The increase of speed of heavy bodies descending naturally through the air is according to the odd numbers counted from unity. Or: the spaces covered in equal times by the motion already mentioned have to one another the duplicate ratio of the compounded times at whose end they have been traversed. Or: the spaces already mentioned are to one another as the squares of the compounded times.

I said "naturally" not only to exclude violent or supernatural motions, but also any preternatural ones, such as the motion that comes from the agitation of our air; for the moving bodies must be such as to overcome this ordinary agitation.

This is against Chiaramonti, who in Book 12 of *De Universo*, chapter 28, held that this increment is not increased but diminished, fearing an infinite speed, as I said in number 2. It is also against Cabeo, who on Book 1 of the *Meteorologica*, text 17, question 3, held it more probable that this increment takes place according to the arithmetic progression: so that if in the first time a heavy body covered 1 foot, in the second equal time it would cover 2 taken separately, in the third time 3, and in the fourth 4; and so, if the motion stopped at the end of the fourth time, the feet added together would sum to 10. Baliani judged this same progression the more probable in Book 4 of *De motu naturali gravium*, pp. 110 to 113, even though he had agreed with us in Book 1, proposition 6.

[Margin: Baliani's later opinion is worse than his earlier one.]

But why did he then depart from himself? He answers himself: *the sixth proposition rests on experiments subject to the deception of the senses, by which an insensible error cannot be detected. This happens here because the portions of time equal to that first one — in which the first portion of the motion, independent of impetus, is completed — cannot be perceived, being insensible, just as that first portion of the motion is insensible; if they were perceived, we would see the motion increase according to the natural progression.* Next, on p. 113, he gives this rule for finding the spaces covered after equal times: *Multiply the number of times, if it is even, by its half, and add the half; if odd, by the portion greater than the half; and the sum of the spaces covered in the given time will result. Let 4 times be given: multiply by 2; to the product 8 add the half, 2; it makes 10, the sum of the spaces. Let 9 times be given: multiply by 5; the product 45 is the sum of the spaces. The motion is therefore increased, unless I am mistaken, according to an arithmetic progression — not the one of the odd numbers from unity believed until now, but the natural one. Nevertheless, since nearly the same effects follow because the discrepancy is insensible, it is no wonder that it was believed that the spaces are in the duplicate ratio of the times; for even if*

this is perhaps not precisely true, it is nevertheless so close to the truth that the senses could not perceive the truth in the experiments employed.

But Baliani acted prudently in not affirming this opinion of his as certain, and in qualifying it with expressions of doubt. For not only Galileo, as he himself did in the second dialogue on the system of the world (to which Gassendi subscribed in his letters *De motu impresso*), but we too, by most certain experiments over sensible intervals of time, have found the proportion already mentioned of the odd numbers from unity. How false the rule given here by Baliani and Cabeo is, and how different the effects that follow, is clear from the experiment we spoke of in number 12. In the first equal time of one second the clay ball covered 15 feet, and at the end of the fourth second it had covered exactly 240 feet. But according to the rule of Baliani and Cabeo it would have covered only 150 feet, or only ten times the first space. Let Baliani therefore restore the ear- lier opinion asserted in his Book 1, proposition 6, as being better than this later one and proved by experiments that are least fallacious.

[Margin: 4th Theorem.]

The increase of speed of some heavy bodies descending naturally through water is in itself as great as that of the same bodies descending through air, although the descent itself is slower through water than through air. That is, their speed grows according to the odd numbers; or, in covering space, it keeps the triplicate proportion of the times; or, the spaces traversed in water in equal times are to one another as the squares of the aggregated times. This is clear from the experiments reported in numbers 16, 17 and 18. I said "some", namely metal, stone and similar bodies; for bodies of boxwood, or of ebony or holm-oak, although they are heavier than water, nevertheless descend more slowly and do not acquire so great an increase of speed in water.

[Margin: [?] Theorem.]

In most light bodies ascending naturally through water, the increase of speed is, per accidens, not as great as that of metal or stone heavy bodies descending through air or through water. This is clear from the experiments reported in number 20 and examined in number 21, where the reason for the disparity is also indicated; and what would happen of itself, with the hindrances that intrude into the experiments removed, I said in the same place.

[Margin: 6th Theorem.]

Of two heavy bodies of the same species, bulk and figure, but of different weight, let fall through the air from the same height together at the same moment, the one that is heavier in the individual descends more quickly to the same pavement or ground. This theorem, and the ones that follow, are against Niccolò Cabeo, Rodericus Arriaga, Bartholomaeus Mastrius and Bonaventura Bellutus, in the places cited in number 2 under the 5th error. