any observation has been passed over, it is because it either had no companion in an observation made elsewhere, or lacked features suited to this inquiry.

[Margin: The principal combinations of the foregoing observations are examined.]

XXIV. Among all the observations already mentioned, you see the greatest agreement as to the hour in the observation of the 13th made at Rome and at Cologne, for in both places the comet covered the tenth star of Boötes. But since the hour is not given, no certain argument can be derived from it? A great agreement also appears in the observation of December 3, between the Goa distance of the comet from Spica, 25° 54′, and the Copenhagen distance from Spica, 25° 52′; from which someone might at once declare, given how far apart the places are, that the comet had scarcely any parallax. And that could indeed be said, if it were established that this happened at the same moment of time. But Longomontanus says that it was then 6^h 30^m in the morning at Copenhagen; the Sun was then at 11° 17′ of ♐ [Sagittarius]; and the seminocturnal arc at Copenhagen, at a polar altitude of 55° 43′, was 8^h 27^m, while at Goa, at a polar altitude of 16°, it was 6^h 27^m. If, then, you subtract the 6^h 30^m from midnight from the Copenhagen seminocturnal time, there remains 1^h 57^m until sunrise. But Goa is more easterly than Copenhagen, according to our Corrected Geography, by 105°, or 7 hours. Therefore the Sun had already risen at Goa, and at Goa it was 5^h 3^m after sunrise at the time when Longomontanus observed the comet at Copenhagen. It was therefore impossible for the comet to have been seen at the same moment at a distance from Spica of 25° 52′ or 54′.

[Margin: Their agreement must be perfect.]

It was worth pointing this out, so that no one, because of the closeness of the distances, should at once declare that a sensible parallax is lacking, since the observers are not found to have agreed on the same distance from the same fixed star at the same moment of time. Much less ought Biancani to have asserted that lack from his own and the Goa observations, since for the same day of December he himself gives the distance of the comet from Spica as seen by him as 26° 30′ — that is, 36 minutes greater than the Goa distance — and that at $13\frac{1}{2}^h$ civil time, when the Sun had already risen at Goa.

Setting aside, then, this pairing [syzygia] of observations, another presents itself to us on December 1, which to all appearance is the best suited of all for investigating the comet's parallaxes. For at almost the same moment — namely at 4^h 45^m in the morning — Longomontanus at Copenhagen observed the comet at an altitude of 18° and at a distance of 24° 56′ from Spica. And Father

Cysat, likewise at 4^h 45^m in the morning, observed the comet at Ingolstadt at an altitude of 12° 20′ and at a distance of 24° 48′ from Spica, that is, 8′ less than Longomontanus. Now Copenhagen is more easterly than Ingolstadt, in my Corrected Geography, by 1°, or 4 minutes of time. Therefore either the hour noted by Father Cysat was correct, and so it was 4^h 49^m at Copenhagen; or, if the hour reported by Longomontanus was correct, it was then 4^h 41^m at Ingolstadt. If we wish both observations to have been made by chance at the same moment of time, or if we wish the moment of each to have been noted correctly, then it must be that either the moment of observation was different, or the meridian was not different, since each of them notes the hour as 4^h 45^m in the morning. Which of these was the case is uncertain, and for that reason we cannot demonstrate parallaxes from this. Next, even if we granted that the observation fell at the same moment, the apparent distances stand in the way. For at Ingolstadt, where the comet appeared at an altitude of only 12° 20′, the parallax of altitude must have been much greater than at Copenhagen, where the comet appeared at an altitude of 18°; therefore the parallax of distance from Spica was also greater there than here, and so the comet's distance from Spica ought to have appeared greater to Father Cysat at Ingolstadt than to Longomontanus at Copenhagen. But the reverse happened: Cysat observed it as 24° 48′ and Longomontanus as 24° 56′. Either, therefore, the moment was not the same, or some error lies hidden in the distances taken. If, however, anyone cares to waste effort on this business and to feign an observation made at the same moment, I shall show how he can do it by the following Problem.

Problema.

Problem.

To find the parallax of altitude, given the comet's apparent distances from the same fixed star at the same moment of time, from two places whose geographical longitude and latitude are known; and given, besides, the moment of time, together with the declination and right ascension of the same star.

[Margin: Problem of Father Francesco Maria Grimaldi.]

XXV. While I was working on these matters I put this problem to Father Francesco Maria Grimaldi, and he solved it with incredible speed and skill by the following figure, which is therefore to be credited to him. Let there be two meridians intersecting at the poles of the world, P and M: one drawn through I, the zenith of Ingolstadt, which is PIM; the other through H, the zenith of Copenhagen, which lies further east, which is PHM. Let the comet's true place be at C, through which arcs of vertical circles are drawn from the zeniths already mentioned to the comet's apparent places: namely, from the zenith of Ingolstadt the arc ICA, to the apparent place A, and from the zenith H the arc HCB, to the apparent place B. Let the fixed star be S, and the apparent distances BS and AS. Likewise let the vertical arcs IS and HS be drawn from the zeniths to the fixed star, and the arc of the star's circle of declination from the pole, namely the arc PS; and finally let the two zeniths be joined by the arc HI.

Diagram. Grimaldi's figure for the problem, set in the left column beside the short lines of §XXV. A large outer arc runs from M at the lower left up to I at the top and down to P at the lower right; a second arc from M, inside the first, rises to the right past H and runs down to P; a lower arc joins S and P. From I, lines run down to S and, through C, to A; from H, lines run to S and, through C, to B; a line joins H and I. Lines run from S to B and from S to A. A large dot marks C.

- I (top): the zenith of Ingolstadt
- H (right of I): the zenith of Copenhagen
- S (left): the fixed star
- B (centre, below): the comet's apparent place seen from H
- C (centre, with the dot): the comet's true place
- M (lower left): a pole of the world, where the two meridians meet
- A (bottom): the comet's apparent place seen from I
- P (right): the other pole of the world, where the two meridians meet

[Margin: First step.]

With these laid down: first, for the given moment of time, the distance of the fixed star from each zenith is to be found, together with its azimuth. For since the right ascension of the midheaven is given from the moment of time, and the right ascension of the fixed star is given too, from the difference of the two the angle SPH will be known in the triangle SPH, and the angle SPI in the triangle SPI. Moreover, in the same triangles SP is given, an arc which is either the complement of the fixed star's declination, or made up of a quadrant and the star's declination towards the other side; and the complements of the polar altitudes, HP and IP, are given as well. Therefore the bases HS and IS, which are the true distances of the fixed star from the zeniths H and I, will not be unknown. Nor will the complements of the azimuths, PHS and PIS, be unknown, and so neither will the azimuths themselves.

[Margin: Second step.]

Second: in the triangle BHS there are given HS, found by the first step; HB, the apparent distance of the comet for an inhabitant under H; and BS, the distance of the comet from the fixed star S as seen by the same observer. Therefore the angle BHS will be known.

[Margin: Third step.]

Third: in the triangle PHI, in which are given IP and HP, the complements of the polar altitudes, and the angle HPI, known from the difference in longitude of the places, that is, from the distance between the meridians, find the arc HI, that is, the distance between the zeniths of the two places, and the angles IHP and HIP. Now the supplement of the angle IHP to two right angles is IHM; compounding this with the angle SHM, found by the first step, and with the angle BHS, found in the second step, the whole angle CHI will be known.

[Margin: Fourth step.]

Fourth: in the triangle AIS three sides are given, namely AS, the apparent distance of the comet from the fixed star for the observer under I; AI, the

apparent distance of the comet from the zenith I; and IS, the distance of the fixed star from the same zenith, found in the 1st step. Therefore find the angle AIS; add to it the azimuthal angle SIM, known by the 1st step, and also the angle HIP, known in the 3rd step; subtract the sum of these three from 180°, and the angle CIH will remain known.

[Margin: Fifth step.]

Fifth, therefore: in the triangle CHI, given now the side HI and the angle CHI, by the 3rd step, and the angle CIH, by the 4th, find the comet's true distances from the zeniths, namely HC and IC; for their difference from the apparent distances HB and IA will show the parallaxes BC and AC. Which was to be done.

You see, I believe, that the apparent distance from Spica at Ingolstadt, namely AS, must be supposed in this problem greater than BS, seen at Copenhagen, on account of the parallax of altitude AC, which is greater than the parallax BC because it is owed to the greater distance CI from the zenith I; and consequently that we cannot infer anything with certainty from the observations mentioned for a determinate quantity of this comet's parallaxes. Much less can we do so from the other observations set out above, because it is not established whether they were made at the same time; nor can we reduce them to the same moment except by feigning a proper and uniform motion of the comet, and by altering the apparent distances with conjectures applied — all of which is full of uncertainty.

An PP. Collegij Romani demonſtrarint abſolutè Cometam Anni 1618. fuiſſe ſupra Lunam.

Whether the Fathers of the Roman College demonstrated absolutely that the comet of the year 1618 was above the Moon.

XXVI. I deny that this was demonstrated by them, or held as demonstrated. For the author of that disputation, who is said to have been Father Orazio Grassi, frankly admits that he lacked instruments reaching to single minutes, and that he could therefore have been less diligent in observing and in the calculations drawn from the observation; and he adds: *"For I know that account should have been taken of the hours at which observations of this kind were made in different places, though on the same day; and besides, of refractions and other things, the investigation of which required much more diligent observers."* Then, from the small difference in the distances of the comet from Arcturus, or from the tenth star of Boötes, observed at Rome, Parma, Antwerp and Cologne on the same day — but chiefly from the fact that on the 13th the comet's head covered the tenth star of Boötes at Rome and at Cologne — he infers that the comet was very high, and higher than the vapours, which he grants rise at most 100 Italian miles; otherwise, the least parallax between the Roman and the Antwerp observations would have been of 56 degrees, as if the comet had been on the horizon for one of the two cities. Indeed, he infers that the comet was either celestial or a little below the Moon, for these are his words: *"You have, then, from the parallax,*

observed after a fashion, that our comet was not sublunary but plainly celestial. But if anyone nevertheless thinks this should be little trusted, and that it is less certainly demonstrated, this at least certainly cannot be denied: since no difference is found in degrees, but only in minutes, then even if we were to grant that it was sublunary, it must nevertheless be judged not very far removed from the Moon itself." From this it is quite clear that the demonstration did not seem to him altogether absolute, nor fit to exclude all doubt about the opposite conclusion.

But even if, in view of the moderation and sincerity with which the Father already mentioned was endowed, he had not admitted what we have said so far, but had declared his demonstration certain and absolute, we could still by no means have admitted it. For he makes the least lunar parallax — that is, the difference of the parallaxes between Antwerp and Rome — 24 minutes, but in the circle of altitude; whereas the parallax of the comet's distance from Arcturus as seen at Rome and Antwerp, that is, the difference of the parallaxes, he says was 16′, and so less than the lunar. But the conclusion drawn from this is not sound, because the terms are exchanged, and a passage is made from the parallax in the vertical circle to the parallax in the circle of distance, which was different from the vertical circle. Moreover, even if it had been of the same kind, the difference of the parallaxes can still be of one minute, let alone of 16 minutes, and yet the absolute parallax of the phenomenon be of several degrees, as has already been demonstrated by us in chapter 19, number 3, and will be shown again in Book 10, penultimate section, chapter 11, numbers 11 and 12, following Chiaramonti. He also demonstrates in this place — that is, in the *Antitycho*, Book 2, chapter 28 — that if the parallax of distance between Antwerp and Rome had been 16′, as it is given to have been on December 5, the parallax in the vertical circle would have been 2° 25′; if the parallax of distance had been 25′, as it is granted to have been on December 13, again between Rome and Antwerp, the parallax of altitude would have been 3° 3′; and finally, if the parallax of distance between those places had been 59′, as it is given to have been on December 16, the parallax of altitude would have been 7° 51′ — that is, always greater than the lunar. These things, I say, were shown by Chiaramonti with a true and exact demonstration. But as for the comet's covering the same star at Rome and at Cologne on the same night: unless this is shown to have happened at the same moment of time, it is worth nothing. For it is very easy for a phenomenon, even one with a large parallax, to cover the same uppermost point for one more northerly place which it had already covered on the same day for a more southerly place, in a different vertical circle and at a different hour or moment, by virtue of its motion, as Chiaramonti showed in the same place, chapter 29. The remaining arguments, which are weaker and merely probable — namely those from the comet's bulk, from its regular path along a great circle, from its receiving no enlargement through the telescope, and from the tail's being turned away from the Sun — have already been answered in number 3.

An Claramontius Demonſtrarit Cometam Anni 1618. fuiſſe infra Lunam, ex incremento Caudæ orto ex Parallaxibus, & à ſe obſeruato.

Whether Chiaramonti demonstrated that the comet of the year 1618 was below the Moon, from an increase of its tail arising from parallaxes and observed by himself.

XXVII. Chiaramonti does indeed profess this, in Book 3 of the *Antitycho*, chapter 20, and in the *Apologia* for the *Antitycho*, Book 2, chapter 11. Kepler, however, opposes him in the *Hyperaspistes*, from page 171 to 176. It will be fair, then, for readers to weigh both the reasons of each of them and our own.

Chiaramonti's argument runs as follows. On December 4 the comet's tail was observed by him at Cesena to be 21°, when the comet's head appeared 26° high. On December 18 the tail was seen by him to be 28° long, when the comet's head appeared 53° high; and at both times it was $12^h\ 40^m$ by the Italian hour of the Sun, that is, reckoned from sunset. Therefore at the smaller distance from the zenith the tail appeared 7 degrees longer than at the greater. Therefore that increase was apparent, and arose from a greater parallax of the head than of the tip of the tail. He proves the last consequence in two ways. First, if the increase had been real, the comet's head would also have grown from the 4th to the 18th, whereas it rather shrank from day to day. Second, if this increase had not come from parallax, the tail would have appeared equal on both days, and would have appeared the same to an eye placed on the surface of the Earth as to an eye supposed to be at the centre of the Earth; and there is no doubt that, if the comet had a sensible parallax, the tail must have appeared longer than it really was, on account of the parallax of the distance of the head from the end of the tail.

[Margin: Construction of the figure for the position of the tail.]

To understand this and the rest, I shall propose a more suitable figure than Chiaramonti's. In it let the meridian be ABCD, with the zenith B in it, and the eastern horizon of Cesena ALC. Let the equator be EF, and let the southern parallel on which the Sun stood on December 18 — the Sun being very near the beginning of Capricorn, that is, to the Tropic of Capricorn — be GHD. Since at the time of the observation [?] it was $12^h\ 40^m$ by the Italian hour of the Sun, that is, $2^h\ 36^m$ before sunrise, let the Sun be at H, and the true place of the comet's head at I. Through I let the straight line HIK be drawn from the Sun, so that the true line of the tail, turned away from the Sun, is IK, which Chiaramonti holds throughout to have been 21°. From the zenith B let two quadrants of vertical circles be drawn, one through the comet's head I, which is BIL, the other through the extreme tip of the tail, which is BKM. On account of the parallax of altitude, let the apparent place of the head be at N and that of the tail's end at P; the parallax of the head is then NI, and that of the tail's end PK, which is smaller than NI because K was nearer the zenith than the head I.

Diagram. Riccioli's figure for the position of the comet's tail at Cesena on December 18, set in the left column beside the short lines of §XXVII. A circle,

the meridian ABCD, with B at the top, A at the left, C at the right and D at the bottom. A straight line from A to C crosses the lower half (the eastern horizon ALC), with L and M on it towards C. A line runs from E at the upper left to F at the lower right (the equator), and a line from G, below E on the left, to D (the southern parallel), on which the rayed Sun H stands. From B two lines run down to L and to M. A line from H runs up through I to K. Two small comet figures are drawn: one with its head at I and its tail reaching to K, the other with its head at N and its tail reaching to P. Q stands on the circle at the upper right, between B and C.

- B (top): the zenith
- E (upper left): one end of the equator EF
- G (left, below E): one end of the southern parallel GHD
- A (left): one end of the horizon ALC
- K (centre, upper): the true end of the tail
- Q (on the circle, upper right): the pole, the arc QC being the altitude of the pole
- I (centre): the true place of the comet's head
- P (centre, right of I): the apparent end of the tail
- N (centre, below P): the apparent place of the comet's head
- L (on the horizon, right of centre): foot of the vertical quadrant BIL
- M (on the horizon, near C): foot of the vertical quadrant BKM
- C (right): the other end of the horizon ALC
- H (lower centre, the rayed Sun): the Sun
- F (lower right): the other end of the equator EF
- D (bottom): the lowest point of the meridian, and the end of the parallel GHD

With these laid down, Chiaramonti's method proceeds through several steps, with another figure drawn in which there are the solstitial colure and the ecliptic. It seeks the parallaxes IN and PK: namely, how great they must have been for the tail, which appeared on the 18th 28 degrees long in the position NP, to have been really IK, 21°; and consequently how great the comet's distance from the Earth must have been.

[Margin: First step.]

First, then, assuming the altitude of the pole QC, 44°; the point of the ecliptic culminating, ♏ 8° 58′; the observed azimuth of the apparent head, LBC, 70° 28′; the apparent distance of the comet from the zenith, that is, the arc BN, 37°; and the apparent length of the tail, NP, 28° — he seeks, by seven resolutions of spherical triangles, the arc BP, that is, the apparent distance of the end of the tail from the zenith, which he finds to be 12° 4′.

[Margin: Second and third steps.]

Second, he seeks the angle NBP, which he finds to be 35° 52′. Third, he tried how great the comet's distance from the centre of the Earth would have to be, so that the parallaxes NI and PK, corresponding to the apparent distances BN, 37°, and BP, 12° 4′, when subtracted from BN and BP, would leave BK

and BI of such a size that from them and the angle IBK, already found to be 35° 52′, the true length of the tail IK, 21°, would follow. Chiaramonti does not, indeed, set out these trials; but where he came closest to it, he finds that the comet's distance from the Earth must be less than 11,500 Italian miles, of which 3035 make one semidiameter of the Earth.

[Margin: Fourth step.]

For fourth, by the problem and figure already set out by us in chapter 18, number 10, from three givens — namely the semidiameter of the Earth, 3035 miles; the distance of the comet's head from the centre of the Earth, 11,500 miles; and the apparent distance of the comet's head from the zenith, 37° — he seeks and finds the parallax NI, 9° 8′. When this is taken from the apparent distance BN, there remains the true distance of the head, BI, 27° 52′.

[Margin: Fifth step.]

Fifth, by the same figure and problem, from the sides 3035 and 11,500 and the apparent distance of the end of the tail, 12° 4′, he seeks and finds the parallax PK, 3° 10′. When this is taken from the apparent distance BP, there remains the true distance of the end of the tail, BK, 8° 54′. Sixth, in the triangle BIK, having found the angle IBK, 35° 52′, by the second step, the arc BI, 27° 52′, by the 4th step, and BK, 8° 54′, by the 5th step, he finds the true size of the tail IK to be 21° 15′. But it ought to have been only 21°, he says; therefore the parallaxes NI and PK must have been somewhat greater still, and so the comet's distance from the centre of the Earth still less than 11,500 Italian miles — which is what Chiaramonti had set out to demonstrate.

[Margin: Kepler did not understand Chiaramonti.]

XXVIII. What does Kepler say to this in the *Hyperaspistes*, from page 171? He confesses that he did not understand what Chiaramonti means, and complains of Cimmerian darkness in his method. Yet he tentatively seeks out his meaning, but only after this preliminary excuse: *"Scipio speaks obscurely, and at the start without a figure; let him forgive me, then, if I shake out of his words some senses that he himself perhaps did not intend."* After many attempts, however, it is plain that he did not understand Chiaramonti's method — which in this place is indeed more obscure than it should have been, for Chiaramonti does not set out his method with as much clarity as I believe I have achieved.

[Margin: Yet Kepler's conclusion is true.]

Nevertheless, Kepler rightly concludes, on page 176, in these words: *"It would have been enough to point this out alone: that there are very many causes, passed over in silence by Scipio, which vary the apparent length of the tail."* These are: 1. its natural generation and consumption; 2. inconstancy in its shooting forth; 3. the difference of eyes in making out the end of the tail; 4. the brightness of the nights from the presence of the Moon; 5. the inclination to the visual rays. When these five are weighed, it is easily seen that not everything is to be ascribed to the comet's approach itself — which indeed I too, elsewhere, accept among the causes of the tail's length. This tail of the comet, therefore, is worth nothing for thrusting the comet down into the air.

Solutio Argumenti Claramontij.

Solution of Chiaramonti's argument.

[Margin: Major premise.]

XXIX. Chiaramonti's whole discourse must be brought into syllogistic form, so that the solution of the argument may be clearer. The syllogism, then, is this: *If on December 18, at 12^h 40^m after sunset by the hour at Cesena, the true length of the comet's tail was 21°, and yet at an apparent distance of the head from the zenith of 37° it appeared 28° long, and that increase of 7 degrees came wholly from parallax, then the parallaxes of altitude of the head and of the end of the tail must have been so great that, for them, the comet's distance from the centre of the Earth had necessarily to be less than 11500 Italian miles, or less than 3 2395/3035 semidiameters of the Earth.*

[Margin: Minor premise.]

But on the day and at the hour already mentioned, at Cesena, the true length of the tail was 21°, and yet at an apparent distance of the head from the zenith of 37° it appeared 28° long, and that whole increase of 7 degrees came from parallax.

[Margin: Conclusion.]

Therefore the comet's distance from the centre of the Earth was necessarily less than 3 2395/3035 semidiameters of the Earth. And so the comet was below the Moon.

The major premise has been shown [?] from observations, which must be admitted for as long as they are not convicted of falsity, and from the trigonometric calculations which I indicated above in number 27, after the drawing of the figure, from the first step to the sixth. I have examined these and found no fault in them that would notably undermine that distance of the comet of about 4 semidiameters of the Earth.

I therefore grant the major premise.

[Margin: Proof of the minor.]

The minor premise was proved by Chiaramonti as follows. On December 4 the tail was observed by him to be of 21 degrees, and on December 18 of 28 degrees, and that increase was not real but optical and apparent. For if it had been real, the magnitude of the head ought to have grown as the tail grew; but the magnitude of the head decreased from day to day; therefore the increase was not real but apparent, and from no other source than parallax. And if from parallax, then the apparent length of 28 degrees was greater than the true, because it is the property of parallax to enlarge distances in appearance, and so the distance of the comet's head from the extremity of the tail, which is to enlarge the length of the tail. Therefore, if the apparent length of the comet's tail, 28°, was greater than the true, it remains that the observed length of 21 degrees was the true one, since it is smaller by 7°. So both parts of the minor seem to be proved: namely, that the true length of the tail was 21°, and that the increase of 7°, by which it afterwards appeared to be 28°, came wholly from parallax.

[Margin: Negative reply to the minor.]

In this discourse, however, some things are false and some are not necessary; and so the minor premise is denied. First, I deny that the true length of the tail was 21° if the length of 28 degrees was apparent and not true. For since both were observed by Chiaramonti, both were apparent; and since, according to Chiaramonti, the parallax was so great, neither could be true, but each was greater than the true. Otherwise, if the parallax had been insensible, both would have been true, and that increase would either have been real, or both would have been enlarged by something other than parallax. Indeed, the length of 21 degrees must have been less true than that of 28 degrees, because when it was seen as 21° the comet is taken to have been much nearer the horizon, namely 64° from the zenith. Further, since on December 4 the comet appeared with a larger head, Chiaramonti ought rather to have inferred from this a smaller distance from the Earth than on the 18th, when he asserts that the head had diminished; for both reasons, then, the parallax ought to have been greater. So if, at a distance of the head of 37 degrees from the zenith, the apparent length of the tail exceeded the true by 7 degrees on account of the parallaxes, then at a distance of 64 degrees the apparent length ought to have exceeded the true much more, and the true length ought thus to have been smaller by about 14 degrees — unless the inclination of the tail required otherwise, which, however, Chiaramonti would have had to show.

Second, I deny that the increase was not real on the ground that the head decreased. For the comet's head could have decreased only optically, on account of its distance from the Earth growing greater day by day, and the tail nonetheless have grown from another cause — for instance, by the arrival of matter behind the comet's back, suited to reflecting to us the rays of the Sun that pass through the comet's head. Or the head could indeed have decreased physically, but because part of the matter that was in the head was drawn out lengthwise into the tail.

Third, I deny that, if that increase was not real, it came wholly from parallax. For the smallest part of the increase could have arisen from parallax, and the greatest part from the other causes indicated above in number 28 by Kepler — except the difference of eyes, since the observer was the same.

[Margin: The comet's tail of varying length on the same day.]

Certainly, on the night of November 29, as I related in the history of this comet, the tail appeared to Kepler to be of 30 degrees, while at Rome and Vienna on the same night it appeared to be 58°. On November 30 it appeared to be of 23 degrees, then at once longer through a certain vibration. On December 9 it appeared to Kepler to be of 70 degrees, but repeatedly greater on account of the darting of its rays; the more constant and more certain length, however, was 70°. On December 14 Biancani at Parma measured the tail at 36 degrees, but noted that it was at times the greater, the darker the air was; and on the same day Millerus saw it likewise at 36 degrees, while on that same day Ambrosius Rhodius saw it now at 50°, now at 60°. And Longomontanus, in his observation of November 23, old style, that is, December 3, new style, has

these words: *"We also measured the length of the tail, about 20 degrees or a little more, although we could scarcely follow its extreme vibration with our eyes."* Finally, see Cysat's observations on this in chapter 4.

That enlargement, therefore, was in large part optical: it came from the vibration of the rays, from their inclination towards the eyes — although Chiaramonti says in the *Apologia* that this was the same — from matter fit to receive and arrest the rays of the Sun and reflect them to the eye, and from the darkness of the air. For on December 4 the Moon had shortly before been full of light, and at $12^h\ 40^m$ after sunset it was still above the horizon, lighting up from the opposite side the eastern quarter in which the comet stood, and so washing out the tail. But on the 18th the Moon, having been in conjunction with the Sun two days before, was below the horizon, and indeed further below it than the Sun; so the length of the tail then showed better in the darker air. How much the Moon hinders the seeing of a comet is clear from Cysat's observations reported in chapter 3; and from them it will also be clear that the head was not really diminished, had it been viewed through a telescope. And indeed, whether that tail is called a flame in inflammable matter or light from the Sun's rays, it is not probable that it really remained the same from December 4 to December 18. Finally, from the very fact of the increase at a smaller distance from the zenith, at which the tail ought rather to have appeared smaller, Chiaramonti should have suspected that the increase did not come wholly, or in large part, from parallax.

Although, then, he did not demonstrate by this method that the comet was below the Moon — as he had professed in the summary of chapter 20 of Book 3 of the *Antitycho*, using the word *"It is demonstrated"*, and saying in the conclusion of the whole problem *"and this is what was to be demonstrated"* — he nevertheless deserved great praise for a truly ingenious method, by which he taught how to find the parallaxes of the head and of the tail on the hypothesis that the whole increase of the tail came from parallax. Nor does Kepler himself, on page 173, deny that it is *"an ingenious and new invention."* Let us pass on to Chiaramonti's other demonstration.

An Claramontius demonſtrauerit Cometam Anni 1618. fuiſſe infra Lunam, ob Parallaxim maiorem,erutam ex collatione Obſeruationis ſuæ cum Romana Obſeruatione.

Whether Chiaramonti demonstrated that the comet of the year 1618 was below the Moon on account of a greater parallax, derived from comparing his own observation with the Roman observation.

XXX. Chiaramonti asserts that this too was demonstrated by him, in Book 3 of the *Antitycho*, chapter 21, and in the *Apologia*, Book 2, chapter 12; Kepler, however, denies it in the *Hyperaspistes*, page 177. Let us weigh to which of the two the case should be awarded. The problem Chiaramonti uses is the one whose figure and method we set out sufficiently, with his own example,

in chapter 19, number 11, to which we refer the reader. It is founded on the difference of latitude and longitude observed at two places. For this he here supposes an observation of the comet duly made at Cesena on the morning of December 4, at $12^h\ 40^m$ after sunset, and the comet's longitude and latitude derived from it by calculation, as you see in the following synopsis.

[Margin: Chiaramonti's first step.]

Quantity	Value
Altitude of the pole at Cesena	0ˢ 44° 0′ 0″
Obliquity of the ecliptic	0ˢ 23° 30′ 0″
Apparent altitude of the comet	0ˢ 26° 0′ 0″
Apparent altitude of Arcturus	0ˢ 43° 0′ 0″
Apparent altitude of Spica	0ˢ 26° 30′ 0″
Azimuthal angle between the comet and Arcturus	0ˢ 3° 0′ 0″
Between the comet and Spica	0ˢ 34° 0′ 0″
Therefore the distance of the comet from Arcturus	0ˢ 17° 10′ 40″
And the distance between the comet and Spica	0ˢ 27° 44′ 35″
And the distance between Spica and Arcturus	0ˢ 32° 26′ 56″
Therefore the apparent longitude of the comet	♍ 4° 33′ 36″
And the apparent latitude	north 21° 48′ 58″
But from the Ptolemaic and Copernican latitude and longitude of the fixed stars there is gathered:	
Distance of Arcturus from Spica	0ˢ 33° 41′ 0″
And the apparent longitude of the comet	♍ 3° 34′ 39″
And the apparent latitude of the comet	north 20° 42′ 36″

But in the *Antitycho*, page 354, having reckoned the matter more carefully, he says that the comet's longitude and latitude derived from the Ptolemaic and Copernican longitude and latitude of Arcturus and Spica is to be preferred to the one that had been derived in the first place from the observed distances of the comet from Arcturus and Spica, that is, from those deduced from the observation.

[Margin: Second step.]

Second, he supposes the comet's distance from Arcturus observed at Rome on the same night, 17° 40′, and from Spica, 26° 33′ — namely by our Fathers in the Roman College; from which, and from the Coperni- can longitude and latitude of Arcturus and Spica, he gathers the latitude of the comet, 19° 26′ 30″, and its longitude, ♍ 3° 7′; and so the difference from the longitude observed by himself, 27′ 39″, and from the latitude, 1° 16′ 51″ — that is, if the observation was made at the same hour. But since the Roman observer did not add the hour, he says that, taking into account the comet's daily motion in longitude and latitude, according to the method he has given elsewhere for reducing an observation to the same moment, the discrepancy cannot have been so great that the difference of the longitudes and latitudes could have been diminished

by more than 5 minutes. So if the observation happened to be made at the same moment of the hour, the difference of the longitudes observed at Cesena and Rome was, he says, 27′ 39″, and that of the latitude 1° 16′ 51″; but if it was not made at the same hour, the difference of the longitudes could still not have been less than 22′ 39″, nor that of the latitudes less than 1° 11′ — especially since he puts the difference in the altitude of the pole at no more than 2 degrees, and the two places lie almost under the same meridian, and likewise do not differ in this by more than 2 degrees, or 8^m of time.

[Margin: Third step.]

Third, then, he proceeds from the problem he gave in Book 1 of the *Antitycho*, chapter 7, problem 1, and from its working, given by him in Book 3, chapter 5, which we have set out in chapter 19, numbers 11, 12 and 13. He supposes it demonstrated by himself, from the difference of longitude of 10′ 15″ and of latitude of 24′ observed at Uraniborg by Tycho and at Kassel by the Landgrave of Hesse, that the comet of the year 1577 was not more than 12657 Italian miles from the centre of the Earth; on which see what we have said in chapter 18, numbers 34 to 37. With this supposed, he now reasons as follows, on page 355 of the *Antitycho*: if a difference of longitudes of 10′ and of latitudes of 24′, observed at Uraniborg and Kassel, shows that the comet was not more than 12,657 miles from the centre of the Earth, then a difference of longitudes of 22′ 39″ and of latitudes of 1° 11′, observed at Rome and Cesena, shows it much more. For the greater that difference is (refraction set aside), the greater the parallax it argues, and so the greater the nearness to the Earth; and still more so if the two places of the observers are nearer to each other and differ less in the altitude of the pole. Now Cesena is nearer to Rome, and differs less from it in the altitude of the pole, than Uraniborg does from Kassel: these cities differ by 4° 36′, whereas Rome and Cesena differ by only about 2 degrees. Therefore the distance of the comet of this year 1618 from the centre of the Earth was less than 12657 Italian miles, or 4 1/6 semidiameters of the Earth.

Solutio Argumenti Claramontij.

Solution of Chiaramonti's argument.

[Margin: Major premise.]

XXXI. This argument of Chiaramonti's likewise, bound to the rules of syllogism, stands thus: *If, for the comet of the year 1618 observed on December 4 at Rome and at Cesena at the same moment of time, the difference of longitude was greater than 10 minutes and the difference of latitude greater than 24 minutes, then the comet was less than 12657 Italian miles, or 4 1/6 semidiameters of the Earth, from the centre of the Earth, and so nearer than the Moon.*

[Margin: Minor premise.]

But for the comet of the year 1618 observed on December 4 at Rome and at Cesena at the same moment of time, the difference of longitude was greater than 10′, and the difference of latitude greater than 24′.

[Margin: Conclusion.]

Therefore the comet was less than 4 1/6 semidiameters of the Earth from the centre of the Earth, and so nearer than the Moon. So it was far below the Moon.

The major premise is plain from Chiaramonti's third step, on which see above, at the end of number 30. The minor is plain from his first and second steps, set out in the same place. For if we suppose, without any reduction, that the observations made at Rome and at Cesena happened to fall at the same moment of time, the difference of longitude was 27′ 39″ and that of latitude 1° 16′ 51″; and if they are reduced to the same moment, the difference was not less than 22′ 39″ in longitude, and 1° 11′ in latitude.

[Margin: Negative reply to the minor.]

I reply: granting the major (for the problem proceeds from those given differences by an evident calculation), I deny the minor. First, because in its proof the distance of Arcturus from Spica is assumed to be 33° 41′, whereas from Tycho's observations and our own, repeated many times with the sextant, it is 33° 2′, as is clear from what was said in Book 6, chapter 10. So Chiaramonti would have erred less had he used the distance deduced from his own observations, 32° 26′ 57″ — granted that not even this is correct, and that Kepler, in the *Hyperaspistes*, page 177, conjectures from this that Chiaramonti's observations were rather rough; and the frequent omission of minutes in them is no slight indication of it. Second, because he used the Copernican longitude and latitude of Arcturus and Spica, which are plainly erroneous, especially the longitude, as is clear from what was said in Book 6, chapter 14, and that by many minutes. Third, the comet's proper daily motion in longitude for December 4 is supposed too small, since Kepler and Longomontanus put it at about 1° 40′ or 1° 30′, of which 25′ or 22′ answer to 6 hours; taken from the difference of longitude, 27′ 39″, these leave 3′ or 5′. And 6 hours could have passed between the Cesena observation and the Roman one, since when Chiaramonti observed the comet it already appeared 53 degrees high. Whether, once Chiaramonti's assumptions are corrected, a distance of the comet from the Earth smaller than the Moon's still follows, it is not my task to show; it is enough to have shown that, from the assumptions already mentioned, it has not been demonstrated that the comet was only 12,657 miles from the Earth.

An Claramontius demonſtrarit Cometam Anni 1618. fuiſſe infra Lunam, ex Obſeruationibus ſuis collatis cum Obſeruationibus PP. Societ. noſtræ in India Orientali habitis.

Whether Chiaramonti demonstrated that the comet of the year 1618 was below the Moon, from his own observations compared with the observations made by the Fathers of our Society in the East Indies.

XXXII. Chiaramonti affirmed this too, in the *Apologia* for the *Antitycho* and in the supplement to the *Antitycho*. There, on page 2, he reports the distances of the comet from Arcturus and from Spica observed at Goa by Father Giacomo

Rho of the Society of Jesus, and from these, from page 4 on, he investigates the comet's longitude and latitude. But in the same place he supposes the distance of Arcturus from Spica to be 33° 41′, as he had supposed it in the *Antitycho*, Book 3, chapter 21, and takes the longitude and latitude of the fixed stars from Ptolemy and Copernicus, as he states expressly there on pages 4 and 5. From the difference between the longitude and latitude deduced from these and those he had gathered from his own observations on December 4, he deduces the parallaxes and the distance from the Earth. But that whole structure collapses, because it rests on false foundations: namely, the erroneous distance of Arcturus from Spica and the erroneous longitudes of Arcturus and Spica, as I taught a little earlier, in number 31, in the reply to the minor premise.

An ex Obſeruationibus aliquorum in diuerſis terræ locis factis demonſtrari poſſit Cometam Anni 1618. fuiſſe infra Lunam.

Whether it can be demonstrated, from the observations of some observers made at different places on the Earth, that the comet of the year 1618 was below the Moon.

XXXIII. This must be affirmed, whether we accept the observations of some observers which, on account of their excessive disagreement or other marks, appear rough and deceptive, or those of others which appear more accurate. Let us begin with the latter. Father Cysat, on this comet, page 20, derives from the distances of the comet from stars of Ursa Major and Ursa Minor, observed on December 28 at $5^h\ 4^m$ in the morning at Ingolstadt, the comet's longitude, ♏ 8° 31′, and its northern latitude, 60° 57′, using the Tychonic latitudes and longitudes of the fixed stars; and from the place observed on the following day, the daily motion in longitude is gathered as 2° 20′ and in latitude as 20′. On the same day, namely December 18 old style but the 28th Gregorian style, Longomontanus, from his own observations made at Copenhagen at $6^h\ 45^m$ in the morning, and likewise using the Tychonic places of the fixed stars, gathers the comet's longitude as ♏ 7° 30′ and its latitude as 61°; and from the motion of the immediately following day, as assigned by him, the comet's daily motion is gathered as 3° 25′ in longitude and 39′ in latitude, as is found in the Appendix to the *Astronomia Danica*, chapter 10, page 34 in my copy. The difference of apparent longitude, therefore, was 1° 1′, and of latitude 3′. The difference of the meridians of Copenhagen and Ingolstadt is at most 4^m of time; so when it was $5^h\ 4^m$ at Ingolstadt, it was $5^h\ 8^m$ at Copenhagen. Taking this from $6^h\ 45^m$ leaves $1^h\ 37^m$, by which the Ingolstadt observation preceded the Copenhagen one. Now the comet's motion was retrograde, as is clear from its ephemeris by Kepler, Lon- gomontanus and Cysat, and pointed out by us in the history of this comet. So in $1^h\ 37^m$ the comet's longitude should have decreased, but its latitude increased. Now the comet's daily motion in longitude was 3° 25′, and in latitude 39′. Conversely, if the Copenhagen observation is reduced to the moment of the Ingolstadt one, the latitude should be diminished but the longitude increased, in proportion to the daily motion corresponding

to 1^h 37^m; and that is 14′ in longitude and 3′ in latitude. Therefore, had the observation been made at Copenhagen at the same moment as at Ingolstadt — that is, at 5^h 8^m at Copenhagen but 5^h 4^m at Ingolstadt — the longitude observed at Copenhagen would have been ♏ 7° 44′ and the latitude 60° 57′; but at Ingolstadt it was then observed at ♏ 8° 31′, with latitude 60° 57′. So the difference of apparent longitude was 47′, and of latitude 0′. With these supposed, and given the altitude of the pole at Copenhagen, 55° 43′, and at Ingolstadt 48° 40′, and so a difference of 7° 3′, it is gathered by the problem given in chapter 19, numbers 11 and 12, that the distance of the comet from the Earth was much less than 41,390 Italian miles, or 10 semidiameters of the Earth.

You may learn this even without calculation, from the following. Chiaramonti, in Book 3 of the *Antitycho*, chapters 4, 5 and 6, demonstrated from a difference of longitude of 10′ 15″ and of latitude of 24′ 24″, observed by Tycho at Uraniborg and by the Landgrave of Hesse, that the distance of the comet of the year 1577 was not greater than 12657 miles; and from a difference of longitude of 15′ and of latitude of 14′, a distance not greater than 24,276 miles — demonstrations which we find to be sufficient. But in our case, although the difference of latitude is nil, that of longitude is three times greater, since it is 47′; nor is there a great difference between the differences of the altitudes of the pole. And it would be demonstrated much more strongly still from other observations, if they were accepted: for instance, from the observation of December 4, on which Cysat at Ingolstadt, at 6^h 52^m in the morning, observed the comet's longitude at ♏ 4° 56′, with latitude 14° 31′, as he himself has it on page 20. But on the same day D. Habrecht observed the comet at Strasbourg at ♏ 3°, with latitude 19° 40′; and Ambrosius Rhodius at Wittenberg saw the comet on the same day at longitude ♏ 1° 24′, with latitude 20°, as Kepler reports in *De Cometis*, page 60. For the difference between Cysat and Rhodius would be 3° 32′ in longitude and 5° 29′ in latitude, from which a huge parallax would be gathered, and an excessive nearness of the comet to the Earth. And finally from many other differences of longitude and latitude, which may be gathered from the first table placed at the end of chapter 3, where it treats of the comet of the year 1618.

But Kepler gathers that some of these observations are rough and deceptive, both from the fact that their authors themselves excuse themselves on this point — namely Rhodius, Habrecht and some others — and because the apparent quantity ought to have been intermediate at a place on the Earth lying in between, namely Wittenberg. I, however, gather the same from the observations of Cysat and Longomontanus, which I know to have been the more accurate; for they differ in the comet's longitude for this day by a single minute only. That the rest stray so far, therefore, must be judged to have come not from so great a parallax, but from some error of observation, or of calculation in reckoning the comet's hours.

Concluſiones ex Prædictis.

Conclusions from what has already been said.

I. CONCLUSION. *It has not yet been demonstrated absolutely that the comet of the year 1618 was above the Moon.* This is plain from what was said from number 1 to 26.

II. CONCLUSION. *But neither has it been demonstrated absolutely that the same comet was below the Moon.* This is plain from what was said from number 26 to 32, and from the fact that it is not established that anyone besides Chiaramonti has so far attempted to demonstrate it, or has actually demonstrated it; for if this should become established, our words will not have concerned him, and we shall change our view at once.

III. CONCLUSION. *Yet, on some probable hypothesis, and with some observations accepted, it has been demonstrated that this comet was below the Moon.* This is established from what was said in numbers 8 and 33, and towards the end of number 26.

IV. CONCLUSION. *It is probable that the comet of the year 1618 was above the Moon, yet in such a way that the opposite is not improbable.* The first part is established not only by the authority of very many astronomers who assert it, but also from their arguments. For although these are not evident, yet if they are considered attentively, many of them — those which take the true daily motion for the apparent one — cannot stray so far from the truth, especially when the observations of several days, made at several places on the Earth, are compared, that the comet would have been far below the Moon in the last days of November. And since from then until January 20 the comet's head decreased gradually but continuously, it is very probable that this came about from its ascent above the Moon: for before, it seemed to have a diameter of 7′ or 6′, but afterwards, at the end, scarcely 1′ or 2′ — granted that this could have come about from a failure of its matter and an extinguishing of its light. The second part is plain from the third conclusion.

CAPVT XXIII.

Chapter 23.

Collectis Opinionibus Aliorum in vnam Synopſim, Statuitur Quid ſentiendum de Loco, Parallaxibus, ac Diſtantijs Cometarum à Terra.

The opinions of others are collected into one synopsis, and it is settled what is to be thought of the place, the parallaxes and the distances of comets from the Earth.

I. I indicated the opinions on the place of comets in chapter 4, number 14, naming their authors, but without any other indication of their works or books. In chapter 6 I set out the same opinions more carefully, separated the doubtful ones from the certain, explained their sense, and vindicated some opinions

falsely attributed to certain authors; this I did partly in the body of that chapter itself, partly in its scholia. Now I must take a middle way, and list the authors of the opinions with the places from which they were gathered, but without any discussion of whether such an opinion was, or was not, that of the author to be named below. Then the opinions on the distances from the Earth and on the parallaxes of certain comets must be added; and finally various conclusions on these matters must be laid down according to our own view.

[Margin: Authors who place comets below the ☾.]

II. The first opinion, then, was that of those who held that all comets are generated and move below the Moon. So thought Aristotle, *Meteorology* Book 1, chapters 7 and 10, with very many interpreters and the whole Peripatetic school. And among the philosophers: the Coimbra commentators, tract 3 on the *Meteorology*, chapter 3; Cottunius, lecture 31 on the first book of the *Meteorology*; Julius Caesar Scaliger, exercise 79 against Cardano; Telesius, *De Cometis*, chapters 2 and 3; Carolus Piso, in the *Speculum physicum* of the comet; Raffaele Aversa, volume 2 of his *Philosophy*, from question 32 on; Laurentinus, in his little book on the comet of the year 1618; Bartolomeo Mastri and Bonaventura Belluto, disputation 4 *De Caelo*, question 4, article 2, number 36. And among the astronomers or astrologers, or the physicists who were, however, more skilled in mathematics: Johannes Regiomontanus and Johannes Vögelin, in their observations of the comets of the years 1572, 1532 and 1533; Giovanni Pontano, on the last aphorism of Ptolemy's *Centiloquium*; Girolamo Fracastoro, in the *Homocentrica*, section 3, ch. 23; Peter Apian, in the *Astronomicum Caesareum*, part 2, last chapter; Jakob Milich, on Book 2 of Pliny, chapter 25; Francesco Giuntini, in the *Speculum astrologicum*, in the note on comets; Petrus Surdus, in his treatise on comets; Ioannes Paduanus in the same place; Scipione Chiaramonti, in the *Antitycho*, Book 3, last chapter, and in its *Apologia* and *Supplement*. And besides these, many others listed by Tycho, volume 1, chapter 10, and volume 2 of the *Progymnasmata*, chapter 10: namely Andreas Nolthius, Nicolaus Winckler, Georg Busch, Conrad Dasypodius, Valentin Steinmetz, Nicolaus Bazelius, Georgius Henischius, Ioannes Huuernius, Theodosius Graminaeus, Thomas Erastus, and Adam Ursinus, in the little books they published on the occasion of the comet of the year 1577 or the star of the year 1572. Finally, all the ancient astronomers, as Angestus asserts in Book 2 *De proprietatibus formarum*, page 34. To this class, moreover, Heraclides, Metrodorus, Xenophanes, Strato, Epigenes, Boethus and most of the Stoics seem to be reducible, as is established from Plutarch, Book 3 of the *Placita*, chapter 2, and from Seneca, Book 7 of the *Natural Questions*, chapters 3 and 21.

[Margin: Aristotle. The Coimbra commentators. Cottunius. Scaliger. Telesius. Piso. Aversa. Mastri. Belluto. Laurentinus. Regiomontanus. Vögelin. Pontano. Fracastoro. Peter Apian. Milich. Giuntini. Surdus. Paduanus. Chiaramonti. Nolthius. Busch. Vinchler. Dasypodius. Steinmetz. Henischius. Bazelius. Huernius. Graminaeus. Erastus. Ursinus. Heraclides. Metrodorus. Xenophanes. Strato. Epigenes. Boethus. The Stoics.]

Two things, however, are to be noted here. The first is that Hájek is falsely counted in this class by Mastri and by Aversa; against them, see what was said in chapter 6, scholium 5. The second is that among the authors listed there are few Peripatetics, and fewer astrologers, who comets in the highest region of the air place them; but that the rest, especially the astronomers, place them above the highest region of the air, or above the vapours and exhalations — which Scaliger and Chiaramonti do not reject. Piso, however, places the bearded comets in the highest region of the air, but the tailed ones in the concave of the lunar heaven.

[Margin: Authors who place comets above the ☾.]

III. The second opinion was that of those who set comets above the Moon, either all of them or without qualification. Among them, of the ancients, were Democritus, Anaxagoras, Zeno, Artemidorus, Apollonius of Myndus, the Chaldaeans, the Italian Pythagoreans, and Seneca, as is clear from Seneca himself, Book 7 of the *Natural Questions*, from Aristotle, *Meteorology* Book 1, chapter 6, and from Plutarch, Book 3 of the *Placita*, chapter 2. Of the more recent: Cardano, Book 4 of *De subtilitate*; Oddus of Padua, Book 2 *De peste*, chapter 4; Cornelius Frangipanius, *De Cometis*; Tycho, volume 2 of the *Progymnasmata*, chapters 6 and 10, and throughout the *Epistolae*, especially pages 161 and 297; Longomontanus, in the Appendix to the *Astronomia Danica*, chapter 3; Marcello Squarcialupi; and, in Froidmont, Book 3 of the *Meteorology*, chapter 2, article 2, Ambrosius Rhodius, Erycius Puteanus and Thomas Fienus; Christoph Rothmann, in his little work on comets, chapter 3, and in Tycho's *Epistolae*, page 161; Galileo, in the first dialogue on the system of the world, and in the *Trutinator*; Mario Guiducci, in his treatise on comets; Giuseppe Biancani, in the *Loca mathematica* on *Meteorology* 1, chapter 6, and in the *Sphaera*, Book 16, chapter 3; Willebrord Snel, *De Cometa anni 1618*, chapters 1 and 4; Antonio Santucci, Ludovicus Columbus, Annibal Raymundus, Io. Echius and Paolo Aresi, in Resta, tract 1 of the *Meteorology*, chapter 1; Giordano Bruno of Nola, in the book *De innumerabilibus*; Descartes, Book 3 of the new *Philosophy*, number 132; Libavius, in a separate treatise, part 2, the chapter on comets; Philippus Millerus and Isaac Habrecht, in Kepler, Book 2 *De Cometis*, page 94.

[Margin: Democritus. Anaxagoras. Zeno. Artemidorus. Apollonius of Myndus. The Chaldaeans. The Pythagoreans. Seneca. Cardano. Oddus. Fringip an [?]. Tycho. Longomontanus. Squarcialupi. Rhodius. Puteanus. Fienus. Rothmann. Galileo. Guiducci. Biancani. Snel. Santucci. Columbus. Raymundus. Echius. Aresi. Bruno. Renatus. Libavius. Millerus. Habrecht.]

Here likewise two things are to be noted. First, that some of the authors already mentioned assign comets a sublunary origin, from elementary matter, but judge that they are afterwards carried up and move above the Moon: so thought Galileo, Guiducci, Aresi and, formerly, in his earlier opinion, Rothmann. Second, that Proclus, Nicephorus, Abū Maʿshar, Fracastoro and Piso are falsely counted in this class by some, as I taught in chapter 6, scholia 3, 4 and 5.

[Margin: Authors who place comets partly above, partly below the Moon.]

IV. The third opinion is that of those who placed most comets above the Moon, yet kept some below the Moon, and called or recognised the former as celestial, the latter as elementary: namely Michael Mästlin, in Tycho, volume 2, page 247; Cornelius Gemma, Helisaeus Röslin, Tadeáš Hájek and Bartholomaeus Scultetus, as may be seen in Tycho, volume 2 of the *Progymnasmata*, chapter 10 — granted that Hájek and Scultetus had once placed all comets below the Moon; Johannes Praetorius, in his catalogue of comets, at the year 1572; Philippus Apianus, in Tycho, volume 1, page 646; Tannerus, *De caelo*, from page 148 on; Froidmont, Book 3 of the *Meteorology*, chapter 1, from article 1 to 5, and article 6; Elias Camerarius, in Tycho, volume 1, page 694; Cabeo, on *Meteorology* 1, text 37, questions 2 and 4; Giovanni Camillo Glorioso, Book 5 *De Cometis*, chapter 1; Fortunio Liceti, Book 5 *De Cometis*, from chapter 41 and from 52; Franciscus Resta, tract 1 of the *Meteorology*, chapters 2 and 4; Balthassar Tellez, disputations 40 and 47 of the *Physics*, sections 1 and 2; Boulliau, Book 1 of the *Astronomia*, chapter 4. To this class can also be referred those who say that comets are made by God, either by himself or through the Intelligences, at will, out of any matter whatever: namely St John Damascene, Book 2 *De fide*, chapter 7; Gulielmus Hirsaugensis, in the *Institutio philosophica et astronomica*; Rodrigo de Arriaga, the single disputation *De caelo*, section 2, subsection 3; and Oviedus, the single controversy *De caelo*, point 3, paragraph 3. Kepler, too, was of a similar view, as is plain from his books on the comets of the years 1607 and 1618, page 45, and from the *Hyperaspistes*, page 149, where he affirms that the comet observed by Regiomontanus came near the Earth about the middle of its motion; and the motion of comets along a rectilinear trajectory, combined by him with the annual motion of the Earth (of which I shall speak in the last chapter), requires that many comets at some time approach the Earth, or the Earth them, granted that they afterwards withdraw into the depth of the aether and vanish. Cysat, too, in chapter 3, proposition 8, does not deny that the comet of the year 1618 advanced along a straight line in such a way that at the beginning it was lower than the Moon by 10 semidiameters of the Earth. Clavius also, and in his work Maurolico, in the *Sphaera*, pages 193 and 194, held that some comets can be generated in the aether above the Moon; and this was also the opinion of our Eusebius Nierembergensis [Juan Eusebio Nieremberg], Book 6 of his *Philosophy*.

Concluſiones de Diſtantia & Loco Cometarum.

Conclusions on the distance and place of comets.

I. CONCLUSION. *Without violating the credibility of history, it cannot be denied that some comets were below the Moon.* This is against Tycho, volume 2, pages 247 and 441, who says: *So that I am entirely of the opinion that no comets have ever shone forth lower than the seats of the Moon.* He has the same in a letter of 1588 August 17 to Rothmann, and in a letter to the same man of 1589 November 24. It is likewise against Longomontanus, in the Appendix to the *Astronomia*, chapter 3, and the others listed in number 3. But it accords with the mind of the authors adduced in numbers 2 and 4. Such seems to have been the comet of the year 13 before Christ, of which Dio says, Book 54: *A comet, after appearing for many days hanging over the City, dissolved into torches.* So too the one which with its tail reached almost to the Earth and hung over Constantinople in the year of Christ 400, as I related in chapter 3, in the history, from Socrates and Sozomen; and the one which in the year 70 was seen to hang over Jerusalem for a whole year, as Zonaras narrates, volume 1; and, manifestly, the one which in the year 1450, passing beneath the full orb of the Moon, produced an eclipse, as I related in the same place from Georgius Phranza, Book 5 of his history, chapter 21; and the one which in the year 1543 drained a certain stream with its tail, another like which Scaliger narrates, exercise 79 against Cardano. Nor is there any ground for someone to say that these were not properly comets, or were not natural; for that very claim is against the credibility of the history, which reckons them among comets.

II. CONCLUSION. *No comet has yet been demonstrated absolutely to have been above the Moon, but only from a hypothesis which is probable indeed, yet uncertain.* This is against Tycho, Longomontanus, Kepler, Rothmann, Snel, Mästlin, Gemma, Cysat, Röslin and Hájek, at the places adduced in numbers 3 and 4, who thought they had themselves demonstrated that some comets were above the Moon; and against many others named in numbers 3 and 4, who affirmed

that it had been demonstrated by them, especially by Tycho. The first part of the conclusion is that of Chiaramonti, Cottunius, Mastri and Belluto, and it is established from the conclusions on the individual comets placed at the end of chapters 18, 19, 20, 21 and 22. From those chapters the second part is also plain. For on the hypothesis of a regular and true daily proper motion of the comet, known as if distinctly from its apparent motion, and on other similar ones which are assumed in the demonstrations of the authors already mentioned, their demonstrations hold — not all of them, indeed, but some of them; yet those hypotheses are not absolutely certain, and so the conclusion derived from them is not even certain, nor is it absolutely demonstrated.

III. CONCLUSION. *No comet has yet been demonstrated absolutely, by a mathematical demonstration, to have been below the Moon, but only from some probable hypothesis.* This likewise is clearly established from the conclusions of chapters 18, 19, 20, 21 and 22, and from the examination carried out in those same chapters. For the observations from which some comet has been demonstrated to have been below the Moon are not such that we can rely on them as certain; and there are other observations of the same comet from which, if they were admitted, that same comet would be shown to be above the Moon with as great certainty as it is shown from the former to have been below it. Nor do we have from elsewhere certain and evident indications for saying that either all these observations or all those were deceptive. I said "by a mathematical demonstration", because it has already been established from the credibility of history, in the first conclusion, that some comets were below the Moon.

IV. CONCLUSION. *It is probable that some comets were above the Moon, and some below it, even of those about whose place nothing is established from bare history.* Each part remains sufficiently proved, both by the authorities brought forward in numbers 2, 3 and 4, and by the arguments adduced for each opinion, partly in chapters 10 and 11, partly from chapter 18 to 23. For since, of the comets observed from the year 1577 to 1618, there is none which, on some hypothesis, is not demonstrated to have been above the Moon, and almost none which, on another hypothesis, is not demonstrated to have been below the Moon; and since both hypotheses are not without probability, each of the opposites is certainly probable. And what is said of these can also be said with probability of many others, on account of their likeness, even if very few of them were observed with astronomical instruments.

V. CONCLUSION. *But whether all comets were below the Moon, or some above and some below, it is certain that many moved above the height of the twilight vapours or exhalations, or above the highest region of our air.* This is established partly from what was said in chapter 14 about the small height of the vapours already mentioned; partly from all the measurements which astronomers or geometers have found by their measuring of the distances of comets, as in the table given above, for no one has obtained a distance in comets less than one semidiameter of the Earth; and partly, finally, from the stay of many comets

above the physical horizon, and from the small difference in their distances from the same fixed stars observed on the same night at different hours, as is plain from the arguments adduced in chapters 18, 19, 20, 21 and 22 to demonstrate that the parallax of some comets is smaller than the Moon's. For although those arguments do not demonstrate this absolutely, they do demonstrate, with at least physical certainty, that the comets could not have been so low that their distance was less than a thirtieth or a fortieth part of the Earth's semidiameter, which is the greatest height of the vapours that can be granted at most; otherwise they would have had a parallax of more than 35 or 40 degrees, that is, one perceptible without any instruments. Nor, in the comets observed from the year 1577 to 1618, can so great a leap in the comets' proper motion be feigned with any probability as to steal so enormous a parallax from the senses, by moving the comet towards the vertex; which will be manifest to anyone who considers the apparent motion of those comets in the tables shown in chapter 3.

[Margin: The author's final opinion.]

I add, moreover, that it is much more probable that the comets of the years 1577, 1585 and 1618 were, if not above the Moon, at least a little below the Moon. Therefore I judge that the region of very many comets is above our air, and that the whole space attributed to elemental fire, together with the whole ethereal air up to the fixed stars, is the field in which Divine Providence, at its own discretion, displays new phenomena of this kind to the eyes of mortals at certain times. There is therefore no reason why either the Peripatetics should insult the Tychonics, or the Tychonics the Peripatetics, with as much haughtiness and swagger as you see some have done. Rather, it would be fair from now on for each side to speak of the other with greater moderation, and in future to rely on more certain observations and demonstrations — if, however, there are any who, when new comets come to light, remember either our labours or our admonitions.

CAPVT XXIV.

Chapter 24.

De Vera Quantitate Capitis, & Caudæ Cometarum ex Obſeruationibus determinanda.

On determining the true size of the head and tail of comets from observations.

Problema 1. Capitis Cometici Magnitudinem veram inueſtigare.

Problem 1. To investigate the true magnitude of a comet's head.

I. To determine the size of a comet's head geometrically, three things must be assumed. The *first* is the apparent diameter of the disc of comets, which for the most part appear round, like stars — which is also why they have been

called "hairy stars" [stellae comatae]. But to measure this very diameter with the astronomical radius is most deceptive, and I am surprised that Father Cysat, chapters 1 and 4, observed the head of the comet of 1618 in this way, since he could have known how far Tycho, in the *Mechanica Astronomia*, and in volume 1 of the *Progymnasmata*, pages 247, 335, 343 and 671, and volume 2, page 31, had taught that this instrument is not to be trusted. But I am still more surprised that the same Cysat, chapter 5, on that comet, adopted the diameter of 7′ observed with the astronomical radius, and from it demonstrated the true magnitude, rather than the diameter of 8′ or 16′ observed with the telescope — not that I think this latter was itself exact, but because the telescope shows a more exact magnitude of the stars by rescuing it from the deception of the eyes. By what method the apparent diameters of the stars and of the lesser planets are to be observed, we have taught fully enough in Book 7, Section 6, chapter 9. All of this is to be understood here of the head of comets.

[Margin: 1. The supposition for measuring the head.]

[Margin: Father Cysat's observation of a comet's head is deceptive.]

Second, the distance of the comet's head from the centre of the Earth must be assumed; how uncertain it is, is plain enough from what has been said so far, from chapter 18 to chapter 23. Granting it, however, consider the triangle GBE, right-angled at E: for the straight line GE, drawn from the Earth's centre G and touching the comet's globe at E, makes with the globe's semidiameter BE a right angle at E, by proposition 18 of the third book of Euclid's *Elements*. In a triangle of this kind the base BG is given, namely the distance of the comet's head from the Earth, and so is the angle BGE, under which the comet's apparent semidiameter is seen, since the whole angle DGE measures the apparent diameter. Therefore, by the laws of triangles, the true semidiameter BE will not remain unknown, in the parts in which BG was known.

[Margin: 2. Supposition.]

Diagram. In the left column: a circle representing the comet's globe, with two straight lines rising from G at the foot and touching it on either side, and a vertical line from G through the circle up to H. A horizontal arc crosses the circle, with A and D at its left end and E and C at its right; F stands at the lower edge of the circle and B within it near the top.

- H (top): the upper end of the vertical line
- B (inside the circle, near the top)
- A, D (left end of the cross arc)
- E, C (right end of the cross arc)
- F (lower edge of the circle)
- G (foot): the centre of the Earth, where the tangent lines meet

Third, the comet's head is supposed to be spherical, or nearly spherical, by Tycho, volume 2, chapter 9; by Cysat, chapter 4; by Longomontanus in the Appendix to the *Astronomia*, chapter 10; by Snel on the comet of 1618, chapter 6; and by most others. With these posited, the threefold magnitude of comets

can be found by the rules we have given on the measurement of the circle and the sphere in Book 1 of this *Almagest*, chapters 4 and 6. But it is very uncertain whether a comet's head is spherical, and whether it is a single continuous body, as is plain from the observation of the comet of 1618 made with the telescope by Father Cysat and by Habrecht, which I reported in chapter 3, at the end of the history of that year's comet, before the first table.

[Margin: 3. Supposition.]

Problema 2. Caudæ Cometicæ Magnitudinem veram inueſtigare.

Problem 2. To investigate the true magnitude of a comet's tail.

II. The magnitude of the tail is much more uncertain than that of the head, because of the inconstant vibration and ejaculation of the rays, even on the same night — as was observed most recently, above all in the comet of 1618, and recounted by us in the history of that year. If, however, the tail's size is to be inferred from some determinate seen quantity of it, three things must be given: namely the distance of the comet's head and the distance of the end of the tail from the centre of the Earth, and then the apparent distance of the head from the end of the tail. For with these given, the true length of the tail will easily be found — and very easily indeed if the tail appears crosswise, so that the head and the end of the tail are equally distant from the eye. For in the triangle ADE, in which the head is D and the end of the tail E, and the given distances from the Earth's centre A are AD and AE, if the angle DAE is also given, measuring the arc DE — that is, the seen distance of the head from the end of the tail — then the chord DCE will certainly be found, in the parts in which AD and AE are known; and it will not differ much from the curvature of the tail DBE, if the tail is not enormously curved. As for how the distance is corrected from the seen distances from the vertex of both the head and the end of the tail, and from the parallaxes owed to the distance of each from the Earth — or the parallaxes from the distances — gather it from Chiaramonti's problem, expounded by us in chapter 19, number 2.

Diagram. In the right column: an arc DBE above a straight chord DCE, with straight lines from A at the foot to D and to E, and a line from B through C down to A.

- B (top): the midpoint of the arc of the tail
- D (left): the comet's head
- E (right): the end of the tail
- C (on the chord, below B)
- A (foot): the centre of the Earth

Problema 3. Longitudinem ac deinde Craſſitiem Caudæ Cometæ, Regiomontani methodo metiri.

Problem 3. To measure the length, and then the thickness, of a comet's tail by Regiomontanus's method.

III. Regiomontanus supposes, with the Peripatetics, that the tail of a comet is a flame, and so by its lightness tends upward in a straight line standing perpendicularly [?] on the Earth. On this assumption, in his treatise on the comet, Problem 15, he directs that from the Earth's centre A a circle be described, or at least a quadrant DE of the Earth, and another, BHC, in which the tip of the comet's tail ends. For he draws from A, through the comet's head F, the straight line AFH, so that FH represents the tail; and he draws from the eye D the visual lines DFG, through the head, and DH, through the end of the tail. He supposes three things given: *first*, the straight line DF, which can be found in the triangle ADF, given the distance of the head AF, the Earth's semidiameter AD, and the angle of parallax AFD; *second*, from the parallax AFD, the angle DFH, as being its supplement to two right angles; *third*, the angle HDF, which measures the apparent length of the tail. From these three, in the triangle DFH, he directs that the true length of the tail FH be sought.

Diagram. In the right column: a quadrant centred on A (lower left), with B at the top of its vertical radius and C at the end of its horizontal radius; a small inner quadrant from D down to E; H and G on the outer arc; F on the line from A towards H; lines from D to G and to H.

- B (top left): top of the vertical radius
- H (outer arc, upper): the tip of the tail
- G (outer arc, lower)
- D (left, on the vertical radius): the eye
- F (on the line AH): the comet's head
- A (lower left): the centre of the Earth
- E (foot, on the horizontal radius): end of the inner quadrant
- C (foot, right): end of the horizontal radius

Afterwards, in Problem 16, he teaches how to find the thickness of the tail: for if the tail is cylindrical, he directs that the true diameter

[Margin: To inquire into the thickness of the tail.]

of the comet's head be multiplied by itself, so that a square number is obtained; this he directs to be multiplied by the length of the tail, so that a square column that can be circumscribed about such a cylinder is obtained. Let it be, then, as 14 to 11, so the number of the column already mentioned to another, and the thickness of the cylinder will result. But if the tail is conical, he directs that a third part of the cylinder already mentioned be taken, because, from Archimedes, a cylinder is triple the cone inscribed in it. See an example of this calculation in chapter 11, number 15.

But if the head and the end of the tail are not equally distant from the Earth, and the distance of the end is not given but only that of the head, and the

comet's tail does not stand perpendicular to the Earth, its length will have to be investigated otherwise. Namely, if the distance from the Earth of the Sun, or of Venus or Mercury, is given — according as the comet's tail is supposed to be turned away from the Sun, or from Venus, or from Mercury — and if the apparent length of the tail is also given by observation, the true magnitude of the tail can still easily be investigated by another route. Before I teach this, I should like to set out first this problem from our Cysat, which is the third in his chapter 2.

Problema 4. Diſtantiam ſeu Digreſſionem Cometæ à Sole inquirere.

Problem 4. To find the distance, or digression, of a comet from the Sun.

IV. Let A be the pole of the ecliptic GEK, in which the Sun's place at a given moment of time is given as D; and let the longitude of the comet B be given, and also its latitude BE. Now let the portion BD of a great circle be drawn through the Sun and the comet, measuring the comet's digression from the Sun. For in the spherical triangle BDE, right-angled at E, the sides BE, the comet's latitude, and DE, the difference between the places of the Sun and the comet in the ecliptic, will be given; therefore, by the rules of triangles, the comet's digression from the Sun will become known — the Sun being that from which it is more probable that the tails of comets are turned away.

Diagram. In the left column: a circle with A, the pole of the ecliptic, at the top. A straight line GK across its lower part represents the ecliptic, with F, E and D just below it; arcs run from A down to E and from A through C to F; B, the comet, stands near the centre, on an arc rising from D.

- A (top): pole of the ecliptic
- C (upper left of centre)
- B (centre): the comet
- G (left end of the ecliptic)
- F (below the ecliptic, left)
- E (below the ecliptic, centre): foot of the comet's latitude BE
- D (below the ecliptic, right): the Sun's place
- K (right end of the ecliptic)

Problema 5. Veram Longitudinem Caudæ Cometæ aliter ac in Problemate 3. inueſtigare.

Problem 5. To investigate the true length of a comet's tail otherwise than in Problem 3.

V. This problem is Tycho's, volume 2, page 203, although there he uses the comet's digression from Venus; and it is Father Cysat's, on the comet of 1618, chapter 5. But we shall use Longomontanus's figure from his Appendix to the *Astronomia*, chapter 6, since it represents comets in various places with the tail turned away from the Sun.

Diagram. In the left column, across its full width: concentric circles about the Earth's centre A, with small circles for comets' heads and narrow cones for their tails pointing away from the Sun S. Heads are marked I (top), C (upper right), N (left), L and R (inside); a further head at the upper left carries a letter too small to settle on the scan. Tails run out to D, B, G, M, H and P. Lines join S to the heads.

- D (top): end of the tail of comet I
- I (top): a comet above the Sun
- B (upper right): end of the tail of comet C
- G (upper left): end of a tail
- [F?] (upper left, inside a small circle): a comet's head; letter not settled
- C (upper right): a comet above the Sun
- L (inside, upper left of A): a comet below the Sun
- H (left of L): end of the tail of comet L
- M (far left): end of the tail of comet N
- N (left): a comet above the Sun
- A (centre): the centre of the Earth
- S (right of A): the Sun
- R (lower right of A): a comet below the Sun
- P (foot): end of the tail of comet R

From the Earth's centre A, then, let the Sun's orbit SH be described, in which the Sun is at S; and a lower orbit LR, for comets below the Sun — for instance for the comet L, with tail LH, and the comet R, with tail PR. But for comets above the Sun let the circle NFI be described from A, in which there is a comet at C, with tail B; or a comet I, with tail ID; or a comet F, with tail FG; or a comet N, with tail MN. And let the heads of the comets be joined by straight lines to the Sun and to the centre of the Earth, and the ends of the tails to the centre of the Earth. Now let the comet be at I. *First*, in the triangle ASI, the angle SAI is given by Problem 4, namely the angle measuring the comet's digression from the Sun; the distances of both the Sun and the comet from the centre of the Earth, namely the sides AS and AI, are likewise supposed given. Find, therefore, the angle AIS, which is called the angle at the comet; for its supplement to two right angles will be the angle AID in the triangle AID, in which, further, the comet's distance from the centre of the Earth, AI, and the angle IAD, measuring the seen length of the tail, are supposed given. Therefore, by solving this triangle, the true length of the tail ID will become known. One must then proceed similarly in the other cases.

[Margin: 1. Step.]

[Margin: 2. Step.]

VI. What can be asked here about the apparent and true magnitude of the head and tail of comets has been set out by us sufficiently for the reader's instruction in chapter 4, where we treated the properties of comets gathered together from the history of observations: namely in number 6, on the apparent magnitude of the head; in number 7, on the apparent magnitude of the tail; and

in number 8, on the true magnitude of head and tail. Let the reader therefore turn back there.

[Margin: Examples of the true magnitude of comets.]

CAPVT XXV.

Chapter 25.

De Situ Caudæ Cometarum & Cauſis eius Phyſicis, & Opticis.

On the position of the tail of comets, and its physical and optical causes.

I. In chapter 4, number 9, we have already shown from observations that the tail of comets properly so called for the most part habitually points, continually, towards the quarter directly turned away from the Sun — granted that at times, because of nearness of position, it has been seen to go rather into the quarter opposite Venus or Mercury, and that some comet has been seen to stretch its tail right down to the Earth. What we said there, then, is to be recalled here; and, with it supposed, we must inquire what cause — whether physical, or optical, or mixed from both — accounts for that tail being seen to flash with so great a variety of shape and length, and with such inconstancy in the vibration and ejaculation of its rays, especially in the comet of 1618, on December 9, 10, 14 and 24. Here, therefore, we must investigate the cause of its turning away from the Sun, of its curvature, of its expansion or dilatation — at times, indeed, into the shape of a broom — and of its alternate lengthening and contraction, or vibration. For these four phenomena cause no small trouble, and one can scarcely find anyone who has brought forward a sufficient cause for all of them.

II. The *first* opinion was that of Aristotle, *Meteorologica* Book 1, chapter 7, and of his followers and interpreters on that passage, especially the Coimbra commentators: namely, that the tail or coma of comets is a kindled exhalation, or flame, but in a matter rarer and less compacted than the matter of the head; and that the figure of the tail — or coma, or tresses, or beard — differs according to the different disposition of the matter that feeds this flame. An argument for this is that the tail appears to us like a flame driven and tossed in one direction by the wind; Cardano uses this comparison for the comet of 1556, saying that its tresses glowed red as in a conflagration, as in torches when the wind blows on them. However, a flame tends upward by its natural lightness — and for that reason Regiomontanus, problem 15 of *De Cometa*, supposes the tail erected perpendicularly upward — whereas the tail or coma of a comet tends always, or for the most part, towards the side turned away from the Sun, and is not erected upward unless the Sun, below the horizon, stands so near the meridian that a straight line drawn from the Sun through the comet's head passes very nearly through the centre of the Earth; and it is established from the history of comets, observed more accurately in this century and the preceding one, that this rarely happens. The more recent Peripatetics therefore had, in order to sustain the ancient opinion, to devise a reason why

[Margin: The Peripatetics' opinion on flame.]

that flaming coma is scarcely ever raised upward. To resort to a wind blowing from the opposite side and driving the flame away from the Sun was to resort to an aerial contrivance devoid of all likelihood. For who would grant that, for whole months, during which comets often last and twinkle, a wind always blows from the quarter of the world in which the Sun is; that the source of the wind, so to speak, rises and sets with the Sun at an equal pace; and that it is carried by its impulse directly towards the part where the comet's head is — and this so constantly, and in so many, indeed in almost all, comets? And yet that this wind, raging so persistently in that direction, is not felt by us? Nor does it seem likely that the fuel and matter of the flame always lies along that line directly opposite the Sun, backward behind the comet's back or occiput, so that ever new matter of similar disposition, continuous with the earlier, is supplied to the flame for the whole time that the comet's tail lasts turned away from the Sun, and that it is never found around the head, above, below, or in front. Therefore, although flame does run to seize its fuel even downward — as when the smoke of a freshly extinguished candle is placed beneath the flame of another candle or lamp, it at once rekindles, and something similar happens in those fiery impressions we call falling stars or leaping goats — this still cannot rightly be applied to the tails of comets.

[Margin: A wind blowing from the opposite side is excluded.]

[Margin: A running-out to fuel is excluded.]

Carolus Piso, then, in his *Speculum Cometae*, chapter 17, granted that hairy comets are indeed in the highest region of the air, but that tailed or bearded [?] ones are in the concave of the lunar heaven, and that the flame of the coma therefore cannot be raised upward, because it is impeded by the solidity of the heaven already mentioned and is forced to bend crosswise — just as the flame of our own fire, shut in a furnace, is carried to the sides and takes a transverse position. He nevertheless also adds the motion of the comet, swept along by the motion of the primum mobile, as though the flame were bent in this way, as in torches carried by a runner; on which account that flame would have to be bent always towards the east, which is false. But since he was certain, both from his own observation and from that of Father Jean Leurechon, that the tail of the comet of 1618 had flowed continually into the quarter turned away from the Sun, he had therefore said in chapter 14 that the flame is indeed also in the front part, between the Sun and the comet's head, but is not seen, being obliterated and darkened by the greater brightness of the Sun. For it has been observed that at full Moon, because of the presence of the greater light, the comet's tail appeared much diminished, just as when the Sun approaches the horizon; and so the part turned away from the Sun, which the Sun's rays cannot reach because the comet's head stands in the way, appeared bright. As for why that flame does not end in a cone, as it would have to if the comet's head is smaller than the Sun and casts a conical shadow that guards the flame and the light, he thinks the cause is the great distance from the Sun — and so

he entangles himself in the difficulty he had foreseen rather than resolving it. The remaining things said against Piso, recall from chapter 11, number 2.

[Margin: Carolus Piso's opinion.]

Cottunius has something similar, in lecture 33 on Book 1 of the *Meteorologica*. For after he had said: *But the tail of comets, to Aristotle's ears, is the thinner, rarer and more spirituous part of the same exhalation in which the comet itself burns; and this part, lying next to the comet's head as to a denser matter, does not shine as the head does, because of its own rarity* — he then inquires why the tail of a comet always inclines towards the parts opposite the Sun, and says this happens because its light, being feeble as it is in rare matter, cannot be seen except in shadow. The part of the comet that faces the Sun, he says, is indeed inflamed and apt to shine of itself, but its light is overwhelmed by the Sun; whereas the part turned away from the Sun shines for us, in the shadow that the dense and opaque head of the comet casts. Finally, he refers the cause why that flame does not appear conical, as the comet's shadow is, to the brightness of the comet's head, which itself also overwhelms and washes out the parts of the tail nearer the head, but not likewise the more remote ones.

[Margin: Cottunius's opinion.]

Mastri and Belluto, on the other hand, disputation 4 *De caelo*, question 2, article 4, deny that the comet casts a shadow, and say that it shines on both sides — sometimes even on the part facing the Sun, because of the density of the kindled matter, as in hairy stars; but that this rarely happens, because the rarer matter and the feebler light are overwhelmed by the Sun's brightness, which does not happen on the part turned away from the Sun. Gemma, for his part, said in chapter 82 of the *Astrolabium* that it is fire in the comet's head, kindled by the Sun and expelled straight out by the Sun's violent action.

[Margin: The opinion of Mastri, Belluto and Gemma.]

III. But the opinion of these men does not seem one to be embraced. For, to say nothing of the solidity of the lunar heaven — less probable in this century — to which Piso attributes the impediment to the flame's rising: if only that part of the flame spread around the comet shines for us which is enclosed within the cone of shadow produced by the head, and is protected from the greater brightness, then it could never appear wider than the head itself, however far it were from the head, as the laws of optics require. Yet it often appears wider than the head itself: thus the tail of the comet of 1618 was seen on December 7 to be 2½° wide, and at times 3½°, although the head, even viewed with the telescope, never exceeded 16′. Next, either the back of the comet's head shines with its own light, or it is dark of itself. If it shines, as Cottunius would have it, it would not only make the lamp of the tail narrow but would cut it off from us entirely, and would cast no shadow; if, on the other hand, it is dark, it would not diminish the width of that flame. A reason therefore still remains to be given why the tail is sometimes seen so wide that it appears much wider than the head. And if it is true that the tail is sometimes so curved that a straight line drawn from the Sun to its convexity, or to the end of the bent tail, does

not pass through the comet's head, this difficulty certainly cannot be met on the hypothesis of these Peripatetics. Nor has Gemma ever explained what that violent action is which drives that flame in the opposite direction and does not do so in our own flames. And to resort to a hidden antipathy of that flame or light towards the Sun's rays, from which they flee away — as Franciscus Fernandez does, in Resta, *Meteorologia* Book 1, chapter 5 — is to resort to a contrivance and to the mysteries of nature, not to say to the dreams of those who philosophise arbitrarily.

[Margin: The preceding opinion is disproved.]

[Margin: Fernandez's opinion.]

IV. The *second* opinion was Seneca's, who held that the coma of a comet is not part of the comet, nor its flame, but rays. For in Book 7 of the *Natural Questions*, chapter 26, to someone objecting that a comet cannot be a celestial star because of its rarity, he says this: *Through the stars, he says, we do not discern what lies beyond; through comets we send our sight. First, if that is so, it happens not in the part where the star itself is of dense and solid fire, but where a rare splendour runs out and is scattered into tresses: you see through the intervals of the fires, not through the fires themselves.* For he holds that comets are stars appearing in the heaven from time to time, and that stars are fires, but eternal ones. And soon after, meeting another objection, taken from their shape, he says: *All stars, he says, are round; comets are stretched out; from which it is apparent that they are not stars. But who would grant you that comets are long? Their nature, like that of the other heavenly bodies, is a globe; but their brightness is extended, just as the Sun sends out its rays far and wide; but the Sun itself has one form, and the light that flows from it another; so the body of comets is itself rounded, but their splendour appears longer than that of the other heavenly bodies.* As for why the splendour of comets reaches farther than that of the other heavenly bodies, in chapter 27 he refers it to their very nature and to causes hidden from us. But surely, since most comets are of fainter light than the other stars, it is not very probable that comets emit so long a light while the stars emit none at all. Moreover, he gives no reason why comets shine towards the part opposite the Sun, nor what that matter is on which the rays of the head strike and are reflected to us; for light is not visible unless it is bounded by some opaque body. Nor, again, the old opinion of Rothmann, who said that the tail is part of the comet's body, of the same substance, and shining with its own light; for, as Tycho objects to him in the *Epistolae*, page 143, there would be no reason why it should always shine turned away from the Sun.

[Margin: Seneca's opinion.]

[Margin: Rothmann's opinion is improbable.]

V. The *third* opinion is that the coma or tail of a comet is the Sun's rays transmitted through the semi-transparent head of the comet as through a glass globe; an opinion which, however, has sprouted into various ways of expounding it. Peter Apian — who, just as he was the first of all to observe that constant turning of the comet's tail away from the Sun, so seems to have been

the first to refer the tail of comets not to the substance of the comet but to the rays of the Sun — said in the *Astronomicum Caesareum*, part 2, that their tail is rather the light of the Sun transmitted through their transparent head, and that comets are therefore much higher than the vapours that produce twilight; otherwise they would run into the shadow of the Earth and could not be lit by the Sun. But Philipp Apian, his son, in a letter written in 1572, December 6, to the Landgrave

[Margin: Peter Apian's opinion.]

[Margin: Philipp Apian's opinion.]

of Hesse, which Tycho reports in volume 1 of the *Progymnasmata*, page 643, held that comets are generated from the concourse of the Sun and the other planets, breaking against one another, and from their meeting in a definite part of the heaven — but chiefly from the Sun, since the tail of comets stretches out towards the quarter turned away from the Sun. Girolamo Cardano, in Book 4 of *De subtilitate*, teaches *that a comet is a globe set in the heaven, which appears lit by the Sun; and while the rays pass through, they form the likeness of a beard or a tail.*

[Margin: Cardano's opinion.]

Nor does Scaliger oppose him on this point, in *Exercitation* 79, although he would have the comet be below the Moon and an elementary body. His words are these: *For a comet is a body so dense that it can be illuminated, and so rare that it can transmit rays — which we also see in a glass globe. But that it is not in the region of vapours is false; it is far more remote from the truth that it is in the heaven.* Telesius, Tassonus and Aversa, question 42, section 1, judge the opinion of these men probable.

[Margin: The opinion of Julius Caesar Scaliger.]

Tycho followed these men. In his letter of 1589 February 21 to Rothmann, in that of 1590, on the Kalends of April, to the Landgrave of Hesse, and in volume 2 of the *Progymnasmata*, chapters 7 and 9, he at length concedes that the tail of a comet is turned away from the Sun rather, or more principally, than from Venus, and that it shines from the Sun's rays. Therefore, when comets are carried into the part opposite the Sun — that is, into the part such that our eyes stand between it and the Sun — they show no tail, or a very small one, because the tail then lies hidden wholly or almost wholly behind the comet's back; whereas when they head towards conjunction with the Sun, they put forth their beard more and more, as he relates happened with the comets of the years 1580, 1582 and 1585. The efflux of the tail, then, is the rays of the Sun penetrating the comet's head, bounded in some matter that is not wholly transparent, and reflected to us; for the substance of the aether is not wholly diaphanous, since the highest heaven appears blue to us because of some opacity after all. As for the cause why the tail of the comet of 1577 appeared curved, he says it is an aberration of sight, because the end of the tail, straight in itself, was nearer to us than the head, or beginning, of the tail. For it has been demonstrated by Ibn al-Haytham, *Optics* Book 2, proposition 28, by Witelo, *Optics* Book 4, theorem 31, and by Io. Pisanus the Englishman [John Pecham], *Perspectiva*, tract

1, proposition 69, that when sight takes in the extremes of some visible thing, whether a line or a surface, from differing distances, it appears oblique even if it is straight in itself. Biancani, in his *Sphaera*, Book 16, chapter 2, subscribed to Tycho, although he raises the difficulty about the curvature and breadth of the tail and does not solve it.

[Margin: Tycho's opinion.]

[Margin: Biancani's opinion.]

But we cannot wholly rest content with Tycho. He gives no reason for the tail being sometimes spread out into the shape of a basket or a clothes-brush; nor can that explanation by optical curvature be fitted to tails whose ends were seen to be farther from the Earth than their heads, as happened in the comet of 1618 and in many others. And that very theorem of Witelo, or proposition of Ibn al-Haytham, not only is not to the point Tycho is making, but actually fights against Tycho. For those two lights of optics say there that our sight distinguishes straightness from obliquity in lines and surfaces when they stand at so small a distance from the eye that it can perceive the differing distance of the extremities; but when the distance is so great that it cannot perceive the more remote of the extremities, it does not distinguish oblique things from straight ones — indeed it judges all things, however oblique, to be straight. This is the cause why the globe of the Sun and of the Moon appear to us as a flat disc. Since, then, for Tycho comets are higher than the Moon, the eye, because of the enormous distance, ought rather to judge their tail straight if it were curved and oblique, than to judge it curved if it were straight. Moreover, Tycho, as well as others who use the comparison of a glass globe or phial struck by the Sun's rays, ought to have explained why the Sun's rays passing through the comet's head do not always come together into a cone, as they come together behind a ball or a glass phial. Let us pass on, then, to Tycho's pupils.

[Margin: Tycho's opinion is refuted.]

VI. The *fourth* opinion was that of Johannes Kepler, who earlier, in the *Optica Astronomia*, chapter 6, number 13, or from page 264 on, tried in two ways to untangle the knots of this tail. He premises that the tail is scattered into the quarter contrary to the Sun, and is not hidden except when our eye is between the Sun and the comet's head opposite the Sun, or when the distance of the comets is immense; and that it is accordingly either kindled or illuminated by the Sun. Then he poses these doubts: *Why do the tails not look precisely towards the point opposite the Sun? Why do they almost always decline? Why are they curved into an arc? Finally, what is that which receives the Sun's rays and shines back by their impact, displaying the figure of a tail? For if you say it is matter belonging to the comet's essence, you will have fashioned a most monstrous prodigy; if the aethereal air, I ask why it is not lit by the Sun every day, so as to shine back, even without a comet?* Nor does he promise there a complete solution of these knots, but an attempt; for he says: *Since I cannot do as much as I wish, let me be allowed, then, to do as much as I can.*

[Margin: Kepler's opinion.]

He therefore supposes that the cause both of the curvature and of the declination from direct opposition to the Sun is the same, but that neither can come from parallax, since in chapter 9 of the same *Optics* he shows that parallax cannot represent curved things out of straight ones; recourse must therefore be had to refraction. He therefore judges it probable that the comet's head is not a bubble hollow within, as he had once supposed, but a solid globe, consisting throughout of the same matter — not hard like glass, indeed, since it is gradually dissolved, but nevertheless of such density, and so transparent, that, like a glass globe, it gathers a great many rays by a double refraction, one on entry and the other on exit, into one point behind the globe's back; and these rays, as the necessity of optics or dioptrics requires, are then dispersed and spread apart beyond that point, diverging again into contrary quarters. And since the aethereal air is not free of all opacity, if the rays, multiplied and coloured by their passage through the comet's head, strike upon it, it can be so strongly painted and illuminated from so near a place that it can shine for us from afar — granted that it cannot when the rays are not gathered together. That the heads and tails of comets radiate very strongly, he proves from the comet described by ʿAlī ibn Riḍwān, which was three times larger than Venus and of as much light as a quarter of the Moon; and from the comet that foretold the rise and death of Mithridates and, as Justin relates in Book 37, shone for seventy days in such a way that the whole heaven seemed to blaze, and occupied a fourth part of the heaven, so that four hours were required for it to rise and to set entire with its tail, and it outdid the brilliance of the Sun with its glare: see what we said in the history, chapter 3, at the year 119 before CHRIST. Since, however, the rays gathered into one beyond the point of common intersection spread apart, and decline from the straight line drawn through the centres of the Sun and of the comet's head, it comes about that the tail appears curved. With these things laid down, he says: *Grant now that one side of the head, by reason either of its figure or of its density, does not transmit the Sun's rays: then that part of the tail will be cut off, and the remainder, declining to the other side, will alone display the appearance of the whole tail, and therefore of a declining one. Since also, when the disposition of the comet's body or its situation relative to the Sun is changed, this inclination can be changed; as in 1596 the tail at first declined to the right, then fell in with the Sun's very diameter, and finally passed over to the left.*

[Margin: 1st mode.]

And this is Kepler's first mode. The second is that some matter proper to the comet be granted, breathing out from the comet's head and, as it were, expelled by the Sun into the opposite part, into which the Sun's rays are gathered from the head by the force of refraction, strongly illuminate such matter, and diverge beyond the point of intersection, etc. If this is granted, it is no wonder if a comet's tail sometimes touches the Earth and infects the air with poison. And the curvature of the tail in this second case can come from the position of the very matter expelled from the head.

[Margin: 2nd mode.]

VII. But to aid with a diagram the imagination of the reader, who is perhaps not well enough instructed in this part of dioptrics: in the following figure let ABCD be a glass globe, or rather the comet's head, through whose centre passes the Sun's unrefracted ray E F, issuing from the centre of the Sun (to be understood here as lying towards E). Now since rays radiating from one and the same luminous point onto a surface at a notable distance fall on it sensibly parallel to one another, as we partly demonstrated in Book 3, chapter 5, and more fully in our book on optics, let the Sun's rays radiating onto the convex surface of the globe already mentioned be GH, NO, SA, VC. First, then, let the ray GH radiate to the point H and there, because of the density of the transparent globe, be refracted towards the perpendicular εS to the point L; and again on exit, since it passes from a denser medium into a rarer, let it diverge from the perpendicular εf and be refracted to the point I, continuing on as far as M. In the same way let the ray NO, refracted at O towards P, again be refracted to the point I, tending as far as R. Likewise let the ray SA, refracted on entry at the point A and again on exit at the point B, come together at the point Q, proceeding from there to the point T; and finally let the ray VC, refracted once at C and again at D, come together at Q, tending towards X.

[Margin: Kepler's doctrine is illustrated by our own experiments.]

Diagram. A woodcut set in the left column: Kepler's refracting globe ABCD, with parallel rays of the Sun entering from the left and crossing beyond the globe, where a field of vertical dotted lines stands for the matter that receives them.

- S, G, E, N, V (left, top to bottom): the starting points of the parallel rays; the ray from E passes through the centre ε and out to F.
- A (top left of the circle), B (top right), C (bottom), D (bottom right): the points of the globe ABCD.
- L (just inside B), H (inside the circle, left, on the ray from G), β (left rim, on the diameter), ε (centre), μ (right of centre), γ (right rim), o (small, inside the circle lower left), P (inside the circle lower right).
- δ (Greek, at the head of the first dotted line, on the line rising from H through ε): the point of the text's perpendicular "εf" (p. 151 line 154, where the sort after ε is read f; not settled against δ).
- I (the first crossing of the rays), V (the upper crossing), a (the middle crossing), Q (the third crossing).
- [?] (a script sort below a; the text names a point Z in "DZM").
- R, X, F, T, M (right, top to bottom): the ends of the rays.
- [?] (a small mark near the foot of the dotted lines).

And in the same way let several other rays be gathered by the force of a similar refraction at the same points I or Q, or as near to them as possible, but most of them at the point *a*. For they will have the power not only of illuminating most strongly, but also of burning combustible matter lying at the point I or Q, because of the union of so many rays interpenetrating in the same place and receiving a formal or equivalent intension of their power in the same

part of space. We have found by experiment (to say this in passing) that there are three points at which burning takes place with crystalline spheres, glass ones, and glass-and-water ones — that is, glass but filled with water: one nearer, at I, and another more remote, at Q, at which the illumination and inflammation are slower and weaker; the third midway between these, at which it is very rapid and very strong. We therefore call this burning cone the primary one, but the cones PIL and BQD secondary. See their measures in the following little table, in parts of which one inch of the Roman foot contains a hundred, for the different sizes of the glass spheres we used.

It will be	If the semidiameter εγ of the sphere is, in parts:		
	334	444	600
γI	60	80	108
Axis μI	87	116	156
γQ	198	264	357
Axis μQ	225	300	405
γ*a*	124	164	221
Axis μ*a*	151	200	269
Base of the cone BD	124	164	221
The portion BγD containing the refracted rays is very nearly 50°.			

[Margin: The distance of the burning point beyond the glass sphere from the sphere, and the height of the axis of the burning cone.]

Moreover, we have found by experiment that if the experiments are made in a dark room, admitting the Sun's light through a hole equal to the diameter of the sphere, and behind the back of the glass globe the usual motes or atoms rise, or dust is scattered downward or thrown upward, or the steam of boiling water is put beneath, the rays appear, and a very great light in the part of space IQ, but a fainter [?] light in the farther part, lit by the rays IR, QX, QT, IM, already dispersed. Kepler therefore judges that the curvature of the tail arises from the figure DZM or BYR; but that if only half of the globe — say βAγ — transmits the Sun's rays, while the other half, βCγ, does not transmit them because of excessive opacity, nothing of the comet's tail appears to us but half, namely the portion BL*a*TM. This will therefore appear curved, because the rays emerging [?] between B and L are so refracted that they cut the straight line LM at one place and another, and LM itself is not the boundary of the tail on its lower side. He thinks, however, that the curvature of the tail can also come from the very matter breathing out, or expelled from the comet's head by the force of the Sun's rays, disposed in position so as to recede and decline from the line EF.

VIII. So far Kepler in the *Optics*, his judgement still in suspense; but afterwards, in the *Opuscula* on the comets of the years 1607 and 1618, Book 2, from page 101 on, he chose the second mode. For he denies *that the Sun's rays are*

seen in the pure aethereal air that is behind the comet; and in the air immediately surrounding it they are not seen unless there is some matter behind the comet onto which the Sun's rays, passing through the comet, strike. For neither with us can a ray of the Sun be seen except in matter that receives the Sun's ray — on walls, for instance, on clothes, on the surfaces of waters, on the earth, mountains, clouds, or in thick air. Next, it is established that the tails of certain comets are curved, but it is impossible for the Sun's rays to be curved in the free aethereal air; for in optics we are taught that the rays of luminous bodies are not arcs but straight lines. Since, then, it is established that the comet's tail is formed by the Sun's rays, it is consistent that the tails or tresses of comets have their own matter, out of the comet's body, expelled by the Sun's rays. He had said a little before: *As the Sun's straight rays strike and penetrate this transparent globe, I think that something of the comet's innermost matter follows and goes out by the same way by which the Sun's rays break through; and that in this manner the comet's body is washed through, strained, worn away and finally annihilated; and that, as silkworms by spinning out their thread, so comets are consumed by breathing out their tail, and finally die.*

[Margin: Kepler's later view.]

Given, then, a continual efflux of the matter already mentioned, it can be disposed in various ways, so that the tail appears now curved, now humped, now long, now short, and at times flickering with a sudden vibration like chasmata or fiery rods, as in the comets of the years 1577, 1607 and 1618 — a tail which, in the blink of an eye, from shorter appeared very long, by an alternate ejaculation of rays. Kepler testifies in the *Hyperaspistes*, pages 125 and 199, that this same second opinion — of a real efflux from the comet's head, or an expulsion made by the Sun's rays — seems to him the more probable; there he thinks not improbable the cause of a certain curvature adduced by Guiducci and Galileo, of which we shall speak below. And Longomontanus wholly subscribes to this second Keplerian opinion, in the Appendix to the *Astronomia Danica*, chapter 6, so that there is no need to report his view in other words.

[Margin: Longomontanus's opinion [?].]

IX. But although Kepler's opinion has much ingenuity, it nevertheless runs into many other difficulties. Those metaphorical words — straining, washing through, wearing away — do not sufficiently explain the Sun's proper action in this business, still less does the comparison with silkworms. For the Sun's rays are not bodies that would burst into the heads of comets with a violent local motion; our own heads, exposed to the Sun, would feel such a motion. It remains, then, that the Sun accomplishes this by an alterative action — heating and drying, and so thinning those parts of the head that are more disposed to it, and making them lighter and rarer. But if that happens, those parts will then be carried upward, not to the sides, and we shall be thrown back into the difficulty about the Aristotelian flame of which we spoke in number 2. Or, if it is granted that the matter does not at once ascend but is carried behind the comet with an oblique motion, the rays coming together at the points I,

a, Q by the force of refraction will at once dissipate and consume it; so that a little beyond there the tail will appear cut off. Or, if the matter is apt to resist inflammation, though not the most vehement illumination, then the tail ought to appear much more brilliant in that part than in the rest. But it is established that these phenomena have not yet been observed in comets; rather, the tail is continuous, and either uniformly bright or darker only at the end.

[Margin: Kepler's [?] Longomontanus's opinion rejected.]

X. The *fifth* opinion was Galileo's, published by Mario Guiducci and defended by Galileo in the *Trutinator* of the *Libra Astronomica*, from page 141 on: namely, that the tail of comets is straight by its nature, being produced by the Sun's rays, but appears curved to us when it is near the horizon and inclined to the horizon, because of the refraction of the species, or visual rays, made at the spherical surface of the air, which around the Earth is filled with dense vapours. Thus it came about that in the comet of 1577 — which Galileo diligently affirms he observed — the tail always appeared very curved, being always near the horizon and much inclined to it; whereas in the comet of 1618 it appeared bent, for the same cause, only in the first days, but afterwards, when it had gone up from the horizon and proceeded on a straighter path almost through a vertical circle, it lost its curvature. They add the comparison of an oar, which is straight but takes on an apparent curvature in water by the force of refraction.

[Margin: Galileo's [?] Guiducci's opinion.]

Against this opinion Lotharius Sarsius set three things in the *Libra Astronomica*, examination 2, question 3: first, that nothing has been said in this matter about refraction that Kepler had not said long before in the *Astronomia Optica*, chapter 6, number 13, though he left this phenomenon among the secrets of nature; next, that the comet of 1618 kept its curvature in its first days even far from the horizon; but that on the remaining days, especially December 20, while it was emerging from the Roman horizon, the run of the tail lay almost in the same vertical, but, carried higher, appeared so inclined towards the horizon

[Margin: Objections of Lotharius Sarsius [?] against Galileo [?].]

that it seemed almost [?] parallel to it, and yet no curvature appeared in it. Finally, that Galileo supposes the vaporous region to be spread spherically around the Earth, whereas it rather swells towards the poles and takes on an egg-shaped figure.

But Galileo replies that the reasoning of Kepler and of Guiducci was quite different. For Kepler spoke of the refraction of the Sun's rays made in the comet's head, and of a real curvature, either of the Sun's rays themselves or of the matter disposed behind the comet; whereas Guiducci was speaking of the refraction of the species and visual rays of the tail itself, supposing the tail straight in reality but apparently curved, because of the refraction made at the convexity of the vaporous air. Next, he replies that the very experience of the first days of the apparition, and of the 20th day, favours him: the tail appeared curved at first because those two conditions were joined — namely nearness and inclination to the horizon — whereas on the other days they were separated;

for when it was near the horizon it was upright and not inclined, and when it was inclined to the horizon it was nevertheless far from it and free of sensible refraction. Finally, that the figure of the vaporous air, whether it is perfectly spherical or egg-shaped, does nothing to hinder this optical demonstration; for all that follows from it is that the curvature of the tail also imitated an oval rather than a circular arc.

[Margin: Galileo's reply.]

Kepler, moreover, in the *Hyperaspistes*, page 199, having read through these quarrels between Galileo and Sarsius, denied that he had left this dispute undecided, since he had settled it in his little book on comets. The curvature apparent from refraction in vaporous air, he says, is very small, and does not account for the remarkable curvature of comets' tails, since it does not exceed half a degree; and even for that it is required that the head be very close to the horizon and that the end of the tail be not higher than 20° above the horizon. Nor can it be well fitted to the tail of the comet of 1618, whose curvature was [?] remarkable and occupied chiefly the extreme parts of the tresses, on which account it was compared to a Persian scimitar. And indeed refraction can show this curvature in no other way than by raising the parts nearer the horizon more and the remoter ones less; yet this can happen in such a way that all are kept in the same visible straight line. Of this we have an example in the stars of Orion's belt, which always appear in the same straight line, although near the horizon the belt is so inclined that the leading star of them, at rising, is higher than the middle one, and the middle one higher than the following one — and so the leading star is subject to less refraction than these.

[Margin: Kepler's objections against Galileo.]

XI. The *sixth* opinion was that of Father Johann Baptist Cysat, *De Cometa anni 1618*, chapter 7, where he asserts that the coma of the comet is not flame but a radiant cone or pyramid, formed by the Sun's rays transmitted through the comet's head, in much the same way as the Sun lights up a room through a hole or a convex glass lens, or produces radiant rods behind clouds. This, he says, can happen partly by refraction, partly by reflection from the many-angled sides of those corpuscles out of which, by an experiment with the telescope, he had reported that the comet's head coalesces, as we related at the end of the history, chapter 3; just as the solar faculae appear on the Sun's disc brighter than the Sun itself, when its rays are transmitted through diaphanous spots. Nor, he says, is the substance of the aether surrounding the comet so subtle that it cannot bound the Sun's rays, gathered by the force of refraction or even of reflection, and reflect them to us. Then, in number 10, he adds: *Why the comet's tail appeared curved, an explanation is given from theorem 11 of Euclid's Optics and axioms 8, 9, 10, 11. For things seen by lower [?] rays appear nearer; and one extremity of the comet (either the head or the end of the coma) was seen by lower rays than the other, since the comet stretched out in a straight line, by proposition 2, chapter 4; and either the head or the extremity of the coma was farther from the observer, by*

propositions 6 and 8, chapter 3. Some curvature, therefore, necessarily appeared, just as in a long gallery the upper ceiling near the exit is seen to slope notably downward.

[Margin: Father Cysat's opinion.]

In fact, however, Euclid does not teach there that the parts of straight surfaces or lines that stand on high, seen by lower rays, appear nearer, still less that they appear curved. For Euclid's theorem 11 runs thus: [Greek: τῶν ἄνω τοῦ ὄμματος κειμένων ἐπιπέδων τὰ πόῤῥω, ταπεινότερα φαίνεται (tōn anō tou ommatos keimenōn epipedōn ta porrō, tapeinotera phainetai, "of planes lying above the eye, the farther parts appear lower")] — that is, *of planes higher than the eye, those that are more remote are seen lower*. From this it does not, of itself, follow that they appear curved; for any points can appear lower the more remote they are from the eye, provided they lie in the same visible plane or in the same visible straight line. Besides, it would then be necessary that all comets' tails, at least those of a longer course, should appear curved — which, however, we do not find in the history; on the contrary, the tails drawn by Apian are without any curvature. And by the same reasoning the belt of Orion would have to appear curved to us in some position.

[Margin: Objection against Cysat.]

XII. The *seventh* opinion is that of Father Niccolò Cabeo, on Book 1 of the *Meteorologica*, text 37, question 7, where he holds that the tail of comets is the Sun's rays shining through the comet's head and refracted. But since rays, however much refracted, are propagated along straight lines, he says that a real curvature cannot be got from this, and that it is rather an apparent one. The cause of this apparent curvature he refers to the differing position, or plane, of the eye and of the tail, in these words: *If the comet's tail is not set straight before you, and is not wholly in the plane in which the eye also is, but is in another vertical, or even in a different plane that is not vertical, and bends to one side, then imagine for yourself also that the tail is, as it truly is, in a straight line; and draw in imagination, through the plane of the eye, another line parallel to the tail. Then the extreme parts of the tail, by the rules of optics, will approach that line, and that whole line of the tail will be seen curved, and the curvature will always bend towards that line.* Soon after, he admits that this imagining of his cannot be illustrated by any diagram — rather, a diagram would obscure it: *But by the example*, he says, *of things painted in perspective, and from the fact that the parts of the tail are not only moved farther and farther from the eye but are also raised, and are not in the same plane with our eye — from all these it comes about that that curvature is represented.* Finally he concludes that, because of the perpetual motion of the Sun, the plane of the comet — the plane in which the Sun and the comet's head and tail lie — comes out perpetually different from the plane of the observing eye; that the apparent curvature therefore varies perpetually; and that it appears greater the more the plane in which the tail lies is removed from the plane in which the eye of the beholder is. He had said above: *When the comet's head and its whole tail — that is, the rays issuing from the comet — are in one and the same vertical plane with our eye, then the tail will be seen not curved but straight.*

[Margin: Father Cabeo's opinion.]

So much for him. Had he explained these things better, with a diagram attached, or at least with the laws of optics he presupposes set out determinately, we could pass a clearer judgement on this opinion. Meanwhile, no efficient cause of the apparent curvature seems yet to have been brought forward, if the tail is in reality straight. For to say that the tail does not appear straight when it is not wholly in the plane of the eye is rather to offer a definition or description of curvature, or of a line that is not straight; for a line is not straight when not every three of its points are in the same plane, but two are in one plane and the third, with the second, in a different plane; and this property belongs to true lines as much as to apparent ones. Nor, from the fact that the tail moves and becomes transverse through one vertical after another, can it lose its straightness or be apparently changed into a curve; for the three stars in Orion's belt appear to us in the same straight line, even though the belt passes through one vertical after another in its oblique ascent and descent. By contrast, the three stars in the tail of each Bear never appear to us in the same straight line, unless perhaps, by the force of a differing refraction on some horizon, they are seen in a parallel of the horizon. Therefore, if someone says that the comet's tail, if it is straight — as the belt of Orion is thought to be — will also appear straight everywhere; and that if it is curved — as the tail of the Bear is thought to be curved, when its stars are joined in imagination — it appears curved because it is curved, he cannot be refuted from Father Cabeo's doctrine.

[Margin: Objection against Cabeo.]

XIII. The *eighth* opinion is that of Descartes, in the *Principles* of his new philosophy, part 3, from marginal number 136 on. He supposes that infinite corpuscles and globules are moved through various vortices, and he tries to account for almost all physical changes by motions of this kind; he also thinks that the Earth is moved annually. Accordingly, he says, the Sun's rays striking the comet's head are reflected towards all parts of the atmosphere surrounding the Earth — which he makes not spherical but spheroidal, and much more depressed towards the poles than towards the ecliptic — and some of those rays are scattered and fall obliquely onto the atmosphere, and are partly refracted because of the motion of the globules already mentioned, which perpetually fluctuate; and from this arises the curvature of the tail. But if

[Margin: Descartes's opinion.]

the foundations of this opinion were to be laid open, it would be necessary to expound many other things — some quite new, others old indeed but already antiquated by others and called back into the light again by him — a digression foreign to my purpose. It is enough for me to have pointed out the place for those who take delight in fictions of this kind. But this must also be noted: comets too are placed by him above the sphere of Saturn.

XIV. The *ninth* opinion is that of Giovanni Camillo Glorioso. In Book 3 of *De Cometis*, chapter 8, he acknowledges that the tails of comets which are not hairy all round are turned away from the Sun, and often do not taper into a

cone but take the form of a broom or of a basket. Then, in Book 5, chapter 2, from page 223, he teaches that a comet becomes hairy all round when the cometic matter has equal density in all its parts; for then the Sun's rays, entering and leaving uniformly, produce that corona. But if the bodies from which the comet's head is formed are several and close together, or a single one but very rare, then the Sun's rays run out beyond, behind the comet — through the space lying between those bodies, or through that rare substance — and generate a beard or a tail for it, in much the way that the Sun shines into a room through a hole, or runs out in luminous streaks through rarer clouds. Nor is the matter of the aether so subtle that it cannot reflect to us the Sun's rays, so intense and crowded together. And so he very nearly subscribes to Cysat. If this does not please, he says, we may philosophize with Kepler, *De Cometis*, page 100, and with Millerus, *De Cometa anni 1618*, page 52 — namely about matter expelled from the comet's head by the force of the rays, etc. When, however, the matter is so dense that it cannot be penetrated by the Sun's rays, then the comet is neither hairy nor tailed nor bearded. The cause, moreover, why the tail sometimes widens into the shape of a clothes-broom or of an inverted pyramid is, he says on page 226, that the Sun's light passing through a narrow opening always widens more and more. As if the comet's head were perforated, and transmitted the Sun's rays without any refraction — the refraction by force of which, on page 224, he had granted that they are gathered, crowded together and intensified! As to why the tail is curved, however, after setting out the opinions of Tycho, Kepler, Mario Guiducci and Cysat, he does not determine absolutely which of them is to be preferred, but only disjunctively: either it must be said that the tail is really curved, because various corpuscles behind the comet, or matter expelled by the Sun, are so disposed as to form a curved course, as Kepler and Millerus held; or it must be said that it is in truth straight but appears curved, either because of refraction, with Guiducci, or because the more remote parts appear more depressed, as Father Cysat taught. There is therefore no reason for us to repeat here what we said against these opinions.

[Margin: Glorioso's opinion.]

[Margin: 1st mode.]

[Margin: 2nd mode.]

XV. The *tenth* opinion is that of Libert Froidmont, *Meteorologica*, Book 3, chapter 4. In article 1 he affirms that the tail of comets is, for the most part, the Sun's rays driven through the brain of the comet's head; that at first it is neither very long nor tends exactly towards the quarter turned away from the Sun, because the depth and opacity of the head make that deviation vary; but that when the opacity has thinned out a little and the matter has been better digested, the rays go out straight and stretch into a longer tail; and that the rays of Venus too, when it is nearer the Sun, can concur with the Sun's rays in this effect. Further, that from the varied disposition of the parts of the head, and from agitation and motion, it comes about that the tail is sometimes split into several branches, as Cornelius Gemma reports in the comet of 1577, and

sometimes, by a sudden vibration, is drawn back into the head and soon darts out lengthwise again, as Cysat and Kepler observed in the comet of 1618. After this, in article 2, he teaches that the matter which sustains, as a subject, the Sun's rays forming the tail is the density of the very deep aether — which on that account shows us a blue heaven — and besides, many flocks of a rarer exhalation, or a fine dust breathed out from the head, lit up by the Sun; although at the end of the article he says: *Yet these things do not wholly satisfy my mind; but I must leave now, even half-starved.* Lastly, in article 3, anxiously seeking the causes of the curvature, he rejects Kepler's opinion about matter boiling out of the head or driven off by the Sun, since it would be of inconstant figure. He himself affirms that the comet of 1618, at the beginning of December, appeared to him sickle-shaped towards the south, and afterwards straightened itself and turned its concavity to the north, and so persevered thereafter to the end; and that a similar change happened in the tail of the comets of 1596, 1580 and 1577. He next reports Guiducci's opinion and refutes it, saying that if it were true, the tail would have to appear most curved when nearest the horizon, whereas in that position it was seen by him and by Cysat rising quite straight from the horizon. But he does not distinguish whether this was seen at a time when the head and the tail were in the same vertical; for in that position Guiducci too asserts that it is straight, since curvature requires inclination to the horizon, and not merely nearness to it. Afterwards he conflates the opinion of Tycho with that of Cysat, and teaches that neither shows the cause of the curvature, but only the cause why the part of the comet nearer the horizon appears more depressed and closer to the Earth. Finally, since he can rest neither on winds fanning and bending the tail, nor on an excessive rarity of the parts in the curved position, unsuited to reflecting the rays, he confesses that here the mind of mortals is blind — and that this is no wonder, since even about the beard of a man opinions are so varied and uncertain: very many think it is inanimate, others that it is informed by a vegetative soul, others even by a rational one.

[Margin: Froidmont's opinion.]

XVI. The *eleventh* opinion is that of Franciscus Resta, *Meteorologia*, Book 1, chapter 5. Having adduced various opinions, he too wavers and does not seem to find where to plant his feet. At last, however, he inclines in part to Kepler's view, and thinks it probable that thin parts are expelled from the comet's head by the Sun's rays into the opposite quarter; that near the head they are not yet dispersed, but at the end are scattered; and that the tail is therefore narrow near the head but looser at the end, and curved by that very declination. But besides what has been said against Kepler, there is the observation of many comets whose tail was not looser at the end than in the middle.

[Margin: Resta's opinion.]

XVII. The *twelfth* opinion was formerly that of the Marquis Sforza Pallavicino, which Cottunius reports in lecture 33 on Book 1 of the *Meteorologica*, page 309. The cause why a comet, the farther it is from the Sun and the more it is opposed to the Sun, shows the shorter tail, and sometimes none, he referred

to the comet's shadow. *Because*, he said, *an opaque body, the farther it is removed from a luminous body, the more it contracts its shadow; therefore a comet, the farther it is from the Sun or the more it is opposed to it, casts the smaller shadow, and accordingly has the smaller tail. Hence also it is that hairy comets are far from the Sun and come nearer to the Earth, whereas bearded ones are very high up.* He says that this reasoning was highly commended, and received with great applause by the learned men who had assembled in the house of Giovanni Ciampoli. But whether Sforza said this very thing at the time, or thought otherwise and was not sufficiently understood by Cottunius, the reasoning cannot stand. First, because it is utterly false that an opaque body contracts its shadow the farther it is removed from the luminous one, unless it is larger than the luminous body. For if it is smaller — as everyone admits the comet's head is, compared with the Sun — the farther it recedes from what illuminates it, the thicker and longer the shadow it casts, as is clear from what was said on eclipses in Book 5, chapter 3. Therefore if the Sun's rays, transmitted through the comet's head and shining in the head's shadow, form a tail as great as that shadow is, they will form a greater one the farther the comet's head has receded from the Sun. Next, he does not seem to have understood what that distance and opposition is in which comets' tails have been observed to appear either not at all or very small, since he judges it by nearness to the Earth. For they can be very remote from the Earth and yet opposed to the Sun, as Jupiter and Saturn are in opposition to the Sun; and so the tail lies hidden behind the head, not because the shadow is shorter there, but because our eye, set between the Sun on the one side and the comet's head on the other, cannot see the tail, however long, because the head stands in the way — especially at so great a distance.

[Margin: Opinion of Sforza Pallavicino.]

XVIII. Having considered so many and such varied opinions, then, we too had to apply some effort to devise various not improbable ways by which there can come about the aversion of the cometic tail from the Sun; the subject from which either the comet's own rays or rays carried over from the Sun are reflected to our eyes; the varied figure; and the motion of vibration. We would have done this by a surer method if observers agreed about the position of the tail and its manner as noted even in the most recent comets, or if we were certain of the place of comets — whether they arise and move above or below the Moon or the Sun.

[Margin: Partly our own, partly Father Francesco Maria Grimaldi's opinion.]

First, I say that it is not improbable that the tail belongs to the substance of the comet and shines with its own light, propagated from the head into the remaining part; but that the face of the comet's head is turned towards the Sun, as the heliotrope is, or as one face of a magnet is turned towards one pole, and is moved by a slow rotation about the centre of the head in such a way that the more perfect part of the comet is turned towards the Sun, while the remaining part, following the same motion, is turned away from the Sun and takes various figures, according to the different species of comets, from the very disposition

and configuration of the matter. Nothing stands in the way of this mode except the sudden vibration by which the tail of the comet of 1618 appeared at one moment short and soon after long — unless you attribute that very thing to little clouds or fumes running across in between.

[Margin: 1st mode.]

Second, I say that it seems very probable that the cometic tail is corpuscles, very subtle and very numerous, flying around the comet's head in the air or in the aether. They are not such as we see in a ray of the Sun let in through the opening of a darkened room, nor such as are in the exhalations that show us the twilight (if indeed not only the head but the whole tail must, on the strength of the observations, be placed above the sphere of the twilights); they are far more subtle and higher, and are not fit — partly by their smallness, partly by their lesser opacity, partly by their greater distance from the Sun — to be seen by us through the Sun's rays reflected from them, unless they are more strongly illuminated. This posited, I say that they are more strongly illuminated because of the Sun's rays gathered into one by force of refraction: not in precisely the way in which the rays come together into one, or into a few very close points, behind a glass sphere, as was stated at number 7, but in a somewhat similar way. For (as becomes probable from what Nicephorus relates of the comet of 392, and from what Cysat and Habrecht observed in the head of the comet of 1618, on which already in their place, pages 6 and 20) the heads of comets may be neither exactly spherical, nor made up of parts continuous and homogeneous in density and opacity, but of various bodies — polyangular, or spherical or spheroidal, or even having a surface bounded somewhere by hyperbolic or parabolic lines — so that, with the laws of both reflection and refraction preserved, many more rays leave the comet's head gathered, though not meeting in a single point, than would if they either did not pass through the comet's head or passed through it unrefracted. To understand this, the problem of Father Bonaventura Cavalieri in the *Speculum Ustorium* (his *Lo specchio ustorio*) can be of no small service, where he teaches how to reflect the Sun's rays from one parabolic mirror into another in such a way that almost infinite rays, gathered into one very slender cylinder, run on to infinity and have the power of burning. For if this can be done by reflection alone, with the help of only two mirrors, how much more if many reflections and many refractions, from many mirrors or dioptric bodies — and very large ones — concur to a similar effect and show us, in the corpuscles already mentioned, the varied form of tails! If to this there is now added a motion, either of trepidation or of rotation, by which the whole head of the comet nods this way and that or turns about its own centre; or a varied disaggregation or dissipation of the partial bodies of which the comet's head consists (of which dissipation the same Cysat likewise produced an example in the same comet of 1618); or an alternating fluctuation of fumes running across between the far end of the tail and our eyes — then it will not be difficult to understand why the tail could be seen now shorter, now longer, on the same night and at almost the same hours.

[Margin: 2nd mode.]
[Margin: The subject of the tail.]
[Margin: Collection of the Sun's rays.]
[Margin: Varied figure of the tails.]
[Margin: Vibration and inconstancy of the tail.]

Third, I say that the curvature of the tail — that is, of the Sun's rays issuing from the comet's head — can arise from one refraction after another, made away from the perpendicular outside the comet's head, in matter that belongs to the comet but is not as dense as the comet's head; indeed, matter having within itself various degrees of density, less and less the farther it is from the head. For if this is granted, and if the centre of the whole cometic matter, from which the perpendiculars that regulate the refractions are to be drawn, is not the very centre of the comet's head, those skilled in the science of dioptrics will easily understand how the lines of each whole refracted ray coalesce into a curve, so that it does not merely appear so but really is such. This perhaps also happens in the rays of the stars refracted in an atmosphere of one density after another, if they pass continuously from a rarer to a denser medium, as we shall say in Book 10, last section. And this, from the speculation of Father Francesco Maria Grimaldi while we were debating these matters together, it seemed good to show in the diagram below.

[Margin: Curvature of the tail: where does it come from?]

In this diagram the matter from which the comet is formed, spread out spherically, is represented by various circles described from the centre C — rarer and rarer, however, the farther it is from the centre C. The comet's head, however, is placed not in the very centre of that matter but outside the centre (whatever the cause of this position may in the end be). For neither are the piths of trees exactly in the middle of the trunk, as is clear from their veins, disposed as it were in circles, if one cuts tree trunks straight across; nor is the yolk always in the middle of the egg; nor do stones that have some principal kernel contain it exactly in their middle, etc. Let the head, then, be above, at AB, and let the Sun be towards V, irradiating the comet's head, and from the head let the ray AS go out, which, if it proceeded unrefracted, would go to G. But since the perpendicular drawn to the point S from which the ray goes out, and so running into the centre, is RSC, and the ray AS is supposed to go out of circle 3 into a rarer medium towards circle 4, it is therefore refracted away from the perpendicular, and would go on from there to H if no other refraction occurred. But because, going out from circle 4 towards 5, which is likewise rarer, it is refracted again, and once refracted would go to I if nothing else happened; and again, having gone out of circle 5, it is refracted away from its own perpendicular towards K; and so on. At length it comes about that the ray AS, refracted almost countless times, finally tends to Q; and so, to an eye placed towards F, it appears under the curved line ASQ. The same is to be understood of the other extreme ray, BDE, and of the rest enclosed between them and making up the comet's tail — provided that different perpendiculars

are understood to be drawn through the different points at which the refraction of the rays takes place.

Diagram. A woodcut set in the right column: nine concentric circles about the centre C, standing for the cometic matter, rarer outwards; the circles are numbered 1 (innermost) to 9 (outermost) along a radius running left from the centre. The comet's head, a shaded disc AB, lies a little above the centre; from it a shaded tail curves out to the left through the rings. From S, at the upper edge of the tail near the head, dotted lines fan out to a column of letters beyond the circles at upper left, and a dotted radius runs up through S to R at the top.

- G, H, I, K, L, M, N, o, P, Q (column outside the circles, upper left): the successive points towards which the ray AS would run after each refraction; the small lower-case o stands between N and P
- R (top): upper end of the perpendicular RSC
- S (upper edge of the tail, near the head): the point at which the ray AS leaves circle 3
- A, B (above and below the head): the head AB
- C (centre): centre of the circles
- D, E (lower edge of the tail): points of the other extreme ray BDE
- Z (below the centre): the alternative position of the head
- V (outside, right): the quarter of the Sun
- F (outside, below): the quarter of the eye
- 9, 8, 7, 6, 5, 4, 3, 2, 1 (along the left radius): the numbers of the circles

The eye, moreover, is supposed to be outside the whole of that matter of which the comet's head and tail have most immediately been formed; and so that curvature of the tail is aided in appearance by the rays of the species issuing, refracted, from the sphere of the matter already mentioned. But if the comet's head is below the centre C, say at Z, then, because of the refractions away from the perpendiculars to be drawn to the individual points of the circles from which the rays go out, the rays will be curved in such a way that the tail's concavity faces upwards and its convexity downwards, towards the eye at F. And similar things will happen if the comet's head were indeed at the centre of the matter already mentioned, but not at the centre of these circles, or quasi-circles, because the cometic matter would not be expanded in the manner of a perfect sphere about one centre. But if the head were at the centre of that matter and of all the circles already mentioned, the refractions already mentioned would not occur; and accordingly the tail would not even appear curved to us, so far as this speculation is concerned.

SCHOLIA.

Scholia.

I. It will not be amiss to indicate some ways, handed down by several authors, of representing to the eyes something like comets and their tails. Among them Cardano, in Book 1 of *De rerum varietate*, taught that a lighted candle should be

exposed to the Sun, so that the solar ray would appear through the candle's flame as though shot through a comet's head; but this, for him, not at all succeeded, as Tycho relates in volume 2, page 162. But he ought to have taken the Sun's ray into a darkened chamber through a hole, exposed the candle's flame to it, and made the Sun's ray transmitted through the flame visible behind it by throwing dust, or by smoke. Indeed, it is certain that the light and species of one lighted candle pass through the flame of another lighted candle or fire, and are seen both directly by us and in a mirror; how much more will the Sun's ray penetrate a candle's flame? Kepler, on the other hand, in the *Astronomia optica*, at the end of chapter 7, or page 267, gives this prescription: *Let a ray of the Sun enter*, he says, *through the opening of a darkened room; and set a globe of water — that is, a glass sphere full of water — half across its path, so that the Sun's ray strikes partly the glass and partly the wall; for you will see a comet on the wall.* Galileo, for his part, in his *Trutinator*, page 106, teaches another way, in roughly these words rendered into Latin: *Take a very clean glass sphere or flask, and set a lighted candle opposite it, not far off; for you will see on the surface of the glass a little image of that small flame. Darken that part of the glass, then, with the breath of the mouth or with some grease, until that image of the flame is almost extinguished; next turn the glass vessel so that the image comes out of the greased or breath-darkened place and appears at its contact, or outermost border. Afterwards wipe off the breath or the grease with a finger in a straight stroke, and you will see a ray propagated from the image of the flame, imitating the hair of a comet; and this ray will cut at right angles the track along which the finger rubbed and wiped the glass. For since the skin of the fingers is not altogether smooth, but is cut by little channels for perceiving the smallest differences of tangible things, by which certain very fine furrows have been ploughed in that breath or grease, from their ridges there arises a reflection of that light, which imitates the tail of comets.* Lastly Giovanni Ciampoli, as Cottunius relates in lecture 33 on Book 1 of the *Meteorologica*, page 309, took a lighted wax taper and, applying it in a dark place to the side of a certain mirror, made a comet with head and tail appear in the mirror, far better than Johannes Kepler prescribes; so says Cottunius, an eyewitness.

[Margin: 1. Cardano's way of representing a comet with its tail.]

[Margin: 2. Kepler's way.]

[Margin: 2. Galileo's way.]

[Margin: 4. Ciampoli's way.]

II. So far we have discussed the tail of a comet turned away from the Sun as if a straight line drawn through the whole length of the tail, or at least through the tail's end and the comet's head, would run into the Sun if it were produced; for Apian, Tycho, Kepler, Cysat and many others assumed this for us from their observations, because the comet's tail, with its head, appeared in the same straight line with the Sun. It does not, however, necessarily follow from this that these three were in the same straight line, but only that they were in the same plane meeting the eyes — as Galileo also notes in the *Trutinator*, page 39. Thus Mars or the Moon sometimes appear to us in the same straight line

with two fixed stars, and yet a straight line drawn through the two fixed stars does not on that account pass through Mars or the Moon. I add, further, that from the fact that, at the same moment, the altitude of the tail's end above the horizon, taken with some instrument, was greater than the altitude of the head, it does not follow that the tail's end was more remote from the Earth than the head. For imagine the comet's head to be where Sirius is when it rises above the horizon, and the tail's end to be at that moment where the Moon is when it crosses the meridian: the tail's end will certainly be much nearer the Earth than the head, even if it appears many degrees more elevated above the horizon than Sirius, and so than the comet's head. It will not have been useless to give this warning.

[Margin: Points to note on the position of the cometic tail.]

CAPVT XXVI.

Chapter 26.

De Cometarum Motu Curuilineo ac Rectilineo.

On the curvilinear and rectilinear motion of comets.

I. This final question about comets — namely, whether they move in such a way that by their motion they describe a great circle in the sphere of the world, or one close to a great circle; or whether rather they descend along a straight line towards the Earth and so come into view, and then ascend and little by little withdraw from the eyes of mortals — was pointed out long ago by Seneca, in Book 7 of the *Natural Questions*, chapter 29. For since he held that comets are celestial, and there was urged against him the slowness of their motion, as an argument of a heavy and earthy nature, and their being carried downwards, he replied that slowness of motion is not an argument of heaviness or of an earthy body, since Saturn, which runs its course most slowly, is neither heavy nor earthy. Next, he denies that either Saturn or the comets are slow, if the amplitude of the circuit they traverse is considered; for the comet last seen by him, namely under Nero, ran through half the heaven within the sixth month. Lastly, he denies that they are carried downwards, and says: *First, what is carried around is not carried down. Next, this most recent one began its motion from the north, came through the west to the south, and, raising its course, vanished. That other one, of Claudius's time, first seen from the north, did not cease to be borne straight on, continually higher, until it departed.* Thus he acknowledges a motion of circumlation in comets, but in such a way that he thinks it ends up rectilinear. The Peripatetics, however, and most astronomers who followed them in this, attributed to comets no motion other than a circular one — Tycho indeed, and many of his followers, a motion along a great circle — and from this they also drew an argument for their celestial nature. Others, by contrast, whether of their own accord or stirred up by Galileo and Kepler, have granted that a rectilinear motion must be attributed to comets, or at least can be.

[Margin: Seneca's opinion on the rectilinear motion of comets.]

II. Mario Guiducci, in his treatise on the comet of 1618, following Galileo's opinion — and Galileo himself, in his *Trutinator*, page 36 and from page 126 — teaches that it does not follow, from the fact that a comet has been seen to advance in the same plane, that its motion was along the circumference of a circle, but only in the plane of some circle; and this could equally have happened even if the comet's motion was along a straight line. Indeed, he teaches that it is not improbable that exhalations from our region, but lighter than the twilight vapours, ascend along a straight line perpendicular to the Earth, as far as the heaven of the Moon or above the Moon, and that from them a comet is sometimes formed, which keeps the same proper motion, or moves along another straight line in such a way that all its phenomena are saved; that for this the annual motion of the Earth is not necessary; and that it does not follow from that rectilinear motion that the comet must at some time reach the observer's zenith — granted that Lotharius Sarsius, in the *Libra Astronomica*, pages 9 and 34, attributed these two points to Mario Guiducci. But since the comet of 1618, by its motion in declination, not only crossed the vertex of the observers at Rome and Florence but, becoming more northerly, reached right up to the pole of the world, neither Guiducci nor Galileo denied that some other motion, besides that perpendicular ascent from the Earth, must certainly be attributed to it. And the same must be said of the comets observed by Seneca, as I said at number 1, and by Pontano — on which see our chapter 3, at the year 1471 — and of many others whose phenomena cannot be explained by a motion perpendicular to the surface of a resting Earth alone.

[Margin: Galileo's opinion on this motion.]

III. Father Johann Baptist Cysat, in *De Cometa anni 1618*, chapter 3, proposition 8, affirms that it is more probable that this comet, besides the motion of the primum mobile, was moved by a proper motion — a motion of rectilinear ascent, though not perpendicular to the Earth; for in this way its distances from the Earth are better reconciled with the observed digressions of the comet from the Sun. To show this he uses chiefly the comet's distances from the Earth and its digressions observed on December 1, 20 and 29, which are written below.

[Margin: Cysat's opinion on the rectilinear motion of the comet [?].]

December, day	Distance from the centre of the Earth, in Earth semidiameters	Digression from the Sun
1	72	32°
20	154	90°
29	252	104°

For, with these posited, the ecliptic described from the centre of the Earth, the Sun placed for the days already mentioned at the corresponding places of the ecliptic, and the comet placed on circles of latitude drawn through the ecliptic according to the comet's longitude observed on the same days, he draws

from the centre of the Earth three lines each, both to the comet's three positions and to the Sun. Of these, the lines drawn to the comet's head are its distances from the centre of the Earth; those drawn to the Sun are the distances of the Sun from the centre of the Earth, taken in Tycho's manner; and the angle at the centre of the Earth contained by them measures the comet's digression from the Sun. From these he gathers that the come- t had been, on those days, very nearly on one and the same straight line; that at the beginning of its appearance it was perhaps lower than the Moon by 10 semidiameters of the Earth, or was no more than 40 Earth semidiameters distant from the Earth; and that at the end, stretching upwards, it penetrated the sphere of the Sun, and indeed of Mars. From this he also gathers that by a trajection of this kind it can come about that stars fall from heaven, as Christ the Lord foretold. He says this not improbably; for nothing demonstrated is established in this matter, since not even the parallaxes or the distances of the comet from the Earth have been demonstrated, as we said in chapter 22.

IV. Kepler, however, built up this rectilinear motion in another way and to another end, in the *Astronomiae Pars Optica*, chapter 10, at the end of which he has this appendix: *Those who have demonstrated the motions of the comet of 1577 by circles took on a very difficult labour, and yet they did not wholly succeed. They will meet much greater difficulties if they undertake to demonstrate the same in the other comets. For my part, in several comets whose recorded observations I obtained, this way succeeded more easily: if, as the nature of things urges, I assigned them straight lines, which in equal times they would for the most part traverse equally — only somewhat slower at the beginning and the end, and nearer to rest, as other trajections usually are too. For the motion of the Earth, insinuating itself, readily lends circularity to such a line. Thus, if that comet of 1577, having risen on a straight line from the plane of the tropic of Capricorn, had ascended towards the northern pole — or on a line somewhat more inclined, but still a straight one — then the Earth, going round a resting Sun (for on this supposition the comet itself tends almost only in latitude), will lend it the same appearance of circular motion. So too the comet of Regiomontanus, carried on a straight line from the deepest aether past the Earth and passing very close to it, will find a most beautiful occasion to complete 40 degrees of a great circle in one day in the middle of its appearance, but very little before and after; and here the cause will also be plain why the tail, at that moment of time when the comet was so swift, matched 50 degrees in longitude, by 4.22 of Witelo.*

[Margin: Kepler's opinion on this rectilinear motion.]

Afterwards, in his books on the comets of 1607 and 1618, he tried to make the same opinion more and more probable by these arguments. *First*, he says on page 3, it is not likely that the motions of things which never return to the same place, as comets are, are circular. *Second*, it has been observed in many comets that, when they approach their heliacal setting and when they have completed a quadrant of the diurnal motion, they become stationary; and the cause of this is not given as well by a circular motion as by a rectilinear one. *Third*, if the annual motion of the Earth and a proper rectilinear motion of the

comet are admitted, the increases and decreases of the motions observed in many comets, especially of latitude and declination, are explained more easily than by a circular motion — especially if it is assumed that the comet's trajection proceeds at first with uniform speed, and that the daily journeys of the comet traversing it then gradually increase by the law by which the tangents of the arcs of a circle increasing by equal parts increase, or by some similar ordered path.

Moved by these considerations, he presents, from page 8 to page 24, 30 theorems, by whose aid he then investigates for the comet of 1607 the trajectory line and its quantity from the observations, as well as the perpendicular line and the distance of the comet from the Earth; and he draws up a small table, which he does from page 37 to page 45, through 13 conclusions. He does the same for the last comet, that of 1618, from page 79 to page 93. And finally, from page 96 to page 98, he professes that through the annual motion of the Earth, by which the Earth approaches the comet's trajectory line or recedes from it, and through the very motion of rectilinear trajection, reasons are given why some comets appear swiftest in their proper diurnal motion at the beginning, others after the beginning, and slow both before and after, and why after the beginning and before the end they appear larger and with a longer tail. 2. Why they are mostly hidden under the Sun's rays. 3. Why the motion of comets at the end of their appearance mostly becomes slow, or stationary, or retrograde. 4. Why it mostly happens at the same time that a comet is both hidden under the Sun and becomes stationary. 5. Why comets mostly appear to describe great circles in the sphere. 6. Why comets, once they have become slow, begin to curve their paths, as the comets of 1607 and 1618 did, and, as he imagines, many others. By these and similar things he was so enticed that on page 98 he said: *In short, as many comets as there are in the heaven, so many are the arguments (besides those drawn from the motions of the planets) that the Earth moves with an annual motion about the Sun. Farewell, Ptolemy; I return to Aristarchus, with Copernicus as my guide.* Finally, in the *Hyperaspistes*, pages 100, 149 and 193, he confirms this same opinion of his, as not certain but more probable: that circular motions suit perennial bodies, but non-circular motions suit perishing ones; that comets always tend towards the same region of the sky; and that, since this motion ceases, it is credible that it is adventitious, and similar to the violent motion impressed from outside on darts, javelins and all projectiles.

[Margin: Argument for the annual motion of the Earth from the motions of comets.]

V. It is not my intention to want all probability taken away from this rectilinear motion of comets introduced by Kepler; but I deny that it is so probable that, from its combination with the annual motion of the Earth, it becomes more probable that the Earth moves with an annual motion than that it rests.

[Margin: Critique of Kepler's opinion.]

First, because the properties of the motion of comets on which Kepler relies are not taken from the history of most comets — granted that he himself, gratuitously and out of his own invention, uses the word *Plerique*, "most" — but from very few comets, namely those of the years 1472, 1577, 1580, 1585, 1590, 1607 and 1618, as he himself expressly admits in the *Hyperaspistes*, page 194. There he also shows inconstancy in asserting these properties; for he admits *that he asserted the motion of comets to be slack at the beginning and end and swift in the middle, not on account of any geometrical demonstrations from the observations of the comet, but from mere contemplation of bolides, or artificial fires, which the Germans call Raketuli. For these, at the start, while the flame has not yet caught in all the chambers, hesitate and set themselves in motion slowly, and at the end of their duration languish again.* Then he adds: *now that I have treated the comets just mentioned,* namely from the year 1572 *to 1618, I find no very great reason why I should make this rectilinear motion slower towards either end; so I leave this inequality in doubt.* So he says — he who nevertheless so often tried to confirm, from this inequality, the combination of the trajectory line with the annual motion of the Earth.

[Margin: 1st argument against Kepler.]

Second: in his book on comets, page 85, speaking of the comet of 1618, Kepler says this: *Since it is now certain that, with the Earth at rest, or as it were even with the comet's motion rectilinear, the observations do not hold* etc. Yet Cysat defends the rectilinear motion of this very comet from his own observations without a motion of the Earth, as we said at number 3; and Cysat's observations were both more numerous and better than Kepler's, who admitted that his own and those of many others were rather coarse, as we said in chapter 22, and as he himself relates most expressly in that booklet, page 30. It is therefore not certain that, to defend his observations, the annual motion of the Earth must be joined with the rectilinear motion of the comet. But I prove this more strongly from his own admission in the *Hyperaspistes*, page 195, where, to Sarsius objecting that Catholics may not defend the motion of the Earth, he replies: *For as the straight trajectory has been propped up by me with the motion of the Earth, Tycho will prop it up just as firmly with the systematic motion of concomitance, which would carry along even the rectilinear trajectory itself — if anyone has oak and triple bronze about his breast for believing such things*; and in the same *Hyperaspistes*, page 98, he professes that he has done this very thing, having put on the person of Tycho. Therefore, if the rectilinear motion of the comet can be preserved just as firmly in the Tychonic hypothesis, which rests on a standing Earth, neither a certain nor a more probable argument for the annual motion of the Earth is drawn from the motion of comets. Father Cabeo too, on Book 1 of the *Meteorologica*, text 37, question 9, taught that this rectilinear motion can be accounted for with the Earth at rest.

[Margin: 2nd argument against Kepler.]

Third: Kepler professes that, with Copernicus as his guide, he withdraws from Ptolemy, the champion of a resting Earth, and returns to Aristarchus. But Copernicus admitted no motion in the heaven that was not circular and regular;

for he taught, in Book 1 of *De Revolutionibus*, chapter 8, and elsewhere, that this alone naturally suits the heaven. Kepler therefore works against Copernicus by introducing into the heaven a rectilinear motion, and one not so ordered as Copernicus requires in the celestial bodies.

[Margin: 3rd argument against Kepler.]

This argument is nearly that of Longomontanus, in the Appendix to his *Astronomia*, chapter 3, where he condemns the rectilinear motion of comets, adding that unless Kepler proves that comets are endowed with sense and recognise the end of such a motion, or teaches that some Spirit presides over governing it, no probable principle of such a motion appears; and he concludes: *These reasons, while with the preced-*

[Margin: Longomontanus's argument against Kepler.]

ing one combined, anyone wishes to weigh them rightly [?], he would say that Kepler accounts for the generation and motions of comets by the hypothesis of trajections more ingeniously — indeed more laboriously — than truly.

Kepler, however, asserted that this motion is rather a violent one, and from an external source, as we have just seen; and yet he did not attribute it to angels. Cabeo, by contrast, in Book 1 of the *Meteorologica*, text 37, page 211, concludes from the exclusion of the other causes of this motion that it comes from a directing Intelligence — a view which, as I have already shown in chapter 6, number 12, has also found favour with several others. With this posited as very probable, it will be easy for an Intelligence to move a comet, whether along a straight line or a curved one, in such a way that all the phenomena of cometic motion can be represented without any motion of the Earth. And this is the fourth argument against Kepler.

[Margin: 4th argument against Kepler.]

VI. Besides the authors I have adduced, there are few who have examined the rectilinear motion of comets indicated by Galileo and asserted by Kepler. It was acknowledged, however, above all by Glorioso, *De Cometis*, Book 5, from page 241, who, I regret to say, wrote on page 247: *It must surely be thought more probable and more likely that comets are carried freely along straight lines through the expanse of the aether, as Kepler thought* — if he says this while mixing in, with Kepler, the annual motion of the Earth. Next, Froidmont, in Book 3 of the *Meteorologica*, chapter 4, article 4, who said: *It is truer, as Kepler and Cysat have recently held, that the proper motion of comets is trajectory and transverse, not circular, nor straight upward.* And he added that the comet is carried upward by its own spirit, which in a certain way animates it, but that, with the weight of the head resisting, it is carried not straight but obliquely. By "spirit", however, he seems to understand the subtler and lighter parts, since he says: *But at the beginning comets are swiftest, because they are then more swollen with spirits and are of unimpaired strength; these then gradually breathe themselves out, as the exhalation is rarefied here and there by heat and the Sun's ray,* etc. At the end of that article, however, not resting content with any reason why most comets are carried towards the north, he concludes: *Unless here again you weep and implore the*

help of the angels. Franciscus Resta, by contrast, in treatise 1 of the *Meteorologia*, book 1, chapter 6, ranks the rectilinear motion of comets below the circular in such a way that he attributes it not to angels but to a multitude of stars flowing together to constitute the comet and mingling their motive force — hence that so varied motion; though he admits: *These things are indeed possible, but how the matter stands in fact could not be determined except by divining.*

[Margin: The opinion of Giovanni Camillo Glorioso and of Froidmont.]

In a matter so uncertain, then, let us at last be allowed, if not to walk out of this labyrinth, then certainly to fly out of it; and, just as we began chapter 1 with Seneca's words, to end this section too with his judgement. In Book 7 of the *Natural Questions*, chapter 25, since the motion of the planets was not yet sufficiently established, he bade that the motion of comets, still unknown, be borne with, in these words: *Why then do we wonder that comets, so rare a spectacle of the world, are not yet held by fixed laws, and that their beginnings and ends are not known, when their return is from enormous intervals?* Then, in chapter 26, he dared to prophesy — which I myself indeed do not dare; but I approve his counsel of admonishing posterity to observe comets more accurately, and with as much subtlety as we have shown to be necessary, so that their place, and everything else that depends on it, can be demonstrated absolutely. He says, then: *There will be someone who will one day demonstrate in which parts comets wander; why they go so far apart from the others; how great and of what kind they are. Let us be content with what has been found: let posterity, too, contribute something to the truth.*

[Margin: Seneca's prophecy or admonition.]

SECTIO SECVNDA

DE NOVIS STELLIS.

Section Two. On the New Stars.

PROHEMIVM.

Preface.

In this second section we have chosen a somewhat different order from that of the first. First we shall set out a short history, or chronology, of the new stars; then we shall present and weigh the observations of three new stars, so as to work out their place under the zodiac and their distance from the Earth and parallax — which we shall be able to accomplish more easily from what has already been said in the first section about the place of comets. This done, we shall investigate, as far as the weakness of human conjecture allows, what they are, and to what end God is believed to have shown these new stars to the world. Lastly, we shall discuss the admirable star divinely shown to the Magi.

[Margin: The order to be kept in the second section.]

CAPVT I.

Chapter 1.

Catalogus Chronologicus Stellarum Nouarum in Cælo obſeruatarum.

A chronological catalogue of the new stars observed in the heavens.

I. New stars, or those reckoned as new, are listed by Fortunio Liceti in his book *De novis astris*; by Cyprianus Leouitius [Cyprián Karásek Lvovický] in his writing on the star of 1572, and from him by Tycho in volume 1 of the *Progymnasmata*, page 331; by Io. Hechius in his disputation on the new star; by Redemptus Baranzanus [Redento Baranzano], part 2 of the *Uranoscopia*, page 112; by Chiaramonti, Book 1 of *De novis stellis*, chapter 1, and Book 3, chapter 6; by Froidmont, Book 3 of the *Meteorologica*, chapter 1, article 2, and chapter 2, article 7; by Franciscus Resta, treatise 1 of the *Meteorologia*, book 1, chapter 7; by Andreas Argolus [Andrea Argoli] in the *Pandosion Sphaericum*, chapter 62; by Antonius Maria de Rheita [Antonín Maria Šírek] in the *Radius Sidereomysticus*, book 4, chapter 1, member 1; and by Giovanni Camillo Glorioso, *De Cometis*, book 5, page 274. The rest, who have written on some of these stars in particular, we shall review below, when we deal with them separately.

II. *First* among the new or extraordinary stars, Liceti, Baranzano, Resta and Froidmont count the seventh of the Pleiades. For it is related that it appeared before the burning of Troy, but after that burning hid itself, and came into view again. From this arose the controversy whether the Pleiades, or Vergiliae, on the back of Taurus are six or seven; or whether they are sometimes six, and that ordinarily, but at other times

[Margin: The seventh of the Pleiades, held to be a new star.]

seven. Indeed Homer, in Book λ [Greek: λ (lambda), the letter that numbers the book, i.e. Book 11] of the *Iliad*, sings that only six were engraved on Nestor's cup; and only six are counted by Attalus and Geminus in their astronomical writings. But seven were recognised by Simonides, in Athenaeus, Book 11; by Marcus Varro, *De re rustica*; by Pliny the Elder, Book 2, chapter 41; by Aratus in the *Phaenomena*; and by Hipparchus. Indeed Ptolemy too counts seven, if you read the Greek codex, as Kepler reads it on page 115 of the *Rudolphine Tables* — and Kepler himself also counts 7, as does Bayer in the *Uranometria*, who adds that this asterism is called the Septistellium, but that because one of them is nebulous and appears only faintly, sometimes only six are seen. Moreover, all who have explored them with the telescope have discovered, besides the 7 usual ones, others too that are invisible to the naked eye. The mythologists, further, relate that they were the daughters of Atlas and Pleione. Of these, the four that form the quadrilateral are Maia — called the bright star of the Pleiades, and of the third rank — who is said to be the mother of Mercury; then Sterope, Taygeta and Celeno. The remaining three are Electra, Merope and Alcinoe. Among them Electra is nebulous and, as it were, sorrowful, because the fable

runs that after the burning of Troy she no longer wished to join the dances. Others, however, in Hyginus, say that the one that hides from time to time is Merope, because she married a mortal man, Sisyphus, whereas the rest married immortal gods — namely Electra, Maia and Taygeta married Jupiter; Sterope, Mars; Alcinoe and Celeno, Neptune. Ovid touches on these opinions, or fables, in Book 3 of the *Fasti*, in these verses:

> *The Pleiades will begin to relieve their father's shoulders, who are said to be seven, yet are usually six: whether because six of them came into the embraces of gods — for they say that Sterope lay with Mars, Alcyone and you, fair Celaeno, with Neptune, Maia, Electra and Taygeta with Jupiter; the seventh, Merope, married you, Sisyphus, a mortal; she repents, and alone hides for shame at the deed — or because Electra could not bear to watch the ruins of Troy before her eyes, and set her hand before them.*

After the invention of the telescope, Galileo, in the *Sidereus Nuncius*, page 17, has this about these stars: *In the second example we have drawn the six stars of Taurus called the PLEIADES (I say six, since the seventh almost never appears), enclosed within very narrow bounds in the heaven; next to them lie more than forty other invisible ones, none of which is elongated from any of the six already mentioned by much more than half a degree. Of these we have noted only thirty-six,* etc.

[Margin: Galileo's observation of the Pleiades.]

Afterwards Michaël Florentius Langrenus [Michael Florent van Langren], in a letter very kindly sent to me, described for me their position, accurately observed with the telescope, adding to two stars besides the seven more conspicuous ones the names of Atlas and Pleione. Very recently Don Vincentius Mutus [Vicenç Mut] did the same: in a letter of 1650 March 5, sent to me from Majorca, where he diligently observes the stars, he depicts and determines, relying on observation with the telescope, a most exact place of the seven Pleiades and their distance from one another; and he adds the following small table.

[Margin: And that of Langren.]

[Margin: And that of Don Mut.]

The position of the seven Pleiades.

Pleiades	Longitude in ♉	North latitude	Magnitude
Western, more southerly	24° 28′ 11″	4° 9′ 40″	5
Western, more northerly	24° 38′ 30″	4° 31′ 36″	6
Lowest, next to the western	24° 45′ 0″	3° 53′ 30″	6
Following the more northerly	24° 45′ 30″	4° 23′ 56″	6
Middle and bright star of the Pleiades	25° 6′ 0″	4° 0′ 0″	3
Eastern, more southerly	25° 31′ 30″	3° 51′ 20″	5
Eastern, more northerly	25° 32′ 30″	3° 54′ 0″	7

He regrets, however, that the position of some of them is set down so wrongly by Tycho, and also by Lansbergius [Philips van Lansbergen] in his tables, page 102; for he puts the distance between the bright star of the Pleiades and the more southerly of the western ones at 1° 18′, as great as that between

the first and the middle star of Orion's Belt, whereas even to the naked eye these two Pleiades appear to be much less distant. I have already said, in Book 6, chapter 3, that Father Zupi and I once detected with the telescope, together with the 7 Pleiades, nearly 50′ other stars belonging to that asterism. Finally, Wendelen is of the opinion that new little stars arise and perish in that asterism almost daily, as Antonius Maria de Rheita reports, from a letter Wendelen wrote to him, in Book 4 of the *Radius Sidereomysticus*, chapter 1, member 1.

[Margin: Wendelen's opinion.]

Let this be said so that the reason for counting the seventh Pleiad among the new stars may now be clear: namely, that it is either rather nebulous, or so close to the sixth that it can be distinguished only by keener eyes. For Baranzano clearly erred when he called this one, whose newness is in dispute, the brighter of the Pleiades.

[Margin: Baranzano's slip.]

III. The *second* new star was the one that appeared in the time of Hipparchus, about the year 125 before the birth of Christ. To it astronomy owes a very great deal — or rather to God, Best and Greatest, its maker. For on its occasion Hipparchus, so that posterity might thereafter distinguish new stars from old, and temporary stars from perpetual ones, set about observing the places of the fixed stars, and on the same occasion detected a proper motion in them. For this he most deservedly received from Pliny, Book 2, chapter 26, that encomium: *The same Hipparchus, never praised enough — since no one has done more to prove the kinship of the stars with man, and that our souls are a part of the heaven — detected a new star, and another one, in his own age; and from its motion, on the day it shone, he was led to doubt whether this happened more often, and whether those stars too that we think fixed were moving. He likewise dared a thing presumptuous even for God: to number the stars for posterity and to set the heavenly bodies out by rule, with instruments devised by which the places and magnitudes of each would be marked, so that from this one could easily discern not only whether they died or were born, but whether they passed anywhere at all or moved, and likewise whether they grew or diminished — the heaven being left as an inheritance to all, if anyone were found who would grasp that method.*

[Margin: The new star of Hipparchus, in his age [?], about the year 125 before Christ.]

[Margin: Pliny's impious opinion about God.]

The same Pliny had said in chapter 24 of the same book: *stars are suddenly born in the heaven. There are several kinds of them*; and soon after, in chapter 25, he treats of all the species of comets. When that chapter is finished, he then passes to chapter 26, in which he treats chiefly of the new star seen by Hipparchus. From this distinction, and from the whole tenor of Pliny's way of speaking, it is quite clear that the star already mentioned was not a comet, whatever some interpreters of Pliny have said. For neither was that whole age in which Hipparchus flourished free of comets, as is plain from what was said in section 1, chapter 3; nor was Hipparchus so unskilled that he could not distinguish

a comet from a non-cometic star, if it was distinguishable and displayed any mark of a comet. But if he had no indication of a comet, and from its new appearance, and from its motion in common with the fixed stars — that is, the motion of the primum mobile — together with some slow proper motion, he doubted whether other stars too, which we reckon fixed, had a proper motion, and whether some of them shone anew in the heaven at fixed times, then it is surely an almost evident argument that Hipparchus judged that star to be far different from the genus of comets. Accordingly Tycho, in volume 1 of the *Progymnasmata*, page 322, with truly sharp irony, taunts those interpreters of Pliny already mentioned, saying: *Hipparchus surely accomplished something outstanding, and Pliny commends him highly, if he saw some comet in his own age? Was he moved by such just and weighty reasons that, on account of some hairy star running swiftly about and quite often returning in like manner, he laid so great a burden on his shoulders, like a second Atlas, as to consecrate to posterity, observed with instruments, all the stars contained in the eighth orb that are in any way open to sight?* Hájek, in Tycho, volume 1, page 511, agrees with Tycho that a new star is to be understood in Pliny. But would that Hipparchus himself, or Pliny, or Ptolemy had recorded for us that star's place, time and duration! Since neither they nor others have done so, we know nothing else about this star except that it appeared new in the times of Hipparchus.

IV. The *third* of the new stars is said to have shone in the times of the emperor Hadrian, namely about the year of Christ 130. But Tycho, volume 1, page 331, suspects that it was made up to please Caesar, or that nothing certain about it is established among the historians.

[Margin: A new star under the emperor Hadrian, about the year 130 of Christ.]

[Margin: New star, or comet, of the year 389.]

V. The fourth among the new stars is the one that Hechius, Liceti and Resta, drawing on Cuspinianus [Johannes Cuspinian], place in about the year of Christ 389. Cuspinianus says that in that year, 389, a certain star rose from the north at about cockcrow, shone like Lucifer, the morning star, and vanished within three weeks. But Tycho (volume 1, page 605) suspects that it was a comet without a tail, similar to the one he himself observed with the Landgrave of Hesse in 1585. That year 389 was followed by the irruption of the Goths and the devastation of Rome by Alaric.

[Margin: New star, or rather comet, of the year 392.]

VI. The fifth new star, in the eyes of some, was the one of the year of Christ 392 — the year, that is, in which Valentinian was found strangled with a noose in his bed. It appeared near Venus, and a great many other stars gathered to it like a swarm of bees. But we listed it among the comets under this year, in Section 1 of this book, chapter 3 — and not without reason, as can be seen from Nicephorus, book 12 of the *Ecclesiastical History*, chapter 37, whose words we quoted there.

[Margin: New star of the year 398.]

VII. The sixth new *Sella* [?] on record is the one of which Claudian sang in *On the Fourth Consulship of Honorius*:

A bold star was seen even at midday, while the peoples marvelled — in nothing to be doubted, nor languid with blunted hair, but as great as Boötes is reckoned by night.

But Tycho (volume 1, *Progymnasmata*, page 542) suspects that it was Venus. Venus is sometimes, though rarely, seen not only by day but even at noon — as we have already related more than once, here in Section 1, chapter 4, in the scholium, and in Book 7, Section 6 — and so it could be believed a new star; for this has happened more than once in our own times, when inexperienced people looked up at it in astonishment as an unusual star. As to the year of this star's appearance, however, Tycho judges from certain words of Claudian that come before these that it shone rather in the year in which Honorius was born than in his fourth consulship; that year, he says, was 388 of Christ, or perhaps 389. If so, it seems to be the same as the 4th star, the one Cuspinianus reports. Honorius's fourth consulship, on the other hand, fell in the year of Christ 398.

[Margin: New star of the year 945.]

VIII. The seventh among the new stars is the one that Cyprianus Leovitius mentions in his writing on the star of 1572. He says that it fell in the year 945, when Emperor Otto I flourished, and that it was seen in almost the same place, between Cepheus and Cassiopeia, where the star of 1572 shone out. But he cites no historian from whom he drew this. Granted that Tycho (volume 1, pages 331 and 706), Liceti, Baranzano and Resta mention it on his authority; yet Cyprianus thought it was a comet without hair.

[Margin: New star of the year 1264.]

IX. The eighth new star shone in Cassiopeia in the year 1264, if we believe Cyprianus Leovitius, who says he had this from a certain manuscript, and adds that it was without hair and proper motion. On his authority Liceti, Baranzano, Resta and Tycho (volume 1, page 331) accept it as a new star — although Tycho also raises the suspicion that it was the comet assigned to that year by Camerarius and Pontano, which, however, they say had a tail; whereas Cyprianus, though he reckons this star among the comets, affirms that it appeared without hair.

[Margin: New star of the year 1572 in Cassiopeia.]

X. The ninth new star, and the most celebrated in the books of a great many writers, is the one that appeared in 1572 in the Chair of Cassiopeia and lasted until March 1574. Just like the star of Hipparchus, it gave Tycho the occasion to observe the fixed stars with new and very costly instruments, and to set a thousand of them in order. His observations of it concern partly its longitude and latitude and its distance from the fixed stars, and its altitude above the horizon — these we shall discuss from chapter 3 onward, in order to determine from them its parallax and its distance from the Earth; and partly its other circumstances, which for the learned reader's benefit we shall gather in chapter 3 from the authors who wrote about it. Tycho lists most of these authors in volume 1, *Progymnasmata*, chapters 8, 9 and 10, that is, from pages 489, 598 and

704. Among them Franciscus Vallesius wrongly says that it began to be seen in 1573, whereas it began in 1572, as will be clear from the history in chapter 2.

[Margin: New star of the year 1596 in Cetus.]

XI. The tenth new star is the one of the 3rd magnitude that David Fabritius [David Fabricius] is said to have observed in Cetus on 1596 August 13, as Kepler reports in *De Stella Serpentarii*, page 112, and in the *Astronomiae Pars Optica*, page 446, and as Froidmont and Resta report; it is said to have remained visible there for 3 months, and Liceti also mentions it. It was seen at Aries 25° 45′, with southern latitude 15° 54′, far from the Milky Way.

[Margin: New star in Cygn[?], year 160[?].]

XII. The eleventh new star appeared in the year of salvation 1600. It was seen first by Gulielmus Iansonius [Willem Janszoon Blaeu], as he himself declares in the inscription of a celestial globe published in 1601, and then by Iustus Byrgius [Jost Bürgi], Johann Bayer, Kepler and others. This star was of the third rank, and in position it lay next to the one that shines in the breast of the Swan, at the junction of the neck and the breast — so you need not think it was relegated among the unformed stars. Never before, however, was any such star recorded in the ancient catalogues or globes, not even in Tycho's; and so Kepler, who wrote an astronomical account of it, says, as Bayer does, that it was *by the tacit consent of all accepted as new*. Clavius, Griembergerus [Christoph Grienberger] and Biancani (*Sphaera*, book 18, chapter 3) also accepted it as new, and so did Baranzano, Liceti, Froidmont, Resta, and Argoli in chapter 62 of the *Pandosion*, where he says that it persisted in the sky until 1629, and that after its disappearance a black gap was seen in the sky in its place — unless this was invented in imitation of Tycho, who asserted something similar in the place of the star of 1572 after its departure. Chiaramonti, however, against Liceti (*De tribus novis stellis*, book 3, chapter 6), contends that it no longer appeared in 1626, nor indeed in '21.

[Margin: New star of the year 1602, or [?] 1603.]

XIII. Kepler reports, though doubtfully, a new star seen by him on 1602 December 21, in the *Astronomiae Pars Optica*, page 237; Froidmont and Resta take it from him. But what if this was the one that lasted into 1603, the year in which Father Philippus Plumeretus, as quoted by Piso in the *Speculum Cometae*, chapter 2, related that a new star had been seen by him at Rome?

[Margin: New star of the year 1604 in Serpentarius.]

XIV. The thirteenth new star was the one seen in 1604, at the beginning of October or at the end of September, in the right foot or heel of Serpentarius. It was larger than Jupiter and almost equal to Venus, and it lasted at least until October 1605, on the 8th of which month Kepler saw it for the last time, and never afterwards — partly because it set heliacally, partly because of clouds and the presence of the Moon. He therefore remained uncertain on what day between October 1605 and February 1606 it vanished; for in March, with every impediment removed, it was quite certainly no longer to be seen. We shall report more on its observations from chapter 14 onward.

[Margin: New star of the year 1612.]

XV. The fourteenth of the new stars is said to have been sighted in 1612 by Simon Marius [Simon Mayr] in the girdle of Andromeda, and another in Antinous by Bürgi, as Froidmont relates (*Meteorologica*, book 3, chapter 2, article 7), and as Simon himself does in the preface to the *Mundus Iovialis*.

[Margin: New star of the year 1618.]

XVI. The fifteenth new star is the one that Vincislaus Pantaleo [Václav Pantaleon Kirwitzer], in his observation of the comet of 1618, wrote that he had seen while sailing to the East Indies, resembling Venus; and he called into doubt whether it was a new star — although others seized on what he himself put forward in doubt as certain, and published it. Resta (treatise 1 of the *Meteorologia*, book 1, chapter 7) and Chiaramonti (book 3 of *De novis stellis*, chapter 6) also mention [?] it.

[Margin: The newest star, of the year 1638.]

XVII. The sixteenth and most recent of the new stars is the one that appeared in Cetus in 1638. Ioannes Phocilides Holuarda [Johannes Phocylides Holwarda] described it in a booklet on this phenomenon, together with the eclipse of the same year, and Wendelen also mentions it in a letter to Antonius Maria de Rheita, which Rheita himself quotes in the *Radius Sidereomysticus*, book 4, chapter 1, member 1.

So if we accepted all those enumerated above, there would be 16 new stars; but we have rejected the first and the fifth. Of the rest, some are held to be quite certain, namely 2, 9, 11 and 13; the others are not equally certain. Among these, however, we must examine 9, 11 and 13, since they have been illuminated by astronomical observations, so that from those observations a more certain judgement may be formed about their place and their distance from the Earth, and hence about their origin.

SCHOLIA.

Scholia.

[Margin: Mars and Venus taken for new stars.]

I. Mars, because of the size of its epicycle compared with the eccentric, appears much larger at the perigee of the epicycle than at the apogee or far from the perigee. This happens to it in alternate years, namely when, having become acronychal, it stands in opposition to the Sun. But it looks larger still by far when it is at the same time at the perigee of the eccentric and of the epicycle, so that some have taken it for a new and unusual star — as happened in 1529, 1561, 1593 and 1608, among people, that is, rather unskilled in astronomy. Indeed, for this very reason Andreas Perlachius [Andreas Perlach], professor of astronomy at Vienna, predicted that in 1529 a new star would popularly be believed to have arisen in the place of Mars in July and August; Tycho also reports this, from Hájek, in volume 1, page 745. He rightly adds that the same thing happens to Venus for the same reasons: because of the size of its epicycle

it sometimes comes so near the Earth that, if it is at once at the perigee of the epicycle and of the eccentric, it is swollen by an incredible increase of light and not only appears very large but can even seem a new star to those little practised in astronomy — as we said happened, in Section 1, chapter 4, scholium 2. And perhaps because of changes of this kind Venus was believed to be an extraordinary portent, as Saint Augustine reports from Varro in *The City of God*, book 21, chapter 8, whose words I have already cited in Book 7, Section 1, chapter 2, number 4.

[Margin: Why the star of the three Magi is omitted here.]

II. As for the star that God, Best and Greatest, raised up by divine power, bidding it shine forth to the Magi and go before the sacred birth of his Son and our Saviour, we could in no way count it among the new stars that we are dealing with here. At the end of this section, however, we shall discuss what others have thought or written about it, rightly or wrongly, and we shall show that some have mistakenly placed it among the comets, or among stars generated from a natural cause. Tycho (volume 1, page 601), and with him, in the same work, the Landgrave of Hesse, judge to be full of vanity what Cornelius Agrippa relates in chapter 30 of *De vanitate scientiarum*: namely that, according to a tradition of the Indians, there are still in the heavens two stars diametrically opposite each other, which complete their course against the order of the signs only in 144 years.

[Margin: Two stars falsely ascribed to the sky by the Indians.]

[Margin: A new star confused by the common people with ♂ and ♀.]

III. It sometimes happens that a new star has indeed appeared, and that a rumour about it, spread by the mathematicians among the unlearned public, has given people occasion to flock into the square or some other suitable place and gaze at the sky in the evening; and since Venus was then appearing as the evening star, it was believed — by the unskilled, as I said — to be the new star. So it happened at Vienna and elsewhere at the beginning of October 1604, when a new star had truly appeared in Serpentarius, as Kepler relates in *De Stella nova Serpentarii*, chapter 1. And because the common people believed that the new star was still lasting in 1606 as well, though it had in fact already been extinguished, they took it to be there in April, when it was Venus, and in June, when it was Mars at acronychal rising, as the same author relates in the same place.

CAPVT II.

Chapter 2.

Hiſtoria Obſeruationum generalium Stellæ Nouæ Anni 1572. in Caſſiopea viſæ : & Opinionum de illius Loco ac Origine.

History of the general observations of the new star of the year 1572 seen in Cassiopeia, and of the opinions on its place and origin.

I. We shall begin with Tycho — not because he was the first to notice this star, but because he is considered to have been the most diligent of all in observing it. As he himself relates, then, in volume 1 of the *Progymnasmata*, chapter 3, this star began to be seen by him on November 11; and although he settles nothing certain about the day of its first rising, he thinks it probable that its beginnings were around the new moon, which fell on November 5. Tycho was then staying with his maternal uncle Steno Bille [Steen Bille] at Herrevad; and as he was returning before supper on November 11 from the building where he did his chemical work, he saw near the zenith an unusual star in Cassiopeia, one he had never before observed, although he had been used to recognising the stars since boyhood. To rid himself of all doubt about the new star, in case his eye was deceiving him, he questioned both his servants and some peasants who were driving past in a cart; they answered that they saw a huge star in that same place of the sky, one never noticed before. Confirmed by them, he set about observing with instruments, from then on, both that star and the other stars of Cassiopeia, and at length a thousand other fixed stars. He says first, then, that it

[Margin: Duration of the star.]

[Margin: Motion and position.]

remained in the same place of the sky until March 1574, when it ceased to be seen, and that it had no other sensible motion besides the motion of the primum mobile; for with three other more conspicuous stars of Cassiopeia, of the third magnitude, it completed a figure like a rhombus or trapezium — namely with the one that is higher in the middle of the Chair, with the one in the breast called Schedar, and with a third near the flank. It was also very close to a star of the fourth magnitude that is in the middle part of the seat and is the eleventh of the asterism of Cassiopeia — that is, at the edge of the Milky Way, where its northern boundary near Cassiopeia faces the Arctic Pole. In this position it was seen for the whole of those 16 months and more. Tycho admits, however (page 304), that coachmen, couriers and sailors noticed this star in the sky and told others of it before learned men did.

[Margin: Shape of the star.]

The star's shape was perfectly round, without any hair, and it twinkled more than the other fixed stars.

[Margin: Apparent magnitude.]

Its apparent magnitude at first surpassed Lyra and Sirius, and even Jupiter somewhat, although Jupiter was then acronychal and moving at the perigee of its eccentric; so that it rivalled Venus at perigee very closely, was made out by day, too, around noon, by men of keener sight, and at night shone through dense clouds while the other fixed stars were hidden. In December, somewhat diminished, it equalled Jupiter; but in January 1573 it was smaller than Jupiter, though still larger than Sirius and Lyra, to which it became equal at the end of February and the beginning of March. In April and May it seemed equal to stars of the second rank; in June, July and August to stars of the third magnitude; in

September, October and November to stars of the fourth magnitude. Then in December and in January 1574 it appeared scarcely larger than stars of the fifth magnitude, and in February it resembled stars of the sixth magnitude, until in March it became so faint that at last it could no longer be seen.

[Margin: Colour of the star.]

Its colour at first was clear, whitish and brilliant; afterwards yellow; in March 1573 reddish, like Mars or Aldebaran. In May it took on a somewhat leaden whiteness, such as we see in Saturn, and it kept this colour to the end, though always growing duller. So far Tycho, chapter 3.

II. Next, in volume 1, chapter 4, Tycho goes on to describe the instruments as well with which he observed this star: namely a sextant requiring the work of one eye, an astronomical radius, and a great quadrant of 14 cubits, which he had had built at Augsburg; for that reason he regards the observations made with it there by Paul Hainzel as if they were his own, and he reports them too. From these and from his own observations he gathers, in chapter 5, the new star's longitude and latitude, right ascension and declination as seen, as in the following little table, and its culmination with Aries 0° 19′.

New star of the year 1572.

Longitude	North latitude	Right ascension	Declination
♉ 6° 54′	53° 45′	0° 26′	61° 47′

After this, in chapter 6, he tries to show by many arguments that this star was in the firmament itself, among the other fixed stars, without any sensible parallax. Finally, in chapter 7, digressing on the distances of the planets and the fixed stars and on their sizes, he assigns the fixed stars a distance of not less than 14,000 semidiameters of the Earth, and the new star, at its beginning, an apparent diameter of 3½′; and from these he gathers by geometrical calculation that its true diameter was to the Earth's diameter as 7½ to 1, and the star's bulk to the Earth's body as 361½ to 1, or at least 360, but to the Sun's body as 2⅔ to 1. On page 487, however, he holds that it diminished afterwards not only in appearance but in reality; otherwise, if it had shrunk from a diameter of 3½′ to an invisible disc because of an ascent, as some think, it would have had to rise higher by 300,000 semidiameters of the Earth to be seen as a little star of the sixth magnitude. He therefore sets its true magnitude as different in different months, as you see set out in the following table.

[Margin: Distance of the new star from the Earth, according to Tycho.]

[Margin: True magnitude of the star.]

True magnitude of the new star of the year 1572, from Tycho, page 486.

	It contained the Earth about this many times
1572 November	360
December	200

	It contained the Earth about this many times
1573 January	100
February and March	70
April and May	29
June, July, August	11
September, October, November	4½
December and 1574 January	1
February and March	0⅓

[Margin: Observations of the Landgrave of Hesse.]

III. After Tycho, Vuilhelmus [Wilhelm IV], Landgrave of Hesse, began to observe this new star and sent his observations to Tycho, who reports them in volume 1, chapter 8, from page 491 to 505. The Landgrave's account opens as follows: *In the year of the Saviour's Birth 1572, on December 3, at the prompting of the Elector of Saxony, I first saw and observed the new star, larger and brighter than Venus itself, in the asterism of Cassiopeia, etc.* He then gives its altitudes and azimuths, with the moments of the observations, up to 1573 March 14, when he gave up observing because he had detected no proper motion in it; and he admits that the altitude of the pole at Kassel that he assumed, 51° 16′, does not seem exact to him. In other letters sent to Tycho, and to Gaspar Peucerus [Caspar Peucer], which Tycho has on pages 599 and 612, he affirms that he detected no parallax in this star, or at any rate none greater than three minutes. From these he gathers a distance of 1062 semidiameters of the Earth, and he judged this star to be something supernatural, distinct from comets and from fixed stars.

[Margin: Observations of Hájek.]

IV. Tadeáš Hájek ab Hayck, a Bohemian, ordinary physician to the court of Emperor Rudolf, published a *Dialexis* on the unusual magnitude and the place of this new star, divided into fifteen chapters, in which he includes many general problems about parallaxes. He says that this star was seen by him around the Nativity of Christ the Lord, and not before, equal in magnitude to Arcturus, to the Dog Star or to Jupiter, and of a reddish colour. He adds many distances of the new star from the stars of Cassiopeia. In chapter 4 he teaches that it was new and set in the aether outside the order of nature; and in chapter 5 he contends, from the uniformity of the motion of the primum mobile and from the lack of parallax, that it was in the heavens — which in chapter 12 he attempts to establish by a safer inquiry, from its distances from the neighbouring stars of Cassiopeia when it was crossing the meridian.

[Margin: Observation and opinion of Paul Fabricius.]

V. Paulus Fabricius [Paul Fabricius], physician and mathematician to the Emperor, in a short writing on this star that he presented to the Archduke of Austria, relates that it began to shine at the end of October 1572, greater in magnitude than Sirius but similar in colour. He gives it a longitude of ♉ 6° 14′ and a latitude of 54° 12′, and says that it was [?] free of proper motion and kept

the same distance at its highest and lowest meridian altitudes. From this he argues that it had no sensible parallax, but was either in the sphere of the fixed stars or at least not below Jupiter, and much larger than the Earth — although he hesitates whether this star should be called a comet or not, and leans to the negative.

[Margin: Observation and opinion of Reisacher.]

VI. Bartholomaeus Reisacherus [Bartholomäus Reisacher], mathematician of the Vienna Gymnasium, had at first thought that this star was not new but the eleventh of Cassiopeia, enlarged by the interposition of vapours and of some transparent medium; afterwards, however, when the eleventh was seen distinctly apart from it, he accepted it as new. And from the fact that at both meridian altitudes it kept the same distance from the fixed stars, he concludes that it was not in the elementary region. Although he commits the origin of this star to the hidden counsel of God, or to the Intelligence that governs each sphere, yet if a physical cause must be adduced, he thinks it probable, with the Pythagoreans, that it was one of the ancient stars of the eighth orb, revealed once impediments were removed, and perhaps the same as the one that Cyprianus Leovitius reported as seen in Cassiopeia in 1264. Further, in determining its place at ♉ 6° 24′ with latitude 53° 49′, he uses the uncorrected Copernican places of the stars, the altitude of the pole at Vienna handed down by Purbachius [Georg von Peuerbach] and Regiomontanus, 48° 22′, and a least meridian altitude of the star of 20° and 5′, or 10′, where he admits that he is uncertain about the 5 minutes.

[Margin: Observation and opinion of Hainzel.]

VII. Paul Hainzel — whose observations of this star Tycho presents in volume 1, chapter 6, together with his reply to Hieronymus Vuolphius [Hieronymus Wolf], head of the Augsburg gymnasium, from page 536 — relates that this new light was seen by him on November 7 at 6^{h} after noon at Augsburg, and that from the meridian altitudes of this star the same altitude of the pole at Augsburg is gathered as from the altitudes of other circumpolar fixed stars; and that this is a sign that its apparent and its true place had no sensible difference. And yet he does not hesitate to count it among the comets, and indeed among the secondary ones, which are kindled below the Moon without tail or hair and are gradually consumed, because he noted that this one gradually diminished. In this matter he either shows himself unskilled in astronomy, since he admits the lack of sensible parallax, or the identity of the seen and the true place, and yet places this star below the Moon; or he certainly undermines his own observations — as Tycho rightly reproves him in volume 1, page 540. Yet Tycho reports on page 542 that Hainzel, once he had read through Tycho's treatise on this star, retracted his opinion and, with Tycho, raised this star to the highest sphere of the fixed stars.

[Margin: Observation and opinion of Mästlin.]

VIII. Michael Mästlin of Göppingen, in a short writing on this star, reports that he observed it in a little town of the Duchy of Württemberg called Backnang [Bachnang], where he was pastor — and with no instrument other than threads, in the way we shall describe in its place in Book 10 — and that in the first week of November. He relates that this star surpassed in magnitude not only Sirius but Jupiter and almost Venus, and that it was at first of a whitish colour, then flame-coloured or saffron, afterwards blood-red, and at length, in February 1573, was restored almost to its original colour. He adds that it was a new star, to be counted among the stars of the eighth orb, because its observed place, both on the meridian and near the horizon, was found exactly the same, without a difference of a single whole minute, and that it had no motion other than the daily revolution of the primum mobile. At so great a distance, then, since it surpassed all the fixed stars in apparent magnitude, it was many times larger than the Earth, and therefore no supply of exhalations was sufficient to generate that star. For this reason its cause was rather *hyperphysical*: *this new star was created by the supreme Creator in these last times, and as it began miraculously, so it will miraculously cease; the cause of both escapes all human understanding*. Mästlin wrote this in 1573, on March 4 [4. Nonas Martij], while that star was still shining in the sky. He assigned it a place different from Tycho's; but had he used Tycho's star places, its places would have come out for him as Tycho computes in volume 1, page 550. Here, then, are the computations of both: the first Mästlin's, the second Tycho's — though from the position of the new star relative to the fixed stars of Cassiopeia observed with threads by Mästlin.

Places of the new star of 1572	From the Copernican stars	From the Tychonic stars
Longitude	♉ 6° 35′	♉ 7° 3′ 2″
North latitude	54° 0′	53° 38′ 42″
North declination	61° 50′	61° 46′ 0″
Right ascension	359° 56′	0° 43′ 0″
Culminates with	♓ 29° 56′	✠ ✠ ✠

[Margin: Observation and opinion of Cornelius Gemma.]

IX. Cornelius Gemma, son of Gemma Frisius, wrote about this star both in a separate booklet and in his work *De divinis mundi characterismis*, book 11, chapter 3. In these he reports that its first appearance was, for him, on 1572 November 9; for Hainzel, on the 7th; and for others among the common people, at the end of October, from popular rumour. He says that it was like Phosphorus [the morning star] in strength of light and in magnitude, but more like the fixed stars in its twinkling, and that throughout the whole time of its duration it did not change its place in the sky:

from the positions he himself observed, he at first detected a parallax of not more than 4′, and afterwards none at all. He assigned the star a place in ♉ 6° 30′, with latitude 52° 40′; but from other, later observations of his there comes out a longitude of ♉ 5° 10′ and a latitude of 53°, as Tycho computes

(page 558). Tycho does not put much trust in them, first because Gemma took the distances of this star from the fixed stars with a radius, and second because they disagree greatly with his own. Gemma further denies that this star was a comet, and compares it with the star that shone for the three Magi, and with the portents which, as Holy Scripture testifies, have at times been produced outside the order of nature. Next, he held that it was in the eighth sphere and gradually descended, so that it could have been seen in March of 1572 or even earlier; that afterwards it rose again, and so vanished from sight; and because of its perpetual twinkling he denies that it was anything elementary. But what he fancies about apparitions of angels, or even of God himself, in the form of this star, and about its ascent and descent and a circular return familiar to divine minds, Tycho himself (volume 1, page 564) judged impious and unworthy.

[Margin: Cornelius Gemma's fictions, hardly pious.]

[Margin: Observation and opinion of Muñoz.]

X. Hieronymus Munosius [Jerónimo Muñoz], professor of the Hebrew language at the University of Valencia in Spain and a distinguished mathematician, wrote on this star in Spanish; his treatise was published by Cornelius Gemma at the end of his book *De Characterismis*, and from that by Tycho (volume 1, page 565). Muñoz states that on 1572 November 2 this star had not yet appeared, both from the report of shepherds and because during those days, while showing his students the positions and names of the stars, he did not notice it. He assigns it a place in ♉ 7° 48′, with latitude 53° 36′. In the meridian altitude of the new star — a maximum of 67° 30′ and a minimum of 11° 30′, from which Tycho (page 567) derives the pole height of Valencia as 39° 30′ — he differs greatly from Tycho; in the distances of the new star, however, only a little: namely, from Schedar by 30″, from the Seat of Cassiopeia by 1′, and from the flexure [flexura] by 8′. Yet from these very distances Tycho (page 569) derives a quite different longitude for the new star. Muñoz also disagrees with Hájek on many points; and in the distance of the new star from the Pole Star, which he puts at 26° 40′, he differs from Tycho, who puts it at 25° 14′, and from Hájek, who puts it at 25° 30′. On the strength of careful considerations, as he himself professes, he affirms that this star was above the Sun and had scarcely any sensible parallax; that it was indeed a comet, but one fixed in the heaven of the fixed stars; and that it was one of those unknown comets of which Lucan says:

Dark nights saw unknown stars.

[Margin: Opinion of Francisco Vallés.]

XI. Franciscus Vallesius Covarruviensis [Francisco Vallés of Covarrubias], in his books *De sacra philosophia* — that is, on the things written on physical matters in the sacred books — discusses this star in chapter 1. He says that it began to be seen in 1573 in the Knee of Cassiopeia; but he is badly mistaken on both counts, for it appeared both in 1572 and not in the Knee but in the Chair of Cassiopeia. He grants that it had no parallax and was above the Sun, but he denies that it was a new star: otherwise God would not have created all things at once, according to the text of Ecclesiasticus 18, *He who lives for*

ever created all things at once; nor would the adornment of heaven have been complete from the beginning, whereas Genesis 2 says: *Thus the heavens and the earth were finished, and all their adornment, and God completed his work on the sixth day.* And since this star did not last long, Ecclesiastes 3 would be saying falsely: *I have learned that all the works of God endure for ever.* Vallés therefore holds that it was an old star which, by a peculiar motion of its own, passed into lower and denser parts of the heaven, by which its size was optically enlarged. To this, however, Tycho (volume 1, page 574) replied that the words of Holy Scripture are to be understood of the things that were created at the beginning out of no pre-existing matter and belong to the ordinary adornment and the constituent parts of the heavens — not of adventitious things, whether stars or comets, generated from some matter or created by a miracle, as the star of the Magi was. Otherwise, by Vallés's reasoning, it would follow from those passages that God cannot work any new portent in the heavens, not even by a miracle.

[Margin: Observation and opinion of Clavius, and also of Biancani.]

XII. Christoph Clavius, as we have it in his commentary on the *Sphere* of Johannes de Sacrobosco (from page 191 in my copy), relates that this star appeared in 1572 and disappeared in 1573; that at first it looked larger than Venus, but afterwards smaller and smaller, so that to him in Rome in December 1573 it seemed equal to stars of the third magnitude. From this one may conclude that, had he persevered in observing it, and had neither bad weather nor perhaps the weakness of his eyes stood in the way, he would not have thought that it vanished so soon. He also teaches that it was not one of the 13 ancient stars of Cassiopeia, but a new and fourteenth one[18], distinctly known both to himself and to Maurolico and others, which completed a rhombus with three other stars of Cassiopeia. He further denies that it was a comet in the air, because it was seen to have no variation of view, and was seen by everyone near the point that lies 23° 30′ from the arctic pole, at which the equinoctial colure intersects the arctic circle. He therefore holds that this new star was in the firmament among the other fixed stars — above all because it had no motion other than that of the fixed stars — and that it was created by God, Best and Greatest, to portend something great; or, if this is not granted, that comets can be generated in the heavens, and that the heaven is a changeable body, though less corruptible than other bodies. This, he affirms, Plato and Saints Basil, Ambrose and Gregory of Nyssa, and almost all the other lights of the Church taught not obscurely.

[Margin: Observation and opinion of Maurolico.]

XIII. Francesco Maurolico, in a disputation on this star, has among much else the following words, which our Clavius selected from it and copied into his commentary on the *Sphere* (page 194 in my copy). They run as follows: *In this year 1572 an unusual and more wonderful sign appeared: namely a remarkable star, of exceptional brightness, in a place where no star was recorded. Nor does it*

[18] printed "nonam"; taken as a turned sort for "nouam", since "ninth" does not construe beside "fourteenth"

seem to me to be a comet of the kind generated in the air; for it appears higher, and belongs to the number of the fixed stars. Perhaps, as it began to shine, so it will cease — especially since certain philosophers, with whom Cardano agrees, hold that comets and new stars can be produced even in the heavens by an aggregation of light from the planets and the other stars. However that may be, I cannot wonder enough at this star's new blazing forth in our time. For it is certain that it is not one of the stars of the first magnitude that are recorded in the Ptolemaic and Alphonsine numbers, that have shone since the founding of the world, and that are fifteen; this new star so surpasses them in brightness that from now on they would have to be called of the second magnitude, provided it lasts. Observing this star here on the horizon of Messina, standing on the meridian at about the third hour of the night, I found its altitude to be 62°. From this I conjectured that it is located as if at the top of the arctic circle, so that it is 28° from my zenith here, and accordingly about 66½° from the equator, since the latitude of Messina is 38½°; and that it lies at the point where the equinoctial colure cuts the arctic circle, or very close to that point. But since he differs greatly in the pole height from the value that Don Carolus Ventimilius testifies he found, 38° 11′, some doubt seems to arise about the parallax; on which see below.

[Margin: Observation and opinion of Pridianus.]

XIV. Paulinus Pridianus, physician and astronomer, observed this same star at Antwerp and, as Clavius reports (*Sphere*, page 194), judged it equal to Venus in brightness and size. He wrote that it stayed fixed in the same place, moved only by the revolution of the fixed stars, contrary to the nature of fiery meteors; and that it was a new star which, with the star in the breast of Cassiopeia, the one above the seat near the legs, and a third in the middle of the Chair, formed a rhombus, and shone at the northern point of that rhombus.

[Margin: Observation and opinion of Peucer.]

XV. Gaspar Peucerus [Caspar Peucer], principal professor of the University of Wittenberg, pronounced on this star in summary, partly in a letter to Hieronymus Wolphius [Hieronymus Wolf], which is found in Tycho, volume 1 of the *Progymnasmata*, page 535, and partly in a letter to the Landgrave of Hesse, which Tycho likewise copied out in the same volume, page 605. He declared that it was plainly new, and surpassed the fixed stars and the lesser planets, Venus excepted, in size and light; that he first saw it on November 16, and that afterwards, around December 14, it appeared more like Mars in colour and size, yet always twinkled and had no motion other than that of the primum mobile. Its maximum meridian altitude, observed with instruments at Wittenberg, was 79° 56′, its minimum 23° 33′. He gives its apparent place as ♉ 6° 25′ when it was nearest the zenith, with a latitude of 54° 16′; but when it was nearest the horizon he puts it at precisely ♉ 6°, with latitude 54° 3′, and a declination near the zenith of 61° 58′ and near the horizon of 61° 39′; and from this a parallax of altitude of 19′ — a difference which, however, he admits was not exactly investigated. Yet if the parallax is no greater, the star's distance from the Earth was 164 semidiameters of the Earth. And although he brings many

arguments on both sides, he finally inclines to the view that it was contained in the elementary orb and had been set alight by Jupiter, which it resembled, and that as it had begun, so it would cease; for he was writing this on 1573 January 1 (the Kalends of January).

[Margin: Opinion of Schuler.]

XVI. Vuolfangus Schulerus [Wolfgang Schuler], a mathematician of Wittenberg, in a reply to a question put to him by Caspar Peucer the younger, which Tycho reports (volume 1, *Progymnasmata*, page 621), relates that he began observing this new star on 1572 November 6, at 6 in the morning, at Wittenberg; and that on November 27 he found its greatest distance from the zenith on the meridian to be 66° 27′, and its least altitude 23° 33′. From this, and from the pole height observed there by Crugerus and Rheinoldus, 51° 54′, he derives a declination of the new star of 61° 39′, in an observation made shortly before seven in the morning; and he derives that its greatest altitude should have been 80° 15′, whereas on the evening of December 4 he says he found it to be 79° 56′, and hence a parallax of 19′; and that it therefore appeared to have been above the Moon. He affirms that his quadrant had twice the radius of the Landgrave of Hesse's, and that he also used parallactic rulers of 10 feet. With this set out, he teaches that this star was not any of the planets, because it twinkled, because it was far from the zodiac, and because it lacked a motion of its own; but neither was it one of the fixed stars, because it gradually changed its colour and size. Consequently it was most certainly a comet — not, indeed, an ordinary one, formed and kindled from viscous exhalations, but an unusual one, placed in the heavens by God outside the order of nature as a kind of prodigy among the τέρατα [Greek: τέρατα (terata, "portents")]. After this, however, Tycho relates (volume 1, page 636) that Wolfgang confessed to him that with those parallactic rulers he had found in this star a parallax of scarcely one or two minutes; but to Tycho those rulers seemed by no means perfect in every respect, granted that Johannes Praetorius also used to employ them — of whom we must speak shortly.

[Margin: Imperfection of the parallactic rulers.]

[Margin: Observation and opinion of Praetorius.]

XVII. Johannes Praetorius of Joachimsthal, formerly mathematician at Wittenberg and later at Nuremberg, in his catalogue of comets, which I have read through in full, under the year 1572, listed this new star among the comets for the reason that it finally vanished. He reports that he too saw it from November 16; that it lasted 14 months; that with stars 2, 4 and 12 of Cassiopeia it formed a trapezium rather than a rhombus; that it was in ♉ 7°, with latitude 54° and declination 62°; that it resembled the fixed stars in colour and light, but at first was larger than Jupiter and smaller than Venus, and after two months appeared redder, so that it surpassed even the glow of Mars; moreover, that it stayed fixed in the same place and was above the orbs of the planets, because no parallax could be detected in it. And so, he says, this confirms the opinion of Io. Penna [Jean Pena]: namely, that the air extends from our sight up to the fixed stars

without any difference of substance; that there is no distinction between air and aether; and that there are no fixed bounds, below or above the Moon, within which comets are generated.

[Margin: Opinion and observation of Philipp Apian.]

XVIII. Philipp Apian, son of Peter Apian, in a letter to the Landgrave of Hesse which Tycho has rendered into Latin for us (volume 1, page 643), sets out what he discovered by observing this new star: namely, that it was equal to Jupiter or even larger; that with the three largest stars of Cassiopeia it formed a trapezium at the edge of the Milky Way, towards the north on the western side; that it was very close to the equinoctial colure; and that it was in ♉ at about 6°, with a latitude of about 53°. He himself saw it from November 10, but on the report of others it was seen earlier, though not before 1572 October 20; and it was driven by no motion other than the diurnal revolution of 24 hours. He further holds that it was a comet without hair or tail, of the kind he thinks are generated from a conjunction of ♃ and ♄, following the view of John the Englishman; yet that it was not in the elementary region, but almost in the sphere of the fixed stars, since comets can arise anywhere in the heavens, not so much from kindling as from the illumination of the Sun. So he wrote at Tübingen on 1572 December 26.

[Margin: Observation and opinion of Digges.]

XIX. Thomas Diggeseus [Thomas Digges], an Englishman, in his *Alae seu Scalae Mathematicae*, which he published on the occasion of this star and which Tycho summarised (volume 1, from page 653), found the distances of this star from the other stars of Cassiopeia, though taken with a radius, very nearly equal to Tycho's; for they differ from them by no more than 3 or 4 minutes. But he uses the Copernican places of the fixed stars. Later, in chapter 10, he affirms that this star was subject to no parallax greater than two minutes, and indeed that it is uncertain whether it had any. Tycho, however, refutes him (page 682), because from Digges's own observations the longitude of the new star comes out now as ♉ 9° 46′, now as 4° 22′. John Dee of London, on the other hand, thought that this star vanished by ascending along a straight line — which Tycho attacks on page 691.

[Margin: Opinion of John Dee.]

[Margin: Observation and opinion of Camerarius.]

XX. Elias Camerarius, professor of mathematics at Frankfurt an der Oder, in his writing on this star, asserts that this new star appeared in 1572, at the beginning of October, in the evening, at about the 10th hour, near the meridian, larger than Jupiter and smaller than Venus; and he assigns it a longitude of ♉ 7° 10′ and a latitude of 53° 44′. He denies, however, that it was a fixed star or a planet. Next, he affirms that the pole height at Frankfurt is, by observation, 52° 24′; from this, and from various meridian altitudes of the new star, upper and lower, he derives a parallax of altitude of sometimes 4½′, sometimes 10′ or 12′. From these he concludes that it was indeed a comet, but above the Moon, and that it vanished by gradually ascending.

[Margin: Opinion of Reinhold.]

XXI. Erasmus Reinhold, son of the Erasmus Reinhold who built the Prutenic Tables and deserved so well of astronomy, a doctor of medicine, in his Prognostication for the year 1572, derives from the Landgrave's observations — as Tycho maintains (volume 1, page 700) — a parallax of altitude of 2′ 12″, and hence a distance from the centre of the Earth of 1079 semidiameters of the Earth; and a true diameter of the star, on 1572 December 25, of 5385 German miles, with a solidity relative to the Earth as 31 to 1; but at the end of August 1573 a diameter of 1888 miles, and a solidity relative to the Earth as 67 to 50. In the end he denies that it was either a planet, or one of the fixed stars, or a comet, and concludes that it was a new work of God, produced outside the order of nature and not to be subjected to astrological rules.

[Margin: Observation and opinion of Karásek Lvovický.]

XXII. Cyprián Karásek Lvovický, a Bohemian, in his astronomical observations on this star, reports that he began observing it on 1572 November 25; that it looked larger than any of the lesser planets, and yellow and half-white in colour, but reddish towards the beginning of December and blood-red at the end of December. He therefore judges that it was kindled by Jupiter and Mars, and that it could be seen between the 2nd and 3rd hour after noon because of its great distance from the Sun and the brightness of the star. Its longitude was in ♉ 8°, and its latitude about 50°; it stayed fixed in the same place and had no proper motion for two months; afterwards, within one month, it was seen to advance a little, up to 3 degrees, northwards towards Cepheus, and to decrease in size daily. Finally he calls it a comet; and Tycho (volume 1, page 704) counts him among the authors who thought it a sublunary meteor, and (page 707) denies that it departed from its original place by even a single minute, let alone a degree.

[Margin: Opinion of Chytraeus.]

[Margin: Tycho's religion suspect.]

XXIII. David Chytraeus, a disciple of Philipp Melanchthon — a most pestilent man, condemned by the Church — (since Tycho, volume 1, page 712, warmly commends both of them in theological matters, just as he also defends Theodorus Beza [Théodore de Bèze] on page 327 and Luther on page 777, let prudent and Catholic men judge what is to be thought of Tycho; Tycho admits, however, that David was not a professor of mathematics) nevertheless counts this star among the comets, compares it with the comet seen under Nero, and from this concocts a great many dreams of astrological vanity. And although later, in his writing on the comet of 1577, he admitted that it had been in the aether, because he heard that no parallax could be observed in it, he nevertheless denied that it was generated in the aether, and thought it was produced in the elementary region.

[Margin: Opinion of Postel.]

XXIV. Gulielmus Postellus [Guillaume Postel], a Frenchman, put forward many astrological claims about this star, and noted, with Tycho, that it fell in

the seventh period of the greatest conjunctions, and on the colure of the vernal equinox, near which the greatest conjunctions take place, as we said in Book 7, Section 5, chapter 9. He adds that it was without parallax, and that it remained in the same state except for its size. The rest is full of the emptiness of astrology and the Cabbala, for which he was in the end expelled from our Society by our holy father Ignatius. On this, and on his death, Father Daniel Bartolus [Daniello Bartoli] says more in volume 1 of the *History of the Society of Jesus*, book 3, from page 371.

[Margin: Opinion of Raimondo.]

XXV. Annibal Raymundus [Annibale Raimondo] of Verona, as Tycho reports (volume 1, page 720), says that this star began to be seen in Italy in 1572, at the beginning of October, and by him on the 5th; and that it was by no means new, but the eleventh of the ancient stars of Cassiopeia. Tycho rebuked him, however, and exposed the occasion of the error: although this new star, to those of sharp sight, appeared distinct from the eleventh from the very beginning, it was more clearly distinguished once it had diminished; so it is not so surprising if, to duller eyes, it was taken at first for the eleventh, to which it was very close. And granted that Hyginus says that in the square of Cassiopeia there are certain stars shining more brightly, those are nevertheless of the 3rd or 4th magnitude, whereas this one surpassed the fixed stars of the first magnitude. Raimondo adds, however, that this star attracted a great quantity of exhalations, by the force of which, and of refraction, it appeared larger than usual. But why, then, do Sirius, Lyra and Arcturus not sometimes do the same? Of almost the same opinion was Cornelius Frangipanus, who thought that this star was the same as the eleventh of Cassiopeia, but that by some violent motion it had migrated two degrees northwards and had increased its light, as Tycho relates from Hájek (volume 1, page 741). He also — from what source I do not know — either invented, or took over the invention, that the Pole Star had hidden itself ever since the capture of Constantinople by the Turks, just as the poets invented of Electra after the burning of Troy.

[Margin: Opinion of Frangipanus.]

[Margin: Opinion of Nolthius.]

XXVI. Andreas Nolthius of Einbeck, in a treatise of eight chapters on this star dedicated to the Landgrave of Hesse, affirms that it was a sublunary comet of the kind that has neither tail, nor beard, nor hair, nor a motion of its own; he holds that a certain kind mentioned by Epigenes in Seneca was of this sort. He adds that it did not keep exactly the same distance from the same fixed stars, but swayed somewhat this way and that because of parallax; and that at an apparent altitude of 12° 21′ he detected a parallax of 39′, which will be discussed separately below. For him the longitude of the star was ♉ 5° 4′, the latitude 54° 48′, the declination 61° 49′, and the right ascension 357° 11′. Further, from that parallax he derives the distance of this star — or, as he himself calls it, this comet — from the Earth as 19, or nearly 20, semidiameters of the Earth, that is, 17,059½ German miles; and since he says that he found its apparent diameter with a

radius to be 10′, he concludes that its true diameter was 46 German miles, and its solidity relative to the Earth as 1 to 50,000. The rest, in which he soothsays astrologically, does not concern us.

[Margin: Opinion of Busch.]

XXVII. Georg Busch, painter and astronomer at once, of Erfurt, published two booklets on this star, which he judged to be a sublunary comet of the species they call the Rose, formed from dry and viscid fumes; he attributes to it a retrograde motion towards Cepheus, and confirms that it was a comet from the fact that it was seen by day at the beginning — as if Venus, which has been seen by day more than once by us and by many others, were therefore sublunary. He sets its longitude at ♉ 6°, and its distance from the Earth at 30 semidiameters of the Earth; and since on 1572 December 12 he assigns it an apparent diameter of 1° 28′, he derives from this and from the distance a true diameter of the head of 664 German miles, and its solidity relative to the Earth as 1 to 18. Later, on February 20, he affirms that this star had moved 2° 20′ away from a small star of Cassiopeia to which it had been close. But what he relates about this motion, and about an apparent size three times greater than the Sun's, runs contrary to the most trustworthy testimonies of very many others, as we have seen.

[Margin: Opinion of Graminaeus [?].]

XXVIII. Theodorus Graminaeus, professor of mathematics at Cologne, contends in a lengthy treatise that this new star was a tailed comet, but with a short and hidden tail, because, while the Sun was passing through ♐ and ♍, the tail was turned away from our sight towards the opposite parts and upwards. But since, turning aside to astrological fictions, he interprets the prophecies of Abbot Joachim and of Lichtembergius [Johannes Lichtenberger] against Luther and his followers, and for this purpose uses Luther's genethliacal theme, constructed long ago by Gaurico and Cardano, Tycho (volume 1, pages 776 and 777) is too much aggrieved that Graminaeus *unjustly and maliciously censures and mocks Luther and his fellow-tribesmen* — these are Tycho's words. Yet he immediately adds: *Nor do I say this because I wish to interpose a judgement on the controversies of religions. Let him judge these who alone knows how to distinguish the true from the false, to search the hearts of all, and to decide all things without prejudice.* But even from this he shows himself suspect of that heresy which denies to the Roman Pontiff infallible judgement in controversies of religion. And where does that iniquity and malice against Luther, charged to Graminaeus, come from, if not from Tycho's excessive affection for Luther? So too on page 712 he commended Philipp Melanchthon far too warmly — a man of the most pestilent doctrines, who bears in his very surname a token of the blackest faith. Io. Heckius, moreover, calls Tycho a Calvinist in his disputation on the new star of the year 1604, page 20; and indeed Tycho (volume 1, page 327) pours himself out excessively in praise of Théodore de Bèze.

[Margin: Tycho suspected [?] of heresy.]

[Margin: Opinion of Adamus Ursinus.]

XXIX. Adamus Ursinus of Nuremberg, in his Prognostication for the year 1574, lists this star among the sublunary comets, the *chrysoi* or golden ones, and says that it surpassed the fixed stars and the planets in size, Venus excepted, at ♉ 6°; but he admits that it kept the same distance from the three more notable stars of Cassiopeia, and had no revolution other than the common one about the pole of the world.

[Margin: Opinion of Andreas Rosa [?].]

XXX. Andreas Rosa Singfurdensis, a physician, in his prognostication, likewise for the year 1574, was in doubt whether he ought to count this star among the Plinian comets, and in the end said that he preferred to call it, with the common people, the New Star. And, on the authority of a certain Elias, a Talmudist, he says that roughly every two thousand years portents of this kind come forth from heaven: something of the kind happened in the first period, at whose end came the Flood, and again at the end of the second period, when the star appeared to the Magi. Of this vanity we shall say more below.

[Margin: Opinion of Antonio Santucci.]

XXXI. Antonio Santucci, mathematician of the University of Pisa, in his book *De Cometis*, chapters 6 and 7, says that this star appeared in 1572, at first of the sixth magnitude, and afterwards grew, so that in March 1573 it equalled Venus and at the end of May had become twice as large as Venus, and remained that large for 3 months; and that it shone so brightly that it cast a shadow from opaque bodies; then that from the end of October it diminished, until in April 1573 it vanished from sight; that it twinkled moderately and always stayed in the same place. How many other authors contradict him on its size, and how greatly, is clear enough from what has been said; but he contends that this star was above the Moon.

[Margin: Opinion of Giovanni Battista Benedetti.]

XXXII. Io. Baptista Benedictus [Giovanni Battista Benedetti], disputing about this star against Annibale Raimondo in a letter that is found among his others (page 371), tries to show that this star was above the Moon.

[Margin: Opinion of Chiaramonti.]

XXXIII. Scipione Chiaramonti, however, in books 1 and 2 of *De tribus novis stellis*, is wholly taken up with refuting the others, who had raised this star above the Moon. We shall weigh his arguments in their place, and report the various distances deduced from various hypotheses in chapter 10, numbers 4, 8 and 9.

XXXIV. Father Giuseppe Biancani (*Sphaera*, book 18, chapters 2 and 5) agrees with Tycho on this star's form, light, twinkling, immobility, place and distance from the Earth; but he thinks it more probable that it became visible by descending towards us, and then invisible by ascending, rather than that it was newly generated and perished.

Anyone who wants the opinions on distance and size gathered together should see chapter 16, to be given below.

CAPVT III.

Chapter 3.

Hiſtoria Obſeruationum Eiuſdem ſtellæ particularium quoad Numeros ac Menſuras.

A history of the particular observations of the same star, as to numbers and measures.

I. Since, for forming a judgement on the place and parallax of this star, a great deal is contributed by a comparison of its distances from the fixed stars, and of its altitudes — especially the meridian altitudes — and its azimuths, which, observed by various astronomers, are found scattered through volume 1 of Tycho's *Progymnasmata*, but collected together in Chiaramonti, book 1 of *De tribus novis stellis*, from chapter 2 to 9 — though in a different form from the one we would wish — we have decided to arrange these observations under definite heads and at the same time to gather them into the synopsis of a single table.

Diſtantiæ Nouæ Stellæ à Fixis obſeruatæ.

Distances of the New Star observed from the fixed stars.

[Margin: Dispute over the rhombus or the trapezium.]

II. First, it should be noted that the New Star, together with the stars of Cassiopeia — the second, called Schedir; the 4th, which is at the flank; and the 12th, which is the bright star of the Chair — formed a rhombus, as Clavius thought, and Paulinus Pridianus, an assertion Clavius calls the common one. Others, however, whom Praetorius leaves unnamed, held that it formed a rhomboid. Still others affirmed that it formed a trapezium, as did Tycho, Johannes Praetorius, Hájek and Philipp Apian — and rightly, if one accepts the distances of the New Star from the already-mentioned stars, together with the distance of the second from the fourth, which for Tycho is 4° 40′, and of the second from the twelfth, which is 4° 59′. For the side opposite this, that is, the distance of the New Star from the fourth, was 5° 2′, and the distance of the New Star from the twelfth, which stood opposite the former side, was 5° 19′.

Secondly, note the disagreement of some observers, expressed without numbers. Cyprián Karásek Lvovický said that the New Star, with its body, fell exactly on that part of the seat on which Cassiopeia's buttocks rest. Digges, by contrast, says that it was always in one and the same line with Cassiopeia's knee and with the star in the right side of Cepheus, below the girdle; and moreover that it lay in another straight line with the stars of Cassiopeia's hair and of Cepheus's left shoulder. Cornelius Gemma, for his part, relates that it was in a straight line with the more conspicuous star in Cassiopeia's loins, the bright star of Perseus (that is, as Tycho interprets it, p. 513, with Medusa's head) and the Pleiades; and likewise in a straight line with the Pole Star and the star in the haunches of Ursa Major.

As for definite distances of the New Star, Tycho reports his own from his earlier writing, *Progymnasmata* volume 1, p. 585. On pp. 593 and 341, however, he admits that they are uncorrected, because at that time he had not taken account of the parallax of the eye, that is, the distance of the pupil from the centre of the instrument, and had not arranged the sighting through parallel slits in the pinnules, but through holes. He therefore corrected them afterwards, as is plain from p. 342 itself, and gives the distances so corrected on pp. 344, 508, 554, 558 and 566. He also reports distances taken by Hájek, p. 508, but corrected by the same Hájek, p. 509; and those taken by Cornelius Gemma, pp. 554 and 558 — for these differ from the ones the same Gemma afterwards recorded in his *Cosmocritice*. The distances taken by Digges Tycho reports on p. 654, those by Muñoz on p. 566, and those by Camerarius on p. 694; and they are set out below.

[Margin: Distances of Tycho, Hájek, Gemma, Digges, Muñoz, Camerarius.]

Distances of the New Star of the year 1572 observed from the fixed stars, collected from various authors.

Fixed stars from which the New Star was distant	Order among the stars of Cassiopeia	Tycho	Digges	Gemma	Hájek	Muñoz	Camerarius
The middle star of the Chair	11	1° 31′	1° 28′	1° 24′	formerly 1° 24′; later 1° 26′		0° 50′
The bright star of the Chair	12	formerly 5° 21′; corrected 5° 19′	5° 15′	formerly 4° 40′; later 5° 4′	5° 15′	5° 20′	
Schedar	2	formerly 7° 55′; corrected 7° 50½′	7° 45′	formerly 6° 58′; later 7° 24′	7° 47′	7° 50′	
Cassiopeia's flank	4	formerly 5° 1′; corrected 5° 2′	4° 58′	formerly 4° 28′; later 4° 36′	formerly 4° 51′; later 5° 3′	5° 10′	
Cassiopeia's girdle	3	6° 53′		6° 36′	7° 0′		
Cassiopeia's knee-joint	5	8° 3½′	8° 5′				
Cassiopeia's leg	6	9° 48′	9° 45′				
The foot of the Chair	7	12° 58½′					
Cassiopeia's head	1	10° 22′		9° 36′			
The Pole Star		25° 14′		formerly 23° 48′; later 24° 40′	25° 30′		
Capella		42° 28′		42° 4′			
The bright star of Perseus		27° 22′		27° 7′			

Altitudines Meridianæ Stellæ Nouæ obſeruatæ cum Declinationibus inde, & ex Poli Altitudine deriuatis.

Meridian altitudes of the New Star observed, with the declinations derived from them and from the altitude of the pole.

III. It is well known that the declination of a star from the equator is obtained if the star's distance from the pole of the world is subtracted from 90°; and that this distance becomes known either if the altitude of the pole is subtracted from the greatest meridian altitude of the star itself, or if the star's least meridian altitude is subtracted from the altitude of the pole. Understand this of a star always visible toward the north, such as was the New Star we are dealing with here. We shall therefore report the altitudes of the New Star observed in the meridian, which Tycho also reports, with the altitudes of the pole, in volume 1 of the *Progymnasmata*: his own on pp. 347 and 351; Hainzel's on pp. 360 and 536; the Landgrave of Hesse's on pp. 491, 599 and 613; Muñoz's on p. 567; Peucer's on p. 605; Schuler's on p. 621; Camerarius's on p. 693; Georg Busch's on p. 769; Adam Ursinus's on p. 782; and Hájek's on p. 514. Maurolico's altitude, both of the pole and of the star, is reported by Clavius on p. 194 of the *Sphaera*, and Santucci's by Chiaramonti in book 2, p. 339. We shall add the declinations deduced from the already-mentioned elements. In the margin, moreover, the time after noon will be noted, unless the observers are silent about it.

Observers and places	Meridian altitude of the New Star	Northern declination of the New Star	Altitude of the pole
Hainzel at Göggingen, near Augsburg	greatest 76° 34′ 0″	61° 48′ 0″	48° 22′
	greatest 76° 33′ 45″	61° 48′ 15″

Altitudines & Azimutha Stellæ Nouæ Obſeruata.

Altitudes and azimuths of the New Star observed.

IV. Tycho reports, in volume 1, the azimuths and altitudes observed by the Landgrave of Hesse at Kassel, on p. 491; those observed by Nolthius at Einbeck, on p. 754; and those of Hájek at Vienna, on p. 514. But on p. 496 he concludes that the altitude at Kassel of 71° 20′ must be corrected, and 73° 20′ put in its place.

I do not add the longitudes and latitudes, or the right ascensions, deduced from the already-mentioned observations: both because they were not observed directly, and because they were derived as differing values — some from the Alphonsine Tables, others from the Prutenic Tables, Tycho from his own places of the fixed stars. They will, however, be indicated below in their proper places, where needed.

CAPVT IV.

Chapter 4.

An Argumentis Parallaxin non inuoluentibus demonſtratum ſit, Stellam Nouam Anni 1572. fuiſſe ſupra vel infra Lunam.

Whether it has been demonstrated, by arguments not involving parallax, that the New Star of the year 1572 was above or below the Moon.

[Margin: Enumeration of the arguments.]

I. The arguments by which many have tried to show, independently of parallax, that this star was above the Moon, or even in the very sphere of the fixed stars, are six: namely, its twinkling; the intensity of its light or brilliance; the absence of a tail and of hair; its simple revolution with the primum mobile, without any motion of its own; its duration; and its aspect among the same stars — that is, its configuration with them — as seen from the whole of Europe. By contrast, the arguments by which the authors of the opposing opinion contended that it was generated below the Moon, like some meteor, are three: namely, its beginning and ceasing after so short a duration; the decrease of its apparent magnitude; and the variation of its colours. But neither kind of argument is demonstrative, as we shall shortly show.

[Margin: 1st argument: from twinkling.]

II. Aristotle (*De caelo* 2, text 48 or 158), and with him many Peripatetics — especially Philalthaeus on that passage, and Amicus, tract. 5, q. 7, d. 3, as well as Cardano in *De subtilitate* — hold that the cause of the twinkling that appears in the fixed stars is their distance. Our sight, they say, cannot reach that far without some tremor and wavering, and, being deceived, it supposes that its own tremor takes place in the stars themselves; the planets therefore do not twinkle, because they are near. Copernicus valued this sign for distinguishing the fixed stars from the planets so highly that in book 1 of the *Revolutions*, chapter 10, he thought it demonstrated from it that there is a vast distance between the wandering and the non-wandering stars, in these words: *"For that there is still a very great distance from Saturn, the highest of the wanderers, to the sphere of the fixed stars, their twinkling lights show; by this sign they are chiefly distinguished from the planets."*

Since, therefore, the New Star of the year 1572 was seen to twinkle no less than any fixed star — indeed more — it seems necessarily to follow that it was not only above the Moon but also above all the planets. Tycho used this argument not as merely probable but as apodictic and demonstrative, in volume 1 of the *Progymnasmata*, chapter 6, p. 401, saying: *"Moreover, its outstanding twinkling, flashing beyond the other lights of heaven, showed most plainly of all that it had chosen its place within the highest and most vast region of the fixed stars, and had surpassed the circuits of all the planets, not to speak of the lowest, elementary world."* And again on p. 405: *"Without any evasion it must rightly be admitted that this New Star — since by its continual twinkling, persisting as long as it was visible, it not only imitated the fixed stars but even surpassed them, especially at the beginning, by this vibration of its light — was not within those limits of heaven in which the circuits of the seven planets are contained, but stood among the most remote fixed stars."* With the same argument Kepler, in chapter 17, contended that the New Star of the year 1604 was among the fixed stars — using, however, an argument drawn from the Peripatos against the Peripatetics. Reduced to form, then, the argument is this:

[Margin: The argument in form.]

III. *Every star that twinkles as long as it is visible is above the planets, not merely above the Moon. But the New Star of the year 1572 twinkled as long as it was visible. Therefore it was above the planets, not merely above the Moon.*

The reply, however, is to deny the major premise, if it is put forward as necessary and infallible; for if it is put forward as highly probable, it is freely conceded. The reason for denying it is that twinkling, even continual twinkling, is neither an effect necessarily connected with a distance greater than the Moon's, nor an infallible sign of such a distance. For twinkling can arise from some cause other than the star's distance and the tremor of sight, as is clear from what was said on the twinkling of the fixed stars in book 6, chapter 2, number 6 — just as the absence of twinkling is not a necessary sign of nearness, since Tycho himself placed all comets above the Moon, although he knew that most of them shone with a faint light that did not twinkle at all. Chiaramonti adds, in book 2 of *De novis stellis*, chapter 2, that lamps twinkle from far off, and so do some comets — which, however, it has not yet been demonstrated were not sublunary, as we showed in section 1, chapter 22.

[Margin: 2nd argument: from light and colour.]

IV. Nor are the light and colour — in which this star closely resembled the light and colour of the fixed stars, and was far more splendid than any comet or sublunary meteor — a demonstrative argument for so great a distance of this star that it would necessarily have to be placed not only above the Moon but also above all the planets. For although Tycho uses such an argument, in volume 1, p. 401, saying: *"In its clear, pure, radiant light, too, it altogether rivalled the genuine stars of heaven, and had nothing in common with sublunary meteors or with the duller and less brilliant light of comets. Therefore it far surpassed the seats both of meteors and of comets, and so necessarily stood among the fixed stars"*; and a

little later: *"A colour plainly celestial was also in this star, so that it never took on any colour of such a kind that some star in heaven itself, very like it and endowed with the same colour, was not seen; from which it is also entirely consistent that it claimed celestial seats for itself as well"* — nevertheless the inconstancy of its colours, in which it was unlike the fixed stars, and the continual decrease of its light, take much away from that former likeness. Nor is it impossible for a sublunary comet to become so intense that it equals that light and colour; or at least, if this cannot happen by the powers of nature, it can by God working beyond nature. Tycho himself admits that this happened in the star of the Magi, volume 1, p. 399, saying: *"The star that appeared to the Magi, although it went before them in the air not far from the Earth, and was doubtless not unlike the other lights of heaven, was nevertheless a particular portent of God, shown to those Magi by singular grace, and not to be counted among natural things, however miraculous."* Now, that this New Star of the year 1572 was a natural work rather than a preternatural one, Tycho did not demonstrate, nor could anyone demonstrate it. On the contrary, many held, not improbably, that it was among preternatural portents — especially Reisacher, Mästlin, the Landgrave of Hesse, Schuler, Cornelius Gemma, Reinhold, Andreas Rosa, and our own Clavius; and those who said this of all comets would have said the same of this star much more, as we related in section 1, chapter 6, number 12. But if this star was made beyond the order of nature by God, whether by himself or through the Intelligences, it could certainly have had that vivid light and a colour rivalling the stars, however far below the Moon it is supposed to have been. Chiaramonti further adds, in book 2 of *De stellis novis*, chapter 2, that if a greater light showed a greater distance, the Sun would have to be placed above Saturn — which no astronomer would grant.

[Margin: 3rd argument: from shape.]

V. But Tycho will say, volume 1, p. 398: no comet was ever seen that was not either tailed, or bearded, or haired all round — unless perhaps, because of its opposition to the Sun and its immense distance, the appendage of the tail or the partings of the hair could not be discerned. Therefore this star, which in shape was most like the other fixed stars, and was neither rayed with any curls of hair nor imitated comets by any train of a tail or growth of a beard, either was not a comet, or, if it was, nevertheless concealed these features because of its almost immense distance from the Earth. And so that you may see with what lavish mouth Tycho bursts out into words of necessity where there is mere probability, here are his own words from volume 1 of the *Progymnasmata*, p. 398: *"Its very face and august form, most like the other stars shining in the world, plainly proved that this star had nothing in common with elementary and sublunary meteors."* But here too I flatly deny that this argument plainly proves this star to have been above the Moon. For if it was produced by divine agency, it could have been below the Moon and yet lacked all projection of rays and been perfectly round. Nor does it necessarily follow that, if it was not a comet, it was something above the Moon. Though I say this, I do not, however, reject

the probability of Tycho's argument. Chiaramonti too, in book 2 of *De tribus novis stellis*, chapter 2, denies that this argument is conclusive, because both perfectly round comets and new sublunary stars, likewise round, can exist — or at any rate are not shown to be impossible.

[Margin: 4th argument: from the common motion and the star's own immobility.]

VI. Perhaps greater weight seems to attach to the argument from the lack of a proper motion — that is, from this star's immobility, together with its revolution with the primum mobile. For in most observations it was always seen to keep the same distance from the same fixed stars, and to revolve with those fixed stars about the pole of the world only by the common revolution of 24 hours. For that reason Tycho said, in volume 1, p. 405: *"Its immobility, by which it stayed perpetually in the same place of the heavens like the rest of the fixed stars, gave sufficient testimony that it also held that seat in common with them"*; and on p. 406: *"That the New Star also complied so exactly with the universal motion — so that it expressed it most perfectly, and neither ran counter to it nor slackened, as happens in the planets and comets except when they appear stationary — proves that, observing the daily revolution as well so firmly and so scrupulously, it must be raised beyond all these, right up to the fixed stars."* And on p. 443, having said that this star did not vary its distance from the fixed stars during the whole time of its duration, he adds: *"And therefore it was placed altogether above the orbs of all the planets, within the sphere of those same fixed stars — which is what we undertook to set out and demonstrate."* Do you see how here too he reckons this argument convincing? Nor was Tycho alone: our own Clavius, too, in his *Sphere*, p. 193, was of the same opinion, for he says: *"Now, I am led to believe that that new star existed in the firmament, and not in any other celestial orb, chiefly by this argument: that neither I nor any astronomer at all (so far as I know) noticed any other motion in it besides the one we observe in the fixed stars. For it kept an ever constant motion, and plainly the same position among the other fixed stars, for almost two whole years. If it had been in the orb of some planet, then, since that orb certainly has a motion different from that of the fixed stars, the star itself would without doubt have had the same motion and course; but the astronomers found the matter to be otherwise. And this same argument evidently concludes that much less did that star exist in the elementary region, since there it could in no way have kept always the same position and distance with respect to the fixed stars. Since this is so, I am convinced* [?] *that that star was created at that very time by God, Best and Greatest, in the eighth heaven, to portend something great."* Biancani too, in book 18 of his *Sphaera*, chapter 2, judged this argument evident, as did Hájek in Tycho, volume 1, p. 513. Since, then, not probability alone — which we freely acknowledge in it — but also necessity and evidence are held by Tycho, Clavius and others to be present in this argument, it must be sharpened into syllogistic form, so that we may reply to it more closely, in this way:

[Margin: The 4th argument in form.]

VII. *Every star that has no apparent motion other than the motion of the fixed stars is in the heaven of the fixed stars. But the New Star of the year 1572 had no apparent motion other than the motion of the fixed stars. Therefore it was in the heaven of the fixed stars.* The major seems manifest from an induction made over all the phenomena that have, or ever had, the appearance of stars; the minor is established from the observation of almost all the astronomers and observers we reviewed in chapter 2. I said "every star", however, and not "every moving thing", since otherwise the Peripatetics, with Chiaramonti in book 2 of *De novis stellis*, chapter 2, would say that the air too is below the Moon and yet is moved with the motion of the primum mobile.

[Margin: 1st reply: distinguishing the major.]

I reply, first, by distinguishing the major premise. I concede it of stars that are already established to be ordinary stars, about which the only doubt is whether they are planets or fixed stars, and of whose nil or slight parallax we are certain from their having the same distance from the same fixed stars, observed at the same moment in several parts of the Earth, any parts whatever. But I deny the major premise of extraordinary stars, of disputed nature and origin, of whose parallax we are uncertain, or about which nothing is yet established — which is how we are using this argument here, in keeping with the title of this chapter: with all mention of parallax set aside for the time being. For insofar as this argument is connected with parallax, it will be examined separately below, and it will be shown not to be an evident argument if the already mentioned equality of distance from the same fixed stars was observed in a single place on Earth, or in different places but not at the same moment of time. In the sense, moreover, in which the major was conceded, the minor can be denied, because in that sense it has not been demonstrated by any of the astronomers.

[Margin: 2nd reply: denying the minor.]

I reply, second, by denying the minor — not only because Nolthius, Busch, Lvovický, Camerarius, Peucer, Schuler and Raymundus observed some variation in its distance from the same fixed stars, or some proper motion, as we related in chapter 2, but also because from its daily decrease an upward motion is inferred — not with certainty, indeed, yet not improbably — in the way it is inferred in the planets, especially in Mars and Venus, in which a marked decrease of the apparent diameter is a physically evident argument of recession from the Earth. It could therefore have happened that for five days at least it was below the Moon, and afterwards, ascending gradually above the Moon, finally vanished; for Cornelius Gemma and Biancani gave this as the cause of its disappearance. From this, then, arises an argument that could be turned back in the following way, and it will serve as an indirect reply.

[Margin: 3rd reply: turning the argument back.]

I reply, third, by turning a similar argument — that is, one taken from motion — back against the opponents, in this way. Every star that is above the Moon either lacks motion upward and downward, as the fixed stars do; or, if it has such motion, it also has a proper motion in longitude, as the planets have. But

the star of the year 1572 had upward motion and did not have a proper motion in longitude. Therefore it was neither among the fixed stars nor among the planets; that is, it was not above the Moon. And just as the opponents will say that this argument is not valid, because its major premise rests on an induction made over ordinary stars, so the same can be said of the major premise of the argument formed by them, or in their person, at the beginning of this number 7.

[Margin: 5th argument.]

VIII. Then there is the argument from its duration of a year and a half, by which Tycho, in volume 1, p. 407, confirms that this star was not a comet, nor any sublunary meteor, because no comet has lasted beyond 6 months. But not even Tycho himself regarded such an argument as demonstrative, since he says only that from so long a duration it is consistent that it was above all comets. And indeed, if some comet shone over Jerusalem for a whole year — whether it was a natural or a preternatural portent, as we related in section 1, chapter 4 — why could this star not have lasted a year and some months and yet have been below the Moon, without needing fuel on that account, being formed and preserved by God in another way? Chiaramonti, on the other hand, in book 2, chapter 2, of his work on these new stars, thinks this argument can be turned back against Tycho, saying: whatever is in the heavens is either perpetual or long-lasting; this star was neither; therefore it was not in the heavens. But the very probable rising and perishing of the solar spots and faculae cuts the strength and sinews of this argument of Chiaramonti's.

[Margin: 6th argument: from the distance of the observers from one another.]

IX. The last argument, taken from the fact that this star was seen on the same nights throughout Europe, is of little force unless something is added that bears on parallax. For we have shown in the first section of this book, chapter 15, that the same phenomenon can be seen at the same time not only throughout Europe but even from parts of the Earth much more remote from one another, even if it is below the Moon. Moreover, the argument itself is worth nothing unless it is shown that the New Star was observed in different parts of the Earth on the same day, or on the same night and at the same moment of the hour. But that cannot be shown from the historical record, as is clear from what was said in chapter 3, and more evidently from what will be said in chapter 6, toward the end of number 7. The configuration of the New Star with the fixed stars of Cassiopeia is also given differently by different authors, as I said in chapter 3, number 2.

[Margin: Is this star shown to be below the Moon?]

X. But neither has anyone demonstrated that this star was below the Moon on the grounds that it diminished until it vanished completely, or lasted only a short time, or changed its colours. For the solar spots and faculae are above the Moon and very close to the Sun, and yet they arise and perish and do not last long, as we taught in book 3, chapter 3; and the planets themselves change

colour according to the variation of the air and of the vapours running beneath them, and render their light to us now vivid, now dull and faint. Indeed, speaking universally, the dissolution of a superlunary body is not manifestly impossible.

CAPVT V.

Chapter 5.

Qua ratione Tycho demonſtrare conatus ſit, ex Parallaxis defectu Stellam Anni 1572. fuiſſe ſupra Lunam, immò ſupra Solem, ac Saturnum.

By what reasoning Tycho tried to demonstrate, from the absence of parallax, that the star of the year 1572 was above the Moon — indeed, above the Sun and Saturn.

I. In volume 1 of the *Progymnasmata*, chapter 6, in the second proof (found on p. 412), Tycho professes that from the nil or barely perceptible parallax of this star he will demonstrate its elevation not only above the Moon but also above the orbs of the planets, and will leave the Peripatetics *dumb and stupefied, not knowing where to turn.* To make his arguments clearer, let the centre of the Earth in the following figure be C. From it describe the Earth's quadrant AB, beneath the quadrant of the meridian VR, and beneath that let there be the quadrant HLN, in which the New Star was. Let the pole of the world be P, and let the zenith of the observer B be V. Now let the star be placed at L at the lowest of its meridian altitudes, and at M at the highest; through these two places let the lines of the true place, CLG and CME, be drawn from the centre of the Earth, and the lines of the apparent place, BLK and BMD, from the centre of the eye B. Let the line KLB be produced to O, until the perpendicular CO from the Earth's centre falls on it; likewise let the perpendicular CF fall on DMB produced to F. And let the Earth's semidiameter BC be, following Tycho, 860 German miles; but for the sake of a more precise investigation let it be reduced to 10,000,000 parts of the radius. On these assumptions he proceeds as follows, from p. 419.

Diagram. A geometric figure set in the left column beside the text. Three concentric quarter-circles stand about the Earth's centre C: the outer arc, the quadrant of the meridian, runs from V at the top to R at the lower right; a middle arc, the quadrant on which the New Star stands, runs from H through M and L to N; a small arc, the Earth's quadrant, runs from B down to A. A horizontal base line runs from F through C, A and N to R, and a vertical line rises from C through B and H to V. Star-marks stand at S, I, Q and T on the outer arc and at M and L on the middle arc. Straight lines run from C and from B through M and L out to the outer arc, and down to O and F near the base. All twenty labels are legible.

- V (top of the outer arc): the observer's zenith
- S (outer arc, beside V): the head of Cassiopeia at its greatest altitude

- E (outer arc): true place of the star at M
- D (outer arc): apparent place of the star at M
- I (outer arc, star-mark): the Pole Star at its least altitude
- P (outer arc): the pole of the world
- Q (outer arc, star-mark): the Pole Star at its greatest altitude
- G (outer arc): true place of the star at L
- K (outer arc): apparent place of the star at L
- T (outer arc, star-mark): the head of Cassiopeia at its least altitude
- R (lower right end of the outer arc)
- N (base line, foot of the middle arc)
- A (base line, foot of the small arc)
- C (base line): the centre of the Earth
- F (base line, left of C): foot of the perpendicular CF
- O (left, above F): foot of the perpendicular CO
- B (vertical line, top of the small arc): the observer's eye
- H (vertical line, top of the middle arc)
- M (middle arc, star-mark): the New Star at its greatest meridian altitude
- L (middle arc, star-mark): the New Star at its least meridian altitude

[Margin: 1st step.]

II. *First*, in the triangle BCO, right-angled at O, BC is given as 10,000,000 parts, and the angle OBC as 62° 15′, since it is equal to the vertically opposite angle HBL — namely the complement of the apparent lowest meridian altitude, the altitude Tycho affirms he observed in the New Star while he was at Herrevad, 27° 45′. Therefore, by the practice of triangles, the side CO is found geometrically to be 8,849,876 of the parts of which BC was taken as 10,000,000.

[Margin: 2nd step.]

Second, in the triangle CLO, right-angled at O, let the distance CL of the Moon at perigee from the centre of the Earth be taken from Copernicus as 52 17′ semidiameters of the Earth, or at least 52, of which BC is one — that is, 520,000,000 of the parts of which BC is 10,000,000. Since, then, CO is 8,849,876 of those parts, it follows by the analysis of triangles that the parallax, or the angle CLO, is 58′ 31″: the parallax the New Star would have had at its apparent altitude NL above the horizon, 27° 45′, if it had been distant from the Earth's centre by 52 semidiameters of the Earth.

[Margin: 3rd step.]

Third, in the triangle CBF, right-angled at F, CB is given as above as 10,000,000 parts, and the angle CBF as 5° 49′, since it is the complement of the highest of the meridian altitudes observed in the New Star, namely 84° 11′. Therefore, by trigonometry, the side CF is 1,016,351 parts.

[Margin: 4th step.]

Fourth, in the triangle CMF, right-angled at F, the side CF, 1,016,351, is given, and the distance CM, equal to the Moon's, 520,000,000, as above; therefore the parallactic angle CMF is found to be 6′ 43″.

[Margin: 5th step.]

Fifth, let the Pole Star be now at I, now at Q, equally distant in both places from the pole of the world P, at its least and its greatest altitude; or let the head of Cassiopeia be now at S, holding its greatest meridian altitude, now at T, holding its least, but equally distant in both places from the pole of the world P. For it was chiefly from these stars that Tycho took the distance of the New Star, at the meridian altitudes. On these assumptions it follows that the new star, placed at M, at its greatest altitude, was seen from the eye B under the point or apparent place D, granted that its true place would have been under E had it been seen from C. Hence the true distance of the new star in the heaven of the fixed stars from the Pole Star at I was EI, and the apparent DI; but from the head of Cassiopeia at S the apparent distance was DS and the true ES. Likewise, while the new star was at L but seen under K, its true place being under G, its apparent distance from the Pole Star at Q would be KQ, greater than the apparent DI, and the true GQ; but from the head of Cassiopeia, now revolved to T, the apparent distance would be KT, less than DS, and the true GT. Now the parallax, or the difference between the true and the apparent place, would have brought the New Star at L apparently closer to the head of Cassiopeia at T by the amount of the acute angle L, that is 58′ 31″, as is clear from the 2nd step, and would have moved it away from the Pole Star at Q by just as much, if the New Star had been distant from the Earth's centre by 52 semidiameters of the Earth. Conversely, the parallax would have moved the New Star at M away from S, and brought it closer to the Pole Star at I, by the amount of the acute angle M, which by the 4th step was found to be 6′ 43″. Therefore, combining these parallaxes — one producing an apparent approach, the other an apparent recession — the difference between the New Star's apparent distances from the same fixed star would have been 65′ 14″. Such a difference would surely have been noticed with the naked eye, let alone with any instrument, however coarse; and yet no distance — or a barely perceptible one — was observed in the New Star from the same fixed stars, namely from the Pole Star when it was at its greatest and when at its least altitude, just as none was observed from the stars of Cassiopeia. It cannot therefore be admitted, with the observations preserved, that the New Star was so near the Earth as to be distant from the Earth's centre by only 52 semidiameters of the Earth, which is roughly the Moon's perigee distance on Copernicus's hypothesis; and much less could it have been distant by only 33 Ptolemaic semidiameters. Therefore the New Star was above the Moon at perigee.

Comprobatio Tychonica Stellæ Nouæ ſupra Solem & Saturnum.

Tycho's proof that the New Star was above the Sun and Saturn.

[Margin: The New Star above the Sun.]

III. By exactly the same method Tycho tried, in volume 1, from p. 423, to show that the New Star was above the Sun at apogee, taking its distance from the centre of the Earth as 1182 semidiameters of the Earth — the amount he had gathered from his observations set out in chapter 3 — that is, 11,820,000,000 of the parts of which the Earth's semidiameter is 10,000,000. For in the triangle LOC (on which see number 2, in the 2nd step), with CO found, as there, to be 8,849,876 parts, and CL taken as 11,820,000,000, the parallax CLB is found to be 2′ 34″. And in the triangle CFM (on which see the 4th step), with CF found, as in the same place, to be 1,016,351, and CM taken as 11,820,000,000 parts, the parallactic angle CMB is found by trigonometry to be 0′ 18″. Hence the sum of the parallaxes is 2′ 52″. So great, then, would the difference have been between the New Star's apparent distances from the same fixed star — say from the Pole Star — when the New Star was, together with the Pole Star, at the greatest and when at the least of its meridian altitudes. But with the instrument no difference of even a single minute was observed between the two distances already mentioned; and yet the instrument, namely the sextant, as Tycho relates in chapter 4, had its degrees subdivided into single minutes.

[Margin: The New Star above Saturn.]

IV. In the same way Tycho, in volume 1, p. 425, takes from Copernicus, book 5, chapter 9, the distance of Saturn at apogee from the Sun as 11,077 semidiameters of the Earth, and from the centre of the Earth as 12,220; indeed, so as to raise the new star somewhat above Saturn, he takes the distance of the New Star as 12,300 semidiameters of the Earth. Using the remaining data, given or found, on which see number 2, he finds by the practice of triangles the parallax CLB to be 14″ and CMB 2″, whose sum is 16″. So great a difference, he says, would have appeared between the distances of the New Star from the same fixed star observed at both of the New Star's meridian altitudes, the greatest and the least, if it had been distant from the Earth's centre by only 12,300 semidiameters; but not even so tiny a dif- ference appeared. Therefore the New Star was higher than Saturn.

[Margin: A fourfold objection against Tycho.]

V. Tycho foresaw, however, that four objections could be raised against him. First, the division of the sextant, which either was not made with the utmost exactness, or at least could not show either single minutes with certainty and evidence, or a difference of 16″. Second, the width of the pinnules, which — even if the sextant, by reason of its division, had shown single seconds, let alone first minutes — did not allow an exact alignment on the centre of the star without an uncertainty of one minute, or at least of 16″. Third, that the New Star did not cross the meridian at the same moment as the Pole Star, or the other stars from which the distances were taken, crossed it — as would be required if the demonstration, and the diagram used in number 2, are to hold. The fourth is that he himself did not observe the New Star's greatest altitudes, but only its least.

[Margin: But resolved by Tycho.]

Tycho meets the first, however, by asserting that the angle of the sextant at which the New Star's distance from some fixed star had been taken at its least altitude was kept unchanged and fastened with screws, and that this same angle was applied to measuring the interval between the New Star and the same fixed star when the New Star was at its greatest altitude, and that by it exactly the same distance was found at both altitudes. Hence, even if the instrument had been faulty in the small minutes, its fault would have done no harm, since the angle was the same and remained so at both altitudes of the star. Indeed, even if it had had no divisions at all, it would have served the purpose in question: for there is no need to know by how many degrees and minutes the New Star was distant from some fixed star; it is enough to know that the distance appeared equal in every position of the new star. So Tycho, volume 1, pp. 347 and 425.

[Margin: Solution of the [?] objection.]

There he also resolves the second objection. For since each of the two pinnules was of the same width and fixed perpendicular to the plane of the sextant, and straight lines had been drawn through their middle from the same centre of the instrument, to which the eye was applied, those lines passed through the centres of the stars and cut the stars' apparent disc in two, so that through the edges of the pinnules an equal portion of the star was seen on either side — especially in the New Star, because of its size. Therefore, if there had been a difference of 16″ between the apparent distances, it would have appeared, notwithstanding the width of the pinnules. Tycho sets out the use and the form of this sextant in volume 1, from p. 336 to 350.

[Margin: Solution of the 3rd objection.]

He resolves the third objection from p. 426 to 436, showing, from the declinations and right ascensions of the New Star and of the stars from which it was observed to be distant, that if the New Star had been as far from the Earth as the Moon at perigee or the Sun at apogee, the difference between the distances at the New Star's two altitudes from stars standing off the meridian would have been much greater than the one detected with the same unchanged instrument. How he shows this we shall explain in the Scholia to this chapter, so as not to break the thread of this discussion — although, for those expert in observations, it would be enough that some of the fixed stars Tycho used crossed the meridian very nearly together with the New Star: especially the Pole Star, and the eleventh and twelfth stars of Cassiopeia, namely the one in the upright of the seat and the bright star of the Chair.

[Margin: Solution of the 4th objection.]

The fourth objection Tycho himself set out, by his own admission, in volume 1, p. 347, saying: *"Although I also took pains to measure the altitudes of the new star at the same time, especially the meridian ones, no suitable quadrant or other instrument properly assigned to this task was at hand, by means of which I might attain this with sufficient precision."* For he was a guest at Herrevad, not at Uraniborg. *"I therefore used this very instrument* — that is, the sextant — *to determine its nearest altitude, when it was placed on the meridian below the pole; for the highest, when it*

was approaching the zenith, I could not take with this instrument because of the star's excessive altitude, since it stood back only 6 degrees from the zenith overhead, and the greatest arc I had fitted to the instrument filled only a sixth part of a circle." But although he could not then take the greatest altitudes himself, he nevertheless used the altitudes taken at Augsburg — or at a place half a German mile from Augsburg toward the south-west, namely Göggingen — by Paul Hainzel, burgomaster of Augsburg, with a very large quadrant, which had a radius of 14 cubits; he describes it from p. 355 to 359, and Tycho himself was the author and director of its construction. He therefore uses the observations made with it by Hainzel as though they were his own. So, comparing the New Star's distances from the pole at both altitudes with the altitude of the pole at Göggingen, taken by Hainzel from the Pole Star, and with the star's least altitude taken by himself, Tycho found what greatest altitude the New Star ought to have had at Herrevad — and this by a method to be set out shortly.

De Altitudinibus Meridianis ſtellæ Nouæ Herritzuadij & Geggingæ obſeruatis; eiuſque Declinatione.

On the meridian altitudes of the New Star observed at Herrevad and Göggingen, and on its declination.

[Margin: The least altitude and the apparent declination of the New Star.]

VI. Tycho himself often observed the New Star's least meridian altitude at Herrevad, with the sextant set in the plane of the meridian, and on p. 351 gives it as established. It appeared to him as 27° 45′. Since the altitude of the pole at Herrevad was observed by the same man to be 55° 58′, subtracting 27° 45′ from it leaves the New Star's distance from the pole of the world, or the complement of its declination, as 28° 13′; and so its apparent declination was 61° 47′, as Tycho has in the same place. Paul Hainzel, for his part, as Tycho relates in volume 1, p. 361, observed with that very large quadrant at Göggingen the greatest and least altitudes on the meridian both of the Pole Star and of eight other stars belonging to Ursa Major, Cepheus and Cassiopeia. From half the difference of these altitudes, added to the least altitude, Tycho finds the altitude of the pole at Göggingen to be 48° 22′; and he confirms that those observations were well made from the distances of the Pole Star from the pole of the world taken afterwards by himself at Uraniborg with his largest instruments. The same Hainzel also observed in the same place, with the same quadrant, the meridian altitudes of the New Star, which I reported in chapter 3, number 3. From all of these, once delimited, Tycho on p. 360 derives the New Star's greatest elevation as 76° 34½′ and its least as 20° 9½′. Their difference is 56° 25′, and half the difference 28° 12½′, which, added to the least altitude, gives the altitude of the pole at Göggingen as 48° 22′ — exactly as it had been found from the altitudes of the circumpolar fixed stars. From this it follows, then, that the New Star kept the same apparent distance from the pole of the world at both its greatest and its least meridian altitude. Since, therefore, it was observed

at Herrevad to be 28° 13′ from the pole of the world at its least altitude, if this distance is added to the altitude of the pole at Herrevad, which is 55° 58′, the New Star's greatest meridian altitude at Herrevad comes out as 84° 11′. And so the 4th objection stands resolved; and at the same time it seems to have been shown that the New Star had no greater parallax than the fixed stars, since through both of its meridian altitudes it gave exactly the same altitude of the pole as the meridian altitudes of the fixed stars gave. This is Tycho's 3rd proof, which, however, I prefer to set out separately, together with Tycho.

Comprobatio Tychonica Stellæ Nouæ ſupra Saturnum ex Maxima & Minima ipſius Altitudine in Meridiano.

Tycho's proof that the New Star was above Saturn, from its greatest and least altitude on the meridian.

VII. Tycho uses this proof in volume 1, p. 443 and following, and his demonstration and method are exactly the same as the one he used when working with the New Star's distances from the fixed stars, as described in numbers 2 and 3. For what was said there of the distance from the fixed stars is said here of the distance from the pole of the world. Let the figure of number 1, therefore, be repeated here, and in it let there be, as we said, the pole of the world P, and the New Star now at L, having its least altitude above the horizon, now at M, having its greatest. For when placed at L it was seen under K, but was truly under G; and when placed at M it was seen under D, although it was truly under E. Hence the parallax L moved it away from the pole, whereas the parallax M brought it closer to the pole; the sum of the parallaxes M and L, therefore, was the difference between the New Star's apparent distances from the pole of the world. This difference was not sensi- ble, as was said at the end of number 6, since through them the same altitude of the pole was found as through the fixed stars. But if the New Star had been where the Moon is at perigee, or the Sun at apogee, or Saturn, Tycho tries to show that this distance from the pole of the world would have come out sensibly different. For this he assumes the following.

[Margin: Step 1.]

First, the New Star's greatest altitude observed by Hainzel, 76° 34½′; hence the angle HBM, that is CBF, is 13° 25½′. Therefore in the triangle CBF, right-angled at F, he finds the side CF to be 2,323,138 of the parts of which BC is 10,000,000. Likewise in the triangle CBO, right-angled at O, from the complement of the New Star's least altitude, HBL, that is CBO, 69° 50½′, he finds the side CO to be 9387,438 of the parts of which BC is 10,000,000.

Diagram. The figure of number 1 repeated, set in the left column at the right of the narrow lines. Three concentric quarter-circles stand about the Earth's centre C: the outer arc runs from V at the top to R at the lower right; a middle arc runs from H through M and L to N; a small inner arc runs from B down to A. A base line runs through F, C, A, N and R, and a vertical line rises

from C through B and H to V. Star-marks stand at S, I, Q and T on the outer arc and at M and L on the middle arc; E, D, P, G and K stand on or beside the outer arc. Straight lines run from B and C through M and L out to the outer arc, and O stands to the left of B. All twenty labels are legible.

- V (top of the vertical line)
- S, E, D, I, P, Q, G, K, T (along the outer arc)
- H (left end of the middle arc); M, L (star-marks on the middle arc); N (lower end of the middle arc)
- B (on the vertical, top of the inner arc); A (lower end of the inner arc)
- O (left of B); F (lower left, on the base line); C (centre); R (right end of the base line)

[Margin: Step 2.]

Second, he assumes from Copernicus, as above, the distance of the Moon at perigee, CL and CM, as 52 semidiameters of the Earth, that is 520,000,000 of the parts of which BC is 10,000,000; and by trigonometry he finds the parallaxes, at L 1° 2′ 4″, and at M 0° 15′ 21″, whose sum is 1° 17′ 25″. So great, then, would the difference have been between the New Star's distances from the pole, or between the altitudes of the pole derived from the New Star's greatest and least altitude, if the New Star had been where the Moon is at perigee — that is, if it had stood no more than 52 semidiameters of the Earth from the Earth.

[Margin: Step 3.]

Third, keeping all the data and results above, but changing the distance CL and CM from the lunar to the solar, and taking it as 1182 semidiameters of the Earth, he finds the parallax at L 2′ 43″ and the parallax at M 41″, and so the sum of the parallaxes 3′ 24″. That is how great the difference would have been between the New Star's distances from the pole of the world, or between the altitudes of the pole taken through its meridian altitudes, if the new star had been where the Sun is at apogee, or had stood no more than 1182 semidiameters of the Earth from the Earth's centre. Since, therefore, no difference was observed between them — and yet it would have been observable with an instrument as large as Hainzel's quadrant, which showed not only single minutes but even some seconds, if any had actually been there — it follows, says Tycho on p. 450, that the New Star was above the Moon and the Sun.

Per obſeruationes quaſdam in diuerſis Horizontibus ab alijs obſeruatoribus factas, Diſtantiam Stellæ Nouæ à terra, Lunari maiorem Tychonicè confirmare.

To confirm, in Tycho's manner, from certain observations made by other observers under different horizons, that the New Star's distance from the Earth was greater than the Moon's.

[Margin: Part 1 of the proof.]

VIII. This is Tycho's 4th proof, which he gives in volume 1 from p. 451 onward, and it runs as follows. If the New Star had been in the concave of the lunar heaven, that is, 52 semidiameters of the Earth from the Earth's centre, its parallax at the least altitude observed at Herrevad would have been 58′ 31″, and at the greatest altitude 6′ 43″, as was shown in number 2, steps 2 and 4. But at the least altitude observed at Göggingen the parallax would have been 62′ 4″, and at the greatest 15′ 21″, as was shown in number 7, step 2. Therefore the difference between the parallaxes of the greatest altitude at the two places would have been 8′ 38″, and between the parallaxes of the least altitude 3′ 30″. So great, then, would the apparent difference have been between the New Star's distances from the pole of the world as observed at Herrevad and at Göggingen; and yet scarcely half a minute was found. Therefore the New Star was not below the Moon.

[Margin: Part 2 of the proof.]

By a similar method Tycho, on p. 455, takes the New Star's greatest meridian altitude, 67° 30′, observed at Valencia in Spain by Hieronymus Munosius [Jerónimo Muñoz], and the Moon's distance of 52 semidiameters, and by the problem set out in number 2 finds a parallax of 25′ 18″; and from the least altitude, 11½°, observed in the same place, he derives with Muñoz a parallax of 64′ 47″. Hence the difference between the parallaxes of the greatest altitude as observed at Herrevad and at Valencia would have been 18′ 35″, and of the least altitude 6′ 16″. So great a difference in the New Star's distance from the pole of the world ought, then, to have been observed at one place or the other; yet by no means was even 6′ observed, let alone 18′. For Muñoz observed its distance from Schedar in Cassiopeia, with which the New Star crossed the meridian very nearly together, as 7° 50′, and Tycho as 7° 50½′; from which Tycho concludes that Muñoz does not differ from him in the New Star's distance from the pole by more than half a minute.

An Tycho putarit à ſe Demonſtratum Nouam ſtellam fuiſſe ſupra ☾ ☉ & ♄.

Whether Tycho thought he had demonstrated that the New Star was above the Moon ☾, the Sun ☉ and Saturn ♄.

[Margin: On the star above the Moon and the Sun.]

IX. If we are speaking of the New Star's place above the Moon, or even above the Sun, there is no doubt that Tycho thought he had demonstrated it with the greatest certainty. For in volume 1, chapter 6, p. 396, he says: *"Relying, therefore, on these aids, etc., we shall undertake to investigate the situation of this star with respect to the diameter of the universe, to show it by undoubted proofs, and to convince beyond all suspicion of error."* And on p. 422: *"It can therefore by no means be admitted that this star stood just within the bounds of the lunar revolutions, and much less in a place still nearer the Earth. This we have set out to demonstrate by this first induction."* Indeed, on p. 434: *"Therefore it is plain here too that this New*

Star must be set still higher above the Earth than the summit of the solar revolutions reaches, and consequently it will occupy a place far less in the space lying between the two luminaries. This we have striven to conclude demonstratively in this way, and no otherwise than before." And on p. 450: *"This star, therefore, by no means found its place just below the lunar revolutions, and much less in some region still nearer the Earth. This we undertook to show from the star's meridian altitudes alone."*

[Margin: On the star above Saturn.]

But if we speak of the New Star's distance above Saturn, Tycho is hardly consistent with himself, and seems to contradict himself within a few lines. For on p. 426 he says: *"It is fitting, therefore, and more probable — if we are to rest here on slender bounds — that the star itself passed beyond the sphere of Saturn, remote as it is."* And on p. 442: *"Hence, not even on this reasoning of ours concerning the nature and circuit of the heavenly bodies could this New Star have lingered at the bounds of Saturn, nor yet within the limits of the other planets — as we wished to infer, with probability, in this way."* And on p. 450: *"But since this does not furnish a sufficiently evident indication"* — where he speaks of the New Star's situation above Saturn; and he says similar things on p. 458.

[Margin: Tycho's inconsistency with himself.]

Notwithstanding all this, however, he steps beyond the limits of probability and does not hesitate, on those same pages, to assert the New Star's place in the sphere of the fixed stars above Saturn as something he has demonstrated. For on p. 426 he says: *"We conclude, therefore, since the star could not obtain any place — not in the elementary world below the Moon, nor from there up to the Sun, nor indeed from there up to the highest summits of Saturn — that would not be overturned when weighed by geometrical observations, that it necessarily follows that it claimed for itself a seat in the outermost eighth sphere of all, among the other fixed stars, above the revolutions of the secondary movables; and this we have set out to make plain and demonstrate by this second proof."* So on p. 451: *"It necessarily follows that it stood unmoved beside the highest lights of the eighth sphere, as we set out to establish by this third proof, from its revolutions about the pole."* Finally on p. 458: *"And so, since we have now confirmed by four invincible proofs that this New Star not only had no commerce with the elementary world, but did not even find a place within the vast revolutions of the seven wandering stars — its total lack of parallax bearing witness to this very fact — we shall conclude that it must necessarily be raised to the highest theatres of the fixed stars, where, like them, it stood unmoved."*

X. So far, then, Tycho works from his own observations, or from his own compared with those of Hainzel and Muñoz; after these, in chapter 7, he goes on to investigate the true magnitude of this New Star. But we shall speak more conveniently of the magnitude of this and of the other New Stars together in chapter 18.

SCHOLIA.

Scholia.

[Margin: From Tycho, volume 1, p. 428.]

I. In number 5 of the preceding chapter, in the solution of the 3rd objection, we promised to show the method by which Tycho, from the right ascensions of the New Star and of certain fixed stars, and also from their declinations, investigated the distances from those same fixed stars that would have been seen, at each of the New Star's meridian altitudes, if the New Star had been where the Moon is at perigee or where the Sun is at apogee — so that the difference from the observed distances might be established from them. To do this, Tycho's diagram must first be set out. Let, then, the meridian be AHQR, the horizon HYR, the eastern semicircle of the equator ÆYQ and the western ÆZQ. Let the pole of the world be A, and let the New Star at its greatest altitude be at B, and at its least at C. Nearest to it at its two altitudes, let there be, first, the Pole Star, at D and at E; then the eleventh star of Cassiopeia, the one that shines in the upright of the seat, now [?] at a, now at ε (but note that through the engraver's error this star is placed on the 2nd circle, AGV, and not, as it should have been, on the third) — the star to which the New Star stood closest; the bright star of the Chair, with which the New Star crossed the meridian very nearly together, at F and G; the head of Cassiopeia at L and S; the breast at K and I; the girdle at M and P; and finally the bend of Cassiopeia at N and O. Through these stars, placed in each of the two positions, let single quadrants be drawn from the pole of the world to the equator — namely AFT, AGV, ANX, AOZ, and so on — and let each star be joined by arcs of great circles to the New Star, placed now at B and now at C; although, to avoid confusion, only three are joined in the diagram: the Pole Star, by the arcs BD and CE; the eleventh of Cassiopeia, by the arcs Ba and Cε; and the bright star of the Chair, by the arcs BF and CG.

Diagram. Tycho's diagram, set in the left column. A large circle stands for the meridian, with A at the upper right, H at the left, R at the right and Q at the lower right. A horizon line runs from H through Y to R, and two arcs run from Æ at the left to Q, one through Y and one through Z. From A a fan of quadrants sweeps down and to the left across the figure to the arcs. Star-marks stand at B at the top, with D to its right, at F and at a below B, at L, K, M and N in a row in the upper left, at E and C on the right with ε below C, and at O, P, I, G and S in the lower right. T stands at the left beside Æ, with three small dots along the arc beyond it. One letter, on the left arc below the row L K M N, is not certain between X and Z on the scan.

- A (upper right, where the quadrants meet); B (top star-mark); C, E (right); D (right of B)
- F, a (upper left, below B); L, K, M, N (row of star-marks, upper left)
- ε (below C); O, P, I, G, S (lower right)
- H (left), R (right), Q (lower right), V (lower right, beside Q), Y (on the horizon line)
- Æ (left end of the arcs); T (beside Æ); Z (cursive, on the lower arc left of S)

• X [?] (on the left arc below L K M N; letter not certain between X and Z)

With these set down, Tycho's aim is to investigate the distances at which the New Star would appear if, at its highest or its lowest meridian altitude, it had been where the Moon is at perigee — that is, 52 semidiameters of the Earth from the Earth — or where the Sun is at apogee — that is, 1182 semidiameters of the Earth from the Earth. This he accomplishes by the following steps.

[Margin: Step 1.]

II. First, from the lunar distance of 52 semidiameters of the Earth, and from the New Star's greatest altitude observed or found at Herrevad, 84° 11′, and its least, 27° 45′, he had found that the New Star's parallax of altitude would be 6′ 43″ at its greatest altitude above the horizon and 58′ 31″ at its least, as is plain from what we said in the preceding chapter, number 2, in the first 4 steps. He had also found the New Star's declination, precisely, to be 61° 46′ 45″. Adding to this, therefore, the parallax of the greatest altitude, that is 6″ [?] 43″, and subtracting the parallax of the least altitude, that is 58′ 31″ — because the parallax, by depressing the star, would have increased its declination when it was above the pole, by bringing it down towards the pole, but would have decreased it when it was below the pole, by moving it away from the pole — the New Star's visible declination comes out as 61° 53′ 28″ above the pole and 60° 48′ 14″ below it.

[Margin: Step 2.]

Second, assuming in the same way the solar distance of 1182 semidiameters of the Earth, and the same altitudes of the New Star, 84° 11′ and 27° 45′, he had found the parallax at the former to be 18″ and at the latter 2′ 34″, as we showed in the preceding chapter, number 3. Adding 18″, therefore, to the New Star's true declination, and subtracting 2′ 34″, the New Star's visible declination comes out as 61° 47′ 3″ when it was above the pole, and 61° 44′ 11″ when below. From these are gathered four complements of the New Star's declination, two for the lunar and two for the solar distance supposed for the New Star, as you see in the following little table.

Complement of the visible declination.

If the New Star's distance is	Arc AB	Arc AC
☾ 52	28° 6′ 32″	29° 11′ 46″
☉ 1182	28° 12′ 57″	28° 15′ 49″

III. Third, now consider the spherical triangle ABD, in which the complement of the visible declination, BA, is given as 28° 6′ 32′ [?], if the New Star had stood 52 semidiameters away. The complement of the declination of the Pole Star D, that is the arc AD, was for Tycho in that year 3° 0′ 15″, and its right ascension 5° 3′ 30″; and the New Star's right ascension, true and apparent alike (since this star is placed on the meridian), was for Tycho 0° 26′ 25″. Subtracting this from the right ascension of the Pole Star leaves the difference

of right ascension, that is the angle BAD, as 3° 37′ 5″. Given, therefore, in the triangle ABD the sides AB and AD together with the included angle, the visible distance BD of the New Star from the Pole Star is found to be 25° 6′ [?] 56″. In the triangle ACE, on the other hand, he gathers the distance CE as 26° 12′ 10″. Hence the parallax of the distance, or the difference between the visible distances, would have been 1° 5′ 14″, whereas none was observed. Therefore the New Star did not stand only 52 semidiameters of the Earth away; otherwise the parallax of the distance would have been 7′ 4″, which would certainly have been observable with Tycho's instrument, especially with its interval kept unchanged.

By exactly the same method he solves the triangles ACE, ABa, ACε, ABF, ACG, and so on for the rest, using, that is, the complement of the visible declination of the star above the pole, AB, and below the pole, AC, under each supposed distance of the New Star, lunar or solar; and also applying the difference of right ascension from the right ascensions of the remaining six stars, together with the complements of their declinations. In this way he investigates the visible distances that would arise from those stars, and their differences, if the New Star had been where the Moon ☾ is, or where the Sun ☉ is — differences that would sometimes be greater than one whole degree; and he would certainly have perceived such a parallax or difference with his instruments, had one so great been present. Therefore, since no such parallax, nor any so great, was observed over a long time, he concludes that the New Star was not where the Moon is at perigee, nor where the Sun is at apogee, but stood farther from the Earth than 1182 semidiameters of the Earth, let alone 52. Here, then, from Tycho's volume 1, p. 436, is a little table of these visible distances with their difference.

A little TABLE showing the visible distances of the New Star from the fixed stars listed below, with which the New Star crossed the meridian very nearly together, in each of its two positions — that is, both above, at B, and below, at C — the New Star being supposed in the concave of the Moon or in the convex of the solar heaven, that is, 52 semidiameters of the Earth away in the former case and 1182 in the latter.

If the New Star of the year 1572 had been:

Names of the fixed stars distant from the New Star	In the concave of the Moon ☾, or 52 semidiameters of the Earth away: below, at C	Above, at B	Difference	In the concave of the Sun ☉, or 1182 semidiameters of the Earth away: below, at C	Above, at B	Difference
Pole Star	26° 12′ 10″	25° 6′ 56″	5′ 14″	25° 16′ 13″	25° 13′ 21″	2′ 52″

CAPVT VI.

Chapter 6.

Soluuntur Argumenta Tychonis ex Parallaxi deducta, & oſtenditur non fuiſſe ab eo demonſtratum, Stellam Nouam Anni 1572. fuiſſe ſupra Lunam, nedum in Octaua Sphæra. Detectis ſubtiliſſimis fallacijs, in Parallaxium profundo latentibus.

Tycho's arguments drawn from parallax are refuted, and it is shown that he did not demonstrate that the New Star of the year 1572 was above the Moon, let alone in the eighth sphere; the very subtle fallacies lying hidden in the depths of parallaxes are exposed.

I. Tycho's argument, resting on the last three proofs he brought forward in volume 1 of the *Progymnasmata*, chapter 6, and reduced to the form of a single syllogism, runs as follows.

[Margin: Major premise.]

If the New Star of the year 1572 had been just below the Moon, or where the Sun or Saturn is, it would not have kept the same visible distance from the pole of the world and from the same fixed stars at whatever altitude it was observed; rather, it would have shown at the observed altitude as great a parallax as the Moon, the Sun or Saturn shows at the same altitude; nor would the same altitude of the pole have been found from its greatest and least altitude as is found from the Pole Star's greatest and least altitude.

[Margin: Minor premise.]

But the New Star of the year 1572, at whatever altitude it was observed, kept the same distance from the pole of the world and from the same fixed stars; nor did it show as great a parallax as the Moon, the Sun or Saturn shows at the same altitude; and finally, as great an altitude of the pole was found from its greatest and least altitude as from the Pole Star's greatest and least altitude.

[Margin: Inference.]

Therefore the New Star of the year 1572 was not just below the Moon, nor indeed where the Sun or Saturn is, but above Saturn.

[Margin: Proof of the major.]

The *major* premise is taken as most certain by Tycho, in volume 1 of the *Progymnasmata*, pp. 422, 443, 450, 455, 458, and throughout that chapter 6 — and not by Tycho alone, but by most astronomers who discuss either this star or parallaxes in general. For the fixed stars always keep the same apparent

distance from one another, at whatever altitude above the horizon they are viewed, whereas the planets, especially the lower ones, even when viewed on the same night, show a distance from the same fixed stars that varies with their altitude. It seems to follow, therefore, that if some phenomenon always shows the observer the same distance from the same fixed stars, or one that varies less than the planets observed at an equal altitude, it is among the fixed stars, or above the planets; and conversely, that if it is where the planets are, it does not keep the same distance from the same fixed stars, or from fixed points (such as the poles of the world), at whatever altitude, but shows as great a parallax of altitude, or of distance, or as great a sum of parallaxes, or as great a difference of parallaxes, as that planet shows at the same altitude. Finally, who would not consider it an evident argument that a star is as high as the fixed stars, when from its altitudes precisely as great an altitude of the pole is derived as from the altitudes of the fixed stars?

[Margin: Proof of the minor.]

The *minor* premise seems to have been shown more than sufficiently by Tycho in volume 1, chapter 6, in proofs 2, 3 and 4, which we brought forward in chapter 4, from number 2 right to the end. For there Tycho appeared to show, on the one hand, how great a parallax, or variation in the distances from the fixed stars or from the pole of the world, the New Star would have shown when it was at its lowest and when at its highest meridian altitude, if it had been in the concave of the Moon, that is 52 semidiameters of the Earth from the Earth, or in the concave of the solar heaven, that is 1182 semidiameters of the Earth away, or in the convex of the heaven of Saturn, that is 12,300 semidiameters of the Earth from the Earth — and a parallax so great that it would have been sensible. On the other hand, through the observations of himself, of Paul Hainzel and of Jerónimo Muñoz, he taught that no such variation had been observed, and yet that it would have had to be observed with the instruments, had it actually been present.

[Margin: Reply 1 [?], to the major.]

II. First, however, I reply by denying the major premise of the syllogism above, if it is asserted as universally and necessarily true.

[Margin: Distinction 1 of the major.]

If this seems too harsh, I reply by distinguishing the major in many ways. First, by granting it if the New Star kept the same visible distance from the same fixed stars, or points of the highest heaven, when observed on the same night by several observers from different parts of the globe; but by denying it if it was observed on the same night by a single observer, that is, from a single place on the Earth's surface, or by several observers indeed, but each on a different night — and much more so if by no one on the same night.

[Margin: Distinction 2.]

Second, I distinguish and grant it if the New Star, in its daily revolution, in which it was seen to imitate the motion of the primum mobile, described a circle parallel to the equator and having its centre on the axis of the world; but

I deny it if it described a circle not parallel to the equator and eccentric to the axis of the world.

[Margin: Distinction 3.]

Third, I distinguish and grant the major if the New Star, in its daily revolution, described on the surface of a right cone, whose axis is drawn from the eye to the pole of the world, a circle or ellipse whose diameter is bisected by the axis of the world, exactly or nearly; but I deny it if the star described about the cone already mentioned a circle or ellipse whose diameter was not even nearly bisected by the axis of the world.

[Margin: Distinction 4.]

Fourth, I distinguish and grant the major if the New Star in its daily revolution did not vary its motion of declination, of latitude or of altitude with respect to the centre of the Earth; but I deny it if it truly varied one of these, or all of them. But so that the reasons for denying or distinguishing, in the ways already mentioned, the major premise may be laid open, and so that we may at the same time show that Tycho, by arguments drawn from parallax and resting on his own observations and those of Hainzel and Muñoz, by no means demonstrated that this New Star could not, with the phenomena saved, have been below the Moon, let alone below the Sun or Saturn, we must draw a diagram — and one fitted above all to the firmest foundation among Tycho's materials, namely the two observations of Paul Hainzel made on the same night, on November 21 and on November 26. On each night he took two meridian altitudes of the New Star with a huge quadrant, the highest in the evening and the lowest in the morning, as we related in the history in Chapter 3, number 3.

[Margin: Drawing of a diagram adapted to Hainzel's observation.]

III. From the centre of the Earth A, describe the quadrant BC of the terrestrial meridian, beneath the quadrant DE of the celestial meridian. On DE let P be the pole of the world, and let the Pole Star stand now at V, at its highest, and now at R, at its lowest meridian altitude, equally distant from the pole P on either side. Now Paul Hainzel, observing from B, saw the New Star at a distance of 13° 25′ 30″ from the zenith D at its highest meridian altitude, which Tycho, after limiting it by various observations, chose as 76° 34′ 30″; the least altitude observed by the same man was 20° 9′ 30″; and the altitude of the pole at Göggingen near Augsburg was found, both from these and from the altitudes of the Pole Star, to be 48° 22′. So, in the quadrant DE, take the arc EG of 76° 34′ 30″, EF of 20° 9′ 30″, and the altitude of the pole EP of 48° 22′. Draw two straight lines to the pole of the world: one, AP, from the centre of the world; the other, BP, from the centre of the eye. From that same point draw two straight lines BF and BG to the points G and F — these are the lines of the New Star's apparent place beneath the fixed stars at each meridian altitude — and join G and F by the straight line GTF. Now, since the New Star, as to its apparent motion, was seen by the eye at B to move with the same revolution as the primum mobile, keeping the same distance from the fixed stars and from the pole of the world, let us suppose that a right cone BGF moves about the

axis BP, with the New Star fixed in its surface; or else that, the cone staying still, the star itself de-

Diagram. A geometric figure set into the left column: the quadrant DE of the celestial meridian about the centre A, with the sides AD and AE; within it a smaller arc BC about A (the terrestrial meridian quadrant). On the arc DE stand G, the stars V and R (drawn as asterisks) and the pole P between them, and F. Lines run from B to G, P and F, and from A to P; GF is joined through T. About B lies a small circle through H, L, K and M with I on the axis, and an oval curve through O, S, Q and N.

- D (top left, end of the quadrant): the zenith
- G (top, on the arc): the New Star's place at its highest meridian altitude
- V (on the arc, asterisk): the Pole Star at its highest
- T (on GF, below V and P): intersection of GF with BP
- P (on the arc): the pole of the world
- R (on the arc, asterisk): the Pole Star at its lowest
- O (left, inside the quadrant): end of the ellipse's diameter
- S (centre): on the ellipse
- Q (centre right): on the ellipse
- F (right, on the arc): the New Star's place at its lowest meridian altitude
- H (left): on the small circle
- I (centre of the small circle): on the axis BP
- M (on the small circle)
- L (on the small circle)
- K (lowest point of the small circle)
- N (right of K): end of the ellipse's diameter
- B (left side, on AD): the observer's eye, apex of the cone
- A (bottom left corner): the centre of the Earth
- C (bottom, on AE): end of the terrestrial quadrant
- E (bottom right): end of the celestial quadrant

-scribes about the axis BP, in the surface of this cone, either a circle or an ellipse: a circle if at every altitude above the horizon it kept, on the same night, exactly the same apparent magnitude and distance from the eye B; an ellipse if it kept the same distance from the centre of the Earth in both places but a different distance from the eye, or if its distance differed both from the eye and from the centre of the Earth. But since, as is clear from the history in Chapter 2, the New Star did not vary its apparent magnitude on the same nights, but only on different nights, let us suppose that it described a circle; afterwards, for another case, we shall suppose that it described an ellipse.

[Margin: Case 1.]

Our aim is to show that all the phenomena indicated in the syllogism already mentioned, and observed by Hainzel — indeed by Tycho and by Muñoz as well — could have been saved even if the New Star had been distant from the Earth by only a single semidiameter of the Earth. From the centre B, then, where the apex of the cone already mentioned lies, with the radii BH and BK each

equal to the Earth's semidiameter AB, take two opposite points, and join them by the straight line HK, which cuts the axis BP at right angles at I. The plane HIK, cutting the cone GBF, will then describe in the section the circle HLKM, whose circumference will lie in the conical surface, as is very well known to geometers from the conic sections of Apollonius and Serenus. Suppose, then, that the New Star was at H at its highest meridian altitude and at K at its lowest, and that in its diurnal motion it described the circle HLKMH in the space of 24 hours. On these assumptions, this circle would not have been parallel to the equator, since it is taken to be at right angles to the axis BP, which differs from the axis of the world AP and is therefore inclined to it; whereas all circles parallel to the equator are at right angles to the axis of the world, or of the equator, as the equator itself is, by Theodosius, *Spherics* Book 2. Nor would its centre have been concentric with the axis of the world AP, but eccentric: for the centre of a circle described on a cone lies in the cone's axis, and the axis of the cone GBF, at the point I, because of its great nearness to the Earth and its remoteness from the pole of the world, is taken to be far removed from the axis of the world, namely from the point K.

For the other case, however, take AO and AN as equal distances from the centre of the Earth, and let the cone GBF be cut by the plane OSN, oblique to the axis BP. The conic section will be the ellipse OMNQO, on whose circumference the New Star could have moved with all the phenomena saved except its apparent magnitude: for on the same night it would have been seen larger at O than at N, since at N it is farther from the eye B — unless perhaps refraction at N produced the contrary. But neither the diameter HK of the circle nor the diameter ON of the ellipse would have been bisected by AP.

[Margin: Case 2 [?].]

IV. Before we go further, however, we want first to determine the parallaxes AKB and AHB which the New Star would have had at its least altitude K and its greatest H, if in both it had been equally distant from the eye B and no more than a single semidiameter of the Earth. This is very easy, and needs no laborious calculation. In the triangle ABK, which is isosceles since BK is taken equal to AB, the angles at the base AK are equal to each other, by I.5 of the *Elements*; and by I.32, the angle DBF — that is, the complement of the New Star's lowest altitude as seen by Hainzel, which was 69° 50′ 30″ — is equal to the angles BAK and BKA taken together. The parallactic angle AKB would therefore have been 34° 55′ 15″. Similarly, in the triangle ABH, isosceles because BH was taken equal to AB, with the angle DBG given by Hainzel's observation as 13° 25′ 30″, the parallactic angle AHB comes out at 6° 42′ 45″. Now this parallax, and any other of at least one minute, I call sensible in itself: for although by accident it might have been imperceptible to a single observer on the same night, or to several observers on different nights, it could nevertheless have been detected with an exact instrument, had both altitudes of the star been observed by the same observer on the same night.

[Margin: The greatest parallax of the New Star possible with the phenomena saved.]

[Margin: What a parallax sensible in itself and insensible by accident is.]

V. With what we laid down in numbers 3 and 4 now in place, I say that if the New Star, with respect to the eye B — that is, to a single observer on the same night — described in its diurnal revolution, on the surface of the cone BGF, the circle HLKMH in the space of 24 hours, with an apparently uniform motion, then all the phenomena reported of it are saved, even if it is supposed to be distant from the eye B by no more than a single semidiameter of the Earth, and therefore to have had, in the horizon of Göggingen, a parallax of 34° 55′ 15″ answering to its least altitude. For the equality of apparent magnitude and of distance from the eye B is saved not only at the lowest altitude K and the highest H, but at every altitude, because all the lines drawn from the vertex of the cone B to the circumference of the base, the circle HLKMH, are equal, the cone HBK being taken as a right cone. Moreover, just as the larger cone GBF, in its revolution about the axis BP — or a star or point of the highest heaven — was carried round about the cone from F through T to G in the space of 12 hours, and back again from G to F in the remaining 12 hours, so as to keep its apparent distance from the pole P and from any fixed stars whatever, say from the Pole Star at R or V, unchanged; so the New Star, carried round from K through L to H, and from there through M to K, in the space of 24 hours at an equal pace about the same cone, of which the smaller cone HBK is a part, could have been held in the same line of apparent place under the same fixed point F, carried round to G, and so, no differently from that point itself, have kept throughout that whole revolution an equal visible distance from the pole P and from any of the same fixed stars whatever. With this posited, the same altitude of the pole EP could not fail to be found from the lowest and highest altitudes of the New Star as had been found from the altitudes of the Pole Star, since the New Star is in this way supposed to be seen now under F, now under G, points equally distant from the pole P. Hence half the difference of the altitudes — that is, of the arc GF, bisected at P — namely FP added to the least altitude EF, or GP subtracted from the greatest altitude EG, gave the same altitude of the pole EP as half the difference VR of the Pole Star's altitudes, PR, added to its least altitude ER, shows.

What has been said of this circle can be said of any other circle that the New Star could have described about the cone GBF in its diurnal revolution, whether nearer to the Earth or farther from it, provided it cuts the axis BP at right angles. And what we have said of one night with respect to a single observer B could have held on other and yet other nights, but always different ones, with respect to different observers: as if Tycho observed on November 10, Paul Hainzel on the 11th, and Muñoz on the 12th, and so on for the other days and observers. Moreover, not only on circles described about the cone GBF, but also on innumerable ellipses — on the ellipse OMNQO, for example — all the phenomena of the New Star could have appeared, except the same

apparent magnitude within one and the same night, even though it was below the Moon: for it could have described those ellipses with a uniform diurnal motion, and have moved under no other points of the highest heaven than those under which a star describing the circle HLKMH, or GTF, would have moved, since they lie in the same surface of the same cone.

[Margin: On different observers on different nights.]

[Margin: The phenomena of the new star explained by an elliptical motion.]

This could not, however, have happened on the same night with respect to any number of observers at different places on the Earth. For by the very fact that the New Star is supposed nearer the Earth than the Moon, it would have been seen at one place more, at another less distant from the pole and from the same fixed stars, at the same moment. From all this, not to be too long, I think it is clear enough for what reasons I have conceded and denied the major premise of the syllogism set out at the beginning, according to the different senses in which it is understood.

It is clear, moreover, that with the star so near the Earth a parallax however large — one that would have been sensible in itself to different observers taking its altitudes or its distances from the same fixed stars at the same moment of time — could by accident have been insensible to a single observer, or to several observing it on different nights. For if, observed by any number of observers at different places on the Earth but at the same moment of time, it had been found equally distant from the same fixed points or stars of the firmament — as the distances of the fixed stars from one another and from the poles of the world are supposed to be observed or observable — that would be an infallible argument that the star lacked any parallax sensible in itself, and therefore was in the highest aether, and most certainly above the Moon.

Finally, it is clear that, on what we posit, the apparent declination could indeed have been seen as equal on the same night, because of the star's equal apparent distance on either side, under G and under F, from the pole of the equator D; but that its true declination was much smaller when it was at H than when it was at K, because at K it was little or not at all distant from the axis of the equator, but at H a great deal.

VI. You will say, however, on behalf of Tycho's opinion, that at so close a proximity to the Earth the New Star could not have appeared equally distant at the top and at the bottom of the meridian from any fixed star whatever, but only from a single one. But this very point is denied. For it would have been seen to be equally distant, at the top and the bottom of the meridian, or at any altitude of its own, not only from several but from all fixed stars whatever, indeed from all points whatever of the highest heaven, by the very fact that in its diurnal revolution about the cone GBF it was held under a single point of the heaven revolving with the motion of the primum mobile. For as to its apparent place it would have behaved just as if it had been in the highest heaven, or as if it had had no sensible parallax.

[Margin: Tycho's objection resolved.]

And yet — to say what actually happened — neither Hainzel nor Muñoz is reported to have observed distances of the New Star from fixed stars other than the Pole Star, in so far as they observed its distances from the pole of the world or from the zenith. Tycho did observe this star's distance not only from the Pole Star but also from several stars of Cassiopeia, but not on the same night, as the force of a demonstrative argument would have required. For when he observed the new star at Herrevad he had no other instrument with which to take either distances or meridian altitudes than the astronomical radius, which he did not trust, and a single sextant. When he had taken the New Star's distance from some one star with it, he fixed it with screws, so that, keeping the same angle of separation, he could test whether, when the New Star returned to the meridian together with nearly the same fixed star, it kept the same distance from that fixed star as in its former position on the meridian — as is clear from Tycho himself, *Progymnasmata* volume 1, pages 335, 342, 347, 349 and 416. Therefore on one and the same night he could not take the distance of the New Star twice, once when it stood at the bottom and once at the top of the meridian, except from a single fixed star.

VII. Second, I now reply by denying the minor premise in the sense in which I conceded the major. For in his arguments Tycho did not adduce any observations made on the same night by different observers, since he named no definite day on which he himself or Muñoz measured the New Star's distances from the fixed stars, or its meridian altitude. It could therefore have happened that, although Tycho often took them, his observations never fell on the same nights as those on which Hainzel observed its altitudes; for he took distances from other stars only indirectly, from the Pole Star. Nor could any follower of Tycho say, except gratuitously, out of a presumed opinion and excessive confidence, that he observed on the same nights as Muñoz and Hainzel. That can in no way be shown from the history that Tycho himself supplies, which we have carefully and faithfully compiled for this purpose and set out in Chapter 3.

[Margin: Reply 2, to the minor.]

Now, however, we are considering only the observations of this triumvirate, because the arguments of Tycho brought forward in *Progymnasmata* volume 1, chapter 6, set out by us in Chapter 5, and finally gathered into a single syllogism at the beginning of this chapter, rest on them alone. Indeed — to give this warning now in passing — none of the observers that he adduces in Chapters 8, 9 and 10 of the first volume is found either to have recorded definite days on which he obtained the New Star's distances from the fixed stars, or to have fallen on the same day on which some other observer took its meridian altitudes, as is plainly evident from the history given above in Chapter 3, numbers 2 and 3. But why do I speak of distances, or of meridian altitudes? In fact, no altitude whatever, no other observation of a determinate measure, presents itself in that history that is certainly established to have been made on the same night by two observers at different places, except on the day of December 4. Here, then,

is the whole parade of those observations displayed for you as in a mirror, as far as the days are concerned on which Tycho himself reports that they were made.

Determinate days on which the New Star of the year 1572 is reported to have been observed.

Days / Observers	Year 1572: November	December	January	February	Year 1573: March	April	May	August
Hainzel	14, 21, 26		2, 4		2, 12			
The Landgrave		3, 4, 10, 26	11	26	11, 14			

Remainder of the preceding table.

Days / Observers	Year 1572: November	December	January	February	Year 1573: March	April	May	August
Camerarius	23 and following		5, 6, 7, 8			7		7
Nolthius	29							
Hájek, Schuler	27	4					6	
Mästlin, however, as reported in Tycho, volume 1, page 545, observed this star on November 16 and on a number of following days.								

VIII. Third, I reply by again denying the minor premise, in so far as it extends to the distances of the Sun and of Saturn. First, because Tycho takes as certain a distance of the Sun at apogee of 1182 terrestrial semidiameters, and of Saturn of not more than 12,300 semidiameters. But neither is certain, as we have already shown in Book 3, chapter 7, on the distances of the Sun, and in Book 7, section 6, chapter 2, on the distances of the lesser planets. Indeed, from what is said there it is more probable that the Sun at apogee is distant from the Earth by about 7500 terrestrial semidiameters, and Saturn by 90,000. Now with the Sun's distance set at 7500 parts, of which the Earth's semidiameter is one, the horizontal parallax comes out no greater than 47″; and with Saturn's distance set at 90,000 terrestrial semidiameters, the parallax comes out no greater than 2″ 20‴. Of these the latter was imperceptible to Tycho's instruments, and the former not so evidently perceptible, given the imperfection of that sextant, which he himself admits.

[Margin: Reply 3, to the minor, and its first reason.]

Second, Tycho uses Muñoz's meridian altitudes (volume 1, page 456) as certain, and yet he reports them as having been taken rather coarsely, with a less exact instrument. Here are Tycho's words, volume 1, page 567: *"Muñoz puts the greatest altitude of the New Star in the horizon of Valencia at 67° 30′, the*

least at 11° 30′, and the declination of the star at 62° toward the north. But he set these down in too broad a manner, with a quadrant not large enough, on which he uses only half-degrees; so it is no wonder that he increased the declination too much, by about a fifth of a degree. From these, moreover, the elevation of the pole of Valencia is gathered to be 39½°, which does not differ much from the geographical maps, although the Canons of Apian and others disagree very greatly on it." In that place, however, he supposes that Muñoz erred in the declination of this star, because he thinks that the declination he himself took was both true — since there was no sensible parallax — and correct. But he did not demonstrate on other grounds that it lacked parallax. Tycho's declination, then, could have been an apparent one, and Muñoz's an apparent one too, but different because of the difference of altitudes arising from the difference of horizons and from parallax; or at least differing by 12′ for the reason that it was taken on different nights.

[Margin: Second reason for the reply.]

[Margin: Tycho's inconsistency and contradiction with himself.]

Third, from the meridian altitudes of the New Star taken by Paul Hainzel, and reported by us in Chapter 3, number 3, Tycho deliberately chose two from which there would follow an altitude of the pole at Göggingen of exactly 48° 22′, as much as had been deduced from the altitudes of the Pole Star. But he ought to have taken two altitudes taken on the same night: namely those of November 21, when the greatest was 76° 33′ 45″ and the least 20° 9′ 40″; or those of November 26, when the greatest was 76° 34′ 0″ and the least 20° 9′ 30″. Had he done so, the altitude of the pole on the 21st would have been smaller by 18″, or by 15″; and from this parallax a distance of the New Star would be gathered smaller than that of Saturn at apogee on his own hypothesis, or at any rate smaller than that of the fixed stars.

[Margin: Third reason.]

Fourth, as Chiaramonti noted (*De tribus novis stellis*, Book 2, chapter 7), Tycho in his demonstrations, in the fourth proof — which we treated in Chapter 5, in the Scholia — uses distances of the New Star from nine stars of Cassiopeia, whereas in his earlier writing he reports distances from only three stars of Cassiopeia, namely from Schedar, from the bright star of the Chair, and from the star at Cassiopeia's flank, as is clear from Tycho, volume 1, pages 343, 585 and 593. This led Chiaramonti to suspect that the remaining distances were invented rather than actually taken by Tycho. But this is not fully proved: for he could have taken them and yet not mentioned them in the earlier writing, as being from less notable stars, or as taken less often or less exactly.

[Margin: Fourth reason, from Chiaramonti.]

Fifth, Tycho admits (volume 1, pages 347 and 416) that in taking the distances of the New Star when it was at its least and at its greatest altitude he used the same sextant fixed with screws, keeping the same angle of the instrument, and from this he infers that the distances were the same. But Chiaramonti (*De stellis novis*, Book 2, chapters 5 and 6), having reduced Tycho's argument to this form — *"Whatever distance of two stars is observed everywhere under the same angle of the*

instrument always remains the same. But the distance of the new star from the same fixed stars was observed everywhere under the same angle of the instrument; therefore the distance of the New Star from the same fixed stars always remained the same" — denies that the major is true if the instrument is inclined to the horizontal plane now one way, now another. For then, he shows, because of the distance of the instrument's centre from the pupil, and because the cheekbone makes the eye's application to the angle of the instrument vary, the visual angle varies, and by several minutes at that. The distance of the New Star from the same fixed stars could therefore have varied between the highest and the lowest altitude, and yet the variation not have been detected by the instrument. But I do not make much of this subtlety of Chiaramonti's, because Tycho took the New Star's distances from the fixed stars of Cassiopeia when they were crossing the meridian nearly together with it, and so used nearly the same inclination of the instrument in both positions.

[Margin: Fifth reason, from Chiaramonti.]

[Margin: The imperfection of the sextant used with one eye.]

Sixth, Chiaramonti (*De novis stellis*, Book 2, from chapter 8 to 14) charges Tycho with a number of errors. These, however, are not so great that, if they were corrected, Tycho would then have demonstrated a large parallax of the New Star, or that they damage the substance of Tycho's assertion. Still, I am glad to point out the chief ones. Tycho, then, in volume 1, page 420, setting out to find the parallax the New Star would have had if it had been in the concave of the Moon, at its greatest altitude of 84⅙° and its least of 27° 45′, supposes that the pole of the world stands midway between these apparent altitudes. But this is not true unless the greatest and least altitudes are taken as true ones; otherwise, at the lower apparent altitude a greater parallax removes the star farther from the pole of the world, and makes its distance from the pole appear greater than when it is at its greatest altitude.

[Margin: Tycho's error 1.]

Moreover, Tycho, on page 429, supposes that the right ascension of stars, when they are on the meridian, is not subject to any parallax. But this is not true except when the meridian is the solstitial colure; otherwise a parallax of right ascension can arise from the parallax of altitude, as can readily be clear to experts, and as Chiaramonti shows (*Antitycho*, Book 1, chapter 1, and *De novis stellis*, Book 2, chapter 8, page 289).

[Margin: Tycho's error 2.]

Again, Tycho on page 429 says: *"The true declination, moreover, was found to be 61° 46′ 45″."* But this is the declination which, on page 331, he had deduced as 61° 47′ from the observed altitude of the pole at Herrevad, 55° 58′, and from the observed least altitude of the new star, 27° 45′. Yet a declination deduced from observation, so long as we are not certain of the parallax — which is the very point in dispute here — cannot be called true; it must be called apparent, and be used as such. So when Tycho adds in the same place, *"Since the parallax at the least altitude was found to be 58′ 31″ for the horizon of our observation, this,*

subtracted from the true declination, leaves the apparent declination as 60° 48′ 14″," the contrary

[Margin: Tycho's error 3.]

entirely ought to have been done, as Chiaramonti points out on page 291: the parallax ought to have been added to the apparent declination, to turn it into the true one. Or rather, since for the trigonometric calculation he was preparing Tycho needed the apparent declination, he ought to have used the declination of 61° 47′, or of 61° 46′ 45″, as the apparent one. For the rest, see Chiaramonti, Book 2, chapters 13 and 14 — points of no great moment, though true.

IX. It is clear, therefore, from Reply 1 to the major premise of the syllogism proposed at the outset, from Reply 2 to the minor, and in part from Reply 3, that Tycho — with his arguments drawn from parallax, resting on his observations of Hainzel and of Muñoz, which he chose in chapter 6 as the strongest — did not demonstrate that the New Star of the year 1572 was above the Moon, much less above the Sun or Saturn. And so this chapter must at last be closed with this conclusion of notable moment.

VNICA CONCLVSIO.

The single conclusion.

Neither by the arguments drawn from parallax and resting on his own observations, or on those of Paul Hainzel, or of Jerónimo Muñoz, nor by his other arguments — from twinkling, brightness and colour, from the lack of a tail, from the duration, from the diurnal revolution without proper motion, and from the sight of the star as viewed from many parts of Europe — did Tycho demonstrate that the New Star of the years 1572 and 1573 was above the Moon, much less above the Sun, above Saturn, or among the fixed stars of the eighth sphere.

The first part, on the arguments from parallax, is established from what has been said in this chapter; the latter part, on the other arguments, from what was said in chapter 4.

SCHOLIVM.

Scholium.

I. Tycho, and most others with him or before him, supposed that if a phenomenon keeps the same apparent distance from the same fixed star at its greatest and at its least meridian altitude, it necessarily follows that it lacks sensible parallax. Since that was their supposition, Chiaramonti demonstrated (*De novis stellis*, Book 2, chapter 4, and *Antitycho*, Book 1, chapters 9 and 10) that a star can keep an equal apparent distance from the same star as seen, even if it has a very large and highly sensible parallax; and we have shown this very thing in Book 10 of this volume, in the penultimate section, chapter 9, theorem 17. But not all the cases can be applied equally to the examples Tycho uses in

this place, and Chiaramonti did not show in particular the manner in which a phenomenon could appear to the same observer through the whole night at the same distance from the same fixed star — indeed from all of them — and yet have any given parallax whatever, and any distance from the Earth however small. How this can happen, however, is clear enough from our figure, set out in the preceding chapter from number 3; and that is why we used it in preference. I freely admit that formerly, when I was younger, overwhelmed by Tycho's arguments, I held the same view as Tycho and so many others about the location of this star — for I am not ashamed either to have erred with so many and such great men, or to confess the error — namely, that its place among the fixed stars had been demonstrated by Tycho. But afterwards, having examined Chiaramonti's *Antitycho* more deeply and looked into the doctrine of parallaxes, I re-read Tycho with a freer mind and found in him many things, either false or not demonstrated, which he himself had passed off as demonstrated. This I would perhaps not have done had Chiaramonti not tweaked my ear. Whether I have achieved more than he, or more clearly, let others judge.

[Margin: In commendation of Chiaramonti.]

CAPVT VII.

Chapter 7.

Whether Tycho, from other observations made in a single place on Earth and adduced in volume 1 of the Progymnasmata, *chapters 8 and 9, or the authors he reports there, or Santucci, demonstrated that the Star of the year 1572 was above the Moon.*

I. Up to this point our business has been with Tycho, but in weighing those arguments of his that are, in his own judgement, the strongest, since they rest on his own observations, or on Paul Hainzel's as though they were his own, because they had been made with a quadrant built by him. For Tycho says, in volume 1, chapter 6, page 451: *"It remains that we also take into counsel the observations made in different horizons and by different observers, weighing them in an equal balance — although, to say how the matter really stands, those experiments are far safer and more certain that are carried out by one single observer in the same horizon with the same carefully made instrument, provided each part is in order and subject to no sensible defect, than if the determination of the thing sought is looked for from different horizons and sighters. For both the variety of instruments, and the diligence and circumspection of observers, which is not the same everywhere in handling the business, can introduce some straying from the mark aimed at; and where the subtle investigation of parallaxes is concerned [?], this nonetheless errs a great deal in excess or in defect."* He presses this opinion on page 489 as well, and in volume 2, page 89; and with him Kepler, in the *Hyperaspistes*, page 129, and in *De Cometis*, page 77.

[Margin: Are observations from one place more certain than observations made in several places?]

[Margin: Error of Tycho and Kepler.]

But Chiaramonti (*Antitycho*, Book 3, chapter 3, and in his *Apologia*, Book 2, chapter 4) rightly held the opposite to be true. For, other things being equal, arguments from parallaxes resting on observations made in several places on Earth at the same moment are to be preferred: from them it can be established with certainty whether a phenomenon has a parallax, and how great, which cannot be established from observations made in a single horizon, as is clear from what was said in the preceding chapter, and from Section 1, especially chapter 22, number 11. Granted, if the operations of the individual observers are taken separately and do not agree, each may rightly keep the faith already pledged to his own observation and his own eyes, if he is evidently sure of the diligence he has sufficiently applied. Tycho, then, uses the observations of others in such a way that he accepts them as legitimate in so far as they favour his own opinion — that is, those that put this star back above Saturn, such as the ones he collected together in chapter 8; or at least those that do not put it below the Moon, of the kind he reports in chapter 9. But those that show this star was below the Moon he rejects or tries to refute — namely those he adduces in chapter 10 of volume 1. Yet this, in the end, is to reduce the force and weight of all observations to the observations of Tycho alone, made in one place on Earth, and to bend them, like a Lesbian rule, to his own norm. We, however, without any prejudice or prerogative of opinion or of author, shall consider how much weight there is in them for determining the parallaxes of the New Star, both in each separately and in all of them collected together.

Obſeruationes Vuilhelmi Haſſiæ Lantgrauij habitæ Caſſellis, ad Parallaxim ſpectantes.

Observations of Wilhelm, Landgrave of Hesse, made at Kassel, bearing on the parallax.

II. Tycho reports and examines these in volume 1 from page 491 to 505, and again on page 599, and we copied them out in chapter 3, numbers 2, 3 and 4. From them he hunts for the parallax of the New Star as follows. The Landgrave found the greatest meridian altitude of this star on December 26 to be 79° 30′, and the least, on the 29th, 23° 2½′ or 23° 3′. With the same instruments he had found, from fixed stars revolving about the pole, the altitude of the pole at Kassel to be 51° 16′, but afterwards 51° 18′. If you subtract this from the greatest altitude of the new star, there remains a distance of the New Star from the pole of 28° 14′; but if you subtract the least altitude of the New Star from it, there remains a distance of the New Star from the pole of 28° 13′ 30″. Conversely, if you add half the difference between the greatest and the least altitude of the New Star to the least, or take it away from the greatest altitude of the same New Star, you will gather an altitude of the pole of 51° 16′ 15″ — as much as was first gathered from the circumpolar fixed stars, but less by 2′ than the later

altitude of the pole. "Therefore," says Tycho, "it had no sensible parallax, nor any greater than the parallax of the fixed stars." But if the New Star had been in the concave of the Moon, that is, at a distance from the Earth of only 52 semidiameters of the Earth, it would have undergone a parallax of 12′ at its greatest altitude and of 1° at its least, which he gathers by the problem and figure already given in chapter 5, numbers 2 and 7; and so at the least altitude it would have appeared 48′ farther from the pole of the world than at the least [?], whereas in fact it appeared equally distant from it at both. But if one supposes the New Star to be where the Sun is on Tycho's reckoning, its parallax would have been about three minutes, and quite perceptible. Tycho's argument, then, reduced for brevity's sake to a single enthymeme, runs as follows:

At the greatest and the least altitude of the New Star, the Landgrave of Hesse detected no parallax, or none greater than the parallax of the circumpolar fixed stars; therefore it had no parallax, or none greater than the parallax of the fixed stars, and so it was above the spheres of the planets.

[Margin: Tycho's argument.]

One could reply, first, by denying the antecedent. On the one hand, if the calculations already mentioned are considered, a parallax is found — that is, a difference of 30″ between the distances of the star from the pole of the world, and of 15″ between the altitudes of the pole; while from the later observation of the pole's altitude a parallax of more than two minutes is gathered, as the Landgrave himself admits in his letters to Peucer, which Tycho reports on pages 600 and 613; and each of these is greater than the parallax of the fixed stars. On the other hand, the Landgrave did not observe both altitudes of the New Star on the same night, but on different nights. It could have happened, however, that had he observed on the same night, he would have found a much greater difference between the two distances from the pole of the world, and so a much greater parallax, which, because of the motion of declination correcting that difference, he did not find on different nights.

[Margin: Reply 1.]

I reply, however, secondly but principally, by distinguishing the consequent. I grant the consequence concerning a parallax sensible at Kassel on those nights, but I deny it concerning a parallax sensible in itself on the same nights in different horizons. For on the nights of December 26 and 29 (although in comparing the altitudes Tycho uses them just as if they had been observed on a single night) the star could have been very close to the Earth, so that, had it been seen on that night by different observers, it would have appeared much farther from the pole of the world and from the fixed stars than it appeared at Kassel; yet to the observer at Kassel it would appear the whole night under the same fixed point of the highest heaven, revolving together with it in the diurnal revolution of the primum mobile, as we set out and showed in chapter 6. The Landgrave adds, however, in a letter to Peucer dated 1572 December 14, that through the eight preceding days he had always seen this star motionless in the same place in the firmament.

[Margin: Reply 2.]

Thaddæi Hagecij Obſeruationes factæ Viennæ in Auſtria circa Parallaxin.

Observations of Tadeáš Hájek made at Vienna in Austria, concerning the parallax.

III. Tycho deals with these in volume 1, from page 505 to 528. He brings into a summary certain selected passages, comprised in 15 chapters, taken partly from Hájek's *Dialexis*, where much is taught about parallaxes in general, and partly from a manuscript copy sent to Tycho, in which Hájek had emended the distances of the New Star he had taken and corrected what he had said in the *Dialexis*. In chapter 5 of the *Dialexis*, then, there is this argument of Hájek's: *Every body that has either no parallax, or one smaller than the Moon's, is in no way to be reckoned to the elementary region, but to the ethereal. Our star has been found to have no parallax; therefore etc.* He proves the minor by this prosyllogism: *Every body that keeps an equal distance from the poles of the world and from the stars, perpetually and everywhere, can have no parallax. Our star keeps an equal distance from the pole of the world and from the stars at all times and places; therefore it can have no parallax.* Presently he adds: *The major of the prosyllogism is known from the doctrine of parallax; the minor is made evident by our observations and those of other learned men, especially Cornelius Gemma and Jerónimo Muñoz, and so by the following demonstration.* He then appends a figure by which he contends to show that the New Star — both at its lowest meridian altitude of 20° 15′, taken on May 6, and at the altitude of 22° which it had after $24^{m}\ 38^{s}$ of time, and at a complement of the eastern azimuth of 12° 13′ — stood equally distant from the pole of the world, namely 28° 7′, using an altitude of the pole at Vienna of 48° 22′. And he offers no other demonstration.

[Margin: Hájek's argument.]

We reply, however, first by granting both propositions of the first syllogism and denying the inference, because the syllogism has four terms: in the major the verb *has* is used, and in the minor the verb *has been found*. It is one thing to have a parallax, another for it to be detectable or sensible; and it could have had one, yet not have been perceived at Vienna on the night of that day, May 6, or on certain other nights too, on which it would nevertheless have been perceived elsewhere, had observations by several observers fallen on the same night.

[Margin: Reply 1.]

I reply, secondly: granting the whole of the first syllogism and the major of the prosyllogism, I deny the minor of the prosyllogism, which Hájek did not demonstrate. First, he puts the observed distance of the New Star from the pole at 28° 7′, which Tycho, on pages 351 and 509, affirms was 28° 13′. Either, then, both were true but at different times, and so the distance was not the same perpetually; or both were seen at the same time, and so a parallax intervened. Next, he uses the azimuth with too short a time, $24^{m}\ 38^{s}$, in which the star

appeared higher by only 1¾°; and even Tycho himself judged this slippery and insufficient for perceiving parallax, saying on page 516: *Indeed, to detect a parallax from so very slight a variation of elevation is scarcely granted, even with the largest instrument, even if the phenomenon had been a little below the Moon.* For Tycho shows there, from the data given by Hájek, that if the new star had been in the concave of the Moon, the difference of the parallaxes it would have had at the two altitudes observed by Hájek would not exceed 48″, which he affirms could not have been perceived except with a very large instrument — and much less from so short a time, and that gathered from the 4th star of Cassiopeia, which, being then very near the meridian, varied its altitude too slowly, as Tycho points out on page 517. And on page 518 he adds: *I say nothing of the fact that finding the azimuthal angle is uncertain, and more liable to deviation than the investigation of the altitude itself. From all of which it follows that Thaddaeus's givens were not exact enough, nor sufficiently suited to the solid investigation of so subtle an inquiry.*

[Margin: Reply 2.]

[Margin: First reason of the reply.]

[Margin: Second reason.]

But let us grant that these reasons are too subtle. I say, thirdly, that it does not follow, if the New Star was seen at two moments of the same night to be equally distant from the pole, that it therefore kept the same apparent distance the whole night. He ought at least to have shown this from the highest and the lowest altitude of this star, which he nowhere did, as Tycho himself attests on page 515: *And although he asserts that it was everywhere equally removed from the pole, he nevertheless sets down no greatest altitude of it, in its lofty position, the one least subject to parallax, which, compared with the least, would show that the difference of the interval from the pole was insensible at both, etc.* And presently he adds about Hájek: *He appeals, however, to the observations of others, especially of Cornelius Gemma and Jerónimo Muñoz — would that they had been so precise and reliable!*

[Margin: Third reason.]

But I say, fourthly: if Hájek had shown from the history of this star that this star, seen on the same night, was equally distant from the pole of the world both at Vienna and at Louvain, where Gemma was, and at Valencia, where Muñoz was at the time, the minor of the prosyllogism would have been sufficiently proved for that night; and if he had shown the same for all the nights on which the New Star appeared, with respect to several places on Earth, it would have been proved absolutely. Since he did not do this, we rightly deny that the minor of the prosyllogism was demonstrated. See also what I shall shortly say about the uncertain altitude of the pole at Vienna, at the end of number 5.

[Margin: Fourth reason.]

Pauli Fabricij Mathematici & Medici Cæſarei Obſeruationes ad Parallaxin ſpectantes.

Observations of Paul Fabricius, Imperial Mathematician and Physician, bearing on the parallax.

IV. Of him Tycho, on page 529 of volume 1, sums up the arguments by which he said that the New Star was not below the sphere of Jupiter, in these words: *Setting out to investigate its parallax, he dispatches himself too quickly and in too broad a manner. He says that it always kept the same distance from the fixed stars, both on the meridian above and below and when it was farthest removed toward the sides on either hand — though he does not add what that distance was, but only alleges the testimonies of others, whom he does not even name. And from this he rightly infers that this star had either no parallax or an entirely insensible one; but he does not, as was fitting, persuade us of it demonstratively from indubitable proofs — perhaps because he was too eager for brevity.* Tycho himself, then, acknowledges that this was not demonstrated by Fabricius; and although he had employed the manner by which Tycho believed this to have been demonstrated, he would in fact have demonstrated no more than that the New Star lacked a parallax sensible in some single place, or in several places on different nights; whereas he would have had to bring both together — observations in several places on Earth, but made on the same nights.

[Margin: Fabricius did not demonstrate the star above the Moon.]

Bartholomæi Reiſacheri Mathematici Viennenſis obſeruationes ad Parallaxin ſpectantes.

Observations of Bartholomäus Reisacher, Mathematician of Vienna, bearing on the parallax.

V. Although Reisacher wrote about this star more lucidly than Fabricius, not even he demonstrated what he asserted — namely, that it was not in the elementary region. For his whole reasoning, as Tycho reports in volume 1, page 531, rests on this: that at both meridian altitudes observed at Vienna it kept perpetually the same distance from the fixed stars of Cassiopeia. But he proves this by no measurements from observations, and so Tycho adds: *Nor does he add what distances from the fixed stars of Cassiopeia this star had, but simply reports that they were alike at both, which another could have denied just as easily, especially since he does not say how great they were. Nor, likewise, does he determine absolutely the quantity of the parallaxes that would arise in the lofty and in the lower position for some presupposed distance from the Earth — the two things I find wanting in this process of demonstration.* There is also the fact that, as Tycho reports on page 532, this astronomer took the least altitude at Vienna as mostly 20°, and sometimes greater by 5′ or 10′. From this it appears that he observed either with a less exact instrument or less diligently — if one admits with Tycho in the same place that the distance of the star from the pole of the world was 28° 13′, and that the

altitude of the pole supposed by Reisacher, and received from Peuerbach and Regiomontanus, was 48° 22′. For in that case the least altitude of the New Star ought to have been 28° 9′ [?]; so when he saw it at only 20°, or 20° 5′, either he was deceived, or the star underwent a parallax. Tycho adds, moreover, that the altitude of the pole at Vienna is not certain, because it was perhaps taken from the greatest altitude of the Sun at the summer solstice and the least at the winter one, without subtracting refraction from the latter, as was necessary.

[Margin: Reisacher did not demonstrate that this star was above the Moon.]

But I came upon a much greater occasion for suspicion about this altitude in my geographical book. For Clavius, in the *Sphaera*, on page 263 of my copy, relates that Regiomontanus observed at Vienna, at the two solstices, a greatest altitude of the Sun of 65° 30′ and a least of 18° 26′. Add to the greatest my solar parallax of 5″, and to the least 23″, but subtract from the least the refraction of 5′ 40″: the true greatest altitude will be 65° 30′ 5″, and the least 18° 20′ 43″. Their half-difference, 23° 34′ 41″ (too large, indeed, since the obliquity of the ecliptic was smaller), added to the least gives an altitude of the equator of 41° 55′ 24″, and of the pole of 48° 4′ 36″ — smaller, that is, than the old value by about 17′. On the other hand, Kepler affirms that the altitude of the pole at Graz was observed as 47° 2′; and in the map of Wolfgang Lazius in which Austria is described — a very exact one, as it appears — Vienna is put 1° 42′ farther north than Graz, and in the Ortelian map 1° 41′; so the altitude of the pole at Vienna would come out at 48° 44′ or 45′. Between these extremes the mean is 48° 20′. The testimonies, then, waver on both sides for this altitude of the pole, and consequently for the distance of the New Star from the pole.

Pauli Hainzelij Obſeruationes ad Parallaxin ſpectantes prope Auguſtam Vindelicorum.

Observations of Paul Hainzel bearing on the parallax, near Augsburg.

VI. Besides what we brought forward with Tycho in chapter 5 on Hainzel's observations, there remains what Hainzel himself wrote to Hieronymus Wolf in letters reported by Tycho in volume 1, page 536. In them he affirms that he found, both on 1572 November 21 and on 1573 January 4, the greatest altitude of the New Star to be 76° 34′ and the least 20° 9⅔′; and he adds: *That there is no difference between the true and the apparent place of this star seems to be made credible by the fact that its greatest and least elevations, joined together, make for us the same number that all the fixed stars which are always in view and never set make, compounded from their greatest and least altitude.* By this argument it is indeed proved that no parallax of this star was perceived by Paul Hainzel on those two nights at Göggingen, and so that it was insensible to him. But whether it was so by accident — because perhaps the star, with respect to that place and observer, was held through all those nights under the same fixed point of the highest heaven by the diurnal motion about a cone having its axis at one end in the eye and at the other in the pole of the world, although it was placed below

the Moon, as we showed in the preceding chapter could happen — or whether it was insensible in itself and in every place, if it had been observed on the same nights in different horizons: this he by no means demonstrated. Tycho, moreover, wonders at this man's inadvertence, in that, though he denied this star a parallax, he nevertheless believed it could be among the comets and perhaps sublunary; for these contradict each other — the lack of all parallax, and a distance of the phenomenon from the Earth less than the Moon's. But when he saw Tycho's writings, he placed this star among the fixed stars, as Tycho relates on page 542.

[Margin: Hainzel did not demonstrate the insensibility of the New Star's parallax.]

Michaelis Mœſtlini Gœppingenſis Obſeruationes, ad Parallaxin ſpectantes.

Observations of Michael Mästlin of Göppingen, bearing on the parallax.

VII. At the time when he observed this star, Mästlin was living in the town of Backnang, serving as parish priest. He lacked instruments, but with the help of a thread he observed the place of this star, as Tycho reports in volume 1, page 543, and from this he tried to demonstrate its lack of parallax. How the unknown longitude and latitude of the star is gathered by spherical triangles — by stretching a thread through the disputed star and two other fixed stars found in the same straight line, then stretching the thread again through the star of disputed place and through two other fixed stars, different from the first, lying in another straight line with the doubtful star, and using the known longitude and latitude of those four fixed stars — we shall teach in Book 10; and Mästlin himself teaches it in the writing he published on this New Star, in Tycho, page 547, as does Longomontanus in Book 2 of the *Spherics*, chapter 9, problem 5. Nor does it concern this place. What bears on our subject is Mästlin's argument, given in Tycho, page 545, in these words: *But we have been taught by accurate observations that this prodigious star is to be numbered not only not among the meteors, but not even among the planets, but among the stars of the eighth orb, or firmament. For on the sixteenth day before the Kalends of December* [November 16], *at* 7^h *after noon, we observed its place most diligently, when it was applying to the top of the sky on the meridian; on the following day, at* 5^h *before sunrise, when it was away from the middle of the sky and nearer the horizon, we noted its place again; on the same day, at the seventh hour before noon, we again considered its apparent place, when, having returned to the meridian, it occupied the lowest point of its circle. The same was done diligently by us on the following days. Yet in all these observations its place in the eighth sphere was found, throughout the whole time since it began to be observed, neither differing nor changed by a single minute. Some indeed assert that it advanced toward the pole by almost two degrees; but we have found nothing of the kind. Since, then, no discrepancy of motion can be perceived by sense in the diurnal revolution, it will easily be demonstrated from Ptolemy's* Almagest *that its true motion does not*

differ from the apparent, and hence that its distance is so great that the half-diameter of the Earth is incomparable to it: from which we necessarily gather that it is neither in the regions of the air nor of fire, etc. After this he shows that if the new star had been in the concave of the Moon, that is, at a distance from the Earth of only 52 17′ terrestrial semidiameters, as Copernicus puts it for the Moon at perigee, it would have come about that at its least altitude, which was about 20°, it had a parallax of 63′. Tycho extols all this with wonderful praise, although he corrects Mästlin's latitude, longitude, declination and right ascension of this star, because in computing them Mästlin used uncorrected places of the fixed stars; nor does he approve of Mästlin's liking for the immense distance of the fixed stars that must be asserted on the Copernican hypothesis.

[Margin: Mästlin's opinion, and his argument for the New Star's place among the fixed stars.]

We reply to Mästlin, however, that if it were established that on those nights on which he observed the New Star to stay fixed in the same place under the sky, it was seen in other horizons to remain under the same place of the sky, it would follow necessarily that it lacked all parallax sensible in itself, and so was above

[Margin: Reply to Mästlin's argument.]

the planets. If, however, this is not established, and one looks at the observations he made in a single place on Earth, that does not follow necessarily: the star could have been very close to the Earth and yet, on many nights — not merely on one night or another — have appeared to him always under the same place among the fixed stars, and so its parallax would, by accident, not have been perceived by him. But what we said had to be established is not established. For from the history of observations brought forward in the preceding chapter, toward the end of number 7, no one is known to have observed this star determinately in November, on the 14th, 21st and 26th, except Hainzel. Mästlin, for his part, could have observed on the 16th and the following days and yet not have observed on the 21st and 26th. And as long as we are not certain of an observation of the star under the same point of the sky made, at the least, on the same night in different horizons, we are uncertain whether the parallax was insensible in itself, because of a great distance from the Earth, or by accident, because of a diurnal revolution of the star attuned to a single eye. Granted, it is very probable that the spectacle of so great a prodigy was not attuned to a single eye — nor indeed to several, on different nights only, as we shall say later.

Cornelij Gemmæ Louanienſis Obſeruationes ad Parallaxin ſpectantes, Louanij initæ.

Observations of Cornelius Gemma of Louvain bearing on the parallax, undertaken at Louvain.

VIII. This author gives us no trouble. In his earlier writing on this star he denies that a parallax of it greater than 4′ could have been detected by him, and in the later one — that is, in the book *De divinis naturae characterismis* — he denies that it had any parallax at all. Yet, as Tycho says on page 553 of volume 1, *he brings forward no reasons, as befitted a mathematician, why he holds this view of the parallax; nor does he indicate sufficiently from what observations he assigned it such a place.* Indeed, reporting on page 554 the distances of the New Star from the fixed stars taken by Cornelius, and comparing them with his own, Tycho says: *Hence it appears how immoderately erroneous Cornelius Gemma's observations were, so that in the distance from the Pole Star he went astray by almost 1½°.* And although Cornelius later corrected them, Tycho says of those very observations, on page 558, that he confused the bright star of Perseus with the Head of Medusa, and adds: *From this comparison it is clear enough how far astray the intervals of the stars are, even as corrected by Gemma, although he thinks he sought them out duly with great and repeated diligence.* From this it follows either that Tycho's distances alone were seen correctly, and so the Cornelian ones are not to be trusted; or, if we wish both sets to be correct, we fall into a parallax — if, that is, we suppose them to have been observed by both men on the same nights. For if on different nights, we shall conclude nothing certain about parallax considered in itself. It remains, therefore, that Cornelius Gemma did not demonstrate that this star lacked all parallax, or that it was above the Moon — especially since Tycho shows on page 560 that the place assigned to this star by Gemma is inconsistent with his own givens.

[Margin: Gemma did not demonstrate that the New Star was above the Moon.]

Hieronymi Munosij Hiſpani Obſeruationes factæ Valentiæ, ad Parallaxin ſpectantes.

Observations of Jerónimo Muñoz, a Spaniard, made at Valencia, bearing on the parallax.

IX. What Muñoz wrote on this star in the Spanish language, Cornelius Gemma translated into Latin, and from him Tycho copied out a great deal, in volume 1 from page 565 on. But what serves to elicit the parallaxes are the distances of the new star from certain fixed stars and the meridian altitudes observed at Valencia; Tycho compares these distances with his own, as below.

Distance of the New Star from the stars of Cassiopeia	Muñoz	Tycho	Difference
from the Seat	5° 20′	5° 19′ 0″	1′ 0″
from the Bend	5° 10′	5° 2′ 0″	8′ 0″
from Schedar	7° 50′	7° 50′ 30″	0′ 30″
from the Pole Star	26° 40′	25° 14′ 0″	86′ 0″
Greatest altitude	67° 30′	84° 11′ 0″	
Least altitude	11° 30′	47° 45′ 0″	
Difference of the altitudes	56° 0′	56° 26′ 0″	

Distance of the New Star from the stars of Cassiopeia	Muñoz	Tycho	Difference

Muñoz affirms, moreover, that with frequently repeated observations he found no parallax in this star, and therefore that it was above the Moon, Mercury, Venus and the Sun — indeed, that it clung to the heaven of the fixed stars; and yet he calls it a comet. Now, even if we suppose with Tycho that the altitude of the pole at Valencia is 39½°, and therefore that this star was seen to keep the same altitude relative to the pole at both its meridian altitudes — indeed, even if we granted that on many nights Muñoz saw the same distances from the same fixed stars — these things still do not suffice to demonstrate that it lacked all parallax, or that it was above the Moon. For it could have been very close to the Earth, and yet its parallax could, by accident, not be perceived in the horizon of Valencia, though it would perhaps have been perceived by others had they observed its distances from the pole and from the fixed stars on the same nights. Add to this that Tycho, not without reason, suspects that Muñoz's instrument showed only whole decades of minutes, since he recorded all distances and altitudes only by their decades; or else that he had a quadrant that showed only half-degrees in taking an altitude. The astronomical radius with which he took the distances, especially the larger ones, Tycho thinks imperfect; and this, he holds, is how it came about that in the difference of the altitudes Muñoz differs from Tycho by 26′, and in the distance of the New Star from the Pole Star by 1° 26′. If anyone wishes to defend the observations of both, he will certainly be forced to ascribe that variation to a great parallax. Hence it is quite clear that Muñoz asserted, but did not demonstrate, that this star had no parallax greater than the parallax of the Moon, Mercury, Venus and the Sun — let alone that it was in the heaven of the fixed stars.

[Margin: Nor did Muñoz demonstrate that the new star was above the Moon.]

Franciſci Valleſij Couarrubiani Opinio potiùs quàm obſeruatio.

The opinion, rather than an observation, of Francisco Vallés of Covarrubias.

X. This author, in the book *De sacra philosophia*, chapter 1, speaks of this star not from any observation of his own but from the opinion of others, as follows: *You will understand that the thing was truly most worthy of wonder, even from the opinions into which very learned men were thrown. For since they knew that no star of the first magnitude, such as this one seemed to be, had ever existed there — namely in Cassiopeia — and yet it seemed, whatever it was, to be above the Sun, because it had no parallax, some affirmed that it was indeed a star, and a new one; others, thinking this easier, that it was a comet generated within the heaven itself, etc.* But he in no way professes a demonstration of what he says about the parallax. So let us pass on to the others.

Gaſparis Peuceri, & Vuolfangi Schuleri Obſeruationes initæ Vittebergæ in Saxonia ad Parallaxin ſpectantes.

Observations of Caspar Peucer and Wolfgang Schuler, undertaken at Wittenberg in Saxony, bearing on the parallax.

XI. Tycho brings forward both the observations and the letters of these men in volume 1, pages 605, 618 and 622. In them it is said that the least distance of this star from the zenith observed at Wittenberg was 10° 4′ and the greatest 66° 27′ — that is, that its greatest meridian altitude was 79° 56′, on December 4, and its least 23° 33′, on November 27 — and that its declination was 61° 58′ near the zenith but 61° 39′ near the horizon; hence a parallax of 19′, and a distance from the Earth of 164 semidiameters of the Earth. Schuler adds, from the observations of D. Cruciger and of Reinhold, the τοῦ πόλου ἔξαρμα [Greek: tou polou exarma, "the elevation of the pole"] — that is, that the altitude of the pole at Wittenberg is 51° 54′ — and goes on: *With these observations of ours (apart from tiny minutes) agree the* παρατηρήσεις [Greek: paratērēseis, "observations"] — *that is, the observations — which the most illustrious Prince Wilhelm, Landgrave, made at Kassel in Hesse, and certain others in Prussia and Silesia, and, as I hear, at Tübingen. For all agree in this, that the present comet has left the elementary region and migrated into the aethereal.* But from this that very parallax which they assert is by no means demonstrated, because both the greatest and the least altitude ought to have been taken on the same night, and it is not established that this was done: for why is one referred to November 27 and the other to December 4? Add that the altitude of the pole used by Schuler seems very uncertain; for Tycho, in volume 1, page 610, affirms that the altitude of the pole at Leipzig observed by Johannes Hommel is 51° 17′. Wittenberg, moreover, does not face Leipzig due north but deflects somewhat toward the east, by a third part of a quadrant, as is clear from the more correct geographical maps; and from the road distance of 8 German miles between these cities, and the angle of position of 30°, he gathers geometrically a difference in the altitude of the pole of 28′, to be added to the altitude of the pole at Leipzig, so that the altitude of the pole at Wittenberg comes out at 51° 45′. Hommel is to be relied on, because the altitude was taken with a quadrant that showed single minutes by the method of Nonius, and from two altitudes of the Sun, the greatest 62° 11′ and the least 15° 15′; from these, neglecting parallax and refraction, he gathers the altitude of the pole at Leipzig as 51° 17′. But Tycho, on page 631, applying both corrections, gathers an altitude of the pole of 51° 19′, and therefore that of Wittenberg as 51° 47′. But if, according to the elder Peucer's booklet on the distances of places, the equinoctial shadow at Wittenberg is to the gnomon as 19 to about 15, or as 76 43′ to 60, the altitude of the pole is gathered from this as 51° 58′. If, however, we use our own solar parallax of 5″ at an altitude of 62°, and of 22″ at an altitude of 15°, and the refraction of 7′ 30″ due to 15° 15′, the greatest altitude of the Sun was 62° 11′ 5″ and the least 15° 7′ 52″, and the difference 47° 3′ 13″. Half of this, 23° 31′ 36″, added to the least altitude of

the Sun, gives an altitude of the equator of 38° 39′ 28″, and of the pole of 51° 20′ 32″; and so, adding 28′, the altitude of the pole at Wittenberg becomes 51° 48′ 32″. And this is much more probable than the value obtained through the uncertain edges of shadows.

[Margin: Schuler's opinion, but not demonstrated.]

Ioannis Prætorij Ioachimici Opinio.

The opinion of Johannes Praetorius of Joachimsthal.

XII. We need not labour here with this astronomer, for he brings no observations of this star from which he determined its distance from the Earth, let alone any demonstration. But in a writing on the comet of the year 1577 he also reports, about this star of the year 1572, the opinion of others and his own, in these words: *This star had no motion except the one it had in common with the fixed stars, and it always kept thereafter the same place it first had. Its distance from the Earth was so great that it could in no way be perceived, except that it was found to have been placed within the orbs of the planets, or above them. For this has been confirmed by the observations of the experts, and those who were the most excellent and most diligent of all in this field affirm that it was stripped of all parallax: for that reason no certain seat could be assigned to it. For although Saturn too lacks all variation of view, yet its distance could be determined from its own proper motion and other accidents — aids that this star wholly lacked.*

[Margin: The opinion of Johannes Praetorius, but not demonstrated.]

Philippi Appiani, & Io. Dee Opinio.

The opinion of Philipp Apian and John Dee.

XIII. Nor did Apian demonstrate his opinion; but he asserted it in a letter written in the German language to the Landgrave of Hesse, who had asked for his view on this star — translated into Latin and printed by Tycho in volume 1, page 643. Apian's words selected on this matter, taken from John Dee the Englishman, are these: *John the Englishman writes in several places, and from other astrologers, that a conjunction of Jupiter with Saturn makes a star like the Moon, without a tail. All these things, he says, happen through aspects too, just as through conjunction, provided that the planets regard each other centrally. Next, that this comet, or second star, does not exist in the elementary region but comes to be numbered among the fixed stars; from which it can be gathered that it is much higher than the Moon, and produces no parallax or causes any variation of view, as the Moon does. And if it had to be placed below the sphere of the Moon, its parallax would greatly exceed the Moon's. There is this too: no motion could be detected in it, but it moves about the poles of the world with the firmament exactly like a fixed star. That it appears without a tail I would also gladly ascribe in part to its very height. For the reasons already mentioned, I judge that this star stands very high in the aethereal region. But in saying that this new star is a comet, and moves in the aethereal region, the physicists and Aristotelians will not side with me.* Moreover, Tycho testifies

on page 690 that John Dee brought forward no observation about this star, let alone a demonstration.

[Margin: The opinion of John Dee and Apian, but not demonstrated.]

Thomæ Diggeſei Cantienſis Angli Obſeruationes ad Parallaxin ſpectantes.

Observations of Thomas Digges of Kent, an Englishman, bearing on the parallax.

XIV. This noble writer, in his booklet which he titled *Mathematical Wings and Ladders* [Alas & Scalas Mathematicas], and in which he gives many subtle problems on parallaxes, reports the distances of the New Star from the fixed stars set down below, taken with an astronomical radius indeed, but in a more correct manner than that used by others. Tycho, on page 654, sets his own beside them, with the difference between them:

Distance of the New Star from the stars of Cassiopeia

Names of the stars	Digges	Tycho	Difference
from the Breast	7° 47′	7° 50½′	3½′
from the Bend	4° 58′	5° 2′	4′
from the Knee	8° 5′	8° 3½′	1½′
from the Leg	9° 45′	9° 48′	3′
from the Foot of the Seat	1° 28½′	1° 31′	2½′
from the Middle of the Ascent	5° 15′	5° 19′	4′

From these distances, kept the same at every altitude in the vertical, Digges concludes that it was detected even by sight alone that the star had no parallax greater than 2′. Let us hear him, in chapter 10, in Tycho, page 674: *Otherwise, too, anyone will be able by this art to discern by sight alone, without any instrument, the ravings of those who think that it is in the elementary region below the Moon and has a conspicuous parallax greater by a whole degree, if he will only compare its situation with that other little star which is in the foot of Cassiopeia's seat. For you will never find the phenomenon to depart from it by three times the Sun's diameter. If, therefore, it had a parallax one degree larger, it would be necessary, while the phenomenon was above it in one vertical, that it should appear nearer to it by two thirds of the former distance, and not differ from it by a single diameter of the Sun, namely thirty minutes or thereabouts — as is clear from what is demonstrated in the tenth and fifteenth problem. But there is no one who could not discern so great a variation, at so small a distance, by sight alone, without any instrument. And anyone who will consider the matter in this way will not only know most certainly that there is not so great a variation of view, but will find it so small and insensible that he will rather hesitate within himself whether he should believe it, being without parallax, to be truly fixed above the orbs of all the planets — so far is anyone (who is not blind, nor blinded by the darkness of the grossest ignorance) from affirming it to be below the Moon.* But this whole reasoning binds us in the end only to grant Digges that, whether he observed this star in Kent or at Ludinum [?], no parallax was

perceived, nor one equal to the Moon's; it is not shown that it could not have been perceived by others observing on the same night in a different place on Earth. Add that Tycho, on page 681, finds among the longitudes and latitudes of the New Star that Digges deduced from his observations a disagreement or discrepancy of 4⅓° in longitude and 55′ in latitude.

[Margin: Digges's opinion not demonstrated.]

Eliæ Camerarij Obſeruationes ad Parallaxin ſtellæ huius ſpectantes Francofurti ad Oderam initæ.

Observations of Elias Camerarius bearing on the parallax of this star, undertaken at Frankfurt an der Oder.

XV. Elias investigates the parallaxes of this new star by the following method, as it stands in Tycho, volume 1, page 693. On 1572 November 23 and the following days, in the evening, this star stood 9° 30′ from the zenith of Frankfurt on the meridian, and in the morning of the following day 65° 52′; the difference was 56° 22′. The altitude of the pole at Frankfurt an der Oder is, by observation, 52° 24′, and the distance of the pole from the zenith 37° 36′. Subtract 9° 30′ from this, and there remains the apparent distance of the new star from the pole, 28° 6′. Conversely, subtract 37° 36′ from 65° 52′, and there remains a distance from the pole of 28° 16′. Therefore, says

Elias, the parallax is 10′. Again, in the year 1573, on January 5, 6, 7 and 8, the distance of the new star from the zenith was 9° 33′ in the evening and 65° 43′ in the morning, from which he gathers a parallax of 4′ 30″. And on April 7 and the following days the greatest distance from the zenith was 65° 45′, while the least could not be taken because of the approach of the Sun; but on August 7 the least was found to be 9° 34′. Now, if the star had not been higher than the Moon but where the Moon is, it would have shown a parallax of 67′. It would therefore have come about, had it been in the elementary region, that the New Star would have stood off from the stars of Cassiopeia by a very sensible and greater interval when it was below the pole than when it was above. But even granting these data, still without any inquiry[19], it does not follow — if no greater parallax was found at Frankfurt — that none was seen, or was visible, elsewhere either, had the star been observed by others on the same nights. Moreover, the altitude of the pole that he supposes, 52° 24′, is uncertain; for Origanus, Kepler, Lansbergen and Wendelen put it at 52° 20′, and from the altitude of Leipzig and the road distance no more than 52° 6′ is gathered, as I said in my geographical book, where I treat the distance of the meridians, or the difference of longitudes.

[Margin: Elias's opinion not demonstrated.]

[19]printed *diquisitione*, for *disquisitione*

Eraſmi Reinholdi Iunioris Opinio & fortè Obſeruationes ad Parallaxin huius ſtellæ ſpectantes.

The opinion, and perhaps the observations, of Erasmus Reinhold the Younger bearing on the parallax of this star.

XVI. This Erasmus the Younger, son of the elder Reinhold, the author of the Prutenic Tables, and a professor of medicine, records in his prognostication for the year 1574 the observations set down below concerning this star, as having been made at Erfurt, as Tycho has it in volume 1, page 700.

	Value
Apparent greatest altitude	79° 30′ 0″
Its parallax	0° 0′ 34″
True greatest altitude	79° 30′ 34″
Apparent least altitude	23° 2′ 30″
Its parallax	0° 2′ 56″
True least altitude	23° 5′ 26″
Altitude of the pole	51° 18′ 0″
True declination	61° 47′ 0″
Apparent declination at the greatest altitude	61° 48′ 0″
Apparent declination at the least altitude	61° 44′ 30″
True latitude	53° 35′ 30″
Apparent latitude at the greatest altitude	53° 36′ 0″
Apparent latitude at the least altitude	53° 33′ 14″
True place, always the same	♉ 7° 12′ 26″
Apparent place at the greatest altitude	7° 12′ 45″
Apparent place at the least altitude	7° 10′ 33″
Distance from the centre of the Earth: 1079 semidiameters of the Earth	

Reinhold says this about so small a parallax, but he does not demonstrate it. Indeed, Tycho sees that he uses an altitude of the pole at Erfurt of 51° 18′ and the altitudes of the New Star observed at Kassel by the Landgrave of Hesse; and since the altitude of the pole at Kassel is 51° 18′, while the altitude of the pole at Erfurt is smaller in the geographical maps — 51° 10′ in the Prutenic Canons, indeed, and 51° 6′ in mine — he rightly suspects that Reinhold is speaking not of his own observations but of the Landgrave's, about which I have said enough in number 2.

XVII. So far, then, none of the authors whom Tycho brought forward in his support in volume 1, chapters 8 and 9, has demonstrated to us from his own observations, made in a single place on Earth, that this New Star lacked a parallax sensible in itself, or had a parallax smaller than the Moon's. For either they demonstrated nothing, but brought forward the opinions of others; or, if they demonstrated anything on this point, it showed only that a parallax was not perceived in their place, or that the parallax that was perceived was smaller than the Moon's. All of this could have happened by accident, so that, had several observers in different horizons observed the New Star on the same night,

they could have detected a parallax greater than the Moon's, as we taught in chapter 6. In this way the argument of Antonio Santucci is also answered, by which he contends, in his book *De Cometis*, chapter 7, that this star was among the fixed stars because at Pisa, at an altitude of the pole of 43° 30′, he observed the greatest altitude of this star as 79° 30′ and the least as 7° 30′, and so equally distant from the pole of the world on both sides, namely by 36°. But whether it can be demonstrated from the observations of the authors already mentioned — taken not separately but all together — that it was above the Moon, we shall see partly in the following chapter and partly in chapter 17. Meanwhile, let this be the

[Margin: Santucci's argument invalid.]

VNICA CONCLVSIO.

The single conclusion.

None of those whom Tycho brings forward in volume 1, chapters 8 and 9 — nor Antonio Santucci either — demonstrated that the New Star of the year 1572 had a parallax smaller than the Moon's, let alone that it had no parallax sensible in itself; and so none of them demonstrated that it was above the Moon.

CAPVT VIII.

Chapter 8.

Whether Galileo, from observations made in different places and compared with one another, demonstrated that the New Star of the year 1572 was above the Moon, or even among the fixed stars.

I. Chiaramonti contends, in Book 1 of *De novis stellis*, chapter 26, that from twelve pairs of meridian altitudes of this star, observed in different places, it follows that this star was below the Moon. But Galileo, in the third Dialogue on the system of the world, affirms that there are many more pairs of observations that raise it above the Moon: five, he says, that put it above the Moon, five others that put it among the fixed stars, and 30 that raise this star to an infinite distance. But in this he asks pardon if, by adding or subtracting a few minutes, he brings observations that do not agree into agreement, so as to raise the star to the firmament; and on page 287 he has these words, faithfully rendered into Latin by us: *So that it may be understood more fully, and so that it may be known readily how much more probably it is gathered, from the observations of the astronomers whom the Author uses, that the New Star was higher than the Moon:* and again on page 302: *From what I have shown so far you can learn how much more probably, and more clearly, it is gathered from them that the distance of the star is to be referred to the most remote fixed stars.* Since, then, Galileo does not contend in that place that the height of the New Star above the Moon has been demonstrated by him, but only that it has been asserted by more probable arguments — while we are still conducting the controversy about geometrical demonstrations, and are to speak about probability later — we could finish this chapter at once from his

own words already quoted, and lay down a negative conclusion. But someone might suspect from his calculations that geometrical certainty had been kept, and accordingly that it had been demonstrated, from some true hypothesis and from some correct observations, that the New Star was above the Moon; and since there are not a few errors in his calculations, they must be uncovered by us, for this will serve the examination of probability to be undertaken later.

Diagram. Set in the right column beside the opening of §II: three concentric quadrant arcs about the centre of the Earth, A, with the radius AO upright at the right and AG along the foot. The outer arc runs from O at the top to G at the bottom left, the middle arc ends at M on the upright radius and at H on the foot, and the inner arc ends near L on the upright and at K on the foot. Two radii run from A out to E and to F on the outer arc. The point C on the middle arc is joined by straight lines to B, near the upright radius, and to D, inside the figure; further lines run from C and from D to A. A small round mark beside the inner arc, left of D, is not identified as a label.

- E (top of the outer arc): point on the vertical ABE
- O (top right, end of the upright radius): end of the quadrant of the highest heaven, OG
- F (left on the outer arc): point on the vertical ADF
- M (on the upright radius): end of the New Star's quadrant, MH
- B (near the upright radius, at the top of the inner arc): the Landgrave of Hesse's station; end of the Earth's quadrant, BK
- L (beside B, on the upright radius): label only; not named in the text on this page
- C (on the middle arc): the New Star
- D (inside the figure, on the inner arc): Tycho's station
- G, H, K (along the foot): ends of the quadrants of the highest heaven, of the New Star, and of the Earth
- A (bottom right): the centre of the Earth

[Margin: 1. Galileo's first inquiry.]

II. In the present figure, with three quadrants of meridians described from the centre of the Earth — the Earth's, BK; the New Star's, MH; and the highest heaven's, OG — let the New Star be at C, seen by Tycho from D and by the Landgrave of Hesse from B, along the lines of the apparent place BC and DC; and let the vertical lines of the two places, drawn from the centre of the Earth, be ABE and ADF. With these laid down, Galileo, in his first inquiry, from the altitudes of the pole, and from the least altitudes of the New Star observed by Tycho and the Landgrave, as set out here, reasons as follows.

	Altitude of the pole	and of the New Star
Tycho	55° 58′	27° 45′
the Landgrave	51° 18′	23° 3′
Difference	4° 40′	4° 42′

Subtract the difference 4° 40′ from 4° 42′: a parallax of 2′ remains, that is, the angle BCD. The chord of the difference of the altitudes of the pole — that is, of the angle BAD, or the arc BD, of 4° 40′ — is 8142 in the tables of sines, in parts of which the radius AB is 100,000. Next, the angle BDC is given. For half the angle BAD, which is 2° 20′, added to a right angle makes the angle BDF, 92° 20′; and if you add to it the angle CDF, 62° 15′ — that is, the distance of the New Star from the zenith of Herrevad, where Tycho observed — BDC becomes 154° 45′ (says Galileo, in error), whose sine is 42,657. The sine of the parallactic angle C, 2′, is 58. Now in the triangle BCD the side DB is to the side BC as the sine of the opposite angle BCD is to the sine of the opposite angle BDC; therefore BC is 42,657 in parts of which BD is 58. But in parts of which DB is 8142, or BA 100,000, BC will be, by the golden rule, 5,988,160 ¼; and so BC is 59 88,160/100000 parts, of which AB is one semidiameter of the Earth. If one semidiameter is added to this, AC will be nearly 61 semidiameters of the Earth; and so the New Star C will be found above the Moon at perigee, which for Copernicus is not more than 52 17′ semidiameters of the Earth distant.

[Margin: 1. Galileo's error in geometry.]

Yet there are not a few errors in this reasoning. First, if the angle BDC is 154° 45′, as he expressly puts it (and that this is no printer's error is clear from the sine 42,657, which truly corresponds to an angle of 154° 45′), and the angle BCD is 2′, then these two angles together are 154° 47′. Now the angle BDF is, for Galileo, 92° 20′, and the other angle below the base of the isosceles triangle ABD, namely the angle EBD, is just as large; and the angle CBE — that is, the complement of the altitude of the New Star seen by the Landgrave at B — is 66° 57′, since the altitude was 23° 3′. Taking 66° 57′, then, from 92° 20′, the angle CBD remains, 25° 23′. Joining the angles of the triangle DBC, therefore, the sum will be 180° 10′, and so greater than two right angles. This is contrary to Euclid, Elements, book 1, proposition 32, and is plain even to beginners in geometry. Five days later I found this error noted also by Chiaramonti, in the *Apologia* in which he defends himself against Galileo's objections, part 3, chapter 22.

[Margin: 2. Galileo's error.]

The second error, which was the source of the first, is that he took the apparent altitudes of the New Star as though made in exactly the same meridian, and indeed at the same moment of time, and at the same time as exact. But it is false that Kassel and Herrevad lie exactly under the same meridian; and it is only gratuitously supposed that both observations fell at the same moment of time, since Tycho did not note the time at which he observed the altitude of the New Star. And although the meridian may be imagined as carried across, because the New Star is supposed to have had no motion other than that of the primum mobile, and both observations may be imagined as made at the same moment, the observations as made still cannot be reconciled with one another, nor accepted as exact. This is clear from the fact that, if the altitudes of the pole and of the New Star given by the observers and accepted by Galileo

are accepted, the triangle BCD is found to be of 180° 10′, or greater than two right angles, which is absurd.

[Margin: 2. Galileo's inquiry.]

III. The second combination, on page 292, is of the observations of Camerarius and Muñoz, from which he strives to find out the distance of the New Star from the Earth. The foundations of the calculation are of the following kind, applied to the preceding figure and with the same method employed as in the preceding number, supposing Camerarius observing at D and Muñoz at B.

	Altitude of the pole	of the New Star
Camerarius	52° 24′	24° 28′
Muñoz	39° 30′	11° 30′
Difference BAD	12° 54′	12° 58′
Difference of the parallaxes BCD		0° 4′

From these he gathers the angle BDC, 161° 59′, with its sine 30,930, and the chord of the angle BAD, 22,466, and the sine of the angle BCD, 116 parts. From this, then, he gathers BC as 59, and AC as about 60, in parts of which AB, the Earth's semidiameter, is one.

[Margin: 1. Galileo's error [?].]

But here too he errs in many ways. First, he assumes the apparent altitude of the New Star by Camerarius as 24° 28′, here and on page 288. You will find this nowhere in Tycho, but only 24° 8′ on November 23, 24° 17′ on January 5, and 24° 20′ on April 7, as is plainly established from the account which I reported with the greatest fidelity in chapter 3, number 3. Nor could he have taken that 24° 28′ from Chiaramonti himself, who in *De tribus novis stellis*, book 1, page 30, reports those least altitudes exactly as Tycho does — 24° 8′, 24° 17′, 24° 20′ — but nowhere 24° 28′. So, whether by guile or, more likely, by a slip of the pen or of the imagination, he founded his calculation on a false assumption.

[Margin: 2. Galileo's error [?].]

Secondly, here too Galileo either supposes these observations to have been made under the same meridian and at the same moment, so as to gather from them the difference of the parallaxes, or the angle BCD — yet Muñoz did not record the time at which he observed, and so it is only gratuitously imagined that both observed those least altitudes of the New Star at the same moment; and neither could that have happened, because, if the star was observed in the meridian at both places, the meridian of Frankfurt an der Oder, where Elias Camerarius observed, is more easterly than the meridian of Valencia, where Muñoz observed, by 17° 11′, that is, by more than the space of one hour. Or else he supposes that the New Star, carried from one meridian to the other with no motion other than that of the primum mobile, kept the same declination. But this is both assumed gratuitously and cannot agree with the altitudes seen by Camerarius and Muñoz, and with the altitudes of the pole and the parallax

accepted by Galileo; for from them it follows either that the triangle BCD has three angles together greater than two right angles, or that the difference of the parallaxes is not 4′, as he would have it.

For the angle BAD, or the difference of the altitudes of the pole, is given as 12° 54′. Therefore, by Elements, book 1, proposition 32, the angles ABD and ADB together are 167° 6′; by proposition 5 of book 1, each of them is 83° 33′; and by proposition 13 of book 1, the adjacent angle DBE, as well as BDF, is each 96° 27′. The angle CBE, the complement of the altitude of the star seen by Muñoz, is 78° 30′; subtracting this from DBE leaves the angle CBD, 17° 57′. Now if to the angle BDF, which is 96° 27′, you add the angle FDC, that is, the complement of the altitude seen by Camerarius — an altitude which was 24° and, first, 8′, then 17′ — the angle BDC will be 162° 19′ or 162° 10′. Adding to this the angle CBD, 17° 57′, the sum is 180° and 11′, or 2′; and if you add to these the parallactic angle BCD, the total will come out still greater than two right angles. But if you assume with Galileo the altitude seen by Camerarius as 24° 28′ (which is, however, falsely invented), BDC comes out 161° 59′, and with CBD 179° 51′; so the third angle, BCD, comes out 9′. And if you assume the last altitude, 24° 20′, BDC becomes 162° 7′, and with DBC 179° 59′, and accordingly the angle BCD is of one minute. This last case would favour Galileo, but he did not see it; for it would raise the New Star far above 60 semidiameters of the Earth. But since two or three other cases are in conflict with this one, it is clear enough that nothing has been solidly demonstrated by him for a seat of the New Star above the Moon — to say nothing of the uncertain altitude of the pole at Frankfurt, of which we spoke in chapter 7, number 15.

[Margin: 3. Galileo's inquiry [?].]

IV. The third comparison that Galileo uses is of the observations of Tycho and Muñoz of the greatest altitudes of the New Star observed in the meridian, as you see here.

	Altitude of the pole	of the New Star
Tycho	55° 58′	84° 0′
Muñoz	39° 30′	67° 30′
Difference BAD	16° 28′	16° 30′
Difference of the parallaxes, or BCD		0° 2′
Angle BDC	104° 14′	

And the method of investigating the difference of the parallaxes BCD, and from it the distance of the New Star from the Earth, — but of 478 semidiameters of the Earth — is exactly the same as the one we set out in the two preceding numbers by means of the figure of number 2; and there is no need to report anything but the foundations of the calculation that he assumes, and to suppose Tycho at D and Muñoz at B.

[Margin: 1. Galileo's error.]

But in this reasoning he assumes the altitude observed by Tycho as 84°, from Tycho's earlier writing — an altitude Tycho did not in fact observe, because he had only a single sextant, as Tycho himself admits in volume 1, pages 335, 351 and 420 taken together. There he also gives the greatest altitude of the New Star as 84⅙°, not observed but deduced from the least altitude, of 27° 45′, and from the altitude of the pole at Herrevad, 55° 58′, as he expressly states in the same place, supposing that the star had no parallax, and accordingly that the apparent distance of the star from the pole must have been equal in both meridian altitudes. This he laid down from a preconceived opinion, not from his own observation, and by assuming as certain the very thing that was in dispute. Therefore to assume the greatest altitude of the New Star as 84°, or 84⅙°, as though observed by Tycho, is to assume something uncertain and resting on nothing but a disputed supposition. Next, Tycho himself regarded Muñoz's observations as uncertain and rather rough, as we said in chapter 6, number 8; for if he accepted them as exact, a large difference of declinations would come out between himself and Muñoz. So not even by this inquiry has Galileo demonstrated that the New Star was above the Moon, except from a false or very uncertain hypothesis.

[Margin: 2. Galileo's error.]

Secondly, Galileo treats the observations as though the star, on passing from one meridian to the other, had not changed its declination — which is in dispute.

[Margin: 4. Galileo's inquiry.]

V. Galileo's fourth comparison is of the greatest altitudes of the New Star observed in the meridian by Muñoz and Peucer. From them, by the figure and the method already set out above, he gathers the distance of the New Star from the Earth as 358 semidiameters of the Earth, from a difference of the parallaxes of 2′. The foundations of the calculation are in the small table added here.

	Altitude of the pole	of the New Star
Peucer	51° 54′	79° 56′
Muñoz	39° 30′	67° 30′
Difference BAD	12° 24′	12° 26′
Difference of the parallaxes BCD		0° 2′
Angle BDC	106° 16′	

[Margin: 1. Galileo's error.]

But Galileo's first error is that he assumes the altitude of the pole at Wittenberg, where Peucer observed, as certain or more probable at 51° 54′, whereas by Tycho's reasoning it is 51° 47′, or by our parallax of the Sun 51° 48′ 32″, but by the observation of the elder Peucer 51° 58′; and so it is very uncertain. Tycho's value, however, or ours, is more probable, as in chapter 7, number 11; and from it there follows a difference of the altitudes of the pole of 12° 18½′, and of the parallaxes of 7½′.

[Margin: 2. Galileo's error.]

The second error, here and in all the preceding and following reasonings, is that he supposes either that the observations were made by both on the same night, at the same moment and under the same meridian — of which the first is uncertain and the second false — or else that the New Star, carried from the meridian of Valencia to the meridian of Wittenberg, and that after some days or hours elapsed between the two observations, had meanwhile been moved by no motion other than that of the primum mobile, and had not sensibly changed its declination, or its distance from the pole of the world. For unless he supposed this, he could not correctly deduce the difference of the vertical parallaxes from the difference between the difference of the altitudes of the pole and the difference of the altitudes of the New Star. But this very point is in dispute. Suppose someone were to say that the New Star, observed indeed on different nights by Peucer and by Muñoz, had those apparent altitudes; but that, had it been observed on the same night under the same meridian by some single observer placed on the parallel of Peucer or of Muñoz — that is, under the same altitude of the pole under which they lived — it would have had quite different apparent altitudes, and a quite different difference between them. If anyone, I say, were to say this, he cannot be refuted from these observations. Therefore Galileo's reasoning and conclusion are uncertain, and accordingly nothing has been solidly demonstrated for raising the star above the Moon.

[Margin: 5. Galileo's inquiry.]

VI. The fifth comparison, which Galileo uses in order to establish from it that the New Star was removed from the Earth by more than 716 semidiameters of the Earth, is of the greatest altitudes taken in the meridian by the Landgrave and Hainzel. The method and the figure are the same as were used so many times above, so it is enough to indicate the foundations of the calculation, and to suppose the Landgrave at D and Paul Hainzel at B.

	Altitude of the pole	of the New Star
the Landgrave	51° 18′	79° 30′ 0″
Hainzel	48° 22′	76° 33′ 45″
Difference BAD	2° 56′	2° 56′ 15″
Difference of the parallaxes BCD		0° 0′ 15″
Angle BDC	101° 58′	

[Margin: 1. Galileo's error.]

But first, Galileo either errs or, by a gratuitous choice, exposes himself to the danger of erring. For among the various greatest altitudes of the New Star given in our account in chapter 3, number 3 — namely 76° 33′ 45″, 76° 34′ and 76° 35″[20] — he chooses the least, 76° 33′ 45″, when it would have been better and more probable to choose the middle one among them, 76° 34′ 30″, as Tycho chose.

[20] so printed, with a double prime; the same altitude is set 76° 35′, with a single prime, further down this page

[Margin: 2. Galileo's error.]

Secondly, he supposes that the New Star, while it was carried from one meridian to the other (for Kassel, where the Landgrave observed, and Göggingen, where Hainzel observed, are not under the same meridian), so that by this fiction, as though the observation had been made under the same meridian at the same moment, he could fish out the diffentiam [?] of the parallaxes — he supposes, I say, that the New Star meanwhile changed its apparent declination not at all. But this very point, so long as it is not shown from the observation itself, is in dispute. For what if someone else, on the same parallel as Göggingen and under the meridian of Kassel, observing at the same moment, had found a meridian altitude of the star far different from Hainzel's? Moreover, Chiaramonti likewise condemns that choice of 76° 33′ 45″, in the *Apologia* for the books *De novis stellis*, part 3, chapter 27, and adds that if he had chosen 76° 34′ 30″, or 76° 35′, the sum of the angles CDB and CBD would be greater than two right angles. But for that very reason Galileo would perhaps say that he had set these aside and chosen 76° 33′ 45″. Still, he cannot avoid the fact that this choice, and the conclusion derived from it, rests on an uncertain foundation. Therefore what Galileo adds after these five combinations and inquiries — namely, that no difference of the parallaxes greater than 10′ 15″ was found in them, and that once these were removed the New Star would easily be placed in the firmament — is subject to the same uncertainty.

VII. After the five combinations already adduced, from which Galileo tried to show that the New Star stood distant from the centre of the Earth by semidiameters of the Earth as you see in the small table:

Combination of observations	Distance from the Earth, in semidiameters of the Earth
1	61
2	60
3	478
4	358
5	716

[Margin: 5. Other inquiries of Galileo.]

he selected five other comparisons of observations reported by Tycho and by Chiaramonti, in which, by comparing the altitudes of the pole and the meridian altitudes of the New Star with one another, he found the differences of the two to be equal, and the difference of the parallaxes to be nil, and so also no sensible parallax. Accordingly he concludes that, taking them as they lie and with no correction brought in to make them agree, it follows that the New Star was in the firmament. The observations are the following.

Observers	Altitude of the pole	Meridian altitude of the New Star
Camerarius	52° 24′	80° 26′
Peucer	51° 54′	79° 56′

Observers	Altitude of the pole	Meridian altitude of the New Star
Differences	0° 30′	0° 30′
the Landgrave	51° 18′	79° 30′
Hainzel	48° 22′	76° 34′
Differences	2° 56′	2° 56′
Tycho	55° 58′	84° 0′
Peucer	51° 54′	79° 56′
Differences	4° 4′	4° 4′
Reinhold	51° 18′	79° 30′
Hainzel	48° 22′	76° 34′
Differences	2° 56′	2° 56′
Camerarius	52° 24′	24° 17′
Hájek	48° 22′	20° 15′
Differences	4° 2′	4° 2′

[Margin: 1. An error of Galileo's, or a doubt about an error.]

VIII. But in all these combinations Galileo, first, supposes the observations to have been made at the same moment of time and under the same meridian — that is, even if they were not so made, then at least in such a way that, the New Star being carried from one meridian to the other, anyone who had observed the altitude of the star under the same parallel of the equator would have seen the same altitude as the other observer saw under that parallel but under a different meridian. For example: Peucer, at Wittenberg, which is more westerly than Frankfurt an der Oder, observed the altitude of the New Star as 79° 56′; the star was then carried, either on the same night or on any other night, to the meridian of Frankfurt, where Camerarius was observing; and if anyone under the meridian of Frankfurt, but at an altitude of the pole equal to that of Wittenberg, had observed the altitude of the New Star, he would have found it as great as Peucer did, namely 79° 56′. The reason is that there was a persistent rumour that the star was endowed with no motion other than that of the primum mobile [primi Mobili], and did not change its distance from the pole of the world or from the fixed stars, as Galileo affirms on pages 307 and 315. But this very point is in dispute. For it is not established that the pairs of observations selected by Galileo, nor any others, a single case excepted, fell at the same time; indeed it is established from the account in chapter 3 that they fell on different nights. And the star could have kept, or returned to, the same distance from the pole and from the fixed stars on those different nights, and yet on other nights have varied it so much that if, for example, Camerarius and Peucer had observed it on the same night, they would have found it very different; and so for the rest. Therefore that supposition of an unchanged declination, and that report spread among the astronomers, although not lacking in probability, is nevertheless uncertain, and insufficient for the certainty of a geometrical demonstration, which is what concerns us here.

[Margin: 2. A doubt about Galileo's foundation.]

Secondly, from the greatest altitudes of the New Star observed by Camerarius — 80° 30′, 80° 27′, 80° 26′ — which he himself had reported on page 288, Galileo then chooses, on page 304, the least, 80° 26′, so as to obtain no difference of the parallaxes, since from the first there follows 6′ and from the second 1′. And from the first, indeed, as Chiaramonti notes in part 3 of this *Apologia*, chapter 28, the comparison could not serve for finding the distance, because the three angles of the triangle BCD, as in the figure set out above, would come out greater together than two right angles; while from the second the distance of the New Star would be gathered as only 29 66/100 semidiameters of the Earth.

[Margin: 3. A doubt about Galileo's foundation.]

Thirdly, in the second and fourth comparisons he uses Hainzel's altitude of 76° 34′, which, however, he chose above, as we said in number 6, as 76° 33′ 45″. And in the third comparison he chooses Tycho's altitude of 84°, which, as is clear from Tycho's volume 1, page 420, should have been chosen as 84⅙°. But from what was said in number 4 it is clear that this very value is uncertain, and not observed by Tycho, but derived, from the presumed absence of papallaxeos [?], from the least altitude of the New Star and from the altitude of the pole at Herrevad. Finally, in the fifth comparison, out of the three least altitudes observed by Camerarius and acknowledged by Galileo on page 288 — namely 24° 28′ (where 24° 8′ should be read), 24° 17′ and 24° 20′ — he himself chose only one, 24° 17′, on an uncertain foundation, certainly.

[Margin: 4. A doubt about Galileo's foundation.]

Fourthly, the altitudes of the pole that he uses — namely of Frankfurt, 52° 24′, of Wittenberg, 51° 54′, and of Vienna, 48° 22′ — are very uncertain and probably in need of correction, as we taught in our geographical book and indicated in chapter 7, numbers 5, 11 and 15. But let us grant that they are certain: why, then, does Galileo not use the observations made at Vienna by Hájek and at Göggingen by Hainzel, these being at the same altitude of the pole, 48° 22′? Now the least altitude of the New Star observed by Hájek was 20° 15′, and by Hainzel 20° 9′ and 20″, or 30″, or 40″, as we related in chapter 3, number 3. So the difference of the parallaxes, or the parallax, would have been at least 5′ 20″, and the New Star accordingly far below the fixed stars.

[Margin: Galileo's error.]

IX. After this, Galileo says on page 306 that there remain 30 pairs of observations which raise this star to an infinite distance; but he neither shows this nor can show it. For, as Chiaramonti rightly argues in this *Apologia*, chapter 29: if some parallax is gathered from the observations, the phenomenon is below the fixed stars; if no sensible parallax, none of the astronomers places that phenomenon beyond the fixed stars, which are themselves also supposed to lack all sensible parallax; or at any rate, if the observations supply a triangle from which some parallax can at last be drawn, even if not a sensible one, that parallax itself requires a finite distance after all; but if the triangle gathered from the observations has three angles greater than two right angles, then no parallax can indeed be gathered from it, but it cannot be positively concluded,

or assumed, to be nil. Moreover, Galileo acknowledges on page 307 three other comparisons from which there would follow a distance of the New Star from the Earth smaller than one whole semidiameter of the Earth — namely those in which the altitude of the New Star taken by the one of the observers under the greater altitude of the pole is the smaller. They are set down here; but he rejects them as improbable.

Observers	Altitude of the pole	Altitude of the New Star
the Landgrave	51° 18′	79° 30′
Gemma	50° 50′	79° 45′
Busch	51° 10′	79° 20′
Gemma	50° 50′	79° 45′
Reinhold	51° 18′	79° 30′
Gemma	50° 50′	79° 45′

But who does not see that these combinations, since they posit nothing impossible, are much more tolerable than those from which it would follow that a triangle has three angles together greater than two right angles? And yet Galileo prefers these very ones, with the infinite distance which he asserts follows from them, claiming that these are corrected more easily, more probably and with less trouble, if even the slightest parallax is added. Nothing certain, therefore, can be concluded about the distance of the New Star from the Earth from all the comparisons selected by Galileo with so much industry. For in observations so different, some placing it above the Moon and others below, some uncertainty and deception must lie hidden in some of them — unless Galileo takes refuge in different times and says that it was now above the Moon, now below it; and this he by no means says.

[Margin: An error of these observations acknowledged by Galileo.]

Rather, he acknowledges some error in these observations, when on page 282 he says the following, rendered into Latin by us: *But I am willing to grant the Author* — namely Chiaramonti — *more than perhaps he himself requires: namely, that in each of the combinations of observations there is some error; which I think absolutely necessary.* That is, so that by emending these errors with some probable correction, as he afterwards does, he may bring the star back to no parallax and to the distance of the fixed stars. But it is not necessary that an error occurred in all of them; or, if one did occur, it is uncertain which of the two observers erred, and by how much, and how great a correction is to be applied; nor can we rely on anything but conjectures that are probable in a broad way. It is therefore manifest, as I said at the beginning of the chapter, that Galileo has not demonstrated from any certain hypothesis that the New Star was above the Moon, let alone among the fixed stars. Let this, then, be the conclusion:

VNICA CONCLVSIO.

The single conclusion.

In the third *Dialogue*, on the system of the world, Galileo did not demonstrate, either absolutely or from any certain hypothesis of observations made under different horizons, that the New Star of the years 1572 and 1573 was above the Moon, let alone among the fixed stars. Let it be granted that he demonstrated it probably, that is, from some hypothesis that may probably be accepted. This is clear from what was said from number 2 to the end.

CAPVT IX.

Chapter 9.

An vllus Authorum, quos Tycho tomo I. cap. 10. adducit contra ſe, demonſtrarit Stellam Nouam Anni 1572. fuiſſe infra Lunam.

Whether any of the authors whom Tycho cites against himself in volume 1, chapter 10, demonstrated that the New Star of the year 1572 was below the Moon.

I. In volume 1 of the *Progymnasmata*, chapters 8 and 9, Tycho reviewed the astronomers, or philosophers or theologians, who asserted that this star was above the Moon; he then closes that volume, in chapter 10, by citing the authors who affirmed that it was situated below the Moon. Let us see whether these men too demonstrated what they affirmed.

[Margin: Cyprián Karásek Lvovický, Chytraeus and Postel demonstrated nothing about this star.]

The first of them listed by Tycho, on page 705, is Cyprián Karásek Lvovický of Leonicia, a Bohemian. He brought forward no demonstrations — indeed, no observations fit for a demonstration. In his writing on this star, which he calls a comet, he says that it was at Taurus ♉ 8°, with a latitude of about 50°, that it was exactly joined in its body to the Chair of Cassiopeia, and that for two months, counted from November 25, it stayed in the same place, with no motion other than that of the primum mobile. He then adds: *But now, within a single month, that star seems to me to have advanced somewhat, by three degrees, toward the north.* Tycho censures him on this point, and in noting the star's place, since he disagrees with most of the observers. For us it is enough that he demonstrated nothing; just as nothing was demonstrated by David Chytraeus, or by Guillaume Postel the Frenchman, whose mere and empty astrological judgements on this star Tycho reports in volume 1, pages 712 and 716.

[Margin: The error of Raymundus and Frangipanus.]

Much less did Annibal Raymundus of Verona or Cornelius Frangipanus of Rome demonstrate anything. Indeed, only through a great hallucination — not to say ignorance of the stars — did they say that this star was not distinct from the old stars of Cassiopeia known before, but was seen as new either because the density of the medium had been removed or because it had moved away from one of them; and, as Frangipanus adds, that it had moved two degrees toward the north. As if any star of Cassiopeia had ever been seen equal to

Jupiter or Venus, as this star appeared at the beginning of its apparition; or as if, granting it was a fixed star, as these authors thought, any of the fixed stars had ever changed its place, while the others remained, or its distance from the other fixed stars, by two degrees. Tycho says more against them in volume 1, pages 720 and 740. Dismissing these, then, let us pass on to others, leaving aside also Bartholomäus Reisacher, who once followed the opinion of Annibal Raymundus and afterwards corrected himself, as is clear from what was said in chapter 7, number 5.

Obſeruationes Andreæ Nolthij Embeccenſis ad Parallaxim Stellæ huius ſpectantes.

The observations of Andreas Nolthius of Einbeck bearing on the parallax of this star.

II. Tycho reviews these in volume 1, from page 750 to 765. There Nolthius first states that he observed the altitude of the pole at Einbeck as 51° 42′. And in chapter 4 of his little book on this star he says that on November 29 its azimuth from the equinoctial east point toward the north was 60°, and its apparent altitude 77°; and that the bright star of the Lyre was then at an altitude of 41° 35′. From its Prutenic longitude, Capricorn ♑ 8° 29′, and its latitude, 62°, he gathers its right ascension as 275° and its declination as 38° 41′; and from these, by triangles, the right ascension of the midheaven as 344° 6′.

[Margin: Nolthius's method of investigating the parallax.]

Then, by another observation of the same night, made when the New Star — or, as he calls it, the comet — reached the meridian, he says that the altitude of the Lyre was 33° 51′. From this he gathers the right ascension of the midheaven, shared with the New Star, as 357° 11″. Subtracting from it the earlier right ascension of the midheaven, there remains an arc of the equator between the two observations of 13° 5′, or $52^{m}\ 20^{s}$ of time. From these data and the altitude of the pole he derives by trigonometry the true declination of the star as 61° 49′, and its distance from the zenith at the time of the first observation as 12° 21′, that is, a true altitude of 77° 39′. Therefore, since its apparent altitude was 77°, he concludes that the star's parallax in the circle of altitude corresponding to 77° was 39′. From this, in chapter 6, he gathers the distance of this star from the centre of the Earth as 19 52′ 12″ terrestrial semidiameters.

[Margin: What Tycho objects against Nolthius.]

But from page 755 Tycho raises many objections against Nolthius. First, that he used incorrect Prutenic places of the Lyre. Second, that even granting these, the arc gathered between the two observations is 13° 4′ 28″. Third, that he did not add any figure by which he demonstrated the parallax already mentioned. Fourth, that he does seem to have used problem 3 of Regiomontanus's *De Cometis*, but too unreliably, since he employed too short a time between the two observations, when he could have employed a longer time by observing the star in a lower position, or could have discerned the parallax more easily and more evidently from the greatest and least meridian altitudes of this star.

Fifth, that the altitude of the star and the azimuth in whole degrees, with no minute noted, are suspect to him, as is the observation of the altitude of the New Star and of the Lyre made without a companion, and therefore at different moments, when it ought to have been made at the same moment. Sixth, that by what Tycho had demonstrated in chapter 5, the right ascension of this New Star was not 357° 11′ but greater by 3° 15′. Seventh and last, if this star had a parallax of 39′ at an altitude of 77°, Tycho indeed demonstrates, by the problem set out earlier in chapter 5, number 2, that the parallax at the star's least altitude, which at Einbeck would have been 23° 30′, would have been 2° 42′; and so at its lowest altitude it would have appeared distant from the eleventh star of Cassiopeia by about three Moons, whereas in fact it kept sensibly the same distance from that star and from the other fixed stars.

[Margin: What Nolthius could answer to Tycho.]

None of this, however, evidently undermines Nolthius's conclusion. For Nolthius would say: that from Tycho's places of the Lyre, as Tycho himself concedes on page 758, a parallax of this star of 40′ 30″ follows after all, greater even than 39′; that the figure of the problem is available enough in Regiomontanus, and that he was addressing learned astronomers who would not be ignorant of it; that he observed carefully with some companion, and would not have concealed minutes in the altitude of the star and in the azimuth if there had been any, since he did not conceal them in the altitude of the Lyre; that a parallax of 39′ or 40′ found by such a method is not false or uncertain merely because it could have been gathered by another, easier and more evident way; that the great disagreement in right ascension arises from the difference of the days on which Tycho and Nolthius himself observed; and finally, that it is not established that on all the nights this star lasted its observed distance from the same fixed stars was the same, so that on some nights it could have been, and appeared, different.

[Margin: What we object against Nolthius.]

What therefore moves me not to acknowledge a demonstration in Nolthius is the uncertainty of the proper motion of this star. On that night it could have been such that, even though the star was above the Moon, the motion would apparently depress it toward the horizon, and an effect of parallax would be supposed which was in fact an effect of motion. For it has not yet been demonstrated — although it is repeated as probable — that this star had no other motion during the whole time of its duration than the motion of the primum mobile. See what we said in a similar case in section 1, chapter 18, against those who thought they had demonstrated absolutely that the comet of the year 1577 was below the Moon, without first demonstrating the comet's true motion.

Georgij Buſchij Erfurdienſis Obſeruationes ad Parallaxin Stellæ huius ſpectantes.

The observations of Georg Busch of Erfurt bearing on the parallax of this star.

III. He was a painter and an astronomer alike, and published two writings on this star in the German language; but what Tycho took from them bearing on our subject, in volume 1, from page 765, we shall pick out. Busch says, then, that he used an astrolabe, a quadrant and a geometric square, and that on November 25 at 7^h 14^m after noon he found the greatest meridian altitude of this star to be 79° 20′, and at about 19^h its least altitude to be 22° 40′; and he takes the altitude of the pole at Erfurt from Apian as 51° 10′. But, as one can see at once, and as Tycho saw on page 769: if the altitude of the pole is subtracted from the star's greatest altitude, the distance from the pole that remains is 28° 10′; while if the star's least altitude is subtracted from the altitude of the pole, the distance from the pole that remains is 28° 30′. The difference of the apparent distance from the pole, that is, the sum of the parallaxes, is therefore only 20′. Yet if this star had been in the concave of the lunar heaven, no more than 52 semidiameters of the Earth distant from the Earth, it would have had at such an altitude above the horizon a parallax, or difference of distance from the pole of the world, of one degree, as is clear enough from the diagram and from Tycho's problem, which we dealt with in chapter 5, number 2.

[Margin: Busch did not demonstrate what he asserted.]

So although Busch counts this star among the sublunary comets, not only did he not demonstrate this; rather, the opposite is gathered from his own observation. Yet even that is not evident, because the star could have had a greater parallax which did not appear greater to Busch; and one would need to consult observations made in different places on the same night, if they could be compared. For Busch's other errors, certain or doubtful, see Tycho if you wish.

[Margin: Graminaeus.]

IV. The remaining defenders of this star's place among the sublunary comets whom Tycho mentions in volume 1, from page 775 to 786, are Theodor Graminaeus, professor of mathematics at Cologne [Coloniæ Agrippinæ]; Adam Ursinus of Nuremberg; and Andreas Rosa of Schweinfurt, doctor of medicine. But Tycho denies that they brought forward any astronomical observation from which the distance of this star from the Earth could be conjectured, let alone demonstrated.

VNICA CONCLVSIO.

The single conclusion.

None of the authors whom Tycho reviews in volume 1 of the *Progymnasmata*, chapter 10, demonstrated that the New Star of the years 1572 and 1573 was below the Moon. This is clear from what has been said throughout this chapter.

CAPVT X.

Chapter 10.

An Scipio Claramontius abſolutè, vel ex certa aliqua hypotheſi demonſtrarit, Stellam Nouam Anni 1572.& 1573. fuiſſe ſublunarem.

Whether Scipione Chiaramonti demonstrated, absolutely or from some certain hypothesis, that the New Star of the years 1572 and 1573 was sublunary.

I. Scipione Chiaramonti is a writer of the first rank, noble not only by his knightly and afterwards priestly dignity but by the uprightness of his character, his talent and his learning; and — as must be openly admitted even by some who are unwilling — he has deserved excellently of the doctrine of parallaxes, as I think is already clear from what was said in section 1 of this book, from chapter 16. In book 1 of *De tribus novis stellis* he completed, in the first nine chapters, the history of the observations of this New Star of the year 1572. Then in chapter 10 he professes that he will demonstrate that it was below the Moon, *if its observations made at that time which can be compared, or at least the more important of them, are accepted*; for he states this limitation and condition at the beginning of the chapter. And he professes that he will investigate the distance of the star from the centre of the Earth by problem 8, given in chapter 2 of book 1 of the *Antitycho*, which is exactly the same as the one we already set out above in chapter 5, numbers 1 and 7. It rests on the parallax being given, together with the star's apparent altitude above the horizon and the semidiameter of the Earth, taken first in parts of which the radius is 100,000, and then taken as one.

[Margin: 1. Chiaramonti's method.]

For investigating the parallax he proposes five methods, or lines of inquiry. The first is from the meridian altitudes of the New Star observed under two horizons and in two places whose altitudes of the pole are given; for from these the difference of parallax is gathered, and from it the parallax and the distance from the centre of the Earth. He had already proposed this method in book 1 of the *Antitycho*, chapter 3, proposition 4.

Chiaramonti, moreover, supposes in book 1 of *De novis stellis*, chapter 11, Lemma 5, which runs as follows: *The New Star of the year 1572 kept the same parallax in all places perioecic [periœcis] to one another, and therefore the same apparent distance from the zenith; for it is posited as unmoved by any proper motion.* For in book 1 of the *Antitycho*, chapter 3, in the note on proposition 4, and in the supplement to the *Antitycho*, he had shown this very lemma in other words. Therefore, although the meridian altitudes were observed under different meridians, the star is posited as carried by the motion of the primum mobile from one meridian to another under the same parallel of the equator; so that, setting aside any other proper motion of the New Star, it is just as if two observers under the same meridian had observed the star at the same moment of time. Chiaramonti does this so as not to depart from the hypothesis that Tycho and most of those who assert this star's supralunar seat held as certain and established: namely, that during the whole time of its duration this star

had no other sensible motion at all than the common motion of the primum mobile.

II. Now, in the figure attached here, let LDK be a quadrant of the terrestrial meridian, under the quadrant OFG of the celestial meridian, and under the same let there be the quadrant MCH; all of them described from the centre of the Earth A. Let the New Star be at C, and let place B be the one that has the lesser altitude of the pole, and D the one that has the greater. Through these let the vertical lines AE and AF be drawn from A; let the same places be joined by the chord BD; and from them let the visual lines BC and DC be drawn to the star. There will thus arise the triangle BCD, in which the angle BCD is the difference of the parallaxes, as we shall show in book 10, in the penultimate section, chapter 8. Finally let AC be drawn, for the distance of the star from the centre of the Earth, which is proposed for investigation.

Diagram. A woodcut set into the right column beside the opening of §II: a quadrant with its centre A at the lower right, its horizontal radius running left through K and H to G and its vertical radius rising through L and M to O. Three concentric arcs are drawn — the outer from G through F and E to O (the celestial meridian), a middle one from H through C to M, and the inner from K through D and B to L (the terrestrial meridian). Lines run from A to E and to F (the verticals), from C to B and to D (the visual lines), with the chord BD and a line from A to C.

- E (outer arc, top, left of O): vertex of the vertical line AE
- O (top right, end of the vertical radius)
- M (vertical radius, below O)
- F (outer arc, upper left): vertex of the vertical line AF
- B (inner arc, near its upper end): the place with the lesser altitude of the pole
- L (vertical radius, beside B): end of the inner arc
- C (middle arc, left): the New Star
- D (inner arc, below B): the place with the greater altitude of the pole
- G (lower left, end of the horizontal radius)
- H (horizontal radius, right of G)
- K (horizontal radius, right of H): end of the inner arc
- A (lower right): the centre of the Earth

[Margin: 1. Step.]

With these things posited: First, in the triangle ABD the arc BD, or the angle BAD, which is the difference of the altitudes of the pole, is supposed given; and consequently each of the angles at the base BD is given, by propositions 5 and 32 of the first book of the *Elements*. For when the angle BAD is subtracted from two right angles, that is from 180°, and the remainder is divided in two, both the angle ABD and the angle ADB become known. From this the adjacent angles EBD and FDB become known, by proposition 13 of the first book of the *Elements*, since they are the complements of the angles ABD and ADB. Then, subtracting from the angle EBD the angle CBE, which is the complement

of the altitude of the star seen by the observer at B, the angle DBC becomes known. Conversely, if you add to the angle FDB the angle CDF, which is the complement of the altitude of the star seen by the observer at D, the angle CDB is composed; and the sum of this and the angle DBC, subtracted from 180°, shows the angle BCD, namely the difference of the parallaxes.

[Margin: 2. Step.]

Second, for the triangle CBD, in which all the angles are now known, the chord of the arc BD — that is, of the angle BAD, or of the difference of the altitudes of the pole — is sought from the tables of sines, in parts of which the radius, or the semidiameter of the Earth, AB is 100,000; and it is reduced by the golden rule to parts of which AB is one, or to miles, according as AB is known in miles.

[Margin: 3 and 4. Step.]

Third, then, BD being known in parts in which AB is known, the side BC is sought by the rules of triangles in the triangle BCD, whose angles are known. Fourth, in the triangle ABC, the sides AB and BC being now known, together with the angle ABC, which is composed of the angles ABD and DBC known above, the sum of the angles CAB and BCA is known; from it and from the sides already mentioned the parallax ACB is investigated, and when BCD is taken from it, the parallax ACD remains.

[Margin: 5. Step.]

Fifth and last, by means of the parallaxes and the sides AB and BC, the distance AC from the centre of the Earth is sought.

EXEMPLVM ex CLARAMONTIO.

An example from Chiaramonti.

III. The first comparison of observations that Chiaramonti uses, in book 1 of *De novis stellis*, chapter 12, is that of Francesco Maurolico, abbot, of Messina, who at Messina, at B, at an altitude of the pole of 38° 30′, observed the greatest altitude of the New Star on the meridian as 62°, and its complement as 28°, from what was said in chapter 3, number 3; and that of Paul Hainzel, who at Göggingen, at D, at an altitude of the pole of 48° 22′, observed the greatest altitude of the New Star as 76° 34′ 30″, as Tycho determined it from his various observations.

[Margin: 1. Step.]

With these things posited: First, the angle BAD, that is, the difference of the altitudes of the pole, is 9° 52′. When this is subtracted from 180°, there remains the sum of the angles at the base BD, 170° 8′; and half of it, that is, the angle ABD or ADB, is 85° 4′. Its supplement to two right angles, that is, both the angle DBE and the angle BDF, is 94° 56′. Subtract from it 28°, that is, the angle CBE, and DBC remains, 66° 56′. Add, on the other hand, to the angle FDB, of 94° 56′, the angle CDF, of 13° 25′ 30″, since the altitude seen by Hainzel is given as 76° 34′ 30″; and the angle CDB becomes 108° 21′ 30″.

Joined with DBC, of 66° 56′, this makes 175° 17′ 30″; therefore the angle BCD is 4° 42′ 30″.

[Margin: 2. Step.]

Second, the chord of the arc BD, of 9° 52′, is 17,200 parts, of which AB is 100,000. Therefore by the golden rule, from proposition 3 of Euclid's *Data*, in the parts of which AB is 3035 — namely miles — BD is 522.

Third, therefore: since, by proposition 1 of Clavius's rectilinear triangles, the sides of these triangles have the same proportion to one another as the sines of the opposite angles; and the sine of the angle BCD, of 4° 42′ 30″, is 8208, and the side opposite it is BD, of 522 miles; while the sine of the angle BDC, of 108° 21′ 30″, is 94,910, and the side opposite it is BC: if one makes, as the sine 8208 is to the sine 94,910, so the side BD, 522, to the side BC, the side BC will be found to be 6036 miles rather than 6035, the fractions being reduced to whole numbers.

[Margin: 4. Step, for the parallaxes.]

Fourth, in the triangle ABC, the angle ABC, composed of the angles ABD, 85° 4′, and DBC, 66° 56′, comes to 152°. Therefore the sum of the angles BCA and BAC at the base AC is the supplement of two right angles, namely 28°, half of which is 14°, whose tangent is 24,933. The sides opposite these angles are AB, of 3035 miles, and BC, of 6036 miles; their sum is 9071, and its half 4535½; and the difference of the sides is 1500½. If, according to proposition 12 of Clavius's rectilinear triangles, one makes, as the half-sum of the sides is to the tangent of the half-sum of the angles at the base, that is, to 24,933, so the difference of the sides, 1500½, to the tangent 8248, the angle corresponding to this tangent will be found to be 4° 43′ 52″, or in round figures 44′. Subtracted from the half-sum of the angles at the base, that is from 14°, this leaves the parallax, or angle ACB, of 9° 16′, corresponding to the distance from the zenith seen by Maurolico at B, that is, to the apparent altitude of 62° — although Chiaramonti's book has 9° 17′. When the angle BCD, which is 4° 42′ 30″, is taken from this, ACD remains, 4° 33′ 30″ — although Chiaramonti has 4° 34′ 30″ — that is, the parallax of the New Star at the altitude of 76° 34′ 30″ seen by Hainzel at D.

[Margin: 5. Step, for the distance of the star from the centre of the Earth.]

Fifth and last, in the triangle ABC, by proposition 1 of Clavius's rectilinear triangles, as the sine of the angle ACB, of 9° 16′, which is 16,103, is to the sine of the angle ABC, of 152°, which is 46,947, so the side AB, of 3035 miles, is to the side AC, of 8848 miles; in which the semidiameter of the Earth AB, 3053, is contained 2 2778/3035 times. But Chiaramonti, because he used the angle ACB of 9° 17′ and its sine 16,132, gathers AC as only 8832 miles.

IV. By the preceding method, therefore, Chiaramonti examines twelve combinations of observations in book 1 of *De novis stellis*, in as many chapters, from chapter 12 to chapter 25. He investigates both the parallaxes of the New Star belonging to the apparent altitudes and its distances from the centre of the Earth; and he finds them less than the distance of the Moon at perigee, even if

that were set, according to Ptolemy, at only 33⅓ terrestrial semidiameters. If you examine Chiaramonti's calculations — which is easily done, since he sets out all the numbers and opinions in order — you will not find in them any error of great moment, or one that would increase the distance he deduced by more than about a hundred Italian miles, or the parallax by more than a minute or two. Here, then, are the foundations of his calculation, reduced to a single synopsis, together with the parallaxes and distances of this New Star that he deduced.

Distances and parallaxes of the New Star of the year 1572, deduced by Chiaramonti from the observations written below.

Combination	Chiaramonti, book 1, chapter	Observers and places on Earth	Altitude of the pole	Apparent meridian altitude of the New Star	Difference of the parallaxes	Parallax of the apparent altitude	Distance from the centre of the Earth, Italian miles	Distance, semidiameters of the Earth
I	12	Maurolico, Messina	38° 30′	62° 0′ 0″		9° 17′ 0″		
		Hainzel, Göggingen	48° 22′	76° 34′ 30″	4° 42′ 30″	4° 35′ 30″	8832	2 2763/3035
II	13	Schuler, Wittenberg	51° 54′	80° 15′ 0″		0° 23′ 15″		
		Hainzel, Göggingen	48° 22′	76° 34′ 30″	0° 8′ 30″	0° 31′ 45″	76215	25 142/927
III	14	Tycho, Herrevad	55° 58′	27° 56′ 0″		2° 40′ 0″		
		Hainzel, Göggingen	48° 22′	20° 10′ 0″	0° 10′ 0″	2° 50′ 0″	57660	18 4895/4934
IV	15 and 16	Tycho, Herrevad	55° 58′	23° 3′ 0″

[Margin: Notes on the preceding table.] In the table already given, we have often put the miles as a round number, since that is enough for what is being sought. It should be noted, moreover, that Galileo, in the third Dialogue on the System of the World, more than once called "parallax" what we, with Chiaramonti, call in column 6 the "difference of parallaxes" — misusing the terms. Further, Chiaramonti, in Book 1 of *De stellis novis*, chapter 22, admits that from the observed altitudes of the New Star, of which there are at least 24 (as can be seen in chapter 3, number 3), 275 combinations can be formed; but that most

of them cannot be compared with one another for the purpose of gathering the parallax and distance of the New Star determinately and geometrically by the first method of inquiry. For observations by the same author cannot be compared with one another, nor the greatest altitudes with the least, or the least with the greatest; nor the observations of authors who have the same altitude of the pole; nor those in which the difference in the altitude of the pole is greater than the difference in the observed altitudes of the star; nor, finally, those from which, in the triangle BCD of the figure already given, three angles together greater than two right angles, that is, than 180°, result. This is why Chiaramonti reduced the combinations to 12. From these, in chapter 26, he concludes that this New Star was beneath the Moon, that is, below the Moon, and that one should rather abide by these 12 comparisons than by only two, which Tycho used to show that the star was above the Moon — namely, Tycho's altitude compared with Hainzel's and with Muñoz's. And it is true, as Chiaramonti asserts, that he demonstrated it from the hypotheses he had premised. But we must now see whether those hypotheses are to be accepted as certain.

V. In short, then, I deny that the hypotheses Chiaramonti assumed in the 12 comparisons and calculations already mentioned are certain; and so I deny that he demonstrated that the New Star of the years 1572 and 1573 was below the Moon — not only absolutely (which not even he himself claims), but also hypothetically, from certain and indubitable hypotheses, as against merely probable ones. For the altitude of the pole, or the altitude of the New Star, or the New Star's immobility as regards proper motion — which are assumed in those demonstrations — are uncertain. [Margin: That the hypotheses assumed by Chiaramonti are not certain.]

First, the altitude of the pole at Wittenberg, Frankfurt an der Oder, Vienna and Erfurt, as Chiaramonti assumes it, is uncertain, as is clear from what was said in chapter 7, numbers 5, 11, 15 and 16. [Margin: Uncertainty of the altitudes of the pole.] Likewise the altitude of the pole at Messina, which Maurolico gives as 38° 30′: although it was once observed to be that much from the shadows of gnomons, as Ptolemy too has it in his *Geography*, and was confirmed by Maurolico, so that it is very probable, nevertheless Don Carolus Vintimilius [Carlo Ventimiglia], who undertook a new and more correct chorography of Sicily, observed the altitude of the pole at Messina as 38° 11′, and at Palermo as 38° 10′. This disagreement may have arisen from not reckoning the Sun's apparent semidiameter in that old operation by shadows, as I have shown happened more than once in my book on geography. And although Chiaramonti, in Book 1 of *De stellis novis*, chapter 13, contends that the altitude of the pole at Wittenberg should be chosen as 51° 54′, as having been observed by Peucer and Reinhold, he will never bring it about that the value which Tycho corrected on other grounds is not probable, as I said in Book 7, number 11.

VI. Second, Chiaramonti assumes certain altitudes of the New Star while knowing that other and different ones were observed by the same authors, as is clear from chapter 3, number 3. [Margin: Uncertainty of the altitudes of the

New Star.] For Schuler, with his instruments, found the greatest altitude of the New Star to be 79° 56′; yet from the least altitude, 23° 33′, and the altitude of the pole, the same man computed it as 80° 15′. Chiaramonti, in Book 1, chapter 13, chooses this one rather than the other, because had he used the former, the three angles of the triangle BCD would have come out greater than two right angles. But given the parallax that Chiaramonti infers from it, the greatest altitude is not correctly gathered from the least apparent altitude and the altitude of the pole; or at any rate the uncertainty of what is assumed is evident from that disagreement. Further, in chapters 14, 15 and 19, Chiaramonti uses the altitude of the New Star of 27° 56′ that Tycho reported in his first writing, but uncorrected. He gives a threefold reason for choosing it: first, because it is the altitude Tycho observed while the star was still lasting, whereas the correction was made after the star had perished; second, because Tycho has it more than once in the second writing, in volume 1 of the *Progymnasmata*, pages 347 and 771; third, because if he chose the altitude of Tycho's second writing, namely 27° 45′, it could not be compared with Hainzel's except by running into a rectilinear triangle BCD having three angles greater than two right angles.

But these reasons are not sufficient for choosing the altitude of the star of 27° 56′, or at least for making it certain. [Margin: Chiaramonti's reasons rejected.] For while the star was still in being, Tycho used a sextant which, because of parallax and the cheekbone, gave incorrect intervals between stars and incorrect distances from the horizon and from the fixed stars. He corrected its defect, however, by a sure geometrical method, gathering how much smaller the angle of the true distance should have been — which he could do by examining the instrument, even when the New Star was no longer in being, as is clear from Tycho himself, volume 1, pages 341 and 593 — granted that in the second writing, where precision was not needed, he indicated the earlier value. And the fact that the later altitude of the star cannot be compared with Hainzel's, because of the three angles of the triangle being greater than two right angles, does not prove that the later altitude is less correct. It proves rather that either Tycho's or Hainzel's is erroneous, or that they were made at different times and that the star was altered by some motion in declination. As for Chiaramonti's saying, in combinations 8, 9 and 10, that some error lies hidden in the observations because a distance from the centre of the Earth of less than two semidiameters follows from them, I do not see on what foundation it is said. For that star could have been distant from the Earth's surface by only half a semidiameter of the Earth — indeed by only 565 miles, or even 55 — and yet be above the sphere of vapours.

VII. Third, Chiaramonti supposes, together with his very opponents, that the New Star never changed its apparent declination during the whole time it lasted, and had no motion other than that of the primum mobile; and therefore that altitudes observed under different meridians can be compared as if they had been made under the same meridian. But this is not certain, because it

is not established that the star was observed by the astronomers on each and every one of the same nights; indeed, from the history given in chapter 3, number 3, it is rather established that it was observed on different nights. If the observations of all, or of most, had fallen on the same night or nights, and on them the New Star had been seen everywhere on Earth to keep the same distance from the same fixed star, or from the pole of the world, then we would have an evident argument that it was altered by no motion in declination, nor by any other motion distinct from the motion of the primum mobile. And indeed, if it had a parallax as great and as varied as Chiaramonti gathers, how could it have happened that it seemed to all those observers equally distant from the same fixed stars? Finally, since Chiaramonti found, for the same time, parallaxes and distances from the Earth so different and so at odds with one another, even for one and the same astronomer — for example, from Tycho's observations a distance of 18, 10 and 32 semidiameters; from Hainzel's, 2, 25, 18 and 4 semidiameters; from Maurolico's, 2 and 1; from the Landgrave's, 10, 4 and 1 semidiameters; from Hájek's, 32 and 1 semidiameters; from Muñoz's, 1, 13 and 7 semidiameters — who does not see that they cannot be certain? For it is not enough that each stands on its own; what would be needed is that all should agree, very nearly, on the same measure.

VIII. Chiaramonti's second inquiry and method, which he proposes in Book 1 of *De stellis novis*, chapters 10 and 27, is the same one he had proposed in Book 1 of the *Antitycho*, chapter 5, proposition 3; and it is similar to the problem we shall give in Book 10, in the penultimate section, chapter 9, problem 5. [Margin: Chiaramonti's second inquiry.] In it an observation is supposed to have been made at the same moment of time and at two different places on Earth, whose altitude of the pole is known, with the star's distance from the zenith and its azimuth observed at both; or, if it was not made at the same moment of time, that it can nevertheless be used as if it had been made at the same moment, because the star neither changed its declination nor ever had any motion other than that of the primum mobile. But we have already shown, at number 7 and elsewhere above, that this very point is uncertain. Moreover, since Chiaramonti, using this inquiry from chapter 28 to 41, employs only the observations of the Landgrave of Hesse compared with Tycho's, and from one and the same comparison always gathers a different and conflicting distance of the New Star from the zenith, we cannot place sure trust in any of those observations. Or at any rate it must be said that they cannot be taken as made at the same moment of time by carrying the star from one meridian to the other, that is, to the perioecic place of the earlier or the later observer. But as for Chia- ramonti's attempt there, on pages 134, 138, 144, 177 and 179, to put that disagreement between the distances down to a refraction of uncertain quantity: this is indeed said not improbably, but it is still not demonstrated that it was so. Finally, as for his concluding, in Book 1, chapter 41, that — notwithstanding the disagreement between the distances derived from the same comparison — since both are nevertheless smaller than the Moon's distance, the New Star

is evidently shown by either of them to be sublunary: he is undoubtedly mistaken. [Margin: Chiaramonti's error.] For since it is uncertain where that disagreement arises from — whether from Tycho's observation, or the Landgrave's, or from refraction, or from some other cause, such as a motion in declination — we are also uncertain whether either of those two distances is to be accepted as the true one. For it could happen that, had no error intervened, or had we possessed elements sufficient for evidently investigating this distance, we would obtain by calculation neither of those distances, but a distance greater than the Moon's; and Chiaramonti has by no means demonstrated that this could not happen. So that the disagreement and conflict already mentioned, between the distances deduced by this second inquiry through Chiaramonti's calculations — which are otherwise correct enough — may be seen, and so that at the same time we may satisfy the reader's learning, here they are gathered into one view in the following table.

Chapters of Book 1	Observers	Parallax	Distance from the centre of the Earth, in semidiameters
28	the Landgrave	0° 43′ 4″	19 3/4
	Tycho	1° 3′ 48″	10 5/9
29	the Landgrave	2° 21′ 49″	7 3/4
	Tycho	0° 46′ 59″	17 9/14
30	the Landgrave	0° 36′ 29″	27 3/11
	Tycho	1° 17′ 14″	11 nearly
31	the Landgrave	0° 48′ 48″	16 3/7
	Tycho	1° 14′ 0″	8 1/3
32	the Landgrave	0° 34′ 39″	24 1/7
	Tycho	0° 55′ 12″	11 3/8
33	the Landgrave	0° 37′ 50″	23 1/29
	Tycho	0° 56′ 12″	11 3/8
34	the Landgrave	1° 4′ 20″	10 9/11
	Tycho	1° 17′ 0″	5 2/3
35	the Landgrave	1° 4′ 56″	10 2/19
	Tycho	1° 16′ 45″	5 5/22
36	the Landgrave	1° 49′ 51″	5 25/32
	Tycho	1° 55′ 41″	3 7/38

Parallaxes and distances of the New Star of the years 1572 and 1573, from Chiaramonti, Book 1 of De stellis novis.

IX. Chiaramonti's third inquiry and method, which he proposes in Book 1 of the *Antitycho*, chapter 5, propositions 1 and 4, and in Book 1 of *De stellis*

novis, chapters 10 and 42, relies on the apparent declinations at different places on Earth, the altitudes of the pole, the difference of longitude or distance between the meridians, and the difference of right ascension; and, besides, on the culminating point of the ecliptic at the same moment of time, or the place of the Sun at that moment. [Margin: Chiaramonti's third inquiry.] The fourth inquiry, which the same author proposes in Book 1 of the *Antitycho*, chapter 7, proposition 1, and in Book 1 of *De stellis novis*, chapters 10, 43 and 44, supposes the observed apparent latitude and longitude of the phenomenon at two places, and hence the difference of the parallaxes with respect to the ecliptic; and that the places on Earth differ either in longitude alone, or in the altitude of the pole alone, or, if in both, that the difference is known; and that the observation was made at both places at the same moment. [Margin: Chiaramonti's fourth inquiry.] Finally, the fifth inquiry, which the same author proposes in Book 1 of the *Antitycho*, chapter 9, proposition 1, and in Book 1 of *De stellis novis*, chapters 10 and 45, proceeds from the apparent distances from the same fixed star at two places on Earth whose altitudes of the pole are given, together with the time of the observations. [Margin: Chiaramonti's fifth inquiry.]

But grant that Chiaramonti's geometrical method and arithmetical computation are not fallacious: that the hypotheses on which they rest are not certain is still clear from this — that from them is gathered a distance of the New Star from the centre of the Earth that conflicts sharply with the distance drawn from the observations of the same astronomers using the first and second inquiries. Or at least it is clear from the fact that it cannot be denied that, from other observations compared with one another, a distance of the New Star from the Earth greater than the Moon's is probable, and rests on plausible, though uncertain, foundations, as is clear from what was said in chapter 8. Therefore the distance of the same New Star smaller than the Moon's, which Chiaramonti found by these five inquiries, can be no more than probable. Otherwise, if it were certain and evident, it would extinguish the probability of the opposite opinion: for a proposition remains probable to the same intellect for as long as neither it is proved false nor the opposite proposition is proved true. From this it follows that the foundations of neither opinion are certain; for if they were certain, the conclusion scientifically deduced from them would also be certain, and so true not merely hypothetically but absolutely.

Nevertheless, so as not to cheat the reader here of the parallaxes and distances of the New Star that Chiaramonti deduced with geometrical and arithmetical precision [acriuia] by the third, fourth and fifth inquiries — though only from single comparisons — let the following small table stand.

Chapters of Book 1	Observers	Parallaxes	Distance from the centre of the Earth, in semidiameters of the Earth
42	Tycho	1° 7′ 24″	9 193/197
	Muñoz	0° 51′ 0″	28 2/5
45	Tycho	0° 37′ 0″	9 4/11

Chapters of Book 1	Observers	Paral-laxes	Distance from the centre of the Earth, in semidiameters of the Earth
	Cornelius Gemma	1° 11′ 0″	9 14/21

Other distances and parallaxes of the New Star of the year 1572, deduced by Chiaramonti in Book 1 of De stellis novis.

From the fourth inquiry, however, no parallax or distance is given, because Chiaramonti teaches there that there are no observations of this star suited to the purpose. For from those which seemed most comparable with one another it followed that the whole is greater than its part, and that the New Star was at the centre of the Earth or below it with respect to the observers — which is absurd. And this confirms the uncertainty of those observations.

CONCLVSIONES.

Conclusions.

I. CONCLUSION. *Chiaramonti, in Book 1 of* De stellis novis, *from chapter 12 to the end, demonstrated that the New Star of the years 1572 and 1573 was sublunary — if many observations of that star are accepted and held to be the more reliable.*

He himself asserted this in Book 2 of *De stellis novis*, chapter 1, as he had promised in the preface and in Book 1, chapter 10; and he carried it out excellently, by a method plainly geometrical and arithmetical, as was clear to me when I considered his figures and problems and went over his calculations, and as will become clear to anyone who wishes to try the same — granted that he sometimes errs by a minute or two, and, in using observations from Tycho's first writing rather than his second, commits an error of 11′, as is clear from what was said at number 6.

II. CONCLUSION. *Yet the same Chiaramonti, in the same place, demonstrated neither absolutely, nor from a hypothesis to be accepted as certain and irrefutable, that the New Star of the years 1572 and 1573 was below the Moon, but only from a hypothesis to be accepted as probable.*

This is clear from what was said above, from number 5 to 9. Nor did Chiaramonti himself claim absolute demonstrations of the distance already mentioned, but only hypothetical ones. In this, however, he overstepped the limits of his demonstrations: he thought that one or other of the observations or hypotheses from which he had deduced two distances smaller than the Moon's, but conflicting with each other, was certain, and that from one of them at least it was evidently concluded that this star was below the Moon. Yet neither of them could be certain as regards this very effect, and once the falsity of both, or of either, was detected, a distance greater than the Moon's could have been gathered. And the same

I say about the comparison of the observations of Antonio Santucci with others, of which I shall speak shortly in the scholia.

SCHOLIA.

Scholia.

I. *Santucci, in his book on comets, chapter 7, contends that this New Star was probably in the eighth sphere, but most certainly above the Moon, because he himself, at Pisa, at a polar altitude of 43° 30′, observed its distance from the pole on the meridian, on either side, to be 36°. For the greatest altitude he saw was 79° 30′, and the least 7° 30′. But* Chiaramonti *refutes him in Book 2 of* De stellis novis, *in the Appendix. There, in chapter 4, using the first inquiry already set out by us in the preceding chapter, number 3, and comparing Santucci's altitudes with Hainzel's, he shows that if both are accepted, the difference of the parallaxes is 7° 48′, and that from it the New Star's distance from the centre of the Earth is gathered to be less than 3563 Italian miles, and from the surface less than 578 miles. Comparing Santucci's altitudes with those observed by Maurolico, by Muñoz and by the Landgrave of Hesse, a difference of the parallaxes of 8°, 4° 30′ and 7° 45′ arises, in the same order, from which follows a distance of the star from the Earth far smaller than the Moon's.* [Margin: Santucci's observation examined.] *Chiaramonti adds, however, in the same chapter, that he suspects the greatest altitude asserted by Santucci, 79° 30′, because it is greater than the altitude observed by Hainzel at Göggingen, whereas it ought to be, or to appear, smaller at Pisa, as a place more southerly than Göggingen by 4° 52′. And indeed, if at Göggingen, where the altitude of the pole is 48° 22′, the greatest meridian altitude of the New Star was seen as 76° 34′, as we related in chapter 3, number 3, and if the star kept the same distance from the pole of the world everywhere and had no proper motion, as Santucci affirms, then at Pisa, at a polar altitude of 43° 30′, it certainly ought to have appeared at an altitude of 71° 32′, not 79° 30′. Nor can so great a difference be put down to refraction, and much less to parallax, which could not have been so great at Pisa — and, if it were admitted, would bring the star close to the Earth, far below the Moon.* [Margin: Santucci's observation suspected of falsity.] *So nothing has been solidly demonstrated by such an observation regarding the distance of the New Star; nor is it shown from it that the star was above or below the Moon; it is only from an uncertain hypothesis that Chiaramonti concludes it was below the Moon.*

II. *In the same Appendix, chapter 6, Chiaramonti detects a manifest error of Santucci's in geometry. For Santucci had said, in his statement 21: "If the New Star had been in the orb of the Moon, and no higher, it would have undergone a parallax of up to 3° 40′." But this cannot be, because not even in Ptolemy — who of all astronomers brings the Moon closest to the Earth at quadrature [□] — does the Moon's horizontal parallax exceed 1° 44′; and in other astronomers the distance of the Moon at perigee is much greater than in Ptolemy, and so the parallax smaller.* [Margin: Santucci's error in geometry or astronomy.] *I add that if the parallax of the Moon, and so of a star placed in the Moon's heaven, were 3° 40′, at least on the horizon itself, the Moon would have to be distant from the centre of the Earth by only 16 semidiameters of the Earth, as will be clear to anyone who solves the right-angled rectilinear triangle in which, taking the Earth's semidiameter as 1 part, the opposite*

angle — that is, the horizontal parallax — is 3° 40′. For the base, that is, the distance from the Earth, will come out no greater than 16 parts. So Santucci erred either in geometry, if he thought that the distance of the Moon at perigee was not less than Ptolemy's and yet that so great a parallax followed from it; or in astronomy, if he believed that, with so great a parallax preserved, the Moon's distance could be reduced to 16 semidiameters of the Earth.

CAPVT XI.

Chapter XI.

The opinions of authors on the place of the New Star of the year 1572 and on its distance from the Earth are collected, and it is established what may be maintained about its distance — if not with certainty, then at least probably — or what is more probably to be asserted.

I. I now call "opinions" those, too, of the people who judged them to be not opinions but certain verdicts, because we have at last found that they are contained within the limits of mere probability. And although I reviewed them in chapter 2, nevertheless, since there the distance of this star was entangled with many other things observed in it, and we did not set out there on what grounds the opinions about the distance had been asserted, I would like now to gather those same opinions, on the distance alone, into one place, and to indicate the manner in which each was asserted by its authors; and afterwards to establish, in distinct conclusions, what can be asserted about it, or what ought to be.

II. The first opinion is that of those who affirmed that this star stood above the orbs of all the planets from beginning to end — either in the firmament, or in the eighth sphere of the fixed stars, or as near to it as possible. They were, first of all: Tycho, volume 1 of the *Progymnasmata*, chapters 6 and 7, that is, from page 396 to 489, though he also drives it home very often in chapters 8, 9 and 10; Longomontanus, in the Appendix to the *Astronomia*, chapter 5; Kepler, *De stella nova*, chapter 25; Tadeáš Hájek, in his *Dialexis*, chapter 5, and in Tycho, volume 1, page 513; Paul Hainzel, in his letter to Hieronymus Wolf, and in Tycho, volume 1, page 536 — though there he denies that it had a sensible parallax and yet counts it among the elemental comets; but Tycho relates there, on page 542, that he retracted this opinion and subscribed to Tycho's once he had seen Tycho's writings; Michael Mästlin, in a published writing on this star, and in Tycho, volume 1, page 545; Cornelius Gemma, in his booklet on this star, and in Book 11 of *De divinis naturae characterismis*, chapter 3, and in Tycho, volume 1, page 553 — for although he had earlier suspected a parallax of 4′, he afterwards excluded all sensible parallax and placed this star in the eighth sphere; as did Jerónimo Muñoz, in his writing translated from Spanish into Latin by Cornelius Gemma, and in Tycho, volume 1, page 570 — granted that earlier he had said only that this star was above the Sun; Francesco Maurolico, abbot of Messina, in his disputation on this star, and in Clavius's *Sphaera*, page 194 of my copy, and

Clavius himself in the same place; Biancani, in his *Sphaera*, Book 18, chapters 2 and 5; Redemptus Baranzanus [Redento Baranzano], in the *Uranoscopia*, page 112; Andrea Argoli, in the *Pandosion sphaericum*, chapter 62; Galileo, in the first and third Dialogues on the System of the World; Descartes, in the *Principia philosophiae*, part 3, marginal number 118; Liceti, *De novis astris*, Book 5, chapter 41; Froidmont, *Meteorologica*, Book 3, chapter 2, article 7; Antonio Santucci, *De cometis*, chapter 7, where he says that it is indeed evidently established for him that this star was above the Moon, but probably in the eighth sphere; Giovanni Camillo Glorioso, *De cometis*, Book 5, pages 275 and 281. To this group can be referred Annibal Raymundus and Cornelius Frangipanus, who, as Tycho reports in volume 1, pages 720 and 741, thought this star was one of the old fixed stars, namely the eleventh of Cassiopeia. [Margin: First opinion, placing this star in the heaven of the fixed stars [?]: Tycho.] [Margin: Longomontanus [?].] [Margin: Kepler.] [Margin: Hájek.] [Margin: Hainzel [?].] [Margin: Mästlin [?].] [Margin: Cornelius Gemma [?].] [Margin: Muñoz.] [Margin: Maurolico.] [Margin: Clavius.] [Margin: Biancani.] [Margin: Baranzano.] [Margin: Argoli.] [Margin: Galileo [?].] [Margin: Descartes.] [Margin: Liceti.] [Margin: Froidmont.] [Margin: Santucci.] [Margin: Glorioso.] [Margin: Raymundus [?].] [Margin: Frangipanus.]

III. The second opinion is that of those who said that this New Star, if not in the firmament itself, was at least among the orbs of the planets, and was not below the Moon. Of this kind were: Wilhelm, Landgrave of Hesse, in his second letter to Caspar Peucer, and in Tycho, volume 1 of the *Progymnasmata*, page 613, where he denies that it had a parallax greater than 3′ — adding, however, the words "if indeed it had any" — and assigns it a distance from the Earth of 1061 37/52 semidiameters of the Earth, concluding: "From this it appears that the comet is placed in the highest part of the sphere of Venus, scarcely nine semidiameters of the Earth below the sphere of the Sun; from which it is most certainly established that it plainly does not exist in the elementary region." For he calls it a comet, and did not yet know that Venus at its highest goes above the Sun. [Margin: Second opinion, placing this star among the orbs of the planets.] [Margin: the Landgrave of Hesse.] And Paul Fabricius, in a writing he published on this star, and in Tycho, volume 1, page 529; for he says that it was either in the aether of the fixed stars or not below Jupiter. [Margin: Fabricius.] Francisco Vallés, *De sacra philosophia*, Book 1, chapter 1, and in Tycho, volume 1, page 572, saying that because it had no parallax it was at least above the Sun. [Margin: Vallés.] Erasmus Reinhold the Younger, who in his prognostication for the year 1574 held the same view about the distance of this star, 1079 semidiameters of the Earth, as the Landgrave of Hesse, as can also be seen in Tycho, volume 1, page 700. [Margin: Reinhold the Younger.] Caspar Peucer, in his letter to the Landgrave of Hesse, which Tycho reports in volume 1, page 606; Wolfgang Schuler, in his reply to Peucer, in Tycho, volume 1, page 622 — for both assign this star a parallax of 19′ and a distance from the Earth of 164 semidiameters of the Earth. [Margin: Peucer the Younger.] [Margin:

Schuler.] Johannes Praetorius, on the occasion of a writing [Margin: Johannes Praetorius.]

of the comet of the year 1577, where he affirms that the star of the year 1572 *was placed either within the orbs of the planets or above them*. So too Philipp Apian, in Tycho, volume 1, page 643, together with John Dee the Englishman, judged that it was either to be counted among the fixed stars or at any rate had been above the Moon. [Margin: John Dee.] [Margin: Apian the Younger.] Thomas Digges thought no differently, in his *Alae ac Scalae Mathematicae*, chapter 10, and in Tycho, volume 1, page 674, where he says that it was most certainly above the Moon, but also doubts whether it was above all the planets. [Margin: Digges.] Elias Camerarius, in Tycho, volume 1, page 693, concludes from a parallax of 10′ that it was above the Moon. Giovanni Battista Benedetti, in his letters, page 371, likewise contends that it was above the Moon. [Margin: Giovanni Battista Benedetti.]

IV. The third opinion is that of those who asserted that this star was below the Moon. They are these. Andreas Nolthius, who in chapter 4 of his work on this star affirms that, from a parallax of 39′, it stood distant from the Earth by 19 52′ semidiameters of the Earth, as Tycho also reports, volume 1, page 755. [Margin: Third opinion, placing this star below the Moon.] [Margin: Nolthius.] Georg Busch, who counted this star among the sublunary comets — although it follows from the observations he himself gave that it had a parallax smaller than the Moon's, as Tycho shows, volume 1, page 769. [Margin: Busch.] Theodor Graminaeus, in Tycho, volume 1, page 776; Adam Ursinus, in the same place, page 781; Andreas Rosa, in the same place, page 783. [Margin: Graminaeus.] [Margin: Ursinus.] [Margin: Rosa.] For Cyprián Karásek Lvovický, David Chytraeus and Guillaume Postel, whom Tycho mentions in volume 1, pages 705, 712 and 715, said nothing about the distance of this star; nor did Annibal Raymundus, of whom the same author speaks on page 720, nor Cornelius Frangipanus, of whom Tycho speaks in the same place, page 741, and who rather calls this star a fixed star. Lastly, Scipione Chiaramonti, in Books 1 and 2 of *De stellis novis*, and Cottunius, on Book 1 of the *Meteorologica*, at the end of Lecture 31. [Margin: Chiaramonti.] [Margin: Cottunius.]

V. So much for the various opinions about the place and the distance of this New Star from the centre of the Earth. We must now come to gathering the conclusions scattered through the preceding chapters, and to substituting others for them, so that what we judge should be held about this New Star may be found here, collected and ready to hand.

CONCLVSIONES.

Conclusions.

I. CONCLUSION. *None of the authors named so far demonstrated that the New Star of the years 1572 and 1573 was above the Moon, much less above the other planets or in the eighth sphere of the fixed stars.* The authors I am speaking of are

those we reviewed a little earlier, in numbers 2 and 3. The conclusion has been sufficiently proved in chapters 6, 7 and 8, at whose end we set down conclusions, from which we have drawn this first one as their marrow. Granted that, first of all, Tycho, Hájek, Mästlin, Digges, the Landgrave, Hainzel, Gemma and Muñoz thought it demonstrated. [Margin: 1st Conclusion, on the star above the Moon.]

II. CONCLUSION. *Likewise, none of the authors already mentioned demonstrated, from a certain and irrefutable hypothesis, that the New Star of the years 1572 and 1573 was above the Moon.* For either the hypothesis rests on observations made in one place on the Earth — and we have already established in chapter 6 that from these alone, taken separately, it cannot be demonstrated that this star was above rather than below the Moon. For the star would have had to be observed in several horizons, but on the same nights, so that it showed the same distance from the pole of the world and from the same fixed stars to different observers at the same time; or else it would have had to show them no variation of distance so great that a parallax greater than the lunar parallax could be gathered from it. Or the hypothesis rests on observations made in different places on the Earth — and we have shown well enough that these are not certain, both in chapter 6, number 7, and in chapter 8, numbers 8 and 9, and from the scholia of chapter 10. This is clear even from the fact that, if those observations are accepted as reported, as certain and irrefutable, those very observations, compared with others that are certain on no lesser evidence, show this star to be sublunary, as is clear from what was said in chapter 10. [Margin: 2nd Conclusion, on the star above the Moon.]

III. CONCLUSION. *None of the authors named so far demonstrated that the New Star of the years 1572 and 1573 was below the Moon.* I am speaking of the authors just reviewed in number 4. The conclusion is clear from what was said in chapters 9 and 10, and from the conclusions asserted one by one at the end of those chapters. [Margin: 3rd Conclusion, on the star below the Moon.]

IV. CONCLUSION. *Likewise, none of the authors already mentioned demonstrated, from a certain and irrefutable hypothesis, that the New Star of the years 1572 and 1573 was below the Moon.* [Margin: 4th Conclusion. On the star below the Moon.] This conclusion is evident from what was said in chapters 9 and 10 and from their conclusions.

V. CONCLUSION. *From observations of the New Star of the years 1572 and 1573 made in a single place on the Earth, however fully they are accepted as certain, it cannot be demonstrated that it was below rather than above the Moon, or above rather than below it.* This was shown sufficiently in chapter 6, with a diagram also supplied. [Margin: 5th Conclusion, on observations made in one place.]

VI. CONCLUSION. *Among the observations of the New Star of the years 1572 and 1573 made in different places on the Earth and compared with one another, if they are accepted as good, there are some from which it is demonstrated that the star was above the Moon, and some from which it is demonstrated that it was below.* The former are established from what was demonstrated by Tycho in chapter 5,

number 8, and by Galileo in chapter 8, numbers 1 to 7. [Margin: 6th Conclusion, on observations in different places on the Earth.]

VII. CONCLUSION. *It is probable that the New Star of the years 1572 and 1573 was above the Moon for the whole time of its duration; yet it is also probable that the same star was below the Moon.* The first part of the conclusion is established by the authority of the men I reviewed in numbers 2 and 3 of this chapter, and by the arguments brought by Tycho, Galileo and others (on those arguments, our chapters 4 and 5, 7 and 8). The second part is evident both from the authority of the men we reviewed here in number 4 and from the arguments brought in chapters 9 and 10. Both parts, however, can hold together, from Conclusion 6 itself. [Margin: 7th Conclusion, on the probability of the star's place.]

VIII. CONCLUSION. *Yet it is more probable that the star of the years 1572 and 1573 was above the Moon than below it.* [Margin: 8th Conclusion: what is more probable.] It is proved, *first*, from the authority of very many, whom we cited in numbers 2 and 3: there are 32 authors, among whom many are distinguished for astronomical learning and erudition. Those who thought it was below the Moon, reviewed in number 4, are about 6, and of no great name except Chiaramonti — and, as far as philosophy goes, Cottunius. Where reason does not prevail to the contrary, the votes of authorities carry great weight; how much more, if reason is added? [Margin: 1st proof, from authority.] *Secondly*, then, the conclusion is proved by reasons. The *first* is the star's greater likeness to the fixed stars — in colour, light, twinkling, motion and figure (on these, chapter 4) — than its unlikeness to them; for it was unlike them only in its decrease and its disappearance. [Margin: 2nd proof, from reason; and Reason 1.] The *second*, and the strongest, is this. Suppose that on each and every night on which this star appeared it had appeared to all observers, or to very many observing at the same time, to stand equally distant from the same fixed stars and from the pole of the world — both when it was nearest the horizon and when it was highest, or higher above the horizon — and to keep the same figure of a rhombus, or of a trapezium close to a rhombus, with the three chief stars of Cassiopeia; and suppose this were certainly established. Then it would necessarily have to be said that it was above the Moon, and this would be physically certain. For it would have been naturally impossible for the star — observed at the same time from different parts of the Earth having different polar altitudes, now near the horizon, now far from it — to show the same distance from the pole and from the same fixed stars, and to keep the same configuration with them, if it had been below the Moon. This is established from the doctrine of parallaxes, and from the distance of the Moon from the same fixed stars observed on the same night in several horizons, both when the Moon is low and when it is high. [Margin: 2nd Reason.] Although, then, this is not established from the history of the observations reported in chapters 2 and 3, it is nevertheless much more probable that the star was observed on many nights besides those recorded there on particular days, so that the observations of many, though not reported in the history, fell on the same nights and hours.

First, because some of those observers affirm that they observed it not only on the days they record but on many others — above all Tycho, Mästlin and Digges. And all those who say that it always appeared in the same place indicate the very same thing — namely most of the authors of the first and second class, cited in numbers 2 and 3 of this chapter and earlier in chapter 2 — granted that they ceased observing with instruments once it seemed already ascertained to them that it remained in the same place beneath the fixed stars. For the Landgrave of Hesse expressly testifies that for this reason he refrained from observing the altitudes and azimuths of this star. For in comets, whose proper motion, manifestly distinct from the common motion of the primum mo- bile, is apparent, observations were made on continuous and very many nights, so that the size and direction of their motion might be established — especially in those that appeared towards the end of the preceding century and in this century of ours. But it is not probable that the astronomers already named did not turn their eyes again and again to so unusual a spectacle as this New Star was, especially in the first months — granted that, as I said, seeing that it had no proper motion, they rarely set their hands to the instruments. *Secondly*, even if we granted that there were no nights in common on which several observers in different horizons actually saw that star equally distant from the same fixed stars, or from the pole of the world, it is nevertheless more probable that this equality would have appeared to them had they observed it together on the same nights. For on all those nights, different though they were, on which they observed it, all who observed it agreed on the same equality, or at least none of them individually noticed a variation great enough to bring the star down below the Moon — except Nolthius alone, whose observations Tycho, for just reasons, renders suspect of deception and of rather crude workmanship, as we saw in chapter 9, number 2. For the observations of Busch, who out of inexperience placed it below the Moon, show that it was above the Moon, as is clear from what was said in chapter 9, number 3. Therefore, since the observations of all the nights, though different nights, attest that an equality of distance from the same fixed stars was kept, as great as suffices for a place above the Moon, and none of them — except one, to be disregarded beside the others — has dared to testify to the contrary, we have from this a more probable argument for affirming than for denying that the equality already mentioned would have appeared on all the remaining nights. *Thirdly* and lastly, it is not probable that God, Best and Greatest, who for the loftiest causes and ends roused mortals to this spectacle, universal to the whole world, would — had he given this star any proper motion — yet have willed that the motion lie hidden from mortals for the whole time of the star's duration; or that he would have so tempered it with respect to some observers that to them the star seemed to have no parallax, no proper motion, and no change of distance from the fixed stars, while to others it would have appeared otherwise, had they observed on the same nights. This being so, let us reduce this argument, already set out at greater length, to this very brief form. [Margin: 2nd Reason, reduced to form.]

If it is more probable that the New Star of the years 1572 and 1573, on all the nights on which it was observed or observable, lacked proper motion and kept the same distance from the pole of the world and from the same fixed stars, as seen or visible by all, or several, observers in different parts of the globe — or at least an equality of distance as great as suffices to preserve a place above the Moon — then it is also more probable that it was above the Moon. But it is more probable that it was so. Therefore it is more probable that it was above the Moon.

Next, whether it was among the fixed stars, or in the space between the fixed stars and Saturn, or between the Sun and Saturn — for I find no valid argument by which I could more probably assign this star a seat in one of these three seats or regions — granted, I lean towards the space between the fixed stars and Saturn, as though it had been assigned by God to these extraordinary stars, lest it be, or seem, idle. The remaining matters that pertain to the size and origin of this star will be treated below, together with the other new stars, so that we are not forced to repeat too often the arguments they have in common.

CAPVT XII.

Chapter XII.

History of the New Star seen in the breast of Cygnus from the year 1600; and whether it was truly new, and how long it lasted.

I. The history of this star has been set out, first of all, by Johannes Kepler, in an astronomical narrative about it published at Prague in the year 1606 and inserted into the book on the New Star of Serpentarius after chapter 27 — that is, at the end of the first part and before chapter 28, where the second part begins; by Scipione Chiaramonti, *De tribus novis stellis*, Book 3, chapters 1 to 6; by Biancani, *Sphaera*, Book 18, chapter 3; and by Liceti, *De novis astris*, Book 5, chapter 16.

The first witness to this novelty, as Kepler relates, was Willem Janszoon [Gulielmus Ianſonius], who, in an inscription on a celestial globe published in the year 1601, declares that he first saw it in the year of Christ 1600 at the top of the breast of Cygnus, or the Hen, or at the border of the neck and the breast. [Margin: The first observer of this star.] By the common consent of all who later observed it, it was of the third rank, or of the third magnitude: that is, like three other stars of Cygnus — the one in the breast, to which it was nearest, the one in the middle of the neck, and the one that shines in the beak; and indeed like three other stars of Cygnus too, of which one shines at the elbow of the upper wing, another at the elbow of the lower wing, and the last at the tip of the lower wing. So Cygnus, which until then had had six stars of the third rank, began in that year to have seven, besides the remaining stars of other magnitudes. [Margin: Magnitude of the star.] The longitude assigned to it by Kepler and the Braheans, and accepted by others, was Aquarius 16° 18′; the northern latitude 55° 30′, or 32′; the right ascension 300° 46′; the northern declination 36° 52′; and it culminated with Capricorn 28° 37′ — as Tycho's

pupils gathered from the star's distances set out below, taken with Tycho's sextant. [Margin: Place of the star in the heavens.]

Distance of the New Star of the year 1600

From the stars written below	Distance
the bright star of the Vulture	29° 49′ 0″
the bright star of Lyra	19° 43′ 20″
Scheat of Pegasus	35° 49′ 30″
the tail of Cygnus	8° 30′ 0″
the Pole Star	52° 0′ 0″

[Margin: Distance of the New Star from the fixed stars.]

This star lasted, most certainly in the same place, up to the year 1616 — indeed 1621 — years in which our Fathers at Parma observed it, and I with them, especially with Father Biancani, who attests this very thing in Book 18 of the *Sphaera*, chapter 3, for the year 1616, in which he published the *Sphaera*. For the year 1621 Fortunio Liceti affirms the same, from an observation by Corgneti, in Book 5 of *De novis astris*, chapter 16 — although Chiaramonti, Book 3, chapter 6, has doubts; and Glorioso, in Book 5 of *De cometis*, page 278, which he wrote in the year 1624, asserted that it was still lasting then. [Margin: Duration of this star.] Argoli, for his part, says in the *Pandosion*, chapter 62, that it lasted up to the year 1629. But on what day and in what year it vanished I do not find in any author. It is certain, however, that in these last years, from 1640 to 1650, it has not appeared to us, and that in duration it surpassed all the new stars whose duration is known to us so far. On the doubt whether it would perish, see Kepler's words in the following chapter, number 2.

II. There was a greater controversy over whether it was truly new, or rather one of the old stars of Cygnus — at least of the unformed ones — but omitted by Hipparchus, Ptolemy and the other authors before the year 1600 because of its smallness. The reason for doubting its novelty is the hesitation of very many, and especially of Mästlin, who leaned to the negative side. [Margin: Doubts about the novelty of the star.] For Kepler says, on page 154: *What I have said of myself I can say of almost all present-day professors of mathematics, who are spread everywhere through the universities of Europe: all of them raise the question of the new phenomenon; they keep their opinion to themselves, or confess that they do not know. Mästlin, indeed, having confessed that he is in doubt, still inclines to this: that the longer he examines his memory, the more he thinks that he too saw it long ago* — which he confirmed from its duration of so many years and from the other stars omitted by Ptolemy. [Margin: Mästlin's doubt.] Kepler himself, having said, *If I am asked whether I saw this star before the year 1601 or not, I shall have to answer that I do not know. For although I began to learn the heavens from the year 1591, with Mästlin pointing them out, I do not remember that we were told by our teacher that one star in the breast of Cygnus had been passed over by Ptolemy*, admits indeed that in November of the year 1601, when the beak of Cygnus

stretched towards the western horizon in the evening, there seemed to him to be in Cygnus as it were an image of the Crucified with bowed head — for the New Star represented the breast of the Crucified — but [Margin: Kepler's former hesitation.]

the star in the breast represented the head, those at the elbows on either side the arms, and the neck the upright of the cross. But whether he had seen it before this time or not, he does not recall, and he concludes about himself: *So here my own memory fails me; nor would I affirm from it alone that this is a new star.* To this is added that Santucci — who, with unceasing labour, by order of Ferdinand, Grand Duke of Tuscany, kept watch with observations of new phenomena from the year 1592 to 1607 — counts among the new stars the one that shone forth in Cassiopeia in the year 1572 and the one in Serpentarius in the year 1604, but nowhere mentions this one, which we are now discussing.

III. It must nevertheless be asserted that this was a new star, and different from the perennial fixed stars. [Margin: Assertion of the star's novelty.] *First*, because it vanished a few years ago. *Secondly*, because Hipparchus of Rhodes, as Pliny the Elder relates in Book 2, chapter 26, *detected a new star, and another, in his own age; and by its motion, on the day it shone, he was led to doubt whether this happened more often, and whether those stars too that we suppose fixed were moving. And he likewise ventured on a thing presumptuous even for God: to count the stars for posterity and to tally the heavenly bodies by rule, with instruments devised by which the places and magnitudes of each might be marked, so that it could easily be discerned from this not only whether they perish or are born, but whether any of them pass across at all, or move, and likewise whether they grow and diminish — the heaven having been left to all as an inheritance, etc.* But if Hipparchus had neglected this star, which is after all of the 3rd magnitude, how could he hope that posterity would be able to discern from his catalogue whether any new stars arose, or any of the old ones perished? Since, then, neither he nor Ptolemy — who nevertheless arranged Hipparchus's stars in a better order and form, not omitting even the nebulous ones, and counted the stars in the Milky Way with such diligence — ever entered this one in the table of stars, it is a very strong indication that it did not appear in the heavens in the age of either. Moreover, Hipparchus of Bithynia too (whom Kepler, through inexperience, in this place makes the same man as Hipparchus of Rhodes), in Book 1 on Aratus, reviews the stars of the Swan, or Hen, carefully and one by one, and criticises Aratus's ignorance about them, yet never mentions this star. [Margin: Kepler's error in the history.] And Tycho himself, who added to the northern stars two hundred others observed by himself, of roughly the fifth and sixth magnitude, passed over by the ancients, did not recognise this one, which is of the 3rd magnitude — granted that in his record he set down very many observations of the whole of Cygnus, the chief of which Kepler reports in this place. Nor, finally, did any of Tycho's surviving pupils, when they heard the report of this new star, dare to detract from its novelty. Weighing these things, Johann Bayer, in his *Uranometria*, said that this star was accepted as new *by the tacit consent of all*.

And Jost Bürgi, automaton-maker to His Sacred Imperial Majesty, built a silver globe at the expense and by order of Wilhelm, Landgrave of Hesse, constructed in such a way that he was told to look at the heavens again and again and to add any stars the ancients had omitted; the Landgrave later sent it as a gift to the Emperor Rudolf. When Bürgi was afterwards asked about this New Star, he appealed to that globe of his, conscious of his own diligence; and since the star was not found on it, *he pronounced most confidently on the novelty of this star* — so Kepler says in the same place. [Margin: Testimony of Bayer and of Jost Bürgi.] Kepler also adds, from a letter of Bayer's of the year 1602, these words about the celestial figure of the Swan, which Bayer had lately inspected: *Besides these, at the end of the neck and the beginning of the breast, I discovered another star, no longer doubtful to me, but in truth never seen until now, of roughly the third magnitude.* To these must be added, above all, Janszoon, of whom we spoke above. So, on account of these testimonies and the reasons indicated above, Kepler rightly laid aside his hesitation and said, on page 167: *The novelty of this star has, I think, been sufficiently attested; for if these things are not enough for anyone, it is credible that he would not believe even if whole nations affirmed it.* After him, all the authors listed, both at the beginning of this chapter and in chapter 1, accepted it as new — except a few, unnamed but indicated by Kepler above and in the words to be cited at the end of number 2 in the following chapter.

IV. Nor does Mästlin's argument stand in the way — namely, that Hipparchus and Ptolemy omitted the star seen above the middle one of the three in the tail of Ursa Major, which farmers call the rider but the Arabs call Alcor. For it is so close to the middle star of the tail, and smaller than its horse, that it can be distinguished from it only by the sharpest eyes; hence that proverb among the Arabs about a man who pretends not to see grosser things but boasts of a finer perception: *You saw Alcor, but not the full Moon.* But where the closeness was not so great as to obstruct the sight, they did not omit to count stars, however double and close, as is clear in the two of the horn and of the tail of Capricorn, in the stars of the shoulder of Sagittarius, in the horn of Aries, and in others like them. Nor could they have omitted this one on the ground that it was unformed: it lay within the very neck of Cygnus, and belonged more to the configuration of Cygnus than the bright star of the breast does. Nor could it have been confused with that star, since it was nearly two degrees distant from it, and was very nearly equal to it in magnitude. We therefore conclude that before the year 1600 it was not recorded because it was not shining in the heavens. Nor can Santucci's omission — whether it arose from forgetfulness or from hesitation — outweigh so many other witnesses and indications of this star's novelty, who observed it afterwards.

CAPVT XIII.

Chapter XIII.

On other observations concerning the New Star of the year 1600; and whether, or with what certainty, it is gathered from them that it was above the Moon.

I. Besides the distances of this star from five fixed stars, taken with Tycho's sextant by Tycho's pupils and reported in the preceding chapter, number 1, Kepler reports distances taken by himself in the year 1602, on August 20, in a very clear sky, at Prague, with Tycho's sextant and with the help of Ioannes Eriksen, who had once served Tycho in his astronomical work — but with the sextant corrected from distances between fixed stars taken anew and compared with the distances taken by Tycho, as below.

Distances taken, of star from star	By Tycho	By Kepler
of the Vulture from the tail of Cygnus	38° 3′ 30″	38° 2′ 0″
of Lyra from the tail of Cygnus	23° 53′ 0″	23° 51′ 30″
of Scheat of Pegasus from the breast of Cygnus	35° 12′ 30″	35° 11′ 0″

So, says Kepler, page 167, *our sextant fell short by 1½′, which will have to be added in the following distances*; and he immediately appends the distances of the New Star, as taken and then as corrected — namely these:

Distance of the New Star from the fixed stars	Taken	Corrected
from the *Vulture*	29° 51′ 0″	29° 52′ 30″
from *Lyra*	19° 44′ 0″	19° 45′ 30″
from *Scheat of Pegasus*	35° 50′ 30″	35° 52′ 0″

From these Kepler gathers the place of the New Star at Aquarius 16° 18′, exactly as the Braheans did from their own distances; but the northern latitude Kepler makes 55° 32′, the Braheans 55° 30′.

II. As regards the parallax, or the distance of this star from the Earth, we have nothing else from Kepler than the words of his letter written to Bavaria when the report about the star spread, which he himself inserted into the astronomical narrative on this star, page 166, where he says: *Whatever this star may be, then, old or new, it is established by geometrical reasons that it is certainly raised very high among the fixed stars themselves. This once found, when one also considers that so many months have already passed while it is always seen at the same size, never equalling its neighbour in the breast, never reduced to the faintness of the one in the beak, and of a constant and pale colour too — indeed it is no wonder if that very lingering, however fully one is convinced by the arguments above, still keeps one anxious about what is to become of it.* [Margin: Kepler's opinion on the parallax of this star.] That is, whether it would perish, and whether its novelty was to be confirmed by its perishing. For he wrote this letter in the year 1602; and of this doubt he had also spoken in the dedicatory letter of this astronomical narrative, written in the year 1606, in these words: *For it must be proved to mathematicians, shown to philosophers, and recorded for the universal memory of posterity, whether at this time there is some star in the heavens which, though it was not there formerly,*

has now for six years at least clung there motionless, unchanging, inextinguishable: so that, if it is one day to perish before the consummation of the whole world, men may understand the magnitude of the miracle that it lasted so many years; or, if it will endure with the rest of the fixed stars, then for as long as that is to be, those who are persuaded by the following arguments that it is new may always have before their eyes this most evident proof of a whole world created in time; while those who have stubbornly persisted in arguing from the star's long duration against the tradition of the astronomers, and in denying that it was lately born, may not be unaware by how great a weight of authorities they are pressed. [Margin: Kepler's notable admonition about this star.]

III. Since, then, he says that this star was motionless for six years — understand: by its proper motion — and indeed it was seen up to the year 1621 at least in the same place and position in Cygnus, viewed on however many nights and from however many parts of the world, it is as certain that it had no greater parallax than the other stars of Cygnus as it is certain that its distance from the same fixed stars was seen on the same nights at different horizons — and indeed both when it was highest above the horizon and when it was lowest. [Margin: On the distance of this star from the Earth.] But since Kepler produced no such observations — none other from which the equality of the distance already mentioned was seen on the same nights by different observers, at a great and at a small altitude of this star — Chiaramonti rightly holds, in Book 3 of *De novis stellis*, chapters 3 and 4, that neither the distance of this star nor its absence of parallax has been geometrically demonstrated. And he taunts both Kepler and Tycho's surviving pupils, because in a portent so new and so astonishing they were so negligent that they did not take its distances from the fixed stars accurately on several nights, nor, besides, its greatest and least meridian altitudes — since in the more northern regions it never set, and it shone for so many years. But why did Chiaramonti himself, who had observed the comet of the year 1618, not observe this star? Let him therefore grant to others too the indulgence he would wish for himself, according to that line of Horace: *We know it, and this indulgence we both ask and grant in turn.* Yet he too lacked observations by which he might show, at least on a hypothesis, that this star was below the Moon.

Although neither has been demonstrated by these authors or by others, so far as I know, it is nevertheless far more probable that the astronomers stopped observing because they judged such observations superfluous, seeing that this star had now clung to the same place in the heavens for so many years, let alone months — and for that reason many were slipping back into doubt whether it was one of the perpetual stars; and that there were many same nights on which different astronomers saw it equally distant from the same fixed stars. For the silence of all about any inequality and proper motion is the more probable testimony that this was never noticed. On this supposition it follows that it is far more probable that this New Star was among the fixed stars, or above

Saturn, and had no greater parallax than they, or none perceptible. Let there be, then, the

VNICA CONCLVSIO.

Single Conclusion.

Although it has not yet been demonstrated whether the New Star, which from the year 1600 up to the year 1621, and perhaps beyond, was seen at the junction of the neck and breast of Cygnus, was above or below the Moon, it is nevertheless more probable that it was either among the fixed stars or above Saturn.

The conclusion as to its place among the fixed stars is Kepler's, above — although he thinks it demonstrated; Biancani's, Book 18 of the *Sphaera*, chapter 3; Argoli's, chapter 62 of the *Pandosion*; Glorioso's, Book 5 of *De cometis*, page 275; Descartes's, part 3 of the *Principles of Philosophy*; and Froidmont's, Book 3 of the *Meteorologica*, chapters 2 and 7; and it now stands sufficiently proved from what has just been said.

CAPVT XIV.

Chapter XIV.

History of the New Star of the year 1604 and 1605, seen in Serpentarius.

I. The history of this star, too, was written above all by Kepler, in the book *On the New Star in the Foot of Serpentarius, and on the Fiery Trigon*, chapters 1 and 12; by Chiaramonti, Book 3 of *De novis stellis*, chapters 7, 8 and 9; by Ioannes Heckius, in a disputation on this star; by Liceti, Book 5 of *De novis astris*; by Biancani, in the *Sphaera*, Book 18, chapter 4; by Antonius Laurentinus Politianus, in a little book about it published in Italian; and by others mentioned by these authors — especially by Kepler, who says that many astrologers, following the doctrine of the Arabs, had predicted a comet for this year because of the Great Conjunction of the superior planets, and that for this reason many astronomers too had fixed their eyes on the heavens, to see whether they might notice some portent in them.

II. By the agreement of all, this star arose in the year of Christ 1604; but not all agree on either the day or the month of its first appearance. [Margin: First appearance of this star.] Georgius Spate, a Pomeranian priest, told Herlicius that it was seen on September 27, new style. Kepler contradicts him, thinking that Spate made this up because Magini and Origanus, in their ephemerides, assign the conjunction of Saturn and Mars to the night preceding September 27. Antonius Laurentinus Politianus, on the other hand, says that it was seen on October 8 in 18° of Sagittarius, in which sign, he affirms, the conjunction of Jupiter and Mars took place on about that day — as the ephemerides of Everhardus Belga also have it, on the faith of his tables, which he says were built upon the observations of 40 years — granted that Cyprián Karásek Lvovický places that conjunction of ♃ and ♂ on October 5, and Magini on the 9th, and

that Kepler affirms, both from calculation and from observation, that it took place around noon [?] of October 9. [Margin: ☌ ♃ and ☍ of the year 1604.]

But Kepler gives no credence to Laurentinus either, because nothing new was seen in the heavens by the Germans on September 27, or on October 7, 8 or 9, although they observed the heavens most attentively: on the 27th he himself; on October 7, Ioannes Schulerus; on the 8th, Ioannes Brunowsky at Prague, Helisaeus Röslin in Alsace, and David Fabricius in East Frisia; and finally on the 9th, which was the feast of St Michael the Archangel, Michael Mästlin at Tübingen. But on the following Sunday, namely October 10, after sunset, Brunowsky — who was devoted to the observation of the sky and by then trained in recognising the stars — when the clouds opened for a moment after sunset, saw in the place where Mars and Jupiter were three stars instead of two, and one of them not smaller than Jupiter; and not long afterwards the sky was wrapped in clouds, and at Prague it was overcast for six continuous days. This star was not seen before October 12 by Giovanni Antonio Magini at Bologna and by Röslin in Alsace, nor before the 13th by David Fabricius — all of whom said that it was very large from the beginning — and by others in Württemberg; on the 14th it was seen by Mästlin, though he was still in doubt about its novelty, but on the 16th it was manifest to him, and to Schulerus and Brunowsky; and on the 17th to Kepler. On that day, Bartholomaeus Crestinus, mathematician to the Prince of Savoy, says a letter had already reached his Prince from Spain announcing the rising of the new star. On the 21st, too, it began to be observed with instruments by Jost Bürgi, by Kepler, and by Franz Tengnagel with the Tychonic sextant in the Emperor's garden.

Ioannes Hechius says that it began to be seen around October 9, Arnerius, however, in the first days of October. Therefore, if it is true that at first it was seen small and shortly afterwards large, as Laurentinus and Arnerius affirm, it could have happened that it was not seen by others at that time, either because its faintness did not draw the eyes of observers to it, or because of intervening clouds. But Kepler stubbornly maintains that it appeared very large right from the beginning and was first kindled on the 10th, because the ☌ of ♃ and ☍ had taken place at noon on the day before — as if, indeed, in the application of the aspects, or a little before, their effects did not often precede the aspects themselves; or as if, granted that the rising of this star is to be attributed to the Great Conjunction, it could not have been born very small at first, immediately after the conjunction of Saturn and Mars, which took place on September 26 in the evening after 8^{h}, and then have grown, and, once reared and increased to its full size, have suddenly become very large after the ☌ of ♃ and ☍. We therefore have its beginning — not, indeed, later than October 10, but, not improbably, already from September 27. [Margin: Our opinion on the day of the star's rising.]

III. The star's duration is certain up to October 8 of the year 1605, on which day Kepler testifies that he saw it, adding that it is uncertain on what day between October 8 of the year 1605 and March of the year 1606 it disappeared.

For in March, although the Sun and the Moon were away, no trace of the New Star appeared to him, while on the preceding days it could not be made out, partly because of the nearness of the Sun and the New Star's heliacal setting, partly because of the presence of the Moon. Its duration, therefore, was not less than a year. Santucci says it lasted 13 months, but does not fix the day of its extinction. [Margin: Duration.]

IV. The apparent magnitude of this star was small at the beginning, if you think Laurentinus and Arnerius are to be believed; but large straight away, if Kepler and his friends — and indeed either equal to Venus or greater than Jupiter, Mars and Saturn, which were near the star and offered a convenient comparison. [Margin: Apparent magnitude of the star.] Kepler therefore affirms that by the account of all it was greater than ♃, ♂ and ♄, but by his own observation less than Venus at any time, and very like the star Tycho had observed in Cassiopeia in the year 1572. But Jupiter at that time — that is, at the beginning of October 1604 — was tending towards its apogee, where it would be about the end of December, and so appeared nearly at its smallest. The star, however, remained of the same size through the whole of October. Then at Prague it set heliacally on November 16, and on January 3 of the year 1605 it rose heliacally, plainly visible, but in magnitude greater than the Heart of Scorpius and less than Arcturus, although Arcturus held a position farther from the Sun. For on January 13, once the twilight had lifted, this new star was seen to be greater than Arcturus and than Saturn, which had risen heliacally on the 10th. But on March 20 it seemed less than Saturn, and not much greater than the stars of the third rank that are in the knees of Ophiuchus. On April 21 it seemed to equal the bright star in the right knee of Ophiuchus. On August 12 it was seen equal to the nearest preceding star in the shin of the same figure, or somewhat smaller than on April 21; yet it still twinkled more conspicuously than they and the others. On September 13 it was seen to be already smaller than the one in the shin; and on October 8, because of the evening twilight, it could scarcely be compared with the one in the shin, though it was better discerned because of its greater twinkling.

V. This star had a livelier light and a greater twinkling than the other fixed stars, so much so that Santucci affirmed that it was most brilliant, and more brilliant than the Dog Star itself, while Kepler said of it: *with a flashing or vibration so rapid that some denied that in all their lives they had ever seen anything in the heavens with so swift a motion, as they themselves put it* — that is, with a flickering of its rays. [Margin: Light, twinkling and colours.] He goes on to say that some compared it to a torch tossed by the wind, now stretching out its flames, now drawing them back, in restless alternation; others to the arms of swimmers flung about very rapidly; others to the pulse of people in a fever. On the colours let us hear the same Kepler, page 5: *I, who looked above all to the variety of the colours of the rainbow, which it threw out according to one state of twinkling after another, chose to use the example of a many-faceted diamond, which, as it is turned, flashes the Sun's rays back to the eyes of the onlookers with a changing*

brilliance, etc. On the colours Mästlin agrees with me entirely: that they changed from moment to moment — from yellow presently to saffron, and at once to purple and red; and that it appeared for the most part white when it had risen a little higher out of the vapours.

VI. The figure of this star was perfectly round, with no hair, no beard, no train of a tail cast in any direction. [Margin: Figure.] Its configuration with the planets ♃ and ♂, which were low towards the south, was such on October 10 that it formed an obtuse triangle with them; [Margin: Aspect.] this was resolved on the 13th into a straight line by the motion of the planets, not by the star's own motion. [Margin: Motion.] For throughout the whole time it lasted it moved with no other motion than that of the primum mobile, as Kepler and Johann Georg Brengger [Io. Georgius Brenggerus] observed: it never changed its distance from the fixed stars, and from Jupiter and Mars only exactly as much as their motion produced; it was always on the same parallel, and always rose from the same point of the horizon. Granted that one Crabbus, whom Kepler ridicules and dismisses on page 7, said that it had a proper motion, though a very small one, and that Herlicius agreed with him in this — yet this Crabbus, on the very first day of his observation, which was October 14, erred about the star's place, putting it at Sagittarius 17° 0′, when on that day Fabricius observed it at 17° 37′ or 40′.

VII. The position of the star was roughly at the heel of the right foot of Ophiuchus, or Serpentarius. [Margin: Position.] Below that heel, on October 10, was Jupiter, and Mars, more southerly, was so joined to it that it covered almost a quarter of Jupiter, while Jupiter all but touched the southern edge of the new star. Its place among the fixed stars is assigned by Kepler at Sagittarius 17° 40′; its latitude, quite certain, northern 1° 56′ or 57′; right ascension 256° 47′; southern declination 21° 1½′; it culminated with 17° 51′ of ♐. The star's meridian altitude observed at Prague in March and April by Kepler was 18° 48′ or 49′, but from the declination it comes out 18° 52½′. Fabricius, however, puts it at ♐ 17° 37′ or 40′; Santucci at ♐ 18°, with latitude 1° 44′; Hechius at ♐ 17° 41′ 30″, with latitude 1° 55′ 30″. It is noteworthy, moreover, as Kepler points out, that before it was extinguished this star was approached by all the planets and was in conjunction with them, at least broadly. But it will be useful to set out the distances of this star from the planets and fixed stars taken by Kepler and Tengnagel at Prague, by Fabricius in East Frisia, and by Brengger in Alsace. Kepler corrected the Tychonic sextant by distances of the fixed stars from one another already examined by Tycho, having found that it sometimes exceeded by 4′ because of a dislocation of the pinnule. [Margin: Distance from the planets and the fixed stars.]

Distances of the New Star of the years 1604 and 1605, observed and reported by Kepler, chapter 12.

Date and observer	Distance of the New Star from the old stars	Distance
In the year 1604	from Jupiter	3° 28′ 30″
October	Mars	8° 31′ 0″
day 17	Saturn	6° 13′ 0″
new style	the shoulder of Sagittarius	20° 0′ 0″
Kepler	the right knee of Ophiuchus	7° 37′ 0″
October	from Jupiter	3° 40′, twice
day 18	the shoulder of Sagittarius	20° 2′ 30″, twice
Kepler	the right knee of Ophiuchus	7° 31′ 30″
October	from Jupiter	4° 1′ 30″
day 21	the head of Ophiuchus	34° 2′ 30″
Tengnagel	the shoulder of Sagittarius	19° 34′ 0″
	the left knee of Ophiuchus	16° 52′ 0″
October	from the head of Ophiuchus	34° 0′ 0″
day 21	the right knee of Ophiuchus	7° 47′ 0″
Jost Bürgi	the bright star of Aquila	45° 43′ 0″
October	from Jupiter	4° 59′ 30″
day 27	the head of Ophiuchus	34° 1′ 30″
Kepler	Afterwards it set heliacally.	
In the year 1605		
January 29	from the left knee	16° 50′ 0″
Brengger	of Ophiuchus, or	16° 45′ 0″
February 2	from the Heart of Scorpius	14° 55′, three times
Kepler	from Aquila, at one time	45° 54′ 0″
	at another	45° 51′ 0″
	at another	45° 45′ 0″
	and at another	45° 44′ 0″
because of the awkward position of the sextant		
David Fabricius	from the head of Ophiuchus	34° 0′ 0″
	the left knee of Ophiuchus	16° 46′ 0″
	the bright star of Aquila	45° 45′ 0″

VIII. Kepler says that he defers to Fabricius, because he admits that he was much hindered by confused vision. From the distances already mentioned, Kepler, in chapter 13, investigates the place of the New Star in the zodiac by various lines of inquiry, and from many places chooses the one I set down above, in number 7; and in chapter 14 he partly corrects many stars of Serpentarius observed on that occasion, and partly adds stars passed over by the ancients and by Tycho himself. But since Kepler worked rather crudely, and compared the star with the planets just as if, because of their small latitude, they were on the ecliptic, Chiaramonti, in Book 3 of *De novis stellis*, chapter 11, criticises him on many points; and in chapter 12, from selected distances among those already mentioned, and from the Tychonic longitude and latitude of the fixed stars, he gathers trigonometrically the places of the New Star, which we set out here below in a small table, together with the places of the stars themselves.

From the stars	Distance of the New Star	Sign	Longitude of the fixed stars, from Tycho	Latitude of the fixed stars, from Tycho
from the head of Ophiuchus	34° 20′ 30″	♐	16° 53′ 30″	35° 37′ B
the shoulder of Sagittarius	19° 34′ 0″	♑	6° 54′ 30″	3° 31′ A
the left knee of Ophiuchus	16° 52′ 0″	♐	3° 42′ 20″	11° 30′ A
the bright star of Aquila	45° 43′ 0″	♑	26° 12′ 28″	29° 21′ B
the Heart of Scorpius	14° 53′ 0″	♐	4° 1′ 0″	4° 27′ A
From these is gathered, for the New Star:			Longitude	Northern latitude
from the longitude of the shoulder of Sagittarius		♐	18° 30′ 30″	3° 10′ 6″
from the longitude of the knee of Ophiuchus		♐	17° 26′ 30″	1° 34′ 23″
from the longitude of the head of Ophiuchus		♐	17° 10′ 30″	1° 34′ 23″
from the longitude of Aquila		♐	18° 46′ 15″	✠ ✠ ✠
from the longitude of the Heart of Scorpius		✠	✠ ✠ ✠	0° 43′ 44″
But from the New Star's distances taken by Fabricius — namely 34° from the head of Ophiuchus and 16° 46′ from the knee of Ophiuchus — there is gathered		♐	17° 52′ 30″	1° 37′ 15″

CAPVT XV.

Chapter XV.

On the parallax of the New Star of the year 1604, and its distance from the Earth.

I. Kepler's first preliminary argument [Prolusio] is found in chapter 1, in these words: *Since, then, this new star corresponded exactly to the other fixed stars, and to the new one in Cassiopeia, in magnitude, splendour, twinkling and purity of ethereal light, it came about that, as soon as astronomers came upon the sight of it, they at once concluded both its rest beneath the fixed stars and its place in the world, common to it with them as well — which the experience of a few days proved, since it kept exactly the same distances from the fixed stars.* But from chapter 15 to chapter 18 he tried expressly to establish this opinion of his. For it is quite clear from what was said in chapter 4 that the things he had brought forward about twinkling and other accidents distinct from immobility are not evident arguments but only probable ones. In chapter 15, therefore, he promises a demonstration in this formula: *First I shall demonstrate that this star was not only placed above the orb of the Moon, but was not even nearer than the Sun itself.* And in chapter 17 he says: *This immobility, etc., plainly proves that no place below Saturn can be assigned to the New Star.* This he takes pains to show by six arguments, though scattered here and there.

The *first* is of this kind. If the New Star had not been higher than the Moon, that is, than sixty semidiameters of the Earth, and yet had lacked a proper motion, then, observed in October at its setting and in March at its rising, it would have undergone a parallax of longitude of 52½′ and of latitude of 5′, as he demonstrates from his parallactic table and from a geometrical figure. [Margin:

Kepler's 1st argument for its seat above the Moon, from a parallax smaller than the Moon's.] But it lacked a proper motion, and, observed at both those times, it showed no parallax of latitude, and none of longitude beyond 6′ — indeed, once the defect of the instrument and refraction are taken into account, none beyond 2′. For in the year 1604, on October 21, from its distance from three stars taken by Tengnagel, Tycho's son-in-law, its place was found at ♐ 17° 39′, or 40′, or 42′, while it stood in its setting. And on February 12, when it was observed rising, it was found likewise, by means of Aquila, at 17° 40½′ of ♐, but by means of the Heart of Scorpius at 17° 44′ 20″ of ♐, and more correctly, from Fabricius's distances, at 17° 42′ of ♐. Indeed, because Bürgi in October and Kepler himself in February measured the New Star's distance from the bright star of Aquila as 45° 43′, and from this and other stars its place in both months was found at ♐ 17° 40′, 42′ or 43′, he concludes that it did not have a parallax of 3′; and therefore, if the Sun is 1200 semidiameters distant from the Earth and its parallax is 3′, as is commonly assumed, that the New Star had a parallax smaller than the Sun's.

II. The *second* argument, put forward on page 81, is this. If the Moon is observed at the same moment of time near the zenith in Bohemia and in Frisia — places about 6° of a great circle apart — it will be seen at different places of the zodiac, by about 6′. But Kepler in Bohemia and Fabricius in Frisia observed the New Star at the same place in the zodiac, without a difference of 6′. Therefore the New Star was not as low as the Moon. [Margin: Kepler's 2nd argument, likewise from a parallax smaller than the Moon's.]

The *third* argument, inserted on page 78 and in chapter 89 in the first exposition, is this. If the New Star had not been higher than the Moon, it could not always have been seen from different parts of the Earth equally distant from the head and from the right knee of Ophiuchus. But its distance from the head of Ophiuchus was always the same, both in the year 1604, when it was near its setting, and in the year 1605, when it was near its rising: therefore it was higher than the Moon. And he adds: and so its northern latitude too was always the same, between 1° 55′ and 1° 57′. [Margin: Kepler's 3rd argument, from the same distance kept from the same fixed stars.]

The *fourth* argument, indicated on page 6 but put into form by us — and in nearly the same way by Chiaramonti, Book 3, chapter 18 — is this. A star which is always observed by the same observer to rise from the same point of the horizon, and so always remains on the same parallel, does not change its distance from the fixed stars and lacks all parallax, so that it is in the eighth sphere. But such was this New Star, as Brengger observed. Therefore it lacked all parallax. [Margin: Kepler's 4th argument, from the star's rising at the same point of the horizon.]

III. The *fifth* argument is from the star's immobility, but by another route than through parallax. Kepler himself treats it in chapter 17, adapted to the Ptolemaic and Tychonic hypothesis of a stationary Earth, and we shall put it into form in this way. If the New Star had been in the region of the planets,

it would have imitated the motion of the wandering stars, and, besides the diurnal motion of the primum mobile, would have had some proper motion. [Margin: 5th argument, from immobility, or the lack of proper motion.] For if the orbs are solid, it could not have failed to be carried in the directions in which the orb of the planet giving lodging to this star was carried. But if, as Tycho holds, the orbs are not solid, then, since the planets follow the Sun by a natural sympathy, or at any rate are drawn by it as it carries them round, and cannot themselves resist, it is incredible, and would be said ἀναιτιολόγητον [Greek: anaitiologēton, "not accounted for by a cause"] — that is, without probable cause — that a New Star placed in a planet's orb could do what the planets cannot: namely, not follow the Sun, and not imitate its motion by a proper motion through the zodiac. But the New Star had no proper motion; rather, throughout the whole time of its duration, it stood in the same place beneath the fixed stars; and its configurations [ſchematiſmos] with the stars of the foot, shin and right knee of the Serpent-bearer [Serpentarij], and with the triangle that shines in the coil of the Serpent, it did not change by even the least amount that could register on the senses. Therefore it was not among the orbs of the planets, but above them, among the fixed stars. For it is consistent that the new stars of which Pliny the Elder said (Book 2, chapter 25), *Some move in the manner of the wandering stars, others stay fixed*, should be in the sphere of the wandering stars if they move like the wanderers, and, if they do not move, in the sphere of the immobile stars, that is, of the fixed stars [Affixarum].

IV. The *sixth* argument, which *Kepler* begins at the end of chapter 15 but completes in chapter 16, tells only against those who admit Copernicus's hypothesis of the annual motion of the Earth. It runs as follows. In the hypothesis of Copernicus, Saturn at apogee is ten times further from the Earth than the Sun is; and then, because of the annual motion of the Earth, it shows a parallax of the annual orb of about 6 degrees when the Earth is carried from the conjunction or the opposition of the Sun and Saturn to their quadrature, as is plain from the Prutenic Tables. Therefore, if the New Star had been in the place of Saturn at apogee, it would have incurred a parallax of 6 degrees; yet it never shifted its apparent place beneath the fixed stars by 6′, that is, not even by a sixtieth part of six degrees. Therefore, in this hypothesis, the New[21] Star must have been higher than the distance of Saturn taken sixty times, or than the distance between the Earth and the Sun taken six hundred times (since the distance between the Sun and the Earth is contained ten times in the distance of Saturn); otherwise, had it not been higher, it would have had a parallax of six minutes. [Margin: 6. The argument from the absence of annual parallax.] Indeed, since the most trustworthy observations all agreed to within 2′, and this star had no parallax greater than 2′, and two minutes are a third part of six minutes, the distance already mentioned — which we said was six hundred times greater than the distance of the Earth from the Sun — must be tripled. *It is certain, therefore,*

[21]printed *Nonam*, for *Novam*

says Kepler on page 82, *that according to the opinion of Copernicus this star was at the least three times higher, and so that two million one hundred and sixty thousand semidiameters of the Earth lay between it and the Earth.* For he assumes the distance of the Sun from the Earth to be 1200 terrestrial semidiameters; multiplied by 10, this gives the distance of Saturn, 12,000; this taken sixty times gives 720,000 semidiameters of the Earth; and this, finally, taken three times gives 2,160,000 semidiameters of the Earth. So he argues at the end of chapter 15. [Margin: The distance of the New Star from the Earth according to Kepler.] But in chapter 16, taking from this the occasion to determine the Copernican distances, he chooses a distance of the Sun from the Earth of 1432 terrestrial semidiameters, and of Saturn 14,320. Taking this sixty times, then, would give 859,200; and this taken three times would be 2,577,600 semidiameters of the Earth — namely the distance of the New Star required in the hypothesis of Copernicus, and by Kepler's measures, for it to show no parallax greater than two minutes. But if it is placed among the fixed stars, he assigns to it and to the fixed stars a distance from the Earth of thirty-four million seventy-seven thousand semidiameters of the Earth, and sixty-six more besides, that is, 34,077,066⅔. [Margin: The true size of the New Star, according to Kepler.] From this distance, he says, the whole sphere of the moving bodies, that is, the sphere containing everything below Saturn, appears no greater than three minutes; and therefore, if the New Star measured at least 4′, the figure he assigns to Sirius, it was of greater bulk than the whole sphere of the planetary system. So he writes on page 89.

V. I now reply to the First argument. First, I deny the minor premise, in which it was said that the star had no proper motion, nor a parallax of 52′ 30″ in longitude and 5′ in latitude. For Kepler has demonstrated neither: not the motion, as I shall show shortly in the reply to arguments 3 and 5; and as for the parallax, first, because the observations of the New Star's distances from the fixed stars vary, as is plain from the table set out under number 7 of the preceding chapter. [Margin: Reply to Argument 1.] On account of this variation, and of the fault in the Tychonic instrument, whose pinnules he admits had been dislodged, and of the dullness of his own sight, and of refraction, he does not deny that there is some uncertainty in them; for he says on page 81: *And although there is some uncertainty in the observations, for the reasons indicated*; yet from them the longitudes and latitudes of the New Star were deduced, and their differences in October and February. Second, because *Chiaramonti*, by careful demonstrations — as is quite clear to me on examining his geometrical and arithmetical procedure in Book 3 of *De stellis novis*, chapters 11 and 12 — gathered from the distances of the New Star from the fixed stars taken on 1604 October 21 and in February 1605, and finally from the distances taken by Fabricius, very various and differing longitudes and latitudes of the New Star, as may be seen in the table we drew up for this purpose in the preceding chapter, number 9. From this diversity a great uncertainty indeed arises; but if those distances are accepted, a parallax greater than 52′ ½ in longitude and 5′ in latitude follows, and indeed one so great that on Kepler's

own hypothesis the New Star would be demonstrated to have been below the Moon. For from the northern latitude of 3° 10′ 6″, which Chiaramonti derives from the distances of the New Star from the shoulder of Sagittarius and from the Knee of Ophiuchus, taken on the 21st day of October, when the New Star was near setting, and from the latitude of 0° 43′ 44″, which the same author derived from the distances of the New Star from the Heart of Scorpio and from Aquila, taken in February, when it was near rising — from those latitudes, I say, a difference of 2° 26′ 22″ is drawn; and from the longitudes in ♐ of 18° 46′ 15″ or 18° 52′ 30″, and 17° 10′ 30″, a difference of 1° 35′ 45″ or 1° 42′ is gathered. Therefore, if a difference of latitudes greater than 5′, and of longitudes greater than 52′ ½, would be an argument that the New Star was below the Moon, as Kepler asserts, then, since a much greater one is gathered from some of the distances Kepler admits — granted that it is not gathered from all of them — it follows that his hypotheses on this matter are uncertain, and that it is no more demonstrated that the star was above the Moon than below it. And so, as the truth of the calculations requires, we are compelled on this point to side with Chiaramonti (Book 3 of *De novis stellis*, chapter 14), who denies that Kepler has demonstrated a parallax of the New Star smaller than the Moon's, and who recognises a fallacy or uncertainty in his foundations.

VI. I reply likewise to the 2nd argument, denying the minor premise, with Chiaramonti above. For it is evident from the last table of the preceding chapter that from the distances of the New Star from the shoulder of Sagittarius taken in Bohemia, and from the Head of Ophiuchus taken in Frisia, the longitude derived there is ♐ 18° 30′ 30″ with a latitude of 3° 10′ 6″, but here 17° 52′ 30″ with a latitude of 1° 37′ 15″; and hence a difference in longitude of 38′ and in latitude of 1° 32′ 51″. [Margin: Reply to 2.] But if on both sides we use the head of Ophiuchus, the difference in longitude was 42′, that is, much greater than 6′ — which *Kepler* does not concede, seeing that if he conceded it the star would be placed below the Moon. But I add that it is not established that these observations were made, in both places, near the meridian and at the same moment of time, which was required, as even Kepler himself demands.

VII. I reply to the 3rd argument, again denying the minor premise: first, because the equality of the New Star's distance from the same fixed stars has not been demonstrated with respect to all observers, nor always even with respect to a few. [Margin: Reply to 3.] For how, from the observations of so few days, all of which we collected in the penultimate table of the preceding chapter, could it be affirmed with certainty that the star behaved so throughout the whole time of its duration? Second, in those very observations a variation appears that is not to be despised. So if he wished to escape the excessive parallax in longitude and latitude just mentioned, there certainly ought to have been more observations made, and the times recorded, and the vertical circles with the azimuths, so that it would be established whether the star kept an equal distance at every altitude and position.

VIII. I now reply to the 4th argument, denying the major premise, with Chiaramonti, Book 3, chapter 18. For any phenomenon, however near the Earth it may be and however great its parallax, will, if it lacks proper motion, always rise for the same observer from the same point of the horizon; for when it stands on the horizon it has the same parallax, because of its equal apparent distance from the zenith. [Margin: Reply to the 4th argument.]

IX. To the 5th argument I reply, *first*, that it is here already assumed as certain that the New Star was either in the spheres of the planets or above them; but neither is certain, and neither has yet been demonstrated. [Margin: Reply to the 5th argument.] *Second*, that it could have been in the sphere of some planet and yet have had within it a singular motion, by which its body, whether by its own epicycle or otherwise, was kept always beneath the same point of the fixed stars — especially since for Tycho the heaven is fluid; and that an argument from the ordinary motion of the planets does not hold for the motion of an extraordinary phenomenon, as is plain in the comets, some of which Kepler admits were within the region of the planets, and yet not the motion of the planet that gave them hospi- tality did they imitate, but one quite different. And so that whole argument moves within the mere bounds of probability.

X. Finally, to the 6th argument we reply, *first*, that the hypothesis of Copernicus is either false or improbable, as we shall show in Book 9, God willing. [Margin: Reply to the 6th argument.] *Second*, that, granting it, a phenomenon whose place is in doubt could be below the Moon and be carried along with the Earth, just as the Moon is carried in that hypothesis, so that it would undergo the parallaxes of the annual orb that Kepler speaks of there. In that argument he reasons about this star just as if it had already been demonstrated that it was either in the sphere of Saturn or above Saturn, when in fact neither has been demonstrated.

XI. After Kepler, Ioannes Heckius of Deventer [Deuentrienſis], Doctor of Medicine and Philosophy, in a disputation on this star published at Rome in the very year 1605, assumes as most certain a longitude for this star of 17° 41′ 30″ of Sagittarius and a northern latitude of 1° 55′ 30″; and because, when it was approaching the horizon, it was not seen in another place, nor at another distance from the fixed stars, than when it was far from the horizon and approaching the zenith, he concludes that it had no sensible parallax and was in the highest heaven. [Margin: Neither Heckius nor Biancani demonstrated that this star was in the firmament.] But we have already shown, in chapter 6 from number 3, that this argument is not demonstrative if the observations are made at one place on the Earth — indeed, not unless this has been observed on the same night at several horizons. Therefore, since Heckius brought forward only his own observations, he did not demonstrate absolutely that the star lacked all parallax sensible in itself, but only that it had none sensible at the place where he was observing. Nor did Biancani, in Book 18 of the *Sphaera*, chapter 1, where, from the fact that for 16 years it was seen in the same place beneath the fixed stars without any proper motion, he concludes that it was among the fixed stars

and stood off from the Earth at the Tychonic distance of the fixed stars, 14000 terrestrial semidiameters. For it would have to be certain, from the observations of determinate days, that on the same nights, viewed at different horizons, that is, from different places on the Earth, it kept the same place beneath the fixed stars, or the same distance from those same fixed stars.

XII. There remains Antonio Santucci, who in chapter 7 of *De Cometis* contends that this star was above the Moon, and not lower than the orb of Venus. [Margin: Santucci's argument is weighed.] His method rests on the stay of the phenomenon above the sensible, or natural, horizon, compared with the stay due to it above the rational, or astronomical, horizon. I have already given the problem for this method in Section 1 of this book, chapter 15, from number 12; and *Chiaramonti* also carries it out, in Book 3 of *De novis stellis*, chapter 30, much more clearly, fully and solidly than either *Giovanni Camillo Glorioso* — who, in Book 2 of *De Cometis*, chapters 3 and 4, restricted the problem to a phenomenon appearing only on the equator, to an observer likewise living beneath the equator — or *Santucci*, who restricted it to the case in which the phenomenon is on the equator or beyond it. But the chief point, which we too confirmed there, Chiaramonti shows in that Book 3, chapter 31: this notable theorem, namely, *When we are uncertain whether a phenomenon undergoes parallax, it is not permissible to deduce its distance from the centre of the Earth with certainty from its stay above the natural horizon.* The reason is that, to deduce this distance with certainty, the true parallel on which the phenomenon stands must be known with certainty beforehand, or (what comes to the same thing) its true declination from the equator, in the case where it is not on the equator, as this star was not; or at least the difference between the true and the apparent parallel must be known. Otherwise, since parallax apparently depresses the phenomenon onto a parallel more remote from the equator, a calculation that relies on that apparent parallel, taken as the true one, will always be fallacious, as is plain from the problem already given in Section 1, chapter 15, number 12. Therefore the parallax of altitude must be known beforehand; and once it is known, the distance of the phenomenon from the centre of the Earth is gathered much more readily by the problem already given in Book 3, chapter 7, number 3. But Santucci used the apparent declination and parallel of this star, that is, the one obtained from observation, as the true one. For, as *Chiaramonti* also reports (Book 3, chapter 32), taking the altitude of the pole at Pisa as 43° 30′, he subtracted from the altitude of the equator, 46° 30′, the meridian altitude of the New Star that he had observed, 25° 20′, and so obtained a declination of 21° 10′. [Margin: Santucci's error in misusing the apparent declination as the true one.] Then he uses the star's stay above the natural horizon observed on April 1, of $9^h\ 4^m$, and on April 14, of $9^h\ 4^m$, and on June 5, of $9^h\ 4^m$. Further, from the apparent declination and stay he gathers the true stay, that is, the diurnal arc of the star, of $9^h\ 4^m\ 40^s$; and hence that between the true and the apparent stay there was no sensible parallax. But, as *Chiaramonti* rightly insists (Book 3, chapter 33), this method is fallacious, because it uses the

apparent declination for the true one and the apparent parallel for the true one; and further, in the observed stay it takes no account of refraction, which, by raising the star, makes it rise apparently sooner and set later than it otherwise would — besides other fallacies which he detects, there and in chapter 35, in Santucci's calculation. Lastly, I note that the declination of this star observed by Santucci, 21° 10′, must be increased by three minutes, because the altitude of the equator observed at Pisa by Master Vincentius Renerius [Vincenzo Renieri], the chief mathematician there, and sent by him to me, is accurately 46° 33′, and the altitude of the pole 43° 27′; so the declination would rather have been 21° 13′. But Kepler, as we said in the preceding chapter, number 7, set it at 21° 1′ 30″; the difference between these is 11′ 30″. Santucci therefore did not demonstrate what he had promised, namely that this star was not lower than Venus — indeed, not even whether it was below the Moon.

XIII. So much for those who have tried, but in vain, to demonstrate that the New Star of the year 1604 was in the highest aether, or at least above the Moon. Now we shall see whether Chiaramonti, in Book 3 of *De stellis novis*, chapter 19, demonstrated from the observations Kepler adduces that it was below the Moon. [Margin: Chiaramonti's method and demonstration of the sublunary seat of this star is weighed.] His method, then, is this. *First*, comparing with one another the latitudes he deduced from the distances Kepler admits, which we set out in the last table of the preceding chapter, he gathers the difference of the apparent latitudes, the greatest 2° 26′ and the smaller 51′; and he assumes, from what was demonstrated in the *Antitycho*, Book 1, chapter 6, proposition 6, that the parallax of altitude is greater than the parallax of latitude when the circle of latitude is different from the circle of altitude, as in our case; and so that the parallax of altitude, from Kepler's data, is not less than 51′. *Second*, he demonstrates from John Dee's treatise on parallaxes, and from a theorem he himself demonstrated in the supplement to the *Antitycho*, part 2, chapter 35, that the sines of the complements of the altitudes have the same ratio to one another as the sines of the parallaxes of a phenomenon seen from the same place on the Earth and keeping the same distance from the centre of the Earth — the parallaxes, I mean, belonging to those altitudes. This we too, with Snel and Cysat, shall show in Book 10, the penultimate section, chapter 2. *Third*, he takes two distances of the New Star from the zenith, the smaller 56° 47′ 50″ and the greater 83° 5′ 47″; and from their sines and the parallax of 51′ he gathers, by the theorem set out above, the parallax due to the smaller distance from the zenith, 2° 1′, and that due to the greater, 2° 51′. *Fourth*, and finally, from the parallax of 2° 1′ he gathers a distance of the star from the Earth of 24 terrestrial semidiameters, and from the parallax of 2° 51′ a distance of 20 semidiameters. I pronounce these theorems and problems, together with the working of the calculations, correct, setting aside for the present the minutiae of the fractions. And so it has indeed been demonstrated by Chiaramonti, on a hypothesis, that this star was below the Moon — but not absolutely, nor on a certain hypothesis,

since other observed distances of this star show a much smaller parallax, as we saw from Kepler; and so each hypothesis is uncertain.

CONCLVSIONES.

Conclusions

I. CONCLUSION. *Neither Kepler, nor Heckius, nor Biancani, nor Santucci has absolutely demonstrated that the New Star of the year 1604 and 1605 was above the Moon, let alone among the fixed stars.* This is quite clear to anyone who weighs what we said from number 5 to 12. To me, moreover, it is not evident that anyone else has attempted to demonstrate this, although some of those already adduced in chapter 1 think it has been demonstrated universally that all New Stars were in the highest aether and far above the Moon.

II. CONCLUSION. *But neither has Chiaramonti demonstrated, either absolutely or on a certain and irrefutable hypothesis, that the New Star of the year 1604 and 1605 was below the Moon.* I showed this sufficiently a little earlier, at the end of number 13, and he himself professes nothing different.

III. CONCLUSION. *Yet on some probable hypothesis it has been demonstrated that the New Star of the year 1604 and 1605 was above the Moon, and on another that it was below the Moon.* The first part is plain from the arguments of Kepler adduced in chapter 2. 3., from number 1; the second from the demonstration of Chiaramonti set out in number 13.

IV. CONCLUSION. *Yet it is more probable that the New Star of the year 1604 and 1605 was far above the Moon than below it.* This is plain not only from the authority of more who assert it than deny it — in *Kepler*, Book 1; in *Froidmont*, Book 3 of the *Meteorologica*, chapter 2, article 7; and in *Glorioso*, Book 5 of *De Cometis*, page 275 — but also from the arguments from its colour, twinkling, light, immobility and shape, which are signs of a heavenly rather than a sub-heavenly place; but most of all from the fact that in so long a duration no one noticed that its distance from the same fixed stars varied very sensibly. It is therefore more probable that, had it been observed on the same nights from different places on the Earth, it would have appeared to each and every observer at the same distance from the same fixed stars; indeed, that the days of such observations were not recorded for this very reason, that even at a simple glance it always appeared equally distant from the same fixed stars, whether it was now grazing the horizon or was nearer the zenith.

CAPVT XVI.

Chapter XVI.

A synopsis of the opinions on the distance and size of the three New Stars which appeared in the year 1572 in Cassiopeia, in 1600 in Cygnus, and in 1604 in Serpentarius.

I. By what technique the apparent diameters of the stars are to be observed, and how the true diameter is to be gathered from their distance from the Earth

together with the apparent semidiameter, we have explained [?] sufficiently in Book 6, chapter 9, and in Book 7, Section 6, chapters 8 and 9; and we said something on this matter in Section 1 of this book, chapter 24. How, moreover, the circumference and the solidity of a star are derived from its true diameter, if it is supposed to be round and spherical, is plain from the common rules for the measurement of the circle and the sphere given in Book 1, chapters 4 and 6, and in Book 7, Section 6, chapter 8, from problem 3 to 9; from these passages taken together the reader will be able to draw the full doctrine on these matters. Here, however, I have decided to gather into one place the opinions on the distance and on the apparent and true size of the three New Stars — with the warning, however, that their authors were deceived about the apparent diameter, which they estimated as larger than was right, for the reasons adduced in Book 6, chapter 9, and Book 7, Section 6, chapter 9. The passages of the authors may be looked up again in chapter 2 for the star of the year 1572, in chapters 12 and 13 for the star of the year 1600, and in chapters 14 and 15 for the star of the year 1604. That Tycho and Reinhold make the star of the year 1572 smaller and smaller arises from his opinion: he thinks that it was seen as smaller because its body was in fact diminished, and not because it receded further and further from the Earth.

II. For the New Star of the years 1572 and 1573, then, *Tycho*, in volume 1, chapters 6 and 7, set its distance as great as that of the fixed stars, namely 14000 semidiameters of the Earth; but the *Landgrave* and *Reinhold* set it at 1062 or 1079 semidiameters — granted that the Landgrave does not deny that it could have been greater; *Peucer* and *Schuler* at 169 semidiameters; *Nolthius* at 19 or 20; and *Busch* at 30. [Margin: The distance of the star of the year 1572.] The rest set no determinate measures, but said only, indeterminately, that it was either above the orbs of the planets, like *Froidmont*, or within the orbs of the planets, or below the Moon, according to the three classes of opinions which I reviewed, with their authors, in chapter 11. But *Chiaramonti* deduces very many and differing distances from various hypotheses, which I reported in chapter 10, numbers 4, 8 and 9.

All testify that its apparent *diameter* was greatest at the beginning and afterwards decreased gradually to an insensible quantity — except *Santucci*, who said that it was smaller at first and afterwards grew, and then diminished. [Margin: Its apparent diameter.] That it was greater than Venus from the very start is affirmed by the *Landgrave* of Hesse, *Clavius* and *Mästlin*; that it was equal to Venus, by *Cornelius Gemma*, *Peucer*, *Ursinus* and *Pridianus*; and that it was smaller than Venus but greater than Jupiter, the Dog Star [Canicula] and Lyra, by *Tycho*, *Praetorius*, *Hájek*, *Fabricius*, *Maurolico*, *Apian* and *Camerarius*. Against them *Santucci* alone imagines that at the beginning it was equal to stars of the sixth magnitude, that it did not equal Venus until March of the year 1573, and that from the end of May to the end of August it was twice as great as Venus. But he is rightly believed to have imagined this in order to establish that it grew in its descent and decreased in its ascent, since so many other witnesses oppose

him. As for a determinate measure, the apparent diameter at the beginning was estimated by *Tycho* at 3′ ½, by *Nolthius* at 10′, and by *Busch* at 88′ — that is, three times greater than the Sun's diameter, unless in Busch there is an error of the printer or of the pen; the rest are silent about it.

The true *diameter* of this star was set by *Tycho*, volume 1, chapter 7, at 7 ½ terrestrial diameters at the beginning; by *Reinhold* at 3 ⅛, or 5385 German miles, but at the end at 1 ⅛ semidiameters of the Earth, or 1888 German miles; by *Nolthius*, again, at 46 German miles; and by *Busch* at 664 German miles. [Margin: Its true diameter.] But if it had been where the fixed stars are, and at least equal to Sirius, it would on our reckoning have been 34 semidiameters of the Earth, as we showed in Book 6, chapter 9, and its solidity would have been to the Earth's as 4913 to 1.

Finally, you have its *solidity* relative to the solidity of the Earth in the small table below; to which Tycho, volume 1, chapter 7, adds that at the beginning it was to the Sun as 2 ⅔ to 1. [Margin: Its solidity.]

The solidity of the star contained the globe of the Earth, times:

Authority	Period	Times	Period	Times
	In the year 1572, November	361 ½	June, July, August	11
	December	200	September, October, November	4 ½
For Tycho	1572, January	100		
	February and March	70	December, and 1573, January	1
	April and May	29	February, March	0 ⅓
For Reinhold	at the beginning	31	at the end	1 3/10
For Nolthius		0 1/50000		
For Busch		0 1/18		

III. As for the New Star that appeared at the boundary of the neck and breast of Cygnus from the year 1600 up to the year 1629, or at least 1621, no one has reported its distance from the Earth determinately; some merely contend, with Kepler, that it was among the fixed stars, but Chiaramonti that it was below the Moon, or at least that it has not been demonstrated that it was above the Moon. [Margin: The distance and size of the star of the year 1600.] Its apparent size from beginning to end was as great as in stars of the third magnitude; nor do I find anything else defined.

IV. Finally, the New Star of the year 1604 and 1605, which shone in the heel of the right foot of Ophiuchus, or Serpentarius, was seen by everyone at the beginning as greater not only than any fixed star but also than Saturn, Mars and Jupiter, to which it was very close in position throughout October; to some it seemed equal to Venus; to *Kepler* smaller than Venus in any state [omni Venere], and of 4 minutes. [Margin: The distance and size of the star of the year 1604.] Kepler places it among the fixed stars, with many others; but *Santucci* either among the fixed stars or not below the sphere of Venus; *Biancani* at a distance of 14,000 semidiameters of the Earth; whereas *Chiaramonti*, on the contrary, contends that it was below the Moon, and no higher than 20

or 24 terrestrial semidiameters. The other measures have been passed over by the authors — by Kepler, perhaps, so that its bulk should not seem incredible, given the enormous distance of the fixed stars from the Earth in the Copernican hypothesis; yet he affirms in chapter 16 that in bulk it was greater than the whole sphere of Saturn and of the planetary system. But mortal weakness labours, or plays, in vain over these numbers, since the distance and seat of these portents are uncertain — portents whose very origin and nature, too, GOD has willed to be unknown to us, as will become clear from the following chapter.

CAPVT XVII.

Chapter XVII.

On the matter, nature and generation of the New Stars.

I. In chapter 11 we reviewed three classes of authors and of opinions on the distance, or place, of the New Star of the year 1572. [Margin: Summary of the opinions.] The authors of the third class, who placed it below the Moon, mostly held that it was a meteor kindled or lit up from elementary matter, just like those comets which they call Roses. But the authors of the first and second classes, who held it as certain that it was above the Moon, then split into various opinions as to its matter, its nature, and the manner of its generation, or of its new appearance and disappearance; and the same happened over the stars of the years 1600 and 1604 — so much so that Ioannes Heckius and Fortunio Liceti collected more than 12 opinions. These are reduced, however, to 4 general heads: the novelty of these phenomena could be explained and defended either by local motion alone, of the star itself or of the heaven; or by alteration alone; or by generation and corruption; or by miraculous creation. Let us now come to the opinions one by one, and to their authors.

II. The *first* opinion is that of those who think that the New Stars were sublunary comets without a tail, generated from elementary matter, either by inflammation or by illumination. Of this kind, speaking of the star of the year 1572, were *Nolthius, Busch, Graminaeus, Ursinus, Lvovický*, and formerly *Peucer*, as reported in Tycho and in the passages reviewed in chapters 2 and 11. [Margin: 1. The opinion of sublunary matter.] [Margin: Of Nolthius. Of Busch. Of Graminaeus. Of Ursinus. Of Lvovický.] What could be said here of this opinion is what was said of comets in general in Section 1, chapters 10, 11 and 12, the questions concerning the tail excepted. But this opinion is opposed above all by the fact that it is far more probable that the New Stars of the years 1572, 1600 and 1604 were above the Moon, as we said in chapter 11, conclusion 8; chapter 13, the single conclusion; and chapter 15, conclusion 4.

III. The *second* opinion was that of *David Chytraeus*, as reported in Tycho, volume 1, page 712, who thought that the star of the year 1572 was produced in the elementary region and afterwards ascended into the heaven. [Margin: 2. The opinion of Chytraeus, of sublunary matter migrating into the heaven.] Against this ascent Ioannes Heckius protests, on page 14 of his disputation: for

if it had ascended, it would surely have done so by the force of lightness; but lightness has no place with respect to the celestial region — otherwise fire too would ascend into the heaven, or else perpetual violence would be done to it by whatever prevents its ascent. But Chytraeus is opposed more by the greater probability which, as we said against the 1st opinion, belongs to placing the new stars far above the Moon. Yet we adduced an opinion similar to this one, concerning comets, in Section 1, chapter 6, number 8.

IV. The *third* opinion was that of *Cornelius Gemma*, Book 11 of *De Characterismis Naturae*, chapter 3, and as reported in Tycho, volume 1, page 563; of *Antonio Santucci*, *De Cometis*, chapter 7; of *John Dee* the Englishman, as reported in Tycho, volume 1, page 690; of *Giuseppe Biancani*, Book 18 of the *Sphaera*, chapter 5; and of other unnamed authors, as reported in Kepler's *Optics* at the end of chapter 10. It holds that these stars were not new but ancient and perpetual, yet hidden in the deepest part of the aether and invisible because of their immense distance; that afterwards, by descending towards us, they became visible, and by ascending, invisible again. [Margin: 3. The opinion of the ascent and descent of the star.] [Margin: Of Cornelius Gemma. Of Santucci. Of John Dee. Of Biancani.] Concerning the ascent, *Elias Camerarius* also held this view, thinking that the star of the year 1572 was a celestial comet which vanished by gradually ascending, as Tycho has it, volume 1, page 695. [Margin: Of Camerarius.] Fracastoro says the same of comets, as do many others, ancient and more recent, whom we named in Section 1, chapter 6, number 4. Gemma adds, moreover, that the star of the year 1572, had it been observed, could have been seen in March of the year 1572, but of tiny size; it was not noticed, however, until November, when by its size it struck the eyes of mortals. So too Santucci says that in the year 1572 it was at first of the 6th magnitude; that afterwards, at the end of May of the year 1573, it became twice as great as Venus; and that at the end, in the year 1574, it vanished again through its own faintness. This opinion is supported by proposition 132 of Book 4 of Witelo; and it is well known in optics that nearer things are seen as larger, while things that are moved further away are seen as smaller.

V. But this opinion, though at first sight it has an air of likelihood, seems to be opposed by many things. [Margin: Objections against this opinion.] First, the star of the year 1600 appeared of the same size from beginning to end, whereas the stars of the years 1572 and 1604 appeared greatest straightway from the beginning; nor was the star of the year 1604 diminished gradually down to an insensible quantity, if we are to believe the many trustworthy witnesses whom I reviewed in the preceding chapter and in chapters 2 and 14. So the increase in apparent size is rightly judged to have been invented by Gemma and by Santucci to establish this opinion. If you grant that the stars appeared greatest straightway from the beginning because of the motion of a very swift descent within a single night, but that they were slower in their ascent, you will have invented a motion in the heaven that is hardly probable. Next, as Hechius says on page 17, either that motion was rectilinear — and such motion

is not to be attributed to celestial bodies without necessity — or it was circular, and through it the New Star would have been seen to vary its distance from the same fixed stars notably; whereas we have said it is more probable that none of the three new stars we are dealing with here varied its distance from the same fixed stars.

But the chief objection is Tycho's argument in volume 1 of the *Progymnasmata*, pages 332, 532, 563 and 691. For since the New Star of the year 1572 appeared to him at the beginning as of 3 ½ minutes, and stood 14000 semidiameters of the Earth from the Earth, then, if it had to diminish by ascending until it became equal to the stars of the sixth magnitude, it must have been moved away from the Earth by at least 300000 semidiameters of the Earth — a distance which he himself considers false and absurd. [Margin: Too great a distance of the fixed stars, if the New Star escaped by ascent.] *Kepler*, however, in his book on the New Star in Serpentarius, chapter 21, asking whether it withdrew into the depth of the aether, digresses to a question not necessary there: whether the sphere of the fixed stars is infinite. For however great it is set, whether by the Copernicans or by the defenders of the opinion we are now discussing, it will still always be set as finite; or, being finite, it will suffice to save all the phenomena whatever. What Tycho said about 300,000 semidiameters of the Earth, however, needs some correction; nor is it impossible or absurd, except ad hominem, against those who do not admit a distance of any fixed stars greater than about 14,000 or 20,000 semidiameters of the Earth.

I said that it needs correction because, according to Tycho, the apparent diameter of the New Star was smaller than Venus and a little greater than the diameter of Jupiter; and this diameter, viewed through the telescope, is no greater than 1′ 9″, as we showed in Book 7, Section 6, chapter 9, and its semidiameter is 35″. A star of the sixth magnitude, moreover, has a diameter of 4″ 24‴; but let 4″ be taken now, and a semidiameter of 2″. Now if we use the Tychonic distance of 14,000 semidiameters of the Earth, and problem 1, set out in Book 7, Section 7, chapter 8, the true semidiameter of the New Star will come out as 2 ½ terrestrial semidiameters. With this, and with the apparent semidiameter of 2 seconds, by no. 4 of our plane right-angled triangles, or by Cavalieri's, a distance of 245,000 terrestrial semidiameters is found. The thickness of the heaven of the fixed stars would therefore have had to be at least 225,000 semidiameters of the Earth, for the New Star, equal to Jupiter at the concave surface of that heaven, to appear equal to the smallest stars of the sixth magnitude at its convex surface. But if we used our own distance of the fixed stars, set in Book 6, chapter 7, at a minimum of 100,000 semidiameters of the Earth, and the star is supposed to have appeared at first at least of the size of Sirius, the true semidiameter of the New Star would have been 17 terrestrial semidiameters; and for the star's diameter to appear as 4 seconds in its ascent, it would have had to be raised as far as 1,750,000 semidiameters of the Earth. This is indeed a finite distance, but it will seem probable to few, since the heaven of the fixed stars would be set thicker than the sphere of all the planets more

than 17 times over. There will be some, however, to whom, considering the multitude of the fixed stars, so great an extent of region will not seem unfitting for so great a population. Finally, with the distance of the New Star, when it appeared equal to Jupiter, set at 100,000 terrestrial semidiameters, its solidity would come out to the solidity of the Earth as 4913 to 1. Yet one ought not to give the heaven of the fixed stars so great a thickness for the sake of the single New Star of the year 1572, if its increase and decrease can be explained otherwise than by descent and ascent.

VI. The *fourth* opinion counts the New Stars among those created of old, or at the beginning of the world, and known long since, but as seeming new because of an optical enlargement produced by vapours. [Margin: 4. The opinion numbering the New Stars among the ancient ones.] So *Annibal Raymundus* [Annibale Raimondo], astrologer of Ve- rona, and formerly *Reisacher*, thought that the New Star of the year 1572 was the eleventh star of Cassiopeia, which shines in the middle of the Chair, and that in the year 1572 it appeared larger and more brilliant because of thick and dense vapours and exhalations interposed between it and the sight of the observers, in which its rays were refracted so as to enlarge its appearance. [Margin: Of Raymundus. Of Reisacher. Of Frangipanus.] *Cornelius Frangipanus*, for his part, says that it was the eleventh star of Cassiopeia, which moved away from the little star nearest to it and enlarged its light, so that it was seen as new partly through motion and partly through alteration of its light. But all the other astronomers affirm that the New Star was distinct from the eleventh of Cassiopeia, although Tycho admits that towards the end, when it appeared smaller and less brilliant, it appeared better distinguished from that star. Yet no probable reason can be given through natural causes why at that time, for a year and a half, so great an abundance and so dense a mass of exhalations should have been beneath the eleventh star of Cassiopeia alone, and should not have been dispersed or carried elsewhere; or why, if that star had a peculiar power of attracting exhalations, it did not attract them at other times, and why many other fixed stars do not have that power.

Moreover, Giovanni Battista Benedetti, in a letter to the Raymundus already mentioned, written in the year 1573 and found among his works on page 371, contends as follows. If that exhalation had been at the concave surface of the Moon, 33 terrestrial semidiameters from the Earth, and the New Star had been seen at so great a size over the whole terrestrial hemisphere through the force of refraction occurring in that exhalation, then the exhalation would have had to occupy as much space in breadth as the Earth's diameter occupies. Given this, it would follow that, for eyes placed anywhere within that hemisphere of the Earth (whose pole would lie beneath the New Star, as beneath the zenith), that exhalation would subtend 6° 58′ in the heaven, and so would likewise enlarge all the stars that are no further than 3° 29′ from Cassiopeia; and since it did not do so, the opinion of Raymundus is false. But if the exhalation is supposed to be only 10 terrestrial semidiameters distant, he shows that it would occupy 23° 4′, and many more degrees if it had been in the highest region of the air. Yet

Benedetti went wrong against geometry on some points, as *Chiaramonti* shows in Book 2 of *De stellis novis*, in chapter 7 of the appendix. [Margin: Errors in geometry of Giovanni Battista Benedetti, noted by Chiaramonti.] He adds that if the exhalation had stood 10 semidiameters of the Earth from the Earth, and had occupied as much space as the terrestrial chord of the arc between the most northerly observer, Tycho, and the most southerly, Muñoz, it would measure only 160 German miles, and would occupy no more than 16′ in the heaven. But it is not worth dwelling on these things.

VII. The *fifth* opinion was that of *Franciscus Vallesius*, *De sacra philosophia*, chapter 1. On the one hand he grants that the star lacked all parallax and was therefore in the firmament; on the other he denies that any star is created anew by God. He gives three reasons: first, because, as is said in Ecclesiasticus 18, *He who lives for ever created all things together*; second, because the heaven would have been imperfect had it lacked this star, against that saying of Genesis 2, *Thus the heavens and the earth were finished, and all their adornment, and GOD completed his work on day 4*; and finally, because this star disappeared, so that, if it had been created anew when it appeared, it would have been annihilated when it disappeared — whereas it is said in Ecclesiasticus 3, *I have learned that all the works of GOD endure for ever*. [Margin: 5. The opinion of Vallesius, numbering the New Stars among the ancient ones and attributing their appearance to denser parts of the heaven.] Accordingly Vallesius affirms that the New Star of the year 1572 (and he would have said the same of the other New Stars) was created together with the rest from the beginning, but did not appear until the year 1572, because denser parts of the heaven passed beneath it, by which its size was optically increased. But so slow a motion of some heaven or other is hardly probable. Next, if that density is inherent in that heaven, why did it not, before and after, enlarge other stars close in position to that New Star? Or how did that denser part of the heaven last so long beneath the New Star of Cygnus? Nor is it necessary that, if GOD created all things in the heaven (for beneath the heaven he creates rational souls daily) by creation taken in the stricter sense, that is, from no pre-existing subject, he can create nothing further anew in the broad sense, that is, from some matter — or even in the strict sense, but as a work belonging to his extraordinary Providence and to miracles. Nor did the adornment of the heavens, according to ordinary Providence and the end intended by GOD, require this star for its completion, just as the earth did not require new rivers or monsters. Finally, it would follow from Vallesius's teaching that not even the Star of the Magi could have been made anew and placed in the heaven (granted that it is in fact thought to have been in the air), and at last extinguished — which is not to be denied to the divine Omnipotence. But that particle *simul*, "together", in Ecclesiasticus 18 does not necessarily signify sameness of the moment at which whatever has been created was created; it can signify the sameness of a creation made in time by one and the same Creator. So, as the Lateran Council explains in the chapter *Firmiter*, GOD at once, from the beginning of time, made from nothing both

kinds of creature, the corporeal and the incorporeal, namely the angelic and the worldly; and he did not create one in time and the other from eternity, nor one himself immediately — the angelic, say — and the other through the mediation of angels.

VIII. The *sixth* opinion was that of *David Fabricius* and others, as reported in Kepler's book on the New Star in Serpentarius, chapter 20: that the New Stars, as to substance and body, were created in the heaven from the beginning, but lay hidden until it pleased GOD to illuminate them anew and through them to signify something to the world — in much the same way as the Moon lies hidden at the interlunium and afterwards is illuminated towards us by the Sun. For since they were among the fixed stars, it is consistent that they were as ancient as the fixed stars as regards their body. [Margin: 6. The opinion of Fabricius, counting the New Stars among the ancient ones and ascribing to them only a new light.] And Fabricius adds that the gap, or hollow, which Tycho (volume 1, page 795) says he saw in the place where the New Star of Cassiopeia had been, after it was extinguished, was nothing other than the body of the star, now deprived of light. But if the New Stars must have been coeval with the other fixed stars as to the substance of their body, because they were in the sphere of the fixed stars, they ought also to have shone together with them, to have been brilliant from the beginning, and not to have lacked the chief accidents of stars. Or if their illumination was deferred in order to signify something extraordinary, why could not their creation or generation also have been deferred, so that they should not be idle in the heaven for so long? Of that gap — of Tycho's mouth rather than of the heaven — we shall speak below.

IX. The *seventh* opinion was that of *Ioannes Heckius* of Deventer, physician and philosopher, in his disputation on the New Star of the year 1604, dedicated to Master Federico Cesi, Marquis of Monticelli. [Margin: 7. The opinion of Heckius, associating the New Stars with the ancient ones and attributing their new appearance to rarer parts of the heaven.] This doctor affirmed that above the firmament there is another heaven; that every heaven, by Aristotle's pronouncement, exists for the sake of a star, and therefore that heaven too exists for the sake of a star and has its own stars created from the beginning, which are in the tract beneath which the Milky Way lies — because all the New Stars, namely those of the years 1572, 1600 and 1604, were seen in the Milky Way; and that those stars of the highest heaven are nevertheless not seen except when the rarer parts of the Milky Way run beneath them, since the denser parts prevent their being seen. But if this doctor thought that the heaven above the firmament is the crystalline or the Empyrean, Aristotle is not to be understood as having spoken of it. Secondly, not all the New Stars were seen in the Milky Way, if what is related is true: of the New Star seen in the year 1596 by Fabricius at 25° 45′ of Aries, with south latitude 15° 54′, a place far from the Milky Way; of the New one seen in the year 1612 by Simon Marius [Simon Mayr] in the girdle of Andromeda; and of the one seen in the year 1602 by Kepler in Pisces, outside the Milky Way. [Margin: Not all the New Stars

in the Milky Way.] Besides this, a motion of the firmament, or eighth sphere, beneath the ninth is invented without necessity, by which the rarer and denser parts of the Milky Way are to run alternately beneath those hidden stars; for this motion would have to follow the course of the Milky Way, obliquely from north towards south. Lastly, even if such a motion were granted, either those stars which are called New would be too few, or the rarer parts of the Milky Way would be too few in proportion to the multitude of the dense ones.

X. The *eighth* opinion is that of *Ludovicus Columbius* [Lodovico delle Colombe], in his book on the New Star of the year 1604, who thinks that the New Stars are in the tenth heaven above the firmament, and are seen when the denser parts of the starless ninth heaven pass beneath them. [Margin: 8. The opinion of Columbius, attributing to density what the 7th attributes to rarity.] Against him what we said against Heckius holds good; and Alimbertus Maurus attacked him.

XI. The *ninth* opinion was that of *René*, or *Reynatus*, *Descartes*, in Part 3 of his *Principles of Philosophy*, from marginal number 111. [Margin: 9. The opinion of René, attributing the appearance of New Stars to intervening atoms.] Since he explains the various changes of nature partly through the annual motion of the Earth and partly through the motion of atoms and corpuscles brought about by various vortices, he thinks that at times certain corpuscles are interposed between the stars and our eyes, blocking their rays so that they cannot move the eyes; but that at other times those corpuscles are driven off by the force of the vortices and the obstacle is removed, and that in this way, for us, New

Stars appear, and afterwards vanish from sight. But besides much in his philosophy that is a novelty of little solidity, it does not seem probable that, in that continual fluctuation of the vortices by which the atoms are moved, new stars should appear so rarely from the atoms' running between, or that the New Star of the year 1600 should have been seen for almost 30 years always of the same size. Nor, finally, do the vicissitudes of that tumultuous motion seem to have any cause except chance.

XII. The *tenth* opinion, indicated rather than asserted by *Maurolico*, as reported in Clavius on the *Sphere*, page 194, was that the New Stars are comets, but made above the Moon, in the heaven, from an aggregation of splendour from the planets and the other stars. [Margin: 10. The opinion of Maurolico, imagining the New Stars from an aggregation of splendour.] But since he does not explain whether the matter or subject of the splendour is new or old, and for what reason either that matter is so rarely gathered together, or the splendour from the stars is aggregated in it; nor the manner of this aggregation — this opinion must be left among the imperfect conceptions of the imagination.

XIII. The *eleventh* opinion was that of those who said that both New Stars and celestial comets are generated anew in the heaven, either by GOD, or by some secondary cause, or by a concurrence of secondary causes that is rare indeed but nevertheless ordained by GOD — and that from celestial matter. [Margin: 11. The opinion admitting the generation of New Stars in the heaven.] This our

Clavius admits above all, on the *Sphere* of Sacrobosco, page 193, granted that he also admits that the star could have been procreated by GOD. I should like to set down here the words of this truly prudent man: [Margin: The twofold opinion of Clavius.] *Since this is so, I am persuaded that that star of the year 1572 either was procreated then by GOD, Best and Greatest, in the eighth heaven, to portend something great (of what kind is still unknown), or else that comets can certainly be generated in the heaven itself, as in the air, although this happens more rarely. This indeed not a few of the ancient philosophers openly acknowledge, and many of the more recent ones adduce several authorities and histories by which to persuade us that stars of this kind have quite often arisen in the heaven, at long intervals of time, some to signify one thing and some another. If this is true, let the Peripatetics see how they can defend Aristotle's opinion on the matter of the heaven. For it will perhaps have to be said that the heaven is not some fifth essence but a mutable body, although less corruptible than these lower bodies — which indeed Plato held before Aristotle, with many other philosophers, and which after CHRIST not a few have taught, not obscurely: among them St Ambrose, Basil, Gregory of Nyssa, and almost all the other lights of the Church.*

Joining Clavius is *Johannes Praetorius*, who held both the comet of the year 1577 and the New Star of the year 1572 to be among the celestial comets, generated in the heaven, as did *Hájek*, *Muñoz* and *Philipp Apian*, as reported in Tycho, volume 1, pages 511, 571 and 643; but Apian thinks that the star was illuminated by the Sun. [Margin: The opinion of Praetorius, Hájek, Apian, Argoli.] Again, the New Stars were placed among the comets generated in the heaven by *Argoli*, chapter 62 of the *Pandosion Sphaericum*; by *Guntherus*, *Mollerus*, *Butenerus* and *Krabbus*, as reported in Kepler, chapter 25; and by *Liceti*, Book 5 of *De novis astris*, chapter 41, and Book 2 *De caelo*, chapter 7 — so much so that he would have it that even Aristotle does not oppose New Stars made in the heaven, because of that quasi-axiom of the Philosopher, *The stars are made of the body in which they have their motion*; and chapter 8, where he says, *That the stars are spherical is consistent for one who generates them from such a body*. [Margin: Of Liceti.] But in truth Aristotle is speaking of the ancient, and indeed eternal, stars. *Froidmont* too, Book 3 of the *Meteorologica*, chapter 2, article 7, thinks that new stars are made from celestial exhalations of the planets, and perhaps of the fixed stars; and these exhalations, being above Saturn, are illuminated by the nearer fixed stars and not only by the planets. [Margin: Of Froidmont.] *Elias Camerarius* counts the New Star of the year 1572 among the celestial comets, but says that it vanished by ascent, so that he seems rather to belong to the 3rd opinion. [Margin: Of Camerarius.] *Guillaume Postel* thinks that the New Star of the year 1572 was generated in the heaven, and refers its efficient cause to the Great Conjunction of Saturn and Jupiter, because this star shone in the equinoctial colure, that is, at the end of Pisces and the beginning of Aries, where the transition is made from the watery triplicity to the fiery, and because it fell in the seventh period of the great conjunctions; on these conjunctions see what we said in Book 7, Section 5, chapters 9 and 10. [Margin:

Of Postel.] Finally *Kepler*, in his book on the New Star of the year 1604, chapter 22, having rejected the 3rd opinion because of the excessive distance which the ascent and descent of the New Stars would require, determined that the matter of the New Stars is celestial and can be generated not only in the Milky Way but in any part of the heaven. [Margin: Of Kepler.] And in chapter 23 he teaches at length that the matter of the heaven is alterable, and that Aristotle would not have dissented: for he set the heaven down as unalterable for this reason, that it was established that in so many ages nothing new had been seen in it; he would therefore have thought otherwise had he seen or heard of that prodigious darkness of the year 1547, by whose force, on the testimony of both Gemmas, the Sun appeared blood-red for three or four days to the Belgians, Britons, French and Germans, as Scaliger confirms in *De emendatione temporum*, Book 5, and before him Bünting in his *Chronicle*. [Margin: Arguments for mutability and alteration in the heaven [?].] This darkness was so great that some stars of the heaven appeared at midday; and like it was the darkness which historians relate was seen for almost the whole year of the murder of Gaius Julius Caesar, and which is sung by Virgil and Lucan. For since the Sun was seen like this at setting and at rising, and in regions so far apart, and yet that matter occupied no other part of the heaven than the part beneath the Sun, it had almost the same parallax as the Sun, and was in the heaven.

Kepler adds those heads of comets which he thinks were demonstrated by parallax to have been in the heaven; but for that, a great probability at least suffices. He could also have added the argument from the matter of the sunspots, but he did not yet know the use of the telescope when he was writing this. The rest of what this author said in chapter 24 and elsewhere — about vapours and exhalations breathed out from the planets and at last collected into one by that celestial faculty whose task is to form that excrementitious matter into celestial monsters, so that, once the matter is at last consumed, the heaven may be purged of its dregs and keep its transparency — I have already reported in Section 1, chapter 6, number 10, and chapter 13. Kepler goes on, and in chapter 25 teaches that the New Stars, which lacked hair, tail and beard, ought not to be called comets — granted that many have counted them among the celestial comets — but stars. For stars seem to be named from the verb [Greek: στιλβεῖν (stilbein), glossed in the text as *scintillare*, "to twinkle"], and the New Stars, especially those of the years 1572 and 1504, twinkled vehemently; moreover, they were not movable by a motion of their own, and flashed not with a pale light but with a lively one; and to invent a tail for them, but one not seen because of their distance, is to rely not on the senses but on uncertain reason or imagination. [Margin: Whether New Stars can be called comets.] With this premised, Kepler inquires in chapters 26 and 27 whether the New Star of Serpentarius coincided by chance with the great conjunction, and how it can be called the star's efficient cause. He assumes, moreover, that the conjunction of Saturn and Jupiter took place in the same year; but we shall treat this question in the following chapter. I note only, with Giovanni Camillo Glorioso, that if

the New Stars were made from exhalations and vapours of the planets or of the fixed stars, kindled or illuminated, it would seem consistent that they should be carried this way and that with a wandering motion; and therefore, since they lacked a motion of their own, this motion of generation does not seem very probable. [Margin: Objection against [?] the generation of New Stars from exhalations of the heaven [?].]

XIV. The *twelfth* opinion was that of *Tycho*, volume 1 of the *Progymnasmata*, from page 794; and with him agree *Baranzano* in the *Uranoscopia* and *Giovanni Camillo Glorioso*, Book 5 of *De Cometis*, last chapter, page 281. It holds that the New Stars are made anew from the same celestial matter from which the fixed stars were once made, by condensation of its parts, especially from the Milky Way, where the matter is more nearly disposed to these novelties; and that they shine partly from their own transparency, having acquired intensity from that compaction, and partly from the Sun and the other nearer stars. [Margin: 12. The opinion [?] of Tycho and of Glorioso, resorting to condensation [?].] But because they do not have as great a perfection, nor as solid a cohesion, as the other fixed stars had, their structure was gradually dissolved and their light vanished. Tycho adds, on page 795, that on the border of the Milky Way, where the New Star of the year 1572 had shone, he noticed after its extinction, on winter nights, a certain gap and hollow about the size of a half-full Moon, as if that portion of matter, gathered into the body of the new star, had afterwards burned up, or, being dispersed, had left the trace of that gap. But this will rather have been an imagination or a deception of sight, which takes for cavities places surrounded by splendour but dark in themselves. Although this opinion agrees with the immobility of the New Stars, it does not give a probable reason why, in so vast an extent of the Milky Way, so nearly disposed to forming new stars, New Stars are nevertheless made in the heaven so rarely. And if Tycho has recourse to GOD as a cause operating outside the order of nature, it is just as easy for God to form these splendid portents by the creation of a whole star, or by the generation of a new substantial form with its accidents, as by condensation. Tycho, however, did not yet know that other New Stars would appear outside the Milky Way; and so he settled on the Milky Way, as on suitable matter, from which New Stars could be assembled.

XV. The *thirteenth* opinion — one I have so far found in no one, but have devised for myself as not altogether improbable nor unworthy of being reported, though I would not wish it to be taken as fully asserted — is this. The New Stars were created by God in the Firmament from the very foundation of the world, but among them were some not luminous on every side; in this they were like the planets, which shine from the Sun only on the side the Sun faces — granted that the stars we call New had a light of their own, in themselves and not from the Sun. So they had one half of the globe luminous and one half dark. When the time came at which God wills to raise and rouse the eyes of mortals to the heaven by these extraordinary signs, either some Intelligence, or a faculty implanted in the star, or God himself turns round with a sudden rotation the

part of the globe that had previously shone upward towards the Empyrean, so that it shines for the eyes of mortals for as long as he wills. Afterwards, either by a similar turning of the globe it suddenly withdraws all its light from men's eyes, or it steals that light away gradually, as happens in the waning Moon, until it seems to be entirely extinguished. [Margin: [?]. Opinion [?] … of the globe … splen[?] … New … stars … [?]ribing.] The vehement scintillation seen in some of them can be attributed not, indeed, to a complete rotation of these stars, but to a certain oscillation or vibration of the globe about its own centre; and if any appeared more splendid than other fixed stars, this can be put down to light doubled, or concentrated into half of the globe, which would otherwise have been dispersed over the whole globe. The remaining fixed stars, I judge it more probable, shine on every side, so that they may shine also for the eyes of the blessed, and *shine with gladness for Christ, who made them*, together with the Father of lights — for so may I borrow the words of the prophet *Baruch*, chapter 3, and turn to Christ God and his saints what Baruch referred to God not yet clothed in the eyes of flesh he was to assume. This opinion becomes highly probable to me — not because it is mine, but because it introduces the least possible change in the heaven, which I think is what should be done so long as no necessity constrains us to anything else. For here there is need of neither creation, nor generation, nor alteration, nor of a motion of the whole machine of any heaven, or of the star itself up or down, but only of the simplest turning of the star alone about its own centre. To make these stars coalesce out of many tiny stars, or to say that they are parts of the Empyrean which God willed at some time to display to mortals through openings in the lower heaven, as a sample of that splendid region, does not much commend itself to me, since the New Star of Cygnus was of the 3rd rank and not suited to providing that sample; [Margin: [?] other [?] in [?] [?].] and that assemblage of little stars or corpuscles is too laborious, nor does it yet receive the testimony of the telescope, as it does in certain comets.

XVI. The *fourteenth* opinion has recourse to God himself, who produced the New Stars outside the order of nature, either creating them from nothing or making them from whatever matter he pleased; it does not express the manner of this operation, as being hidden from us and uncertain. [Margin: 1[?]. Opinion [?] … [?]tion … God … [?].] The chief authors of this opinion were *Clavius, the Coimbra commentators, the Landgrave of Hesse, Mästlin, Bartholomäus Reisacher, Schuler, Reinhold, Rosa*, whose words and passages we shall adduce shortly, in the following chapter, number 5, where the efficient cause will be discussed. Rosa adds, moreover, from the Talmudists, that portents of this kind have regularly appeared by divine agency every two thousand years: one New Star appeared at the time of the Flood, another before the coming of Christ, and the last in the year 1572. But the history of so many other new stars, related in chapter 1, does not agree with these Talmudic fictions. Finally, when *Ioannes Heckius*, in his disputation on the New Star of the year 1604, page 15, had said:

The fourth view is that of those who say that these stars were created by God by a miracle,

he immediately added:

Of this opinion is the greatest part of the philosophers and mathematicians.

Why not of the theologians too?

CAPVT XVIII.

Chapter XVIII.

On the Efficient and Final Cause of the New Stars.

I. The opinions on the efficient cause of the New Stars, and the causes themselves, are reduced to three heads: namely, to the wandering or the fixed stars; or to a particular power and faculty in the heaven or below the heaven, whose proper function is to produce comets and New Stars; or to God, who produces these portents of the heaven either by himself or through the Intelligences. But among the opinions that have recourse to the ancient stars, as the agents by which the New ones are made or illuminated, none is more celebrated than the one that ascribes this to the greatest or great conjunctions of two or three planets; and so we shall begin from it.

II. The *first* opinion, then, is that of the astrologers who, following the tenets of the Arabs, attribute the New Stars to the Greatest or Great Conjunctions of Saturn and Jupiter, or of Saturn and Mars, or of Jupiter and Mars. [Margin: 1. The opinion of the Great Conjunctions.] By what conditions the Greatest and Great conjunctions are distinguished from each other, and how long their period and apocatastasis [apocataſtaſis] are, we have set out fully in Book 7, Section 5, chapters 9 and 10, and to that passage we refer the reader. Of this opinion was *Guillaume Postel* the Frenchman, who also noted that the Star of the year 1572 fell in the seventh period of the Greatest conjunctions, whose trigon makes its passage from the watery to the fiery signs, and that it lay on the border of Pisces and Aries. Likewise *Mollerus and Krabbus*, as Kepler reports in his book on the New Star of the year 1604, chapter 26: having predicted that a comet would arise in the month of October of the year 1604, they contended with all their might that the New Star of that year was generated by the Greatest Conjunction. For in the year 1603 the Great Conjunction of Saturn and Jupiter in 8° of Sagittarius fell, from Kepler's observations, on December 17, a little after noon — granted that in his Ephemerides Lvovický gave it for noon of December 29, Magini from the Prutenic Tables for the 24th, and Tycho's calculation, from his own papers, for the 19th. And in the year 1604, on September 26, the conjunction of Saturn and Mars took place after 8^h, in 10° of Sagittarius; and on October 9, at 1^h before noon, there was the conjunction of Jupiter and Mars in 19° 14′ of Sagittarius, which completed the Great Conjunction. So *Kepler* has it, from observations, in his book on the New Star of Serpentarius, chapter 11. Therefore, since it was near the beginning of Sagittarius, and seven periods of these conjunctions have been completed at the beginning of Sagittarius,

assigning about 800 years to each, the rising of this star is rightly said to have fallen in the seventh period of the Great Conjunctions held in the fiery signs. And what was singular to this star is the very place in the heaven in which the superior planets were conjoined; for the New Star was in Sagittarius 8°, which seemed truly marvellous and ominous.

III. But see how many things stand against the opinion of the Arabs! [Margin: 1. Objection against the force of the Great Conjunction.] First: how many Great or Greatest conjunctions have gone before without New Stars? Go over their periods, and then the events, which we treated in Book 7, Section 5, chapters 9 and 10: you will see a single example of a Greatest conjunction, in Sagittarius in the year 1604; and at the beginning of Aries, not indeed in the year 1572 but in the year 1583 — a succession of the conjunction 10 years after the rising of the New Star, which shows that the star was independent of it. As for what Kepler devises about the star of the Magi, it will be refuted below, in chapter 20. Nor is the outcome of a single star or comet of the year 1604, answering to the astrologers' prediction, enough to establish a sure law; for *Ioannes Vueidnerus*, a physician, replied in those learned verses which *Kepler* reports in chapter 27:

But if some idle astrologaster should contend, with mouth wide open, that the conjoined stars of the two planets, Jupiter and Mars, begot a beardless comet, and that it was foretold by him, we shall set against him a hundred meetings of the wandering stars that begot no comet, and that he spoke true by chance, having told a thousand lies.

Besides this, the Arabs bid us, so that a comet or a new star about to arise can be predicted from the Great Conjunctions, to consider the degree of the zodiac in which the conjunction takes place, and the exact day. [Margin: The vanity of astrology.] But meanwhile the astronomical tables have not yet received so final a polish that we can be certain of the day of the greatest conjunctions of Saturn and Jupiter, because of the slowness of the motion of both; and in the Great Conjunction of the year 1603 the difference among the authors of the tables was 13 days. Moreover, when one observes without a telescope, the disc of each planet looks larger, and for this reason, combined with the slowness of their motions, they seem to stay in conjunction for one whole day. Further, if the New Stars come into being in the Firmament, the aspect we are speaking of is not such absolutely, nor with respect to the fixed stars, but only relatively to us, for whom the circle of the zodiac is divided into the various aspects. For with respect to some fixed stars Saturn and Jupiter are perpetually in conjunction, and wherever they are, a straight line drawn through them falls on some point of the Firmament; so New Stars would have to come into being perpetually. Lastly, both the huge distance and the bulk of the New Stars make this opinion improbable. For if they are placed in the Firmament and yet appear no smaller than Jupiter, they are in reality much larger than Jupiter; how then can Jupiter and Saturn generate a star of such bulk, much larger than either of them? Or if they can, why so far away rather than near? For this reason, then, *Kepler*, in chapter 27, denies that the New Stars are of

themselves the offspring of conjunctions of the planets; although he argues learnedly against the Epicureans, who ascribe such effects to fortuitous chance, and teaches that the New Star of the year 1604 did not fall by chance into the conjunction and gathering of the three superior planets, and that it is not safe, with the Epicureans or the atheists, to belittle divine portents and drive all fear of the Deity out of human minds.

IV. The *second* opinion is that of those who attribute the making of the New Stars to some more secret Nature, or to a faculty residing in the heavens. [Margin: 2. The opinion of a hidden Nature and Faculty.] But this opinion scarcely explains the manner. Natural philosophers have been accustomed to regard as natural works the things that happen always or for the most part, and are compelled to ascribe the rest either to Chance or to Fortune or — if they wish to speak soberly — to God working beyond nature. And not even Kepler himself, who in chapter 24 had hinted at a certain faculty of a quasi-vegetative soul of the heavens, which preserves their transparency for the heavens and gathers the vapours and soots of the planets so that, kindled and consumed, they leave the heaven purged, afterwards rested in it, in chapter 27; rather, he referred the work of any more secret nature to God. Since, I say, these things are so, I do not care to wander any longer through uncertainties, but to pass to the third kind of cause and the third class of opinions.

V. The *third* opinion, then, is that of those who attribute the novelty of the stars — whether as to substance, or as to the accidents of illumination or of motion by virtue of which the New ones appeared — to God himself, working as above or beyond nature, either by himself alone or through the ministry of the Intelligences. [Margin: 3. The opinion that takes refuge in God.] So *Clavius*, in the *Sphere*, page 191, on the star of the year 1572, put this one first of two opinions, in these words: [Margin: Of Clavius.]

Since these things are so, I am persuaded that that star was either then created by God, Best and Greatest, in the eighth heaven, to portend something great, of what kind is still unknown.

So the *Landgrave of Hesse*, in Tycho, volume 1, page 600, and *Hájek* in chapter 4 of his *Dialexis*, and *Wolfgang Schuler*, in Tycho, volume 1, page 635, said that the same star of the year 1572 was *placed in the aether by God outside the order of nature; for he is not bound to secondary causes*, so as to be unable at times to work something beyond what they require. [Margin: Of the Landgrave. Of Hájek. Of Schuler.] So *Bartholomäus Reisacher*, in a writing of his, ascribed that same star to *the hidden counsel of God, or to an Intelligence governing the celestial spheres*. [Margin: Reisacher.] So *Mästlin*, in a short writing on the Star of the same year, determined that *its cause was hyperphysical, and that it was created by God in these last times miraculously, and beyond human comprehension*. [Margin: Mästlin.] So, in Tycho, volume 1, page 700, *Erasmus Reinhold the Younger* likewise affirms that the Star of the year 1572 was *a new work of God beyond the order of Nature, and not to be ascribed to astrological rules*. [Margin: Reinhold.] So too, concerning the New Star of the year 1604 and all the New ones, the

greatest part of the philosophers and mathematicians — as *Ioannes Heckius* attests on page 15 — hold that they were *created by God by a miracle*. So likewise *Tycho*, volume 1, page 799, acknowledges no other cause of the New Star *beyond the first and universal cause of causes*; [Margin: Most [?]. Tycho.] and *Kepler*, in his book on the New Star of Serpentarius, chapter [?] 27, after searching out its cause long and hard with marvellous anxiety, could at last rest neither in the Great Conjunction of the planets, nor in chance, nor in Nature alone; and so he concluded in these words: [Margin: Kepler.]

Since an apparent conjunction of the planets is at hand, which offers itself as the cause, this other thing must therefore be said, which I pronounce most securely and with full confidence: that this new celestial prodigy was associated by Almighty God himself with the three planets Saturn, Jupiter and Mars, then in conjunction, by a definite counsel directed to the salvation of men. To mark, with this as it were monument, the place and time of the Great Conjunction of the three superior planets, for a perpetual memory of the event, and to admonish the human race concerning the greatest matters, he needed no care and no labour to create such a thing — whether he used Nature as his minister, or put forth this as it were a ray of his extraordinary Omnipotence.

Finally, the *Coimbra commentators* taught this very thing, Book 1 *De Caelo*, chapter 3, question 1, article 4. [Margin: The Coimbra commentators.] We have seen, moreover, many others having recourse to God as the efficient cause of comets, as is clear from Section 1 of this book, chapter 6, number 12; they would doubtless have done the same for the New Stars, whose duration, form and place in the heaven, more probably asserted, make such prodigies more wonderful. Nor is this to summon, as they say, a god from the machine [Greek: θεὸν ἔκ μηχανῆς (theon ek mēchanēs, "a god from the machine")], as though from inexperience in untying the knot. For the cause of these effects, which transcend the order of Nature by such novelty, is not to be invented from one's own wit, nor searched out in the bowels of Nature; rather we must look up to God, who is above Nature, and who perhaps reserved certain works to this end: that in the order of Nature as well as of Grace we should be compelled to acknowledge, revere and adore the supreme Author of both.

VI. Hardly, then, could the efficient cause of the New Stars be inquired into without the final cause also being indicated. [Margin: The final cause of the New Stars.] And many authors indeed thought that they were created, or generated, or shown to mortals in order to signify to them something great, which was secret at that time but was to be made manifest afterwards. Others, driven by an itch for astrology and by a fever — not to say a frenzy — for predicting new things, filled the ears of idle men with a great many pamphlets published for the common people, with various rumours, but with empty sound; that lightness of leaves, however, should have been left as a plaything to the winds. For whatever changes in human affairs occurred around the times of the New Stars were not so great that either they deserved to be foretold by God through such unwonted tongues or characters from the heaven, or that the records of history have not handed down greater ones — which were

nevertheless preceded by no portents of comets or new stars. Much less did the catastrophe of all things take place which some had feared, or hoped for, from them. If, however, there is anyone who has the leisure and the liking to squander time reading through the prognostications of those who soothsay about these prodigies, he has, first of all, what *Tycho*, at the end of volume 1 of the *Progymnasmata*, from page 800, on the significations of the New Star of the year 1572, and what *Kepler*, from chapter 28 to 30, on those of the star of the year 1604, attempted to propose with conjectures gathered from every side, and to bring into suspicion: whether the Indians were to be converted universally to the Catholic Faith; whether the sect of Mahomet was to perish; whether some Monarchy was to arise that would rule over all the rest; whether a huge and universal change of religions was to come; whether, finally, the three new stars within a few years were the heralds of the second coming of Christ, and that last Fiery Trigon shone in advance of the ecpyrosis and the final conflagration of the world — just as, as Tycho and Kepler point out, the former on folio 802, the latter on 209, the first Fiery Trigon was distinguished by the creation of the world, and the fifth by the Nativity of Christ. However, when Kepler had shaken out all the pockets of divination, he seems to me to have said nothing more prudent than when, on page 208, he said of the end of the world: [Margin: Kepler's view.]

And so they cannot fit this Star in any particular way to the coming of Christ, and from it count the times and fix the limits — a knowledge God has reserved to himself. Meanwhile they certainly do not sin if, admonished by this Star, they renew a Christian life, and so prepare themselves, as men about to receive Christ the Lord at any moment. So far Kepler, who was certainly more sober and cautious than Tycho in defining the significations, and the times, of the events signified by the Star of the year 1572.

VII. For Tycho, volume 1, page 802, first set down these words: [Margin: Tycho's conjecture on the signification of the star of the year 1572.] *It is fitting that, just as that moving star of Hipparchus preceded the decline of the Monarchy of the Greeks and the growth of the Roman Empire, until almost the whole world was subjected to this one City, so now too some special and very great innovation in political administrations is pressing upon the following centuries. For just as this star displayed a most rare miracle, and stood forth from the heaven as it were unexpectedly, beyond the expectation of all men, so too it is likely that it will have most rare, huge and unforeseen effects; and what these will be in particular is, I judge, not sufficiently seen through by any mortal.* Shortly after this he ventured to carry these words over also to *a notable alteration of the religions, from those things which come from the stars and display a certain Jovial splendour and pomp*. Setting out to investigate the time of this change by the rules of astrological Directions and Progressions, he noted that the New Star of the year 1572 was the forerunner of the Greatest Conjunction of Saturn and Jupiter, which fell at the end of April of the year of Christ 1583; this conjunction put an end to the watery Trigon and began the seventh period of the fiery Triplicity. Since, then, it took place in 21° of Pisces,

he says that if a direction is made by right ascensions from that place to the place of the New Star, it will reach the point of the equator which the New Star marked after nine years, to be counted from the Greatest Conjunction, that is, in the year 1592; and that then the beginnings and seeds of those changes would be sown. But by setting up the direction to the place of the zodiac marked by the New Star, which was ♉ 7°, from the place of the Greatest Conjunction, which was ♓ 21°, he says that it will come about 48 years from the first shining of the Star, that is, about the year 1632; and that then the vigour and effect of this fiery Trigon would come out into the light. [Margin: 7. Period of the fiery Triplicity.] On these premises he lists the changes made at the restitutions of the fiery Trigon since the foundation of the world: the first in Enoch; the second in Noah and the Flood; the third in Moses and the liberation of the Israelite people from Egyptian servitude; the fourth in the Kings of Israel; the fifth in Christ and the summit of the Roman Monarchy; the sixth in Charlemagne and the translation of the Empire to the Germans. The seventh, therefore, indicates a kind of sabbath rest, and a change to a peaceful and most happy state before the end of the world comes, since those restitutions of the fiery Trigon that were completed in odd number — namely the third, in Moses, and the fifth, in Christ — were also the happiest. Having explained these things at greater length, Tycho, as if seized by enthusiasm, bursts out on page 807 in these words:

I augur, therefore, from this Star and its kinship with the new Trigon, that quite another overturning of worldly things is at hand, as regards the administration of Religion as much as of commonwealths.

We have come to the top; the highest things will suffer ruin. God, who rules in the heavens, and will rule all things on earth, etc.

Since, moreover, the New Star was in the zenith of Muscovy at the moment at which the new moon nearest to the rising of the new star took place — namely on November 5, at $7^{h}\ 31^{m}\ 40^{s}$ after noon at Uraniborg — he therefore devises, though by way of conjecture, that the first occasions of disturbances and changes would arise from Muscovy; and that Gog — of whom Ezekiel 38 and 39, Isaiah chapters 17 and 56, and Micah chapter 5 speak — and Magog, of whom Revelation 20 speaks, are, according to the interpretation of some, the Muscovite, because in Holy Scripture Gog is said to be the future prince of Mosoch, that is, of the Muscovites. These conjectures of his, however, Tycho calls general, and such as they are, on page 811, where he also strives to drag in to them the prophecy of the Tiburtine Sibyl found in the year 1520 among the Swiss, in the bowels of Mount Taurus laid bare by the rushing force of waters and snows, which Cornelius Gemma reports in his book *De divinis Naturae Characterismis*. [Margin: The forged oracle of the Tiburtine Sibyl.] It was in Latin, but in the old Oscan dialect, and was either written long ago or ingeniously forged by someone more recent, and carved in ancient characters on stone. But it does nothing for what Tycho wants, since in that oracle — a forged one, I think — the star is said to rise *over the Ubeni towards the Great*

House of the North; for Muscovy is no more designated there than any other kingdom of the North. Again, because a comet shone in the heaven about the fourth year after the disappearance of the star, of the year 1573 — that is, in the year 1577 — Tycho thinks that these verses of the Babylonian Sibyl refer to that star: [Margin: The Babylonian Sibyl's verses.]

Then shall a huge sign be given from on high; for a most brilliant star shall shine out, like the bright Crown, gleaming in the shining heaven beneath the setting Sun; the star, truly called a comet, shall shine out..... But from the fourth year after the huge Star has shone, from heaven a Star shall come which, hurling flame, shall flash across the great sea and the deep Ocean: .... Again God, the dweller in the great heaven, shall preserve the remnants of men everywhere, wholly. Then peace and the highest wisdom of the truth shall flourish, and the Earth shall bear more abundant fruitful crops, no longer divided, nor to be in servitude hereafter.

VIII. There were, however, those who said outright that the new star of the year 1572 was the herald of the second coming of Christ, such as Theodorus Beza [Théodore de Bèze] and the Landgrave of Hesse, whose words we shall report on another occasion below, chapter 20, number 18; for Beza thinks it the very same as the star of the Magi, and the Landgrave very like it. But *Tycho*, page 328, says that among the signs that are to precede the end of the world Christ does not number the risings of new stars, but rather the destruction of the ancient stars, and the fall and darkening of the Luminaries.

CAPVT XIX.

Chapter XIX.

On the Admirable Star which foreshowed to the three holy Magi the birth and cradle of Christ the Lord. What the astronomers, and what the holy Fathers and Doctors of the Church, have thought of it.

I. The Sun does not so lead the other planets, long since vanquished by the majesty of its splendour, perpetually round in triumph, as that admirable star surpasses all the New Stars. Made most illustrious long before by the oracles of the prophets, it became itself an oracle of the divine vicissitudes and the most sacred miracle of the celestial lights; with the same most eloquent tongue of its ray it commanded, by the authority of an almost divine brilliance, that the time and place of the Saviour — not about to be born, but born — be sought out; and to those who sought them it showed them most obligingly. What, then, the astrologers and what the astronomers have pronounced about it, sanely or insanely, I judge it my part to examine in this place, and to undertake to weigh their pronouncements against the canons of the holy Fathers and theologians, as against the weight and teaching of the Sanctuary. What was discussed most learnedly and eruditely about this star seemed sufficient: by *St Thomas* [Thomas Aquinas], part 3, question 36, article 7; *Abulensis* [Alfonso Tostado] on chapter 2 of Matthew, from question 11 to 16; *Thomas Beauxamis* in his Commentaries on the Gospels, from page 97; *Jansenius* on the Gospels, from page 67; *Salmeron*

[Alfonso Salmerón], volume 2 of his Commentaries on the Gospel history, tractates 38 and 39; *Io. Maldonatus* [Juan Maldonado] on chapter 2 of Matthew; *Suarez* [Francisco Suárez] on the third part, disputation 14, sections 5 and 6; *Sebastianus Barradius* [Sebastião Barradas], volume 1 on the Gospels, Book 9, chapter 9; *Cornelius a Lapide* on chapter 2 of Matthew; *Vincentius Regius* in his elucidations of the Gospels, Book 1, chapter 10; *Corderius* [Balthasar Cordier] in the *Catena* on the Gospels, from page 49; *Antonio de Escobar* on the Gospels, Book 6, section 3; *Salianus* [Jacques Salian], volume 6 of the *Annals*, page 787; *Tirinus*, volume 3 on Holy Scripture, page 5 — besides the holy Fathers and others, in homilies or sermons on the most sacred day of the Epiphany. And yet, although these seemed sufficient, I wish to set out their view together with the opinion of the astronomers.

[Margin: Matter and substance of the Star.] II. That the star which appeared to the Magi, then, was one of the ancient fixed stars, or one of the seven planets, which descen- ded to earth, was the view of *St Gregory of Nyssa* in his homily on the incarnation of Christ, and of certain unnamed writers cited by *Abulensis* on chapter 2 of Matthew, question 11, and by *Salmeron*, tractate 39. *St Augustine*, too, said in his third sermon on the Epiphany: *While God hangs at the breast and endures the poor wrappings of swaddling clothes, a new star suddenly shone out from heaven*; and in the same place he calls it *the tongue of the heavens*. But the air is not seldom called by the name of heaven.

The common view of the Fathers and the Doctors whom I named above, however, is that it was a New star, altogether different from the ancient stars of the heaven. For it would have portended nothing new to the Magi had it kept the course, place and figure of the ancient stars; but the very opposite happened. It was not carried round by the motion of the primum mobile, as the fixed stars are, nor was it borne eastward by a motion of its own; instead it moved from the East towards the West, bending somewhat to the South towards Bethlehem. Nor did it shine only by night: it shone by day as well, since it is more probable that the Magi made their journey by day rather than by night, or at least no less by day than by night. Nor did it move with a circular and continuous motion, but rather with a rectilinear and interrupted one, since it halted when the Magi rested and went on when they travelled. Nor did it last long: once it had shone motionless for some hours above the cave or hut of the newborn Child JESUS, its office discharged, it vanished — although it had also hidden itself earlier, when the Magi entered Jerusalem. [Margin: Place of the star.] Lastly, it was neither in the heaven nor in the highest part of the air; otherwise it would not have marked out exactly the house where the Child was — as *Tycho* rightly says, volume 1, page 564, and before him *Nicephorus*, *History* Book 1, chapter 13 — but the whole province of Palestine. For suppose it had stood at a height of 50 or 60 Italian miles, the height the older writers on optics assign to the highest region of the air: it could have been seen from a distance of 700 or 800 miles. If instead we set it at a height of 25 miles, it would have been seen from

a distance of 520 miles, as is plain from what was said in Book 2, chapter 10. So it was far lower.

None of the things we have listed so far belongs to the ancient stars. The Fathers therefore deny that it was one of the stars formed by GOD in the Heaven long ago, and above all *St Augustine*, Book 2 *Against Faustus*, chapter 5, who says: [Margin: The view of St Augustine.] *It was not one of those stars which from the beginning of creation keep the order of their courses under the Creator's law; but at the new childbearing of the Virgin a new star appeared.* And *St John Chrysostom*, in homily 6 on Matthew, pursues at length almost all the arguments we have indicated, beginning with these words: [Margin: The view of St Chrysostom.] *That this star was not one of the many — indeed, as I judge, not a star at all, but some invisible power shaped into the appearance of a star — is shown first of all by its very course.* He also thinks it almost touched the head of the newborn Child, when he says: *How, then, could a star point out so small a place, namely that of a hut and a manger, unless it had left its lofty place, come down to lower regions, and stood almost over the very head of the Child?*

The novelty of this star, and its difference from the other stars, was asserted as well by *St Basil* in his homily on the human generation of Christ; *St Ambrose*, Book 2 on Luke; *Origen*, Book 1 *Against Celsus*; *St Damascene* [John of Damascus], Book 2 *On the Faith*, chapter 7; *Saints Fulgentius* and *Leo*, Pope, in the sermon on the Epiphany; *St Thomas*, part 3, question 36, article 7; and before all of them *St Ignatius* in epistle 14, to the Ephesians; and finally *Nicephorus Callistus* [Nikephoros Kallistos Xanthopoulos], *Ecclesiastical History* Book 1, chapter 13. And although *St Augustine*, Book 2 *Against Faustus*, chapter 5, and sermon 3 on the Epiphany, held entirely the same view, *Maldonatus* and *Suarez* (part 3, disputation 14, section 5) nevertheless observe with him that the arguments we have touched on so far are not altogether conclusive, but only very probable. For the Maker of the stars could have called one of the ancient stars and commanded it to come down into Mesopotamia, Chaldea or Arabia, to suspend its ordinary course for a while, and to offer the Magi guidance by a new motion. Baruch, chapter 3, describes this power in these words: *And the stars gave light in their watches, and rejoiced; they were called, and they said, Here we are; and they shone with gladness for him who made them.* Yet the gentleness of divine Providence persuades us to think that he rather made a new star in the air, and out of the air, and heaped it with unaccustomed splendours, than that by a greater miracle he called an ancient star down from the heaven, filling its place in the heaven in the meantime and afterwards leading it back up again; for greater miracles are not to be asserted unless they are proved. I said "out of the air": for that it was made of celestial matter is denied both by St Thomas and Abulensis and by those who call it a comet, in keeping with the ancient opinion about the seat of comets.

[Margin: Was the star of the Magi a comet?] III. Whether it should be numbered among the comets, however, can be doubted because of these words of Origen, Book 1 *Against Celsus*: *We judge it to have been a new star, like none*

of those known ones that are either in the Firmament or in the lower orbs, but of the kind that comets are seen to be. Relying on this, our *Adam Tannerus* [Adam Tanner], question 7 *On the Heavens*, confirms from this star that some comets are sublunary; and *Beza*, in Tycho, volume 1, page 327, calls it a comet. But Origen said shrewdly that it was of the genus of comets, or like a comet — hinting, that is, at a remote genus, and at a likeness only in matter and place, since it was formed out of the air and in the air. To it there was probably added, besides, an appendage of a tail, or of a ray stretched out towards the hut at Bethlehem, as it is shown in many of the Church's pictures. In many other respects, however, it differed from the comets.

For most comets move with the motion of the primum mobile, or one or two of them, out of the history we gave in chapter 3 of the first section, have been found motionless; but this star moved, and with no other motion than from Mesopotamia, or Chaldea, or Arabia into Judea — not setting and rising again and completing a circle round the earth. Nor did it move by a natural motion, as they do, but by the will of a mover who carried it down or drove it on at his own nod, and halted it when the Magi halted. Moreover, the motion of comets is either circular or, according to Kepler, rectilinear indeed, but along a trajectory by which they are let down and afterwards withdraw upward again; whereas the rectilinear motion of this Star was transverse, and nearly parallel to the plane of the horizon, as *Salmeron*, tractate 39, teaches together with *Abulensis*, question 11 on Matthew 2.

Further, comets are visible only by night, and the mere light of twilight extinguishes them; but the star of the Magi, shining by day, was not overwhelmed by the light of the Sun — rather, it overcame it, as will be said shortly. Comets dwell either in the highest part of the air, or in the region of fire, or even in the heaven, as is plain from what was said in section 1, chapters 6 and 23; but the star of the Magi stood a few ells or cubits from the little house where the Child JESUS lay hidden. Comets, if they have a tail or a beard, cast it away from the Sun into the opposite quarter; but the ray of this star, which served as its tail, was turned towards its own Sun, JESUS. Comets do not always appear of equal size: mostly they are larger at the beginning or a little after it, and then, as their matter fails, they shrink and at last vanish. This Star, by contrast, was either of the same apparent size from beginning to end, as Abulensis holds, so as not to give the Magi an ambiguous sign by its inequality; or rather, when it was above the House of the Child Saviour, it bore witness to its joy at its task by a sudden increase of form and splendour and by a flashing of scintillating lights, and then, once they had entered the cave, it vanished all at once. Salmeron adds, with Abulensis, that comets hardly or never appear at the births of kings or princes, but are rather signs of their fall and destruction; yet it is established from our history of comets, given earlier in the first section, chapter 3, that comets shone out before the birth of Alexander the Great, of Mithridates, and of some other princes. St Thomas, however (part 3, question 36, article 7, reply to the third objection), notes that a cometary signification was not wholly absent: *Because*

the heavenly kingdom of Christ shall break in pieces and consume all the Kingdoms of the earth, and it shall stand for ever, as is said in Daniel 2.

A better argument, then, is taken from the natural origin and signification of comets, since the star of the Magi, on the contrary, was produced by a supernatural action and appointed for a supernatural end and signification, as we shall say shortly. Rightly, therefore, *St Thomas*, part 3, question 36, article 7; *Cottunius*, lecture 33; *Maiolus*, colloquy 1, page 15; the *Coimbra commentators*, tractate 3 on the *Meteorologica*, chapter 7; *Abulensis* on Matthew chapter 2, question 11; *Nicephorus*, Book 1, chapter 13; *Salmeron*, volume 2, tractate 39; and *Tycho*, volume 1, page 324, deny that it was a comet — although *Maldonatus*, on Matthew chapter 2, concludes thus: *I would call it either a comet or an angel*; and *Tannerus* thought it a comet.

IV. The truer and more common view, therefore, is that this Star was neither one of the ancient Stars in the heaven, fixed or wandering, nor properly a comet, nor a New Star produced by natural generation; but a New Star formed by divine power out of the air or meteorological matter, in a way ex- ceeding the order of Nature, and by a miracle — yet in such a way that it was a supernatural being as to its mode, if not as to its substance. [Margin: The supernatural character of the star of the Magi.] So, nearly, *St Thomas*, part 3, question 16 [recte: 36], article 7, when he says: *It seems more probable, however, that it was a Star newly created, not in the heaven but in the air near the earth, which moved according to the divine will.* And more clearly *Abulensis* on Matthew chapter 2, question 11: *It must be said that this Star was a certain impression produced supernaturally in the lowest air about the earth; and that body was very dense, having much of light, and because of its sphericity and its flames it was called a star. Such impressions are not usually produced naturally; God makes them for some special end.* Our *Salmeron*, volume 2, tractate 39, agrees with both, fusing the words of the two into one and calling this Star *a certain Impression made above the powers of nature in the lowest air about the earth.* The words of *Cornelius a Lapide* on Matthew 2 say the same: *For the angels formed it out of condensed air, putting splendour into it*; and a little later: *This Star, then, was a New Meteor, formed by angels in the air and informed with an immense light.* Before all of these, moreover, *St Fulgentius* had said plainly in his sermon on the Epiphany: *This Star had never appeared, because that Child created it then and appointed it to go before the Magi coming to him: that Child is laid, a little one, in the Manger, but he works wonders, a great one, in the heaven.* Tycho himself, in volume 1 of the *Progymnasmata*, comparing the New Star that appeared in 1572 in Cassiopeia's Chair, says this on page 324: *That star which appeared to the Magi in the East was not of the kind of the celestial stars, nor did it agree in any way with this New star that is mentioned here, or with the comets: it was rather a peculiar and admirable work of GOD.* And he hints the same on pages 584 and 784. Moreover, the *College of Coimbra*, on Aristotle's books of the *Meteorologica*, tractate 3, chapter 7, lays it down thus: *The already mentioned Star, then, was a certain new and unaccustomed Meteor, compounded out of subcelestial matter not by natural but by angelic or divine power,*

and sprinkled with the brilliance of an exceptional light; and it was carried along not by its own force but by the ministry of some angel. Its supernatural character, however, will be clearer from what is to be said about its splendour and form, about its mover, and about the way in which it signified Christ's birth to the Magi.

Meanwhile, the statements of *Suarez* on the third part, disputation 14, section 1, do not seem clear enough. For he says of Origen: *When he said that it was in the likeness of a comet, he does not mean that it was of the same nature as to splendour and motion, but only as to the matter of which it was made*; and a little later, asking whether that splendour belonged to a perfect mixed body and was connatural to that Star, he answers: *If one may guess, it must be said first that that body was such that that light was connatural to it*; and soon after: *It is probable that that body was some perfect mixed body.* For if the splendour of this Star was not like that of comets, which are reckoned imperfect mixed bodies, but connatural to some mixed body, and we know of no perfect sublunary mixed body to which so great a light is due, then the substantial form of that mixed body was supernatural, and hence supernatural as to its substance, and not only as to its accidents and mode: that, at least, is what seems to follow from what he says.

[Margin: Splendour and Size of the star.] V. That the splendour of this Star was very great, and more excellent than the light of all the Stars, is plain from the Fathers. First, *St Ignatius*, epistle 14, to the Ephesians: *A Star shone in the heaven above all that were before it, and its light was inestimable, and it appeared new and strange to those who saw it. The rest of the stars, together with the Sun and Moon, were a chorus to that star; but it surpassed them all by its splendour, and there was perturbation over where that novelty that had appeared came from. St John Chrysostom* teaches the like in homily 6 on Matthew, where he says: *But this star surpassed even the rays of the Sun with a brilliance of its own and a special one, appearing indeed brighter than they, and in so great a light of theirs shining out the more itself.* No less illustrious is that testimony of *St Leo*, Pope, in Sermon 1 on the solemnity of the Epiphany: *To the three Magi, then, in the region of the East, there appeared a star of new brightness which, being more brilliant and more beautiful than the other stars, easily turned the eyes and minds of those who looked upon it towards itself, so that it was at once perceived that what seemed so unaccustomed was not idle.* And in Sermon 3 on the same solemnity: *A star more brilliant than the other stars moves the Magi, dwellers in the further East; and these men, not unskilled in observing such things, understand from the wonderful brightness of its light the greatness of its signification — divine inspiration doubtless working this in their hearts, so that the mystery of so great a vision should not be hidden from them, and what was shown to their eyes as unaccustomed should not be obscure to their minds.* In that place he had taught, with a most beautiful observation, that GOD used a Star for this reason: that that innumerable succession promised to the most blessed Patriarch Abraham, and therefore compared to the multitude of the stars — so that from the father of all nations a progeny not earthly but heavenly might be hoped for — should also be shown to the Gentiles by a star. And accordingly

he adds at once: [Margin: Why a star, rather than some other sign, was given to the Magi.] *To bring forth, therefore, the promised posterity, the heirs designated in the stars are roused by the rising of a new star, so that the service of the heaven should attend on that in which the testimony of the heaven had been invoked.* Finally the Church sings with Prudentius: *Whom the star, which surpasses the Sun's wheel in beauty and light*, etc.

Notwithstanding this, *Suarez* in the place cited thinks it unnecessary to say that this Star had a light more intense and greater than the light of the Sun, because, he says, it is hard to believe that a more perfect light was connatural to some lower body, or was given it by God without necessity; for, for it to shine at midday and be visible, it was enough that it was near the earth and had a very perfect light and a quite dense matter. To me, however, it seems more consonant with what the Saints say if we say that it was equal or superior to the Sun, not indeed in bulk, but in splendour — especially since we hold that light to have been not connatural to it, but added supernaturally. [Margin: Size of the star.] *Cornelius a Lapide* on Matthew chapter 2 and *Barradius* teach, however, that it was not greater than the Sun, although, being near the earth, it would have looked very large — lest it be called a second Sun rather than a Star.

VI. On this occasion, however, *Suarez*, on part 3, disputation 14, section 5, asks: if that Star was endowed with such splendour and was so beautiful, how was it seen by no one but the Magi? [Margin: Was this star seen by everyone?] Or, if it was seen, how did it not carry everyone away in admiration of itself, and how did its fame not spread through the whole world? Answering the question, he says: *The reason perhaps is that, being near the earth, it shone only in nearby places, especially by day; at night it was perhaps raised higher, so that it could be distinguished only by those who devoted themselves to knowing the stars, as Nicephorus says, Book 1 of the History, chapter 13.* But Nicephorus's meaning is that it was so like the fixed stars that it could have been reckoned one of them, and was not distinguished from them except by skilled astronomers, as will be plain from his words, to be quoted in chapter 20, number 17. On the contrary, *Alphonsus Tostatus* on Matthew chapter 2, questions 14 and 41, replies: *It must be said that this star appeared for the manifestation of Christ's Nativity; it was therefore not fitting that the star should hide itself, so that no one but the Magi should know of this nativity; rather it was fitting that the star be seen by many, and that many should know of Christ's nativity, because this redounded to his glory. And in this way no one is unworthy to see such miracles, since they are done immediately more for the glory of God than for our benefit, although both concur there; the like was the case in the pillar of cloud of the Jews*, etc. And *Salmeron*, tractate 39, holds for the same reason of divine glory that it was seen by others too; *Cornelius a Lapide* subscribes to this, though, he says, few followed the Magi, because of their ignorance of the divine Mysteries and the hindrances of domestic cares.

Tycho, on the other hand, volume 1, page 326, dissents from Abulensis and puts forward a diametrically opposite view, which I shall not mind setting out

in his own words. He says: *Moreover, this star was seen by the Magi alone (for the Jews did not perceive it, however much it passed through their region; otherwise Herod would not have inquired so diligently about its appearance and state, since he could have learned the same from his subjects), either because GOD by some singular dispensation granted them this gift, or because they, endowed with some more recondite knowledge, perceived things that were hidden from other mortals, by the benefit of some excellent Magic.* As if Magic could make visible to them what was invisible to others, and do what the Telescope now does for little stars otherwise inconspicuous! Nor does it follow that, if it was not seen by the Jews because it hid itself near Jerusalem, it was not seen elsewhere by the servants of the Magi, and perhaps by some others. For *St Chrysostom*, homily 62 on the Epiphany, volume 2, says: *And this star was indeed seen by all, but not understood by all.*

VII. As for its form, since the star is said in the sacrosanct Gospel to be a star, it certainly had the form of a Star — whether of a tailed xiphias, or sword-shaped comet, with its point stretched out towards the earth, or of a perfectly round one. [Margin: Figure or Form of the Star.] Whether the image of the Child JESUS shone in that Star, however, is uncertain. *Pliny the Elder*, indeed, Book 2, chapter 25, setting out the various kinds of comets and prodigies, says: *There is also a white Comet, with silvery hair, so resplendent that it can scarcely be looked at, showing in itself, in human form, the likeness of GOD. Fromondus* [Froidmont], Book 3 of his *Meteorologica*, chapter 4, article 1, says that these words are cloudy, but that they can not improbably be understood of the star that was guide to the Magi to the cradle of Christ; for perhaps there was both a report and a fact, under the rule of Augustus, of a comet seen in the East and in Judea in which was expressed the image of a little boy, whom the Christians would call the man-GOD. The Author of the *Unfinished Work*, too, as cited by *Maldonatus* on chapter 2 of Matthew, relates an apocryphal story: that the likeness of a boy appeared in the Star, who spoke to the Magi and taught them that Christ was born. But it is more probable that they did not see the image of the boy before the Boy himself, in accordance with that prophecy of the Erythraean Sibyl in Book 8 of the *Oracles*:

And the Magi worshipped the divine new Star, And the Infant, shown to those who follow GOD's precepts, Is in the Manger, etc.

Granted, that Star may have signified Christ, or his Most Holy Mother, allegorically. That is where these words of *Blessed Peter Damian*, in his sermon on the Epiphany of the Lord, point: *There was a Star in the air, a Star on earth, a Sun in the manger: the Star in the air, that shining body; the Star on earth, the Virgin MARY; the Sun in the manger, our CHRIST*; and a little before he had said: *So the Sun rose from the Star*, namely CHRIST from MARY. So too that saying of *St Bernard*: *Look at the Star, call upon Mary*; and *St Ambrose*, Book 2 on chapter 2 of Luke: *Christ is the Star, for a Star shall rise out of Jacob, and a man shall spring up out of Israel; in short, where Christ is, there is the Star too: for he himself is the bright and morning Star; so he marks himself out by his own light.*

If anyone, however, wants also the words of the Author of the *Unfinished Work*, homily 2 on Matthew, he may have them, for all I care. For after relating, out of the books of the Sethians, that twelve successors of Balaam appointed in each generation some men to contemplate the heaven continually, or at least after the threshing of the harvest, to watch for when the star foretold by Balaam's oracle would rise, he added: *It appeared to them descending upon that Victorial mountain, having in itself the form as of a little boy, and above itself the likeness of a Cross; and it commanded them to set out for Judea. As they set out, the Star went before them for two years, and neither food nor drink failed in their wallets.* These fictions, however, were devised by the Sethian heretics, as is gathered from *St Epiphanius*, heresies 26 and 39. Who it was, then, that appeared to them hidden in the star, or who was the mover and director of the star, must now be related.

[Margin: Mover and Ruler of the star.] VIII. About the moving and directing power of this Star, two opinions are put about. The first attributes it to the Holy Spirit, who, just as he appeared to St John the Baptist above Christ in the form of a Dove, so appeared to the Magi in the form of a Star. The second is that it was God acting through an Angel, whether the Angel assumed that Star or merely carried or drove it. *St Thomas*, part 3, question 36, article 7, embraced both opinions, saying: *Some say that, just as the Holy Spirit descended upon the baptized Lord in the form of a Dove, so he appeared to the Magi in the form of a Star. Others, however, say that the Angel who appeared to the Shepherds in human form appeared to the Magi in the form of a Star.* He took both from the Author of the work *On the Wonders of Holy Scripture*, which is found in volume 3 of the works of St Augustine, Book 3, chapter 4; but about the Angel he says this: [Margin: Was the star of the Magi the Holy Spirit, or an Angel under its appearance?] *What objection is there if the Star in this place is held to be called an Angel? On this occasion an Angel is made the guide of the Magi, who, for astrologers, is transformed into the likeness of a Star. St Chrysostom*, homily 6 on Matthew, seems to hint at this with that form of words: *That it was not one star of the many, but a certain invisible power in the appearance of a star, full of reason.* No differently *Euthymius* [Euthymios Zigabenos], saying: *The Star had not the nature but only the figure of stars, and there was in it truly a certain divine power transformed into this figure. Theophylact*, however, uses plainer language when he lays it down thus: *Do not think it a star such as we see, but a divine and Angelic power appearing in the figure of a star. That the star was an Angelic power is plain from the fact that it both shone by day, and moved at the motion of the Magi, and rested at their rest. Abulensis*, on chapter 2 of Matthew, question 15, was of the same opinion; there he argues at length that God was accustomed to move this Star and similar things not by himself but through Angels, and above all the pillar of fire and of cloud, according to that verse of Exodus 14: *And the Angel of the Lord, who went before the camp of Israel, removing, went behind them, and with him the pillar of cloud.* The same is asserted by *Maldonatus* on chapter 2 of Matthew, *Barradius*, volume 1 on the Gospels, Book 9, chapter 9, and *Salmeron*, tractate 39, who denies that it

was the Holy Spirit and says that it was an Angel as mover, though not one transformed into a star.

[Margin: Time of the star's appearance.] IX. A greater controversy has arisen, and still continues, about the time at which that wonderful Star appeared to the Magi. Some say it was seen two years before Christ's birth; some, that it first appeared at Christ's birth and appeared again two years later, when the Magi left Jerusalem; most, that it appeared again only thirteen days after its first appearance (but that Herod nevertheless put off the slaughter of the infants to the 2nd year of Christ) — that is, the number of days the Church counts from the day of the Nativity of Christ the Lord to the day of the Epiphany. The foundations of these opinions are those words of St Matthew 2: *He learned diligently of them the time of the star which appeared to them*; and soon after: *he slew all the male children that were in Bethlehem and in all its borders, from two years old and under, according to the time which he had diligently inquired of the Magi.* Macrobius, too, speaks of this age of two, in Book 2 of the *Saturnalia*, chapter 10, reporting among the jokes of Augustus this one: *When he had heard that among the boys under two whom Herod, king of the Jews, ordered killed in Syria, his own son too had been killed, he said: It is better to be Herod's pig than his son.* For the Jews, under Leviticus 11, did not slaughter pigs, as being unclean to eat; whereas Herod had obtained leave from Augustus to kill his three sons — Alexander and Aristobulus, whom he put to death long before, and Antipater, whom he ordered killed five days before his own death, as Josephus reports, Book 17 of the *Antiquities*, chapters 10 and 11. Macrobius, however, as Salianus noted together with Deckerius under the year 1 of Christ, committed a paralogism if he thought Antipater a two-year-old because he was killed at the same time as the two-year-old infants.

[Margin: 1. Opinion: the star[?] two years before Christ's birth.] The *first* opinion, then, was that the star appeared to the Magi in the East two years before the Saviour's birth. So *St Augustine*, Sermon 7 on the Epiphany; *St Chrysostom*, homily 7 on Matthew; the Author of the *Unfinished Work* on Matthew, homily 2; *Theophylact* on chapter 2 of Matthew; *Nicephorus*, *History* Book 1, chapter 13; and *Kepler* in the *Silva Chronologica*. St Augustine, however, did not hold to this opinion, since he also proposed another, as St Chrysostom did too. For St Augustine had said in homily 4 on the Epiphany: *On the day on which Christ was born, they saw the Star in the East.* Of St Chrysostom I shall speak below, at the 4th opinion. So *St Leo*, Sermon 2: *The Magi by a Star and the Shepherds by Angels learned of the Lord's birth at the same time*; and *St Fulgentius*, Sermon on the Epiphany, indicates the same in the words already quoted: *This star had never appeared before, because that child has now created it.* And indeed, if the Magi saw the Star two years before Christ's birth, either they girded themselves for the journey at once — and then they would have arrived far too early, and would have asked after a king about to be born rather than one born, since no region of East India, let alone of Arabia, Persia, Chaldea or Mesopotamia, lies so great a distance of travel from Palestine — or, if they did

not set out at once, they would stand convicted of slowness and negligence. Nor was it fitting that the star should appear to them before the time needed for that journey.

[Margin: 2. Opinion: two years from the birth of Christ and of the star to the Adoration.] The *second* opinion was that Christ and the star arose on the same day indeed, and that it then first appeared to the Magi, but that the Magi did not reach Jerusalem and Bethlehem until two years later. So *St Epiphanius*, Book 2, heresy 30, who adds that they found the Infant not in the cave where he had been born, but in another house, because his parents returned to Bethlehem every year out of veneration for the Nativity. But this opinion both brands the holy Magi with the mark of slowness, since the distance of the places does not require so long a delay, and agrees less well with the letter of the Holy Gospel, which says that they found the Infant laid in the Manger — by which words an infant's age of a few days is sufficiently indicated, and so is the place in which he had recently been born, namely the Manger. And the very words *When he was born, etc., behold, Magi* indicate their speed, and an interval of very few days between the rising of the star and of Christ and the arrival of the Magi. And *St Justin*, in the dialogue with Trypho, says: *As soon as Christ was born, Magi coming from Arabia adored him*; and he refers to their speed those words of Isaiah: *Make haste, take away the spoils, etc.*

[Margin: 3. Opinion: on the deferral of the slaughter of the infants to year 2.] The *third* opinion was that the Star indeed rose on the same day as Christ, and that the Magi reached Bethlehem on the thirteenth day from its shining, but that the slaughter of the infants was deferred to the year 2 of Christ, so that Herod ordered all who did not exceed two years of age to be killed, secure that Christ was among them. For, having made a computation of the time that he had diligently inquired of the Magi, he knew that the Star had been seen by them a few days before their arrival; and, having likewise reckoned the time that had run on since their arrival, and the time by which, in his opinion, the star had perhaps risen after the birth of Christ, he judged that all this taken together could not exceed two years. *St Augustine* seems to have been of this opinion, Book 2 *On the Agreement of the Evangelists*, chapter 11, when he says: *I forbear to say with how many and how great occupations the royal care could have been distracted, and over very many days either turned aside altogether from that intention, or hindered. St Thomas*, part 3, question 36, article 6, reply to the 3rd, approves this one more, and with him *Salmeron*, volume 2, tractate 44, who says that Herod did not kill the infants until two years later, because he had been summoned to Rome by Caesar to defend himself against the accusation of his sons. Suarez, however, there, disputation 14, section 4, judges that this agrees poorly with Eusebius, Book 1 of the *History*, chapter 8, who says that after the slaughter of the infants Herod was afflicted with domestic calamities and seditions. *Cornelius a Lapide*, on Matthew chapter 2, verse 16, defends this very opinion tenaciously, adducing on his side Hugo Victorinus [Hugh of Saint Victor], St Antoninus, Lyranus [Nicholas of Lyra],

Abulensis, Dionysius the Carthusian, Barradius and others. He says that the slaughter of the infants was perpetrated about the 15th month from the birth of Christ, and that Herod put off the killing partly because of domestic cares, partly so as to learn better both the parents and the genealogy of Christ, and a sure way of registering the infants and afterwards gathering them for death, under the pretext either of a banquet or of some festival. *Nicephorus*, *History* Book 1, chapter 14, and *Cedrenus*, in his *Compendium of Histories*, favour this opinion, since they think that St John the Baptist fled into the desert because of this persecution of Herod's when he was two years old. For he had been born six months before Christ; if you add 15 months to these, they make 21 months, so that he would be completing the greater part of his second year. *Iacobus Tirinus* subscribes to it, volume 3 of the *Commentary on Sacred Scripture*, on chapter 2 of Matthew, and so do *Onuphrius Panuinus* [Onofrio Panvinio], under the year 1 of Christ, and *Genebrardus* [Gilbert Génébrard], Book 2 of the *Chronicle*. *Abulensis* too, on Matthew chapter 2, question 71, thinks this the more reasonable, and *Barradius*, volume 1 on the Gospels, Book 10, chapter 10, thinks it probable.

[Margin: 4. Opinion: on the enlarged age of the infants to be slain.] The *fourth* opinion is that the star appeared to the Magi on the day on which Christ was born, and that they arrived at Bethlehem after 13 days, whether because of the nearness of the places or because of the speed of the dromedaries indicated by Isaiah; and that the slaughter of the infants was carried out about the third month after the Nativity of Christ — when, that is, Herod saw that he had been deceived by the Magi, and heard the report of the King newly born and Presented in the temple. On this view, for the sake of greater security, and out of headlong fury and lust to retain his dominion, he enlarged the impious decree so that all who fell within the age of two should be killed; yet he ordered that those whom he was certain had been born after the rising of the star should not be killed, and this is what is signified by those words: *According to the time which he had diligently inquired of the Magi*. So he feared more for himself from those born before the star, or before the declaration of the star's rising, than from those born after it. So, namely, *St Thomas*, part 3, question 36, article 6, reply to the 3rd, who, reporting this opinion in the third and last place, seems to choose it; *Iansonius*; *Baronius*, under the year 1 of Christ; *Maldonatus*, on Matthew chapter 2; *Suarez*, part 3, disputation 14, section 4; *Salianus*, volume 6 of the *Annals*, under the Year 1 of Christ, from number 14. Barradius, volume 1, Book 10, chapter 10, thinks this the more probable, as do *Torniellus* and *Gordonus* under the year 1 of Christ; and *St Chrysostom*, homily 7 on Matthew, favours them, saying: *That he killed from two years old and under, let no one wonder, since fear and fury, for the sake of greater security and certainty, extend even the time, etc.* But we too have already shown in our *Chronology* that Herod died after the feast of the Passover in the same year in which Christ was circumcised, and that the slaughter of the infants was therefore perpetrated in that year. Perhaps Herod also feared lest the boy, whom the stars served, should transform his appearance

to somewhat above his age — as St Thomas notes, with St Augustine, in the place cited above.

[Margin: Did it always go before the Magi?] X. It is now asked by some whether the Star, after it appeared to the Magi in the East and roused them to undertake the journey, withdrew itself from their eyes and did not offer itself to be seen by them again until they had left Jerusalem; or whether, from its first appearance all the way to Jerusalem, it shone on them with an unbroken sight of itself.

Of the former opinion were certain persons left unnamed by St Thomas, part 3, question 36, article 7, in the body of the article, and by the Coimbra commentators [Conimbricenſes], tractate 3 on the *Meteorologica*, chapter 7. But *Cornelius a Lapide*, on Matthew chapter 2, verse 2, attributes it to Iansenius, Caietanus [Cajetan] and Clarius, and Barradius thinks it probable.

But the more common opinion is that the Star went before them from the East all the way to Jerusalem, and was visible at least at the time when they were awake and making their journey. In this too, then, it was like the pillar of cloud in the desert, which always appeared: it went when the Magi went, halted when they stood, and accommodated itself to their alternations. So teach *St Thomas*, part 3, question 36, article 7; *Abulensis*, on Matthew chapter 2, questions 13 and 14; *Suarez*, on part 3, disputation 14, section 5; *Salmeron*, volume 2, tractate 39; *Maldonatus*, on Matthew chapter 2; and *Cornelius*, in the place adduced, together with *Lyranus*, *Pererius* and the *Coimbra commentators*. Abulensis, however, judges that it differed from the Pillar of cloud in this: the Israelites moved at the motion of the pillar — for so great a multitude had to be governed in that way, to avoid the discord that would arise over the time of moving camp — whereas the Star moved at the motion of the Magi. Finally, the holy Fathers thought so. For *St Chrysostom* says, in homily 6 on Matthew: *But this star came from the North to the South, in which position Palestine faces Persia*; and soon after: *For until the Magi came to Palestine, it always appeared as the guide of their journey*; and again: *For that star did not then hold any course of its own; but when it saw them going on, it too went on, and when it saw them standing, it stood, ordering everything entirely to the will and the advantage of the travellers. St John Damascene* indicates the very same, Book 2 *On the Faith*, chapter 7: *The star that appeared to the Magi advanced now from the Rising to the Setting, now from the North to the South, etc.* But most eloquently of all *St Peter Chrysologus*, Sermon 156: *When the Magus walks, the star walks; when he sits, it stands; when he sleeps, it keeps watch.* And the Church sings in harmony with them in the hymn:

The Magi went on, following The star they had seen going before them.

These words are not to be restricted to the journey from Jerusalem to Bethlehem. And the phrase *We have seen the Star in the East* does not mean that it was seen only there, but that it began to be seen there, and was not seen at Jerusalem.

[Margin: Where was the star seen?] XI. It is disputed, however, where the Magi first saw the Star: above Judea, or above the place where they themselves

lived? For the *Ordinary Gloss* and *St Anselm* leave the dispute undecided, and *Barradius*, volume 1 on the Gospels, Book 9, chapter 9, thinks either view likely. For the former opinion stands Balaam's prophecy, *A Star shall rise out of Jacob* — as if to say that out of the house of Jacob, or out of Judea itself, a star will come into the East. Pagnino's version in the Royal Bible hints at this, when it says: *A star went forth out of Jacob*. Accordingly *Procopius*, treating of Balaam's prophecy, says: *When they saw a strange and unaccustomed star standing motionless perpendicularly above Judea.* And lest the text of the holy Gospel seem to conflict with this, where it is said *We have seen his star in the East*, the interpretation of *Haymo* is ready to hand, Sermon 3 on the Epiphany, which runs thus: We, placed in the East, saw his star shining in the West, over against Jerusalem. *Barradius* and *Cornelius a Lapide*, on Matthew chapter 2, verse 2, thought these should be reconciled thus: that the star was first seen above Judea and the town of Bethlehem, but from there flew off with swift motion to the East and stood above the place of the Magi until it moved them to undertake the journey towards Judea.

But against this stand the objections that Abulensis raised on Matthew chapter 2, question 18. For since Judea was distant from the place of the Magi by a journey of 13 days, that is, by about 400 miles, then if the star was near the earth it could not have been seen, because of the swelling of the earth; if, on the other hand, it was higher, it could not mark out a definite place, nor would it have seemed to hang above Judea any more than above the other neighbouring regions. And so he concludes that the star was seen by them hanging above their own head, and afterwards directed them into Judea. If, however, they had seen the star from a look-out on a high mountain, they could have seen it even though it was near the earth; or at any rate it was enough that it should show them roughly the region towards which they had to go, since afterwards it was to go before them *and, as it were with a finger, point out the place of the newborn Boy*, as Isidore of Pelusium puts it, Book 1 of the *Letters*, to Olympius, 378.

[Margin: What became of this star afterwards.] XII. Next, what became of this star after it had discharged its office and, as I was just saying, had pointed out the Lord's Manger with its ray as with a finger? Some have thought that the Star led the Magi back to their homeland. But *Abulensis*, on Matthew chapter 2, question 55, opposes this, because this miracle was not necessary, and had there been one the Evangelist would not have passed over it in silence; nor would there have been need of the Angel's warning in their dreams, since it would have sufficed to follow the star leading them by another way. The star therefore disappeared once they had entered the house where the Divine Boy was. *Haymo*, however, writes in Sermon 3 on the Epiphany, from a tradition of Gregory of Tours, that that star fell into a certain well at Bethlehem, and that of three men, one of whom was a virgin and the others not virgins, it was seen by him alone who was a virgin. But *St Anselm*, on chapter 2 of Matthew, thinks this frivolous, and with him *Barradius*, volume 1, Book 9, chapter 9. The star was therefore dissolved and vanished, since it had not been established for

any other end — like the pillar of cloud and the other signs of this kind. So it did not begin to shine in the Firmament, as some have imagined; *Abulensis* refutes them on Matthew chapter 2, question 16.

[Margin: How the star indicated JESUS.] XIII. But the chief question remains: by what means, namely, this Star taught the Magi that the King of the Jews was now born, and by what indications they could discern that it pertained to signifying the birth of this King rather than anything else — so much so that they could say *We have seen his star*: his, I say, and not another's. The answer is that three things concurred to their knowing this determinately and certainly: namely, a remote disposition in the Magi, arising from their skill in the stars, or from their astronomical profession, to which GOD willed to accommodate himself, though it did not demand it, by calling them through the splendour of an unaccustomed star; next, a particular knowledge of the oracle of Balaam; and lastly, but chiefly, an interior ray of divine illumination and of exciting Grace, which both accompanied and followed them up to the adoration and the return into their own region — indeed, all the way into heaven, to the contemplation of the form of the divinity. These three we shall show briefly from the holy Fathers and Doctors of the Church.

First, then, very many of the Fathers affirm that those Magi were philosophers and wise men, devoted to the study of Astronomy, or even of Astrology, and that GOD therefore willed in some way to speak to them through a Star. [Margin: The Author of the Unfinished Work.] The Author of the *Unfinished Work* on Matthew, homily 2: *Who are the Magi? Eastern men who came from Persia; for among them Magi are understood not as sorcerers but as wise men.* [Margin: St Cyprian.] Well known is that saying of *St Cyprian* in the Sermon on the Star and the Magi: *Not long afterwards the knowledge of this matter penetrated the borders of the Arabs, and to the inhabitants of Sabba a star of brilliant light indicated the heavenly godhead with new splendours. There were in those regions men accustomed to the inspection of the stars, who by the mathematical art knew the force and course of the Planets; for, measuring the reckoning of times from the nature of the elements, they had learned by sure experiments the ministries of the stars, assigned to their proper effects.* [Margin: St Leo.] *St Leo*, Pope, recognised the same science of contemplating the stars in them, Sermon 3 on the Epiphany, in words already adduced on another occasion: *A star more brilliant than the other stars moves the Magi, dwellers in the further East; and from the brightness of its wonderful light these men, not unskilled in observing such things, understand the greatness of its signification*; and in Sermon 4: *A nation that was strong in the art of observing the stars.* [Margin: St Anselm.] *St Anselm* agrees, on Matthew chapter 2: *They were not sorcerers, but wise Astrologers*; [Margin: Bede.] and the Venerable priest *Bede* said: *The Magi are so named not on account of the magic art, but on account of a certain Philosophy.* [Margin: Nicephorus.] No differently *Nicephorus*, Book 1 of the *Ecclesiastical History*, chapter 13: *These were wise men, distinguished by nobility of birth and by wealth.* [Margin: Innocent.] *Innocent III* himself too, the supreme Pontiff, in the Sermon on the Epiphany: *The Magi*

were not soothsayers, but philosophers, who were so called from the greatness of their knowledge; for those whom the Greeks call Philosophers, the Persians call Magi.

[Margin: Gloss.] It is no wonder, then, that the *Ordinary Gloss* said: *The Magi were not sorcerers, but belonged to the Chaldean Philosophers, who philosophise about each thing*; [Margin: Abulensis.] and *Abulensis* on chapter 2 of Matthew, question 6: *Magi, that is, great in wisdom; and so the wise are called Magi among the Persians, while among the Hebrews they are called scribes*; and a little later: *and those are most of all said to be Magi who are wise in Astrology; and these men appeared to be such, since God directed them by a star.* [Margin: St Jerome.] But *St Jerome*, on chapter 2 of Daniel, teaches most distinctly that the name of the Magi does indeed sound bad in common usage, but that among those who understand the force of the word the matter stands otherwise. For when he had said: *They seem to me, therefore, to be enchanters, who accomplish things by words. The Magi, who philosophise about each thing*, a little later he added: *Moreover, among the Chaldeans I think the* γενεθλιαλόγους *[Greek: genethlialogous, "casters of nativities"] are signified, whom the common people call Mathematicians. But custom and common speech take the Magi for sorcerers, though they are held otherwise among their own nation, since they are the Philosophers of the Chaldeans; and kings too, and princes of the same race, do everything according to the knowledge of this art.* The same writer, Book 2 *Against Jovinian*: *Eubulus relates that among the Persians there are three kinds of Magi, of whom the first, who are the most learned and most eloquent, take nothing more as food than meal and vegetables.* [Margin: Laertius, On the Lives of the Philosophers.] He seems to have taken this from Diogenes Laertius, Book 1, chapter 1, where, after asserting that the Magi devote themselves to the worship of the Gods, he describes their food and clothing in this way: *Their clothing is white, their bed the ground, and their food vegetables, cheese and coarse bread; they use a reed for a staff, and they eat the cheese fixed on its top by putting it to their mouths. Aristotle says that they were ignorant of magical divination.* [Margin: Strabo.] Not without reason, then, did *Strabo* say, Book 15: *The Magi follow an honourable kind of life*; [Margin: St Isidore.] and *St Isidore*, Book 8 of the *Etymologies*, chapter 9: *Interpreters of the stars were called Magi, as we read of those who announced in the Gospel that Christ was born.* To these let two followers of Platonic philosophy be added. [Margin: Philo.] The first is *Philo*, in the book *That every good man is free*, for he says: *Among the Persians, the Magi, investigators of nature, out of zeal for knowing the truth, who at leisure contemplate the divine powers more clearly.* [Margin: Chalcidius.] The other is *Chalcidius*, on Plato's *Timaeus*, who said on page 36: *There is another, holier and more venerable story, which tells that by the rising of a certain star were announced not diseases and deaths, but the descent of the venerable GOD, for the sake of human converse and of mortal affairs. When men of the Chaldeans, truly wise and well practised in the consideration of heavenly things, had looked up at this star on a night journey, they are said to have sought the recent birth of God and, having found that majesty in boyhood, to have venerated it, etc.* [Margin: Mantuan.] Why should we not also lend our ears

to *Io. Baptista Mantuanus* [Battista Spagnoli, called Mantuan], singing of the Epiphany:

He is a Magus among the Persians who knows the stars, Who knows the powers of herbs, and the worship of the Gods: At Persepolis this threefold wisdom makes men Magi.

[Margin: St Jerome.] But I return to *St Jerome* on chapter 2 of Daniel, who goes on to write of them thus: *They acquired this Magic from Physics and Mathematics, yet in such a way that from these they contemplated the things that were God's. These the Indians called Gymnosophists, the Gauls Druids, the Greeks Wise Men, the Hebrews Prophets.* Thus Magic either included Astrology among its other sciences, or was very closely akin to it. [Margin: Cedrenus.] Accordingly *Cedrenus*, in his *Compendium of Histories*, gathers from Josephus, Book 1 of the *Antiquities*, chapter 16, that Abraham taught the Egyptians Αστρολογίαν, καὶ Μαγεῖαν [Greek: astrologian kai mageian, "astrology and magic"]; and he so defines Magic that it depends on Astrology, adding: Αστρολογία γὰρ, καὶ Μαγεῖα, ἀπὸ Μαγουσαίων, τοὶ Περσῶν ἤρξατο [Greek: "for astrology and magic began from the Magusaeans of the Persians"] — that is, Astrology and Magic arose from the Magusaeans, or Persians. And indeed the Persians are called Magog by the natives. [Margin: Where did the name of the Magi come from?] The Syriac Gospel, too, calls them *Magusin*, and the Persian *Magusan*, that is, wise Astrologers. *Genebrardus*, however, on Psalm 1, thinks that this name springs from the root *Haga*, which in Hebrew means to Meditate; hence the Hebrew name *Magia*, that is, those who meditate or are deep in thought. For, as Ptolemy wisely said in the preface to the *Almagest*, *Meditation is the key of wisdom.* Or else this word also signifies the Silent, as the Author of the *Unfinished Work* on Matthew, homily 2, has it, because the Magi gave themselves, in the greatest quiet and silence, to the contemplation of Nature and of heavenly things, and afterwards came together among themselves to converse about the things they had learned by meditating; [Margin: Cicero.] as we have in Cicero, Book 1 *On Divination*: *And among the Persians the Magi take auguries and divine, who gather in a shrine for the sake of discussing and conversing among themselves. Nor can anyone be King of the Persians who has not first received the discipline and science of the Magi.* [Margin: The kings of the Persians steeped in Magic.] [Margin: Philo.] Not unlike this is what *Philo* attests in the book *On the Special Laws*: *That true Magic, the perspective science, by which the works of nature are seen more clearly, is pursued as honourable and worth seeking not only by commoners but also by kings, and the greatest of kings, especially the Persian ones, who are so curious of these arts that no one is permitted to reign unless he has been familiarly versed with the Magi.* [Margin: Eugubinus.] But I had almost forgotten *Eugubinus* [Agostino Steuco], Book 1 *On the Perennial Philosophy*, chapter 3, who says that the leaders of the Chaldean Theology were those whom they called in their native tongue Magi, as if to say wise men, or philosophers and Priests. There is also extant in *St Justin*, in the *Apology* against the Gentiles, that Oracle of Apollo:

Only the Chaldeans obtained wisdom, and the Hebrews with them.

Those whom the Babylonians called Chaldeans, the Persians called Magi, the Egyptians Hierophants, the Indians Brahmins, and the Etruscans Haruspices, as Strabo attests, Book 16, and Cicero, Book 1 *On Divination*. [Margin: Baronius. Salmeron. Maldonatus. Barradius. Suarez. Beauxamis.] Finally, very many of the more recent writers took this name in the better sense when speaking of these holy Magi, and above all *Baronius*, under the year 1 of Christ; *Salmeron*, volume 2, tractate 38; *Maldonatus* and *Cornelius a Lapide* on Matthew chapter 2; *Barradius*, volume 1 on the Gospels, Book 9, chapter 8; *Thomas Beauxamis*, volume 1 of the *Gospel Harmony*, from page 96; *Suarez*, on part 3, disputation 14, section 2; and very many others cited by them.

[Margin: The name of the Magi taken in a bad sense.] XIV. Granted, however, that the name of the Magi has had a bad reputation even in the sacred writings — since Magic is threefold, Natural, Artificial, and Superstitious, that is, infamous for commerce with demons, and it is easy to slip from the first to the second and from the second to the third unless one restrains, within the limits of sobriety and prudence, the curiosity of knowing secrets or of working marvels. So in Exodus 7, where those sorcerers of Pharaoh are called Magi by some translators. And in Leviticus 19 it is said: *Do not turn aside to the Magi, and do not inquire anything of soothsayers*; and in chapter 20: *The soul that turns aside to the Magi and to soothsayers, I will cut it off from the midst of my people.* Granted, too, that the Seventy Translators, at Exodus 7 and 8, Deuteronomy 18, Paralipomenon 33, Jeremiah 27, Daniel 2 and Malachi 3, were accustomed to call them φαρμακοῦς or φαρμακεῖς [Greek: pharmakous, pharmakeis, "sorcerers"]. For *Pliny the Elder*, Book 30, chapter 1, notes that the magical arts took their origin from Medicine, and grew through superstition and Mathesis to such a height that they gave commands to the kings of kings. And although our translator and the Seventy call the Magi observers of the stars, or interpreters of dreams, as in Daniel 1, 2, 4 and 5, they are nevertheless called by the same translators Pythons, or ἐργαστριμίθους [Greek: engastrimythous, "ventriloquists"], that is, ventriloquists. Munsterus [Sebastian Münster] too, in the Hebrew Gospel, chapter 2 of Matthew, put for Magi *Macassephim*, that is, enchanters or conjurors. [Margin: Saints Justin, Augustine, Basil, Ignatius, Thomas, Ambrose, Jerome, Hilary; Theophylact; Origen.] And *St Justin* in the Dialogue against Trypho, *St Augustine*, Sermon 2 on the Epiphany, *Origen*, Book 1 *Against Celsus*, *St Ignatius*, epistle 14, to the Ephesians, *St Basil*, homily on the human generation of Christ, *St Thomas*, part 3, question 36, article 3, reply to the 2nd, *St Ambrose* on Luke, the chapter on the Magi, *St Jerome* on chapter 19 of Isaiah, *St Hilary*, Book 4 *On the Trinity*, and *Theophylact* on Matthew 2, suspected that the three holy Magi had in fact once been such men. Of these, Origen relates that, having seen the portent of so unaccustomed a star, they consulted the demons; and when these, already struck dumb by Christ scarcely born, made no reply, they conjectured from this that he who was signified by the star was more powerful than the demons, and from that time resolved to adore him. So the demon was despoiled by the Infant JESUS of those very

persons whom he had plundered through wretched superstition, according to that saying of Isaiah: *Make haste to take away the spoils; hurry to plunder; for before the boy knows how to call his father and his mother, the strength of Damascus shall be taken away* — which St Justin, above, and St Augustine, Sermon 4 on the Epiphany, understood of the Magi, brought over from superstition to his worship. [Margin: Tertullian.] Noteworthy, however, is the sentence of Tertullian, in the book *On Idolatry*, chapter 9: *We know the alliance of Magic and Astrology with each other: it was the interpreters of the stars, therefore, who first announced that Christ was born.* For, as *Theophylact* says on Matthew chapter 2: *Since the Magi were Astrologers, the Lord for that reason drew them by a familiar sign*; and St Chrysostom, homily 6: *The Lord calls the Magi through the things that custom had made familiar to them, condescending to the salvation of men.*

XV. The *second* cause disposing the Magi to recognise through that star the recent birth of the King of the Jews was their foreknowledge of the ancient oracles: not only of the Samian Sibyl, prophesying of the Messiah:

Whom a Virgin, inviolate, will cherish in a human bosom. Heaven assents to this; the glowing stars show it.

nor only of the Erythraean Sibyl, in Book 8 of the *Oracles*, singing of the future as of a thing past:

And the Magi worshipped the divine new star, And to those who follow God's precepts the infant is shown In the manger.

— if indeed knowledge of these reached them — but also, either solely or chiefly, of that ancient Balaam, who had said, already 1500 years and more before, in Numbers 24: *I shall see him, but not now; I shall behold him, but not near: A STAR SHALL RISE out of Jacob, and a rod shall spring up from Israel, etc.* This Prophecy was handed down, either in written volumes or by tradition, to the descendants and successors of Balaam, who lived in Sabaea or Arabia, or Mesopotamia, or Persia (for those regions border on one another, and the Fathers and Doctors commonly say that the Magi set out from them). At length, when the fullness of time came and the Star rose out of Jacob — that is, the most holy Virgin MARY, and from her CHRIST, who were signified allegorically by that Star, while to the letter it was that Star which appeared in the East — the star was seen with such certainty to be the one Balaam had foretold that they said, as of a thing known among the Jews, *Where is he that is born King of the Jews? For we have seen his star in the East* — as if they were to say: For we have seen the star which is without doubt the index of no other than the King of the Jews newly born, and is no other than the one of which Balaam once prophesied. [Margin: Cyprian. Origen. Basil. Gregory of Nyssa. Jerome. Ambrose. Augustine. Leo. Anselm. Bede. Theophylact. Euthymius. Maximus. Remigius. Chrysostom. Thomas. Isidore. Abulensis. Lyranus. Maldonatus. Salmeron. Suarez. Maiolus. Chrysologus.] That the Magi were struck into this knowledge by Balaam's prophecy, and that they preserved it as his descendants, or as a particular memory in their records, very many Fathers teach most openly: above all *St Cyprian*, in the Sermon on the star and the Magi; *Origen*, homilies

13, 15 and 18 on Numbers; *St Basil*, in the oration on the generation of Christ; *St Gregory of Nyssa*, in the oration on the Nativity; *St Jerome*, on Matthew chapter 2 and on Isaiah chapter 47; *St Ambrose*, on Luke chapter 2; *St Leo*, Sermon 4 on the Epiphany; *Bede*, *Theophylact*, *Euthymius* and *St Anselm*, on Matthew chapter 2; and *St Maximus*, Sermon 3 on the Epiphany. The opinions of all these our Barradius recites one by one, volume 1 on the Gospels, Book 9, chapter 9, from page 149. The same is taught by *St Chrysostom*, volume 2, homily 62; *Blessed Remigius* on Matthew; *St Thomas*, part 3, question 36, article 5, reply to the 4th; *St Augustine*, Book 3 *On the Wonders of Holy Scripture*, and in the *Questions on the Testament*, question 39; *St Isidore*, in the book *On the Passion of the Lord*, chapter 13; *Abulensis*, on Matthew chapter 2, question 7; *Nycolaus Lyranus* [Nicholas of Lyra] in the *Gloss* on Matthew chapter 2; *Maldonatus* on Matthew chapter 2; *Salmeron*, volume 2, tractate 39; *Suarez*, on part 3, disputation 14, section 6; and *Simon Maiolus* [Simone Maioli], *Dog Days*, colloquy 1, page 15. Of all these, it suits our matter — which we are to treat afterwards, in the following chapter — to bring forward only the noteworthy words of St Peter Chrysologus, Sermon 156: *Not by Chaldean curiosity, not by the Magic art, but by Jewish prophecy*; and Sermon 157: *Not by the Chaldean art, but from the ancient tradition of the holy forefathers.* For granted that they were remotely disposed to judge that something great was portended by that star, they could nevertheless not divine from the rules of the casters of nativities [Genethliaci] what it signified, but only from their foreknowledge of the Prophecy of Balaam, with divine illumination above all supervening.

XVI. For the *third* and most powerful cause, which made plain to the minds of the Magi what that star signified, and drove their will to undertake the journey and to seek out the cradle of our Saviour, was without doubt the ray of divine illumination, as is most certain from the Fathers and from the common sense of Catholics: [Margin: St Leo.] *Divine inspiration without doubt working this in their hearts, so that the mystery of so great a vision should not be hidden from them, and what was shown to their eyes as unaccustomed should not be obscure to their minds* — these are the words of St Leo, Pope, Sermon 3 on the Epiphany. And the same writer, in Sermon 4: *But, as the event showed, the grace of God presided over this miracle, etc.*; and a little later: *O wonderful faith of perfect knowledge, which no earthly wisdom taught, but the Holy Spirit instructed! For from what source had those men — who, when they set out from their homeland, had not seen JESUS, nor had perceived by any sight of him anything to make them venerate him in so ordered a way — learned to observe this plan in the gifts they were to bring, unless it was because, besides that appearance of the star, which stirred their bodily gaze, a brighter ray of truth had taught their hearts through and through?* And in Sermon 5 the same Supreme Pontiff: *But this sign, etc., was without doubt the Sacrament of that grace, and the beginning of that calling, etc.* For in Sermon 1 he had said: *He therefore gave understanding to those who looked, he who supplied the sign; and what he made to be understood, he made to be sought.* [Margin: St John Chrysostom.] Before him, however, St Chrysostom, in Homily 62 on the Epiphany, which is found in

volume 2, attributes this knowledge first to the gift of divine condescension, and then to the prophecy of Balaam, and adds: *The splendour of this light, penetrating even the hearts of the Magi, flooded them with spiritual light, so that by the sign of a new star being born they should recognize the king of the Jews as the creator of heaven.* [Margin: Blessed Remigius.] Piously, too, and ingeniously, Blessed Remigius, on Matthew, teaches that they came from the East, that is, drawn by Christ through grace: *Beautifully are they said to have come from the East, because all who come to the Lord come from him and through him; for he himself is the East, according to the saying: Behold a man, the East is his name.* [Margin: Eusebius Emissenus.] To these let Eusebius Emissenus [Eusebius of Emesa] be added, in his homily on the Epiphany of the Lord: *It came about that, once the star was seen, they at once understood whatever was signified through it — not, however, by the certain demonstration of Astrology, but by that of the Holy Spirit. They were therefore seeking in the star Christ, whom they understood by divine inspiration to be signified through the star.*

[Margin: St Peter Chrysologus.] Yet at the first sight of the star they perhaps tried, like astrologers, to inquire what GOD signified by that sign; and at once, taught inwardly by heavenly light about the emptiness of their art, they received from God the occasion of their error as a remedy for their blindness. For that reason St Peter Chrysologus, in Sermon 157, himself answers someone questioning him: *Why Magi? Why a star? So that through Christ the very material of error might become the occasion of salvation, just as through Christ the cause of death was made the cause of life. To confound the enemy with his own sword is a singular mark of valour. Among the Magi the fault was ignorance, not will; and what lay under the charge was not their zeal but their error, in seeking and knowing God. To seek is a matter of necessity more than of guilt. It was therefore a loving act that God should both grant the seekers to find, and set the fault down to error. Finally Paul, by such a judgement, was made a preacher out of a persecutor, because through zeal for the law he was assailing the law, and was sinning against God out of love of God.* And just as St Paul became a preacher out of a persecutor, so these men were made Evangelists out of Magi. [Margin: St John Chrysostom.] This was the view of St John Chrysostom, Homily 16 of the various homilies on Matthew, addressing Christ the Lord thus: *You by your coming called the Magi from the East, and sent them back to their own people as Evangelists.* Thus that golden mouth of the Church. But the chapter must be closed with that other seal, golden as it were, namely that of [Margin: St Chrysologus again.] St Peter Chrysologus, Sermon 156: *From the East to the East the Magi come, so that he who had bidden them come might himself receive them as they came. For when would a Magus seek out God unless God bade him; when would an Astrologer have found the King of heaven unless God revealed him; when would a Chaldean, without God, adore the one God on earth — he who in heaven served as many gods as there were stars?* They had need, therefore, of God rising in their hearts; of God bidding, of God revealing.

CAPVT XX.

Chapter XX.

The Errors of Some concerning the Star of the Magi, but chiefly of the Casters of Nativities, are Reported and Refuted; where also of the Natal Horoscope of CHRIST erected with little piety by some, and of the Great Conjunction of the Planets that preceded this star.

I. If I am not mistaken, it is sufficiently established from the preceding chapter that the sense of the Catholic Church, or at least the more common opinion of the Fathers and Doctors, is that the origin and signification of the Star which appeared to the Magi must be acknowledged as plainly above the order of nature. Now we must refute those who, abusing the brightness and the gift of so great a light, have either impiously dared or imprudently tried to refer the causes of that star, or its force and signification, to some natural necessity. [Margin: 1st error, of the Priscillianists.] And in the first place the Priscillianists meet us. As St Gregory relates in Homily 10 on the Gospel, they said that this star had been the fate of Christ, and seized from it an occasion of confirming their error, namely that the Stars are the mistresses of nativities and of the things that depend on nativity. Yet GOD so ordered the appearance, motion, place and duration of this star that from these that error could rather be refuted — as in fact it was refuted by the holy Fathers. For the Stars from which the astrologers boast that they can predict the fortune or misfortunes of a newborn infant precede the infant's birth from the beginning of the world, and are placed in the heavens by the natural Providence of the Creator. They do not invert or change their course so as to move towards the place of an infant born or about to be born, nor do they accommodate themselves to his will or that of others; rather (as the astrologers indeed pretend) they incline or draw to themselves the wills and nature of others. Nor are they extinguished before they have worked out all the events of the child once born, up to his death; on the contrary, they persist in the heavens even after his death, so as to pour like characters of life, inclinations and morals into others who will be born under a like constitution of the stars. But everything was otherwise with this star of the Magi, as is clearly evident from what was said in the preceding chapter, where also, at number 4, we sufficiently showed that the star was supernatural, from Tycho himself, let alone from the Fathers. [Margin: 2nd error, of the Manichaeans.] A second error, akin to this one but tending elsewhere, was that of the Manichaeans. As is gathered from St Augustine, *Against Faustus the Manichaean*, Book 2, chapter 5, they abhorred Fate, and for that reason rejected the Gospel of St Matthew, because they thought that in its chapter 2, where the star and the Magi are treated, the fatal necessity of the stars is handed down and approved by him. Against both parties the arguments and opinions of the Fathers and Doctors of the Church must be set out distinctly, since they drew a medicine from this very star from which others drew the poison of error. [Margin: St Chrysologus's warning.] Otherwise, as St Chrysologus forewarned

on this very occasion in Sermon 156, *what is the material of life becomes the occasion of perdition*; and he at once adds: *We must take heed, brothers, that what has been divinely written for our advancement does not, through unskilfulness in hearing, turn to the detriment of souls. Do you think that the Evangelist today taught that Chaldeans, searchers of the stars; Magi wandering among the stars, investigating the affairs of heaven in the darkness of the nights; ascribing the causes of being born and of dying to the courses of the stars; establishing the goods or evils of men by the decision of the luminaries — that these found, with a star as guide, the rising of Christ hidden from the ages? Far from it: so the world thinks, so the gentiles understand, so the surface of the reading deceives. But the Gospel discourse speaks not human things but divine; not customary but new; not deceiving by art, but resting on truth; not playing to the eyes, but fixed in the hearts; not wavering on conjectures, but confirmed by authority; coming from God, not from fate; not gathered by numbers, but acquired by virtues.* [Margin: Enumeration of the arguments against the Priscillianists, etc.] Now we shall bring the arguments of the Fathers and Doctors against the Priscillianist casters of nativities and the Manichaeans under 8 heads. They are: 1. The independence of Christ, inasmuch as he is Lord and Creator of the star itself. 2. The service of the star towards Christ. 3. The compliance of the star, which moved at the nod of the Magi. 4. The place of the star. 5. The novelty and singularity of the star, without the company of others, or its supernatural origin. 6. Its signification of the nativity rather than of the events that follow from the nativity. 7. The miraculous Nativity and the deeds of Christ. 8. The supernatural force and manner of signifying by which the Star instructed the Magi.

II. [Margin: 1st argument: the independence of Christ from the Star.] The first argument, then, is taken from the Divinity of Christ, and so from his independence of that star and of all other creatures. For by the very fact that he was God, and Creator and Lord of it and of all the stars, no star could certainly be a cause influencing that person, which consists of both natures, the human and the divine; nor could it influence his operations, which theologians call θεανδρικὰς [Greek: theandrikas, "theandric"], that is, divine-human. [Margin: St Augustine.] St Augustine meant to indicate this to us in Book 2 *Against Faustus*, chapter 5. For when he had said: *And we indeed place the birth of no man under the fate of the stars, so that we may vindicate the free choice of the will, by which one lives well or badly, from every bond of necessity, on account of the just judgement of God* — for indeed, if a man sinned out of necessity, God would be unjust to condemn him by his own judgement — he at once adds: *How much less do we believe that the temporal generation of him who is the eternal creator and Lord of all things was brought about under the condition of the stars? Accordingly, that star which the Magi saw when Christ was born according to the flesh did not rule him by decree, but served him as a testimony; for it did not subject him by command, but pointed him out by its service.* [Margin: St Chrysologus.] The very same argument is that of *St Chrysologus* in Sermon 156. Having first said: *When Jesus is born, the origin of things arises; the bestower of kind is begotten; the author of*

nature is born, he then attends to the words *We have seen his star*, and teaches that through the particle *his* a peculiar dominion of Christ over this star is signified, saying: *He who made the whole creation, who holds and contains it, began to have one star. He who has a star is not had by the star; nor is he driven by the course of the star, but he himself drives the star's course.* And again, further on in the same sermon: *The star appeared not willing but commanded: not at the nod of heaven, but by the impulse of the divinity; not by the law of the stars, but by the novelty of Signs; not by the clime of heaven, but by the power of the one being born.* And in Sermon 157, driving home the same particle *his*, he says: *And what is not his? The star is his; he is not the star's: it received being, but did not give it. A Star whose rising its author held, not one that held the rising of its Author; coming not from a nativity but from the begetter, by command, not by fate; not from a calculator but from its author; not one that would give a rising, but one that would undergo a setting.* For, having discharged its office, it set, and appeared nowhere any more.

III. [Margin: 2nd argument, from the service of the star towards Christ.] The *second* argument, akin to the preceding one and following from it, is the motion and service that the star rendered to Christ, by which it professed itself a servant and handmaid to its Creator and Lord — so much so that it rather felt the power of Christ than exerted any on Christ's body, let alone on his soul or his divinity, which was utterly ἀδύνατον [?] [Greek: adynaton, "impossible"]. [Margin: St Thomas.] *St Thomas* uses this argument in Part 3, question 36, article 5, reply to 3. For when he has said: *The star, manifesting the nativity of Christ, removed every occasion of error* — since the other stars complete their courses and carry off with them, if it were right to believe the casters of nativities, the fates and fortunes of men, but it went otherwise with this star — [Margin: St Augustine.] the holy Doctor therefore aptly brings in the argument of *St Augustine*, taken from Book 2 *Against Faustus*, chapter 5, where he reasons thus: *What astrologers, pray, ever so placed the fates of men at birth under the stars as to assert that one of the stars, when some man was born, left the order of its circuit and went to the one who had been born? For they think that the lot of the one being born is bound to the order of the stars, not that the order of the stars can be changed on account of the day of a man's birth. Therefore, if that star was one of those that complete their orders in heaven, how could it decree what the newborn Christ was going to do, when it was itself ordered, at Christ's birth, to leave what it was doing? But if (as is more probably believed) it arose to point out Christ, having not existed before, then Christ was not born because it existed; rather, that new star arose because Christ was born.* Having concluded this most acute dilemma, he infers from it this conclusion: *Hence, if it had to be said, we would say not that the star was Christ's fate, but that Christ was the star's fate; for he brought it the cause of being born, not it him.* [Margin: Whether the Word of God can be called Fate?] On this occasion, with no less acuteness of mind, he suggests that Fate is nothing other than the Word of God — which is certainly most worth noting. He adds, therefore: *If, then, there are Fates, which are named a fando, that is, from speaking: since Christ is the Word of God, in whom all things were spoken before*

they existed, the company of the stars is not the fate of Christ, but Christ is the fate even of the stars. He also assumed the very flesh created under heaven by the same will by which he also created heaven; and he laid it down and took it back by the same power by which he also commanded the stars. [Margin: St Gregory.] From this source, indeed, *St Gregory*, Supreme Pontiff, seems to have drawn what he carried over into Homily 10 on the Gospels, which is on the Epiphany, when he said: *The Priscillianist heretics think that every man is born under the constitutions of the stars; and they take up in support of their error the fact that a new star came forth when the Lord appeared in the flesh, and they think that this same star which appeared was his fate. But if we weigh the words of the Gospel, in which it is said of that same star, Until, coming, it stood over where the child was — since the child did not run to the star, but the star to the child — then, if one may say so, the Star was not the child's fate, but the child who appeared was the Star's fate.*

IV. [Margin: 3rd argument, from the service of the star rendered to the Magi.] The *third* argument is from the service that the star rendered to the Magi, which *St Augustine* employed in Book 2 *Against Faustus the Manichaean*, when he said: *Accordingly this was not one of those Stars that from the beginning of creation keep the order of their journeys under the law of the Creator; but at the new birth from the Virgin a new star appeared, which rendered the ministry of its office even to the Magi themselves as they sought Christ, until, by going ahead of them, it led them to the very place where the Word of God was an infant.* [Margin: St Chrysologus.] Therefore, connecting the first argument with this third one, *St Chrysologus* says in Sermon 156: *Nor is he driven by the course of the Star, but he himself drives the Star's course; he so directs its course through the heaven, so governs its gait, so tempers its way, that it serves the step of the Magi and is sent to suit it. For when the Magus walks, the Star walks; when the Magus sits, the Star stands; when the Magus sleeps, the Star keeps watch. So the Magus perceives that those who share an equal condition of living share also an equal necessity of serving; and he no longer believes the Star a God, but judges it a fellow-servant, which he sees bound over in this way to his own services.* And no less acutely in Sermon 157: *This star is the minister of the way, not of life; the companion of the Magi, not the kinswoman of Christ; not the mistress of the Ruler, but the little handmaid of the servants.* Similar things are noted by *St Gregory of Nyssa* in the Sermon on the holy Nativity of Christ; by *Theophylact* and *Euthymius* on chapter 2 of Matthew, disputing against the casters of nativities; and by *Abulensis* on chapter 2 of Matthew, question 17.

V. [Margin: 4th argument, from the place of the star.] The *fourth* argument is taken from the place. For there was *a Star in the air, a Star on earth, a Sun in the manger*, as Blessed Peter Damian says, and as we have already shown in chapter 19, number 2. Accordingly Abulensis, on chapter 2 of Matthew, question 17, argues as follows. The star showing the nativity of Christ was not in the heaven but near the earth — a star of a kind by which the astrologers indicate nothing; indeed, astrologers never saw such a one, because it appeared only at the nativity of Christ, to lead the Magi to Bethlehem. Therefore this was

no occasion for thinking, against Christ, that his deeds came about naturally; rather it was a firm argument of his Deity. Thus far Abulensis.

VI. [Margin: 5th argument, from the singularity of the new star.] The *fifth* argument is from the singularity and novelty of the star, which appeared apart from the other stars and Planets, through whose company or mutual aspects the astrologers are accustomed to form a conjecture about the future. For Abulensis, on chapter 2 of Matthew, question 17, holds that if around the nativity of Christ, together with this star, some notable conjunction of the Planets had occurred in conspicuous places of the heaven, the Magi might perhaps have foreknown from it, by natural means, the Nativity or the deeds of Christ. But since nothing of the kind appeared then, and this star was seen near the earth apart from every other star, it could not give the Magi an occasion for judging such things about Christ by natural means — especially since no experience of such a star had gone before on which they could rely, as Cornelius a Lapide notes on chapter 2 of Matthew, verse 2.

VII. [Margin: 6th argument, from the signification, which presupposes the nativity.] The *sixth* argument is drawn from the Method that the casters of nativities use. For they presuppose that the moment of the child's birth is already known, and for that moment they investigate the Horoscope, so as to divine from it the other events that will befall the man; but they do not attempt to divine from the aspect of the stars that the one about whom they are concerned, or about whom they are questioned, is going to be born or is already born. *St Thomas* likewise uses this argument, Part 3, question 36, article 5, reply to 3, and took it from *St Chrysostom*, Homily 6 on Matthew. In that place, when he had said: *If Christ was born according to the law of the stars, how did he dissolve Astrology, destroy fate, take away this whole error entirely, and overthrow the whole workshop of this most vain art?*, after a few words he adds: *For it does not belong to the art of Astrology to recognize from the Stars those who are being born; on the contrary, it learns of the hour or point of those being born, and from that predicts what is going to befall them.* Therefore, since this star announced to the Magi one already born, they could not foresee the nativity of Christ from it by the astrological art.

VIII. [Margin: 7th argument, from the supernatural object.] The *seventh* argument we take from the supernatural object signified by this star, which involved many miracles: namely the Incarnation of the Word, a man to be born of a Virgin, and many other things done wonderfully at that time concerning Christ's body and soul, and afterwards done or to be done through Christ. But Astrology cannot exceed the limits of natural effects or events, since it does not reach with certainty even these. Our *Cornelius a Lapide* touches on this argument on chapter 2 of Matthew, verse 2.

IX. Finally, the *eighth* argument is to be sought from the supernatural manner by which the Magi learned from this star

[Margin: 8th argument, from the supernatural manner of knowing.] that Christ had been born. This manner was twofold: one depended on knowledge

of the prophecy of Balaam, which was certainly not natural, nor contained within the natural object of the Genethliac Art; the other proceeded from the inner revelation and inspiration of the Holy Spirit. Both of these remain sufficiently proved from the Fathers by what we said in the preceding chapter, numbers 15 and 16. [Margin: St Chrysologus.] For that reason, various sayings of *St Chrysologus* in Sermon 156 hold good of knowledge of this kind through this star: *Not deceiving by art, but resting on truth; not gathered by numbers, but acquired by virtues; not the science of the Astrologer, but the foreknowledge of the Maker; not by arithmetical reckoning, but by divine sanction; by heavenly provision, not by Chaldean curiosity; not by magic art, but by Jewish prophecy.* Nor does *St Augustine* stand in the way of this argument, in Book 3 *On the Wonders of Holy Scripture*, chapter 4 — if indeed the work is St Augustine's — where he seems obscurely to concede that the Magi could have attempted that knowledge by the art of Astrology; [Margin: St Jerome explained, and the objection solved.] nor does *St Jerome*, on chapter 47 of Isaiah, when he says: *The Magi came from the East, saying that they had seen the star of the Lord, either from the science of their art or from the prophecy of their prophet Balaam.* For he speaks only disjunctively, and in the first member he speaks to suit the understanding of the common people, or with regard to that remote disposition by which, through the use of Astrology, they could judge in general that the star portended something great; but he does not speak of the particular and determinate nativity of Christ, for this they learned partly from the prophecy of Balaam, partly from divine illumination. So, together with the holy Fathers, teach *Salmeron* [Alfonso Salmerón], volume 2, tractate 39; *Abulensis*, question 17 on chapter 2 of Matthew; *Thomas Beauxamis* in the *Gospel Harmony*, from page 99; *Suarez* on Part 3, disputation 14, section 6; *Cornelius a Lapide* on chapter 2 of Matthew; and others cited by them.

De illis & contra illos, qui Geneſim & Natalitium Thema Chriſti auſi ſunt erigere, ac de Chriſto ex legibus Aſtrologiæ iudicium ferre.

On those, and against those, who dared to erect the nativity and natal horoscope of Christ, and to pass judgement on Christ from the laws of Astrology.

X. We have now seen the decisions and Sanctions of the Fathers, which ought certainly to have moved every pious man so that, even if he knew the moment of the Nativity of Christ the Lord our King with more than certainty, and even if most splendid syzygies of the stars and concurrences of aspects had occurred at that moment, he would still think that he must refrain from passing judgement on the admirable prerogatives and works of Christ — lest he either offend pious ears, or offer the sect of the casters of nativities, which begs reputation from every quarter beyond measure to spend on the emptiness of its art, so noble a handle for erring and so specious an opportunity for soothsaying. But, alas, not a few have been found who tried to found a tower of Babylon in the very cave of the Lord's most holy Manger. And what kind of men, I ask? For I am suffused with a blush even at their purple, men who themselves stained their own purple with this blot of vanity: [Margin: 3rd error, of those

who configured the horoscope of the nativity of Christ. Cusanus. Alliacensis. Gauricus. Bacchon.] namely two Cardinals, in other respects most learned, *Nicolaus Cusanus* [Nikolaus von Kues] and *Petrus de Alliaco* [Pierre d'Ailly], Cardinal and Archbishop of Cambrai, in question 30 on Genesis and in the book *On Laws and Sects*. *Lucas Gauricus* [Luca Gaurico] dared the same in his *New Ecclesiastical Calendar*, page 25; he also brings forward the Cambrai cardinal's figure, or planetary constitution, as agreeing with the Nativity of Christ; and, as reported by him, *Rogerius Bacchon* [Roger Bacon] did the same, and finally *Hieronymus Cardanus* [Girolamo Cardano] in Book 2 of Ptolemy *On Judgements*, page 163. [Margin: Cardanus. Albumasar. Albertus Magnus.] In this vain curiosity, however, *Albumasar* [Abū Maʿshar] went before them, in his *Greater Introduction*, tractate 6, from which *Albertus Magnus* drew, in the book of the *Mirror*, the things we shall presently report. But against Abū Maʿshar and Alliacensis, in this horoscope of Christ, *Io. Picus Mirandulanus* [Giovanni Pico della Mirandola] rose up sharply, Book 5 *Against the Astrologers*, chapter 14, and *Sixtus Senensis* [Sisto da Siena] in his *Bibliotheca sancta*, Book 6, Annotation 10; and some things, though only in passing, are indicated by *Salmeron*, volume 2, tractate 39, page 357; *Alexander de Angelis* [Alessandro de Angelis], Book 4 *Against the Astrologers*, chapter 24; *Suarez*, Part 3, disputation 14, section 6; *Cornelius a Lapide* on chapter 2 of Matthew, verse 2; and *Tycho*, volume 1, page 326. But let us begin with Abū Maʿshar.

XI. [Margin: The opinion of Abū Maʿshar and Albertus Magnus on the Ascendant of Christ.] The words of Abū Maʿshar, as reported by Albertus Magnus, Sisto da Siena and Salmeron, are these: *There rises in the first face of that Sign a Virgin, beautiful and honourable, holding two ears of grain in her hand; and she nurses a boy, and a certain nation calls this boy Jesus; and with her rises the star of the Virgin.* From these words, and from the calculation of I know not whom, or from I know not what tables, Albertus Magnus in the *Mirror* — if indeed it is by Albertus (for learned men, says Salmeron, and Sisto too, deny this) — deduced that the Lord Jesus Christ was born under the ascendant of Virgo, namely with ♍ 8° 30′ ascending at the point of the nativity, as he himself computes. Then he adds: *Not that the most longed-for of those born was subject to the motion of the stars or to their judgement, he who had created the Stars themselves; but because, when he stretched out the heavens like a skin, forming the book of the universe, he did not wish to be lacking from its letters any of the things which, according to his providence, are written in the book of eternity — even that most elegant thing in nature, that he would be born of a Virgin; so that by this it should indeed be intimated that he was a man of flesh, and true, who was not born naturally. Not that the figure of the heaven was the cause why he was born, but rather its signification; indeed, and more truly than true, he himself was the cause why the manner of his wonderful nativity was signified by the heaven.* [Margin: Refutation of this opinion.] But not even so will whoever is the author of that book escape the censure of rashness or of vanity. For if before Christ the Lord some other person was born under that ascendant, namely under the 8th

degree or some other degree of Virgo, either he was born of a virgin — and this is false, for it would detract from the singular privilege that both Christ and his immaculate Mother had, of whom the Fathers and the Church sing in the Lauds of the Nativity of the Lord, antiphon 2: *She who gave birth bore the King whose name is eternal, having the joys of a mother with the honour of virginity: she is seen to have had none like her before, nor to have one to follow, alleluia.* And this is entirely Catholic dogma: that it was granted to the sole and only Virgin MARY to be a mother, and to this mother alone to be a Virgin before giving birth, in giving birth and after giving birth. As a signal miracle granted, or to be granted, to no other, the holy Fathers and the interpreters of the sacred codex everywhere proclaim and venerate the fruitfulness of motherhood together with the intactness of Virginity, especially at that oracle of Isaiah, chapter 7: *Therefore the Lord himself will give you a sign: Behold, a VIRGIN shall conceive and bear a son, and his name shall be called Emmanuel.* This sign would certainly not have been infallible, and notable above the rest, unless it had been unique and singular. But if no one born before Christ under the degree of Virgo was so born as to be born of a Virgin, then that Astrological rule likewise could be founded on no experience, and accordingly could have no rationale of the art in this case; nor could God, through that point of the heaven taken precisely and by itself, have signified determinately to astrologers, as if by some character, that the one born under that horoscope would be born of a Virgin, since he had decreed from eternity that no one else should be so born. I pass over now what *St Augustine* argued most eloquently, in Book 5 of *The City of God*, chapter 1, against that subterfuge of the astrologers by which they say that the parts of the Zodiac and the stars are not indeed causes, but signs and characters of future things; for our business now is not to show the fallacy of judicial Astrology in general.

XII. [Margin: The opinion of Petrus Alliacensis on the nativity of Christ.] After Albertus Magnus, or some other spurious author of that *Mirror*, Petrus Alliacensis — Archbishop of Cambrai, Cardinal of the Holy Roman Church, once Chancellor of the University of Paris, and teacher of Ioannes Gerson [Jean Gerson] — flourished and was distinguished at the Council of Constance in the year of the Lord 1416, 136 years after the death of Albertus Magnus. In question 30 on Genesis and in the book *On Laws and Sects*, he affirms that the Magi, as men most skilled in Astrology, could have foreknown from the position of the stars the future nativity and life of Christ, though not with the certainty with which they afterwards knew of Christ's rising when the New star showed it beforehand. For although, he says, the conception and Nativity of Christ surpass in most respects all the powers of the heavens and all the faculties of nature, yet in some respects the natures of the orbs and of the stars, serving their lord like handmaids, supplied the same Christ abundantly at his birth with as many friendly lights and benign influences as they had received from Christ, God. Accordingly he says that it was possible for the Magi, besides this appearance of the star, to have foreknown by two other indications that

a man illustrious in religion, empire and glory would be born. First, from a certain great conjunction of Jupiter and Saturn, which came together in the sixth year before Christ in the sign of Cancer, all the astronomers of those times predicting that a great change of religion was portended. Then, from the observation of the configuration of the heavens that Christ's nativity itself had. That nativity fell in the 42nd year of Octavius Augustus, on the eighth day before the Kalends of January [December 25], before the middle of the night. In it the Horoscope was the eighth part of Virgo, which signifies a change of religion; Saturn stood at the summit of the heavens, the Sun held the lowest point of the heavens, and the other planets were disposed in a certain order. These are precisely the words of Pierre d'Ailly, although here they are not marked in cursive type, as the saying goes. He sets the figure and configuration of the stars for the horizon of Jerusalem, to which he assigns a latitude, or altitude of the pole, of 36°, and for the 24th day of December at $10^h\ 4^m$ after noon, that is, $1^h\ 56^m$ before midnight. Luca Gaurico transferred this into his *Calendar*, page 26, more correctly than Sixtus Senensis did; and its characters and notes are as follows.

Christ's nativity theme from Pierre d'Ailly, corrected by Gaurico.

House	Beginning of the house	Planet	Place of the planet	Planet	House of the planet
1	♍ 7° 40′	☉	♒ 2° 46′	☉	4
2	♎ 3° 25′	☾	♉ 2° 2′	☾	9
3	♏ 2° 0′	☊ ☾	♐ 9° 3′	☊	4
4	♐ 5° 48′	♅ ☾	♊ 9° 3′	♅	10
5	♒ 10° 52′	♄ ℞	♊ 14° 10′	♄	10
6	♓ 11° 53′	♃	♎ 7° 41′	♃	2
7	♓ 7° 40′	♂	♈ 10° 22′	♂	8
8	♈ 3° 25′	♀	♓ 18° 43′	♀	6
9	♉ 2° 0′	☿	♒ 6° 50′	☿	4
10	♊ 5° 48′	Part of Fortune	♉ 7° 39′	(roundel of dots)	9
11	♋ 10° 52′				
12	♌ 11° 53′				

XIII. In this nativity scheme, however, besides the objections we shall raise a little further on against all such themes, the following faults are noted in particular. [Margin: Faults of this theme.] First, as *Pico* observes (book 5, chapter 14), the Lord JESUS was not born with Virgo ascending. Granting the tables of the astronomers, that could not have happened on the horizon of Bethlehem except about two hours before the midnight preceding December 25; and yet by the tradition of the Church he was born either at midnight, as St Anselm holds in the *Elucidarium*, and Pico too, [Margin: The hour of Christ's nativity.] or a little after midnight, so that the Lord's nativity belongs to the 25th day of December rather than to the 24th. That is the view of *Caietanus* [Cajetan] on chapter 2 of Luke, of *Baronius* [Cesare Baronio] in the *Apparatus*

to the *Annales*, of *Cornelius a Lapide* on chapter 2 of Luke, verse 8, and of *Suarez* on Part 3, question 35, disputation 12, section 4. Suarez adds that the nearer to the point of midnight the Lord is asserted to have been born — provided he is said to have been born after it — the better this agrees with those words of Wisdom 18: *While quiet silence held all things, and the night was in the middle of its course, your almighty word leapt down from heaven, from the royal seats, a stern warrior, into the midst of the land of destruction.* With very few changes from another version, the Church has adapted these words to this night.

Petrus Blesensis [Pierre de Blois], however, in Sermon 6 on the Nativity of the Lord, expounds that passage of Wisdom on the Lord's nativity by saying that he was born in the *conticinium* of the night, which is after cockcrow and just before dawn. For that is how *Macrobius* (book 1, chapter 3) and *Censorinus* (*De die natali*, chapter 10) take *conticinium*: namely, the time when the cocks fall silent and men are at rest. And *St Augustine*, on Psalm 109, and *Tertullian*, in book 5 *Against Marcion*, chapter 9, confirm that same hour of Christ's nativity, a little before dawn, from those words of Psalm 109: *From the womb, before the day star, I begot you.* And *Isichius*, as cited by Baronius, says that he was born at hour 3 — understand: after midnight, that is, at the beginning of the third watch of the night. Such were the watches the shepherds were keeping, to whom the angel appeared when the Lord was born, as is related in Luke 2. Granted that *Anastasius Nicenus*, a bishop, in his book of questions on Scripture, question 92, says that he was born at hour 7 — which Suarez interprets rather of the morning hour — and granted that the antiphon the Church sings on the vigil of the Nativity seems to favour Anastasius: *When the Sun has risen from heaven, you will see the King of kings proceeding from the Father, like a bridegroom from his chamber.* Nevertheless the Church, by celebrating the third Mass at dawn, indicates that this business was already accomplished by then, and it is certain that Christ was born at night. For where St Luke said, *And she brought forth her firstborn son, etc.*, he at once added, *And there were shepherds in the same region, watching and keeping the watches of the night over their flock.* Those words, then, *when the Sun has risen*, can be understood of the Sun having already passed midnight, in the way that in the hymn of Prime, which is very often sung before sunrise, *Now that the star of light has risen* is sung without falsehood.

Further, it is clear from what has been said that the moment at which Christ was born is uncertain — something GOD perhaps willed to remain hidden, so that, if by nothing else, by this at least the foundation of genethliacal construction might be withdrawn from the astrologers. It is clear, too, that it is more probable that his birth took place either at midnight or after midnight before sunrise, but in no way probable that it took place before midnight. For no one has followed Anastasius Sinaita, who says in book 7 of the *Hexaemeron* that he was born at evening — unless by evening he understood the whole night and any part of the night, according to that phrase of Genesis 1: *And there was evening and morning, one day.* So much for the first and chief fault of this

theme. In it, moreover, d'Ailly assumed the altitude of the pole at Jerusalem to be 36°, whereas it is only 32° 10′, as Gaurico too assumes.

XIV. Accordingly *Luca Gaurico*, on page 25 of his *New Calendar*, assuming the altitude of the pole at Jerusalem to be 32° and the longitude from the Fortunate Isles 66°, computed from the Alphonsine Tables the configuration of the heavens for the year of the World 5200, for December 24 and the 12th hour after noon of that day, which was the point of midnight. [Margin: Gaurico's nativity theme for Christ.] He drew up the nativity scheme of Christ, in which the cusp of the first house — the Ascendant and Horoscope — is not Virgo 8° but Libra 2° 35′. The rest stand as in the following small table.

Christ's nativity theme according to Gaurico.

House	Beginning of the house	Planet	Place of the planet	Planet	House of the planet	Planet	Planet	As-pect
1	♎ 2° 35′	☉	♍ 2° 52′	☉	4	♄	♂	✶
2	♎ 28° 37′	☾	♉ 2° 53′	☾	8	♄	♀	△
3	♏ 28° 32′	♄	♊ 14° 10′	♄	9	♃	♂	☍
4	♍ 2° 45′	♃	♎ 7° 41′	♃	1	♃	☿	□
5	♒ 6° 54′	♂	♈ 10° 24′	♂	7	♂	☿	□
6	♓ 6° 25′	♀	♒ 18° 43′	♀	5	☉	☿	☌
7	♈ 2° 35′	☿	♍ 6° 52′	☿	4	☉	☾	△
8	♈ 28° 37′	Part of Fortune	♍ 2° 37′	(roundel of dots)	4	☿	☾	△
9	♉ 28° 32′							
10	♋ 2° 45′							
11	♌ 6° 54′							
12	♍ 6° 25′							

XV. But *Girolamo Cardano*, commenting on book 2 of Ptolemy's *De astrorum iudiciis*, text 54 — where Ptolemy, speaking of hairy stars, had said among other things: *When they are matutine and have shone for a long time, they will signify swiftness; if vespertine, slowness* — takes occasion from these and other words to propose the nativity theme of Christ as the greatest and most notable example of the precepts he had set out at length in expounding that text. I shall report, almost in his own words, what he teaches there, partly rightly and partly not. First, then, he says that so many and such wonderful things shine forth in the nativity of Jesus Christ that, if one had to rely on natural reasons alone, the nature of Christ would have been as admirable as could be devised from the concourse of all the heavens; [Margin: Praises of Christ and of the Christian law, from Cardano.] and that, naturally, our law is a law of piety, justice, faith, simplicity and charity, excellently established, and will have no end except after the return of the ecliptics. Then he declares as follows: *Do not, however, believe that I mean to say that either the divinity in Christ, or his miracles, or the holiness of his life, or the promulgation of his law depends on the stars. Rather, just as nature adorned him with the best temperament, with beauty of body, perpetual health and gravity of countenance — all of which are gathered almost entirely from*

the testimony of Josephus in his book On the Jewish War — so also God, the Best and glorious, adorned his nativity with the best and an admirable configuration of the stars. Had Cardano kept within the natural endowments of the body, many of his statements might perhaps be tolerated. But not content with these, he adds: *Not everything in his geniture would have been so singular, magnificent, glorious and worthy of so great a concourse, and moreover so congruent with everything that followed — the holiness of his life, the gravity of his conduct, his wisdom, his persecution, the promulgation of the best law, the majesty and concourse of peoples, and finally his death and the time of his death — that nothing more exact could be devised.* Relying on this confidence, then, Cardano judged that this nativity should be published, as though complying with the divine will. He had constructed it twenty years and more before, but had not dared to publish it, out of religious scruple, lest he should seem to co-opt so great a majesty of light into the number of the others. Now, if anyone wishes to know that position of the stars and planets — to reject it rather than to approve it — for the 12th hour after noon of December 24 and an altitude of the pole of 32°, here is its synopsis in the following small table.

Christ's nativity theme from Cardano.

House	Beginning of the house	Planet	Place of the planet	Planet	House of the planet
1	♎ 2° 43′	☉	♑ 2° 53′	☉	4
2	♏ 3° 0′	☾	♈ 28° 5′	☾	7
3	♐ 3° 0′	♄	♊ 14° 17′	♄	9
4	♑ 2° 53′	♃	♎ 8° 3′	♃	1
5	♒ 3° 0′	♂	♈ 9° 56′	♂	7
6	♓ 3° 0′	♀	♒ 18° 36′	♀	5
7	♈ 3° 43′	☿	♑ 6° 38′	☿	4
8	♉ 3° 0′	(roundel of dots)	♑ 27° 55′	(roundel of dots)	2
9	♊ 3° 0′				
10	♋ 2° 53′				
11	♌ 3° 0′				
12	♍ 3° 0′				

Cardano goes on to say that there has been no more illustrious law in the whole world than Christ's, whether you consider its extent, which has embraced the whole world, or its duration, by which it had by then persisted for 1,520 years, or that it was promulgated against the Caesars, the lords of the world, or — what is greater than all — against vices. For it would have been easy for Mahomet to drag men prone to vice along with him to destruction, by attaching laws of laxity to them as if with a hook; *but to fight against the inclination of nature, and against human levity and greed — this alone is divine and the gift of God.* Having laid this down, he descends to the particular prerogatives of this nativity, drawn from the configuration of the stars. I would not be reluctant to report them, if it were permitted; but they are full of vanity, contrary to the

decrees of the Church and the sanctions of the saints, and put forward under the appearance of piety with too little piety or too little prudence. Such are these: that the Christian religion will last at least 36,000 years, because at that moment there was a conjunction of the heads of Libra of the ninth and the eighth orb at the intersection of the ecliptics; that the most brilliant comet — for so he calls the new star of the Magi — signifies the disturbance of the whole world and the most celebrated name of Christ; and that Jupiter in the Ascendant signifies wisdom, sweetness and eloquence, by force of which he disputed in the temple at twelve years of age. Finally, he affirms that from the position of the houses and planets one could have foreknown Christ's wisdom, his majesty, his endurance of evils, his zeal for overturning the law in which he was born — that is, the Mosaic — his poverty, his flight, his public but glorious death, and things like these.

XVI. But Tycho rightly says this in volume 1 of the *Progymnasmata*, page 325, speaking of the star of the Magi: [Margin: Tycho's censure of Cardano.] *There were indeed some who did not hesitate to assert that this star which appeared to the Magi was a comet. Among them is Cardano, who places it in the Ascendant for CHRIST at his birth, as though it were the same as what the Evangelist calls the star seen by the Magi in the East. But he and the rest of his followers assert this more impiously than with just reason, however they may in the end excuse it — to say nothing of the rest (for I am ashamed to report it) that he inserted on this matter into his astrological commentaries.*

It is not repugnant to the Faith to assert that Christ had either Virgo or Libra in the Horoscope, or Ascendant, together with splendid and benign aspects of the stars, as Salmeron teaches in volume 2, tractate 39, page 357, column 1, with *Cornelius a Lapide* subscribing, on chapter 2 of Matthew. [Margin: Salmeron's censure.] Yet, as the same Salmeron asserts in the same place, to wish to predict from them — whether as predominant causes or as infallible signs — things that depend on the freedom of God and of men, or that are supernatural, is foreign to the sacred Scriptures, and was condemned by the Church in the Priscillianists and others, and most recently by the holy Synod of Trent, at which he himself had been present. Suarez, moreover, on Part 3, volume 2, disputation 14, section 16, says that it is heretical to subject human freedom to the fatal necessity of the stars: [Margin: Suarez's censure.] *And it is much more absurd,* he says, *and more* intolenabilius [?], *to think this about the divine works and the supernatural mysteries, the order to which Christ's conception and nativity belong.*

For the birth of Christ from a Virgin; the most perfect organization of his most sacred body in the first instant of conception; the very many endowments of body and soul; the hypostatic union of the two natures, human with divine, in one and the same Person of the divine Word in the same first instant; the divine knowledge, beatific and infused of itself; the power of all miracles and of the supreme supernatural law; and the highest holiness, with the incapacity to sin, with which the Holy of Holies was anointed — [Margin: Our censure, and argument 1.] these were wholly the work of the Holy Spirit. No natural

disposition could contribute anything to them that would include any connatural claim or exigency, as I assume from what we have said in the treatise *On Grace* against the Pelagians and Semi-Pelagians. Next, either no one has ever had such a nativity, or someone has. If you say someone has had it, you are a blasphemer; [Margin: Argument 2.] for no one has had — I will not say all, but not even one — of those singular prerogatives that we have just pointed out in Christ, namely birth from a Virgin Mother, etc., granted that someone may have received by divine gift some small portion of some heavenly gifts. If no one has had it, then the rules of astrology could not have been founded on any experience, so that these things about Christ could be foreknown from the aspect of the stars. Further, it is most certain that judicial astrology, in the part in which it tries to predict, from the position of the stars, with certainty or with probability, future contingents that presuppose the freedom of God and of men, [Margin: Argument 3.] is opposed to the divine precepts and to the decrees of the Church, and so to Christ himself, who through his Church has so often condemned the casters of nativities. It is therefore not reasonable to believe that God so ordered the concourse of the stars that he would kindle the light for the Word to be made flesh from those half-dead sparks, and fetch splendour for that sacrosanct Majesty, as for the Sun, from those little fires. Otherwise St Chrysostom would exclaim here again, in Homily 6 on Matthew: *If Christ was born according to the law of the stars, how did he dissolve astrology and destroy fate, remove the whole error utterly, and overturn the entire workshop of this most vain art?* What of the fact that to this end too, unless I am mistaken, un- certain he willed the year of his nativity to remain even now [Margin: Argument 4.] (as will be clear from the opinions of all who have written on this matter, collected and weighed in book 3 of our *Chronology*), so that he might withdraw from the casters of nativities every foundation for building a nativity theme and for fitting it to the Nativity of his Son? Nor indeed did he who came to condemn the pomps of this world, who shrank from all pride of birthday display, and who sought out everything humble and most abject for his nativity, aspire to the nobility of a natural nativity drawn from the configuration of the stars. [Margin: Argument 5.] Rather, he either neglected it or concealed it, just as if he then had no stars serving him except one, new and soon to perish. In this he showed us a certain example of humility and poverty, as *St Peter Chrysologus* observes with most acute piety in Sermon 156. [Margin: St Chrysologus.] For, explaining the words *We have seen his star*, he draws out this point too among many: *Truly, as the Apostle said, though he was rich, he became poor: though he was rich in his Godhead, he becomes poor in our flesh; and he began to have one star — he who made the whole creation, and has it and holds it.* As for the arguments of Pico, book 5, chapter 14, against the astrologers who chatter about the nativity theme of Christ — arguments drawn from the astrologers' own rules — we have decided not to copy them out here, lest I should become too long-winded, or we should seem to prick with lighter goads those whom we judge must be slain and run through with more solid and stronger weapons.

CAPVT XX.

De Alijs Authoribus, qui Stella Magorum abuſi ſunt.

On other authors who have misused the star of the Magi.

XVII. Among the others who have thought and written about this star of the Magi less correctly than they ought, the first to present himself is *Cornelius Gemma*, in his writing on the star of Cassiopeia and in his book *De divinis Mundi characterismis*. [Margin: Cornelius Gemma's error about the star of the Magi.] He affirmed that this star too was similar to the new star seen in Cassiopeia in the year of the Lord 1572, and very high above the Earth; because, he says, if it had been in the air above Judaea, it could not have been seen in Persia, and it would rather have had the appearance of an ignited exhalation than of a star. But he also invents I know not what about the apparition of angels and of God in the form of a star, and about an ascent and descent and a circular return proper to divine minds, fabricated from Platonic fables — things which even *Tycho* himself, volume 1, page 564, thinks unworthy of being raked up again. He also adduces Nicephorus as favouring his fictions; but how wrongly will soon be made plain. Tycho, in volume 1, pages 555 and 564, criticizes him more than once, and not undeservedly. Tycho teaches that the star of the Magi had nothing in common with the new star of Cassiopeia except the appearance of a star; that it appeared to the Magi not in Judaea but in Persia, or in some other region lying to the east of Judaea itself; and that it led the Magi all the way to the house in which the child Christ was — which could by no means have happened had it not been in a place close to the Earth.

Further, Nicephorus Callistus, who flourished around the 600th year of the Lord, in book 1 of his *Ecclesiastical History*, chapter 13, [Margin: Nicephorus's opinion on the star and the Magi.] speaks thus of the Magi, whom he calls Persians, and of their star: *For they had seen a star in their own region — not one of those that from the beginning of things have been fixed to the firmament of heaven, nor one of those that by a prodigy, and as if by a riddle, foretell the successions of kings, and are named, according to the variety of their forms, casks, bearded stars, beams, javelins and comets; the origin of all of which, from exhalations, takes its substance above the air.* And shortly after: *They therefore did not see a star of that kind, but one quite new and unusual, inclining towards the Earth and shining very brightly, very like the other stars of heaven, and conspicuous and apparent to none but those who had devoted their efforts to knowing the stars.* Gemma ought therefore to have noted those words, *inclining towards the Earth*. This at least must be understood of the time when, after they had left Jerusalem, it pointed out to them the cave of the Saviour; otherwise it was so like the stars in form that to those unskilled in astronomy it could be thought one of the ancient stars of the first magnitude, whereas to the Magi, who knew the ancient stars and had counted them, it appeared plainly new. Nicephorus goes on, and after saying that they were greatly helped by the oracle of Balaam, he adds: *But above all, since GOD himself was rousing their minds to this, they therefore understood that by the providence of CHRIST, the supreme King of all, now born, the star was being moved from Persia towards Judaea just like some animate force participating*

in intelligence; and, using it as a guide for the way, they followed behind it, setting everything else aside. Here he by no means says that it was absolutely animate, or that some divine Intelligence slipped into their minds through that star; rather, he spoke metaphorically, or at most he thought that the motion of that star came from some Intelligence.

XVIII. In the second place we strike against *Théodore de Bèze*, the most wicked follower of Calvin. Tycho, in volume 1 of the *Progymnasmata*, page 327, calls him *a man noble in birth and learning, distinguished and excellent, who, if anyone in this age, has deserved splendidly of letters both sacred and philosophical*; in doing so Tycho deservedly renders himself suspect of Calvinism, [Margin: Tycho suspect of Calvinism and of Lutheranism alike.] although *Ioannes Heckius*, perhaps on other grounds and from more intimate knowledge, calls him an outright Calvinist in his book on the new star, page 20. Moreover, the same Tycho, in volume 1, page 712, pours himself out in praises of David Chytraeus and of Philipp Melanchthon — a most pestilent man, and, as his surname sounds, of the blackest faith — and extols them to the skies even in theological matters; and on page 777 he champions Luther with excessive zeal, regrets that he himself and the followers of Luther were reproached by Theodor Graminaeus, and says: *I wished at least to point this out in passing, so that it might be clear how unjustly and maliciously Graminaeus, even on a frivolous occasion of no moment, censures and cavils at Luther and his fellow-tribesmen.* In all this he shows himself a supporter of Luther no less than of Calvin. Nor did Tycho clear himself sufficiently of this suspicion by appending that protestation: [Margin: Tycho's protestation insufficient.] *Nor do I say this because I wish to interpose a judgement on the controversies of religions: let him judge them who alone knows how to distinguish the true from the false, to search the hearts of all, and to decide all things without prejudice.* For it is the part of a Catholic man not to praise heresiarchs in matters of religion or of sacred letters, but rather to depress their authority as far as can be done consistently with the truth. And then, why does he appeal to God alone in controversies of faith, as though in the Church there were no visible judge of these controversies, and God alone, and not the supreme Roman Pontiff and Vicar of Christ, were their infallible definer? But let this have been said by us in passing.

Tycho, then, in volume 1, page 327, as I said, reports the opinion of Bèze, who says that the new star of Cassiopeia of the year 1572 was a comet, and indeed the very same one that once led the Magi to Christ and that now shines before the second coming of Christ and the end of the World — granted that Tycho says Bèze did not affirm this seriously, but composed it with poetic playfulness. For Bèze played thus, boldly and with little piety: [Margin: Bèze's verses on the star of the year 1572.]

This new comet, with no furious hair, and radiant, whose splendour shines with pure fire — what it portends to the lands, that GOD of gods knows, and the fates will show it in their own time. But if human minds can praescissere [?] *anything, it is no sin for me to search out such signs: this is he who once led the Magi from the eastern*

world to the little city of David; and the same that shone before him at his birth, now returned, announces: Behold, GOD is here again, returning. To him, then, O happy throng of the pious, give applause; but you, bloody Herod, fear.

That the star of the Magi was not a comet is, however, clear enough from what was said in chapter 19, number 3; and no one fails to see that it cannot be asserted to have been the same as the new star of the year 1572 without the mark of rashness and of profane novelty, since that would be without the foundation of any authority or probable reason. Far more cautious was *Wilhelm, Landgrave of Hesse*, who compared the new star of the year 1572 with the star of the Magi in this respect, that each foretold the coming of Christ, but nevertheless said that it was different from it. [Margin: The Landgrave of Hesse's opinion on the new star of the year 1572.] For his words, in a letter of 1572 December 14 written to Caspar Peucer and reported by Tycho in volume 1, page 600, are these: *We cannot conclude that it is a comet, because of its great brightness and because it lacks motion — for it has so far stood still at one point of the eighth sphere — and then because it is set so high, outside the elementary region. Nor can we easily assert that God created some recent star, since nothing of the kind has been heard of since the founding of the world.* Understand this of a star properly so called, which is to be numbered among the Fixed Stars and is to last with them for ever afterwards. For he adds: *Moreover, in our judgement, its size and colour are falling away somewhat, little by little, so that it seems likely that it will soon come to an end.* He was writing this, as I said, on 1572 December 14; yet the new star did not vanish until 1574. He concludes as follows: *So far, then, as we are able to judge, we consider it a remarkable miracle, and indeed one of the number of those that are to precede the last day. For just as the Lord God willed that the first coming of his Son, our Lord Christ, should be signified beforehand by a star and announced to the Magi, so we hope that by this one too He will foretell the last coming of the Lord Christ.*

XIX. There is also an opinion, of I know not what delay [?], held by *Andreas Rosa* Suingfurdensis, physician and astrologer. As reported in *Tycho*, *Progymnasmata* vol. 1 p. 783, in his prognostication for the year 1574, speaking of the new star of 1572, which lasted until 1574, he asserted that miracles of this kind come forth from heaven roughly every two thousand years, and agree in threefold fashion with the ages of the world according to the saying of Elias the Talmudist. Thus before the Flood something of the kind appeared, or at least the pillar of fire shone forth before the Exodus of the Israelites from Egypt; then, about four thousand years after the founding of the world, a star appeared to the Magi in the East — that is, as he interprets it, near the beginning of the Earth — to show the beginning of salvation; and finally, in 1572, a new star appeared near the arctic pole to foreshow the end of the world, as though the revolution of the heavens about the poles were to cease not long after. But these stars were not distributed at intervals of two thousand years; nothing is established about a star seen before the Flood; and the region of the Magi was not the beginning of the Earth, except to the ignorant common people,

who think that the limit of the eastern horizon is the beginning of the Earth. [Margin: The opinion of Andreas Rosa on the star of the Magi and on the new star of 1572.]

XX. Finally we must contend with *Kepler*. In his book on the new star in Serpentarius of 1604, chapter 27, he denies that the star in Serpentarius was the offspring of the great conjunction begun in 1603 and completed in 1604, for the reasons we have already set out in chapter 18, number 5; but he nevertheless thinks that it was associated by God with that conjunction, by a definite design directed to the salvation of men, so as to signify something great to them. On the same reasoning he holds, in chapter 26 and in his *Silva Chronologica*, that the star of the Magi was not, indeed, produced from the greatest conjunction of Saturn, Jupiter and Mars by God using natural causes to that end; but that God nevertheless, to accommodate himself for a while to the rules of the Chaldeans — who expected some notable change of affairs at the transit of the greatest conjunctions from the watery trigon to the fiery trigon — kindled that star at the very moment of that greatest conjunction, so that the Magi, who were watching that greatest conjunction, might more easily catch sight of the new star; and that He so ordered the times of that greatest conjunction that it should serve this star and His Son, soon to appear in the flesh. [Margin: Kepler's opinion of new stars connected with the great conjunction.]

Now that conjunction took place in Julian year 39, and was indeed triple, one of its three falling in December, and it had remarkable astronomical characters, which we have already disclosed in Book 7, Section 5, chapter 10, number 3; and that year preceded the first year of the common Christian Era by 6 whole years. So, in order to establish that the star of the Magi was kindled in that year 39 at the moment of the greatest conjunction, he chose two positions in sacred chronology: that the star of the Magi appeared two years before the Nativity of Christ, and that the common Christian Era, which the Church and the Roman empire use everywhere, falls short by 4 years. Christ would thus have been born not in Julian year 45, as the common era supposes, but in Julian 41, and the star of the Magi would have appeared in Julian year 39. To confirm that the common era falls 4 years short, he gathers from the histories of Josephus, Dio and others the year of the death of Herod the child-slayer, in whose lifetime, as the Gospel of St Matthew makes certain, Christ was born; and he shows that Herod died no later than Julian year 42, which he tries to confirm also from an eclipse of the Moon. Kepler's opinion that the star of the Magi was connected with the greatest conjunction of Saturn and Jupiter is moreover favoured by Pierre d'Ailly, as is clear from what was said in number 12, although he says that the great conjunction made in Cancer preceded the Nativity of Christ by 6 years.

XX. My reasons for not assenting to Kepler are these. First, the opinion is far truer that the star of the Magi was kindled by God not before Christ's birth but at Christ's very birth, as I taught in chapter 19, number 9. Second, Christ's birth in Julian year 44 or 45 is likewise far more probable than in year 41, as I

showed at length in Book 3 of the *Chronology*, and that without prejudice to the eclipse of which Josephus the historian speaks. Third, both the rising of the star of the Magi and its signifying that Christ had now been born were plainly supernatural, and had no dependence on or connection with the Fixed Stars or the planets; nor did the star need, in order to be observed, to be observed on the occasion of watching the greatest conjunction of Saturn and Jupiter. For it was of such splendour and so near the Earth that it could not escape men's notice, especially of those who repeatedly explore the sky. Indeed the new star of Cassiopeia of 1572 too was observed by its own brightness right from the start, by many even who were unskilled in astronomy, and yet it preceded the great conjunction of 1583 by 10 years. It is, moreover, much more consistent with the sayings of the Fathers and Doctors of the Church, already adduced in chapter 19, number 16, and in chapter 20, numbers 1 to 10, to remove from that star all commerce and affinity with the rules of the casters of nativities [Genethliaci]. [Margin: Kepler's opinion rejected [?].]

Fourth, very many of the new stars recorded in history were kindled not only outside the moments of the great or greatest conjunctions; and conversely, by far the most of the great and greatest conjunctions from the beginning of the world down to this year in which we write have had no new star appear with them as companion, or follow them in the same year. This will be clear if you re-read, in our Book 7, Section 5, chapter 9, number 8, the table of all the great and greatest conjunctions and their years, and at the same time compare them with the years in which new stars appeared, whose chronicle we compiled in chapter 1 of this section. For although the new star seen by Hipparchus could have been kindled in the year 125, when there was a great conjunction at 11° of Pisces, its time is nevertheless not established by any history. With that one excepted, then, of the 15 new stars enumerated in chapter 1 only one is found, that of 1603 or 1604, whose rising fell at a great conjunction; all the rest are distant by several years from the year of the nearest great conjunction, and the greater number of them precede it. So God seems rather to wish deliberately to intimate to us their independence of the great conjunction, so that such miracles should be ascribed to Him alone. For here is a synopsis, drawn from the two chapters already mentioned, of the great or greatest conjunctions of Saturn and Jupiter that stood nearer to the beginnings of the new stars; conjunctions of Jupiter and Mars, or of Saturn and Mars, usually happen in the following year, or in the same year but some months apart from the conjunction of Saturn and Jupiter.

Years of the conjunctions of Saturn and Jupiter ♂	Years of the rising of the new stars
before Christ 125, great	before Christ 125, perhaps
in the year of Christ 135, great	in the year of Christ 130
393, great	389
393, great	392
393, great	398

Years of the conjunctions of Saturn and Jupiter ♂	Years of the rising of the new stars
948, great	945
1266, great	1264
1583, *greatest*	1572
1603, great	1596
1603, great	1600
1603, great	1603
1603, great	1604
1603, great	1612
1623, great	1618
1643, great	1638

Since, then, it is established by induction over about 1600 years that the risings of new stars have, rather, nothing to do with great conjunctions, and that from Christ down to us 80 great conjunctions and 2 greatest have taken place without the rising of any new star, the Arabs had no foundation for expecting new stars from those conjunctions; nor from the single new star in Serpentarius, which neither in the greatest nor in the great conjunction of Saturn and Jupiter, but only in the gre- at conjunction's completion — namely, in the conjunction of Jupiter and Mars — fell, ought Kepler to have dragged sacred chronology towards his own findings and his own ideas, so that the star of the Magi too would have been kindled by God at the moment of the greatest conjunction, in Julian year 39, which was the seventh before the first year of the common, generally used Era of the Christian world. On the contrary, from the opinion — no less, indeed more, probable — that the star was first seen on the night of Christ's Nativity, and that the Nativity of Christ took place at the end of Julian year 45, he should rather have argued that God put off by 6 whole years, after the greatest conjunction of Julian year 39, the kindling of the new star that was to be shown to the Magi, so that it should have nothing in common with this star and should in no way favour the errors of the Chaldeans and the Arabs. For this was not only more pious and more in harmony with the teachings of the holy Fathers and Doctors of the Church, but also consistent with experience and with the induction made through the other new stars.

This would have had to be maintained even if everything else on either side had been equal. For neither the Nativity of our Saviour, which was wholly a miracle, nor the splendours of that most holy night, nor that sacrosanct union of the divine Word with our human nature, needed that smoky little lamp of a great or greatest conjunction of Saturn and Jupiter, so as to seem from it either more illustrious and more evident, or more notable to observe. Finally, if anywhere at all, it is here above all that things which stand so far above nature must be separated from the rubbish of nature, and that miracles worked by God outside and above the order must not be forced into the order of human customs — even if the risings of new stars had usually accompanied the synods of the superior planets. That the star shown from heaven to the three holy Magi was a miracle of this kind, we have by now sufficiently proved.

FINIS LIBRI OCTAVI.

End of the Eighth Book.

LIBER NONVS DE MVNDI SYSTEMATE.

The Ninth Book: On the System of the World.

SECTIO PRIMA DE SVBSTANTIA ET ACCIDENTIB. QVIBVSDAM CÆLORVM AC CÆLESTIVM CORPORVM.
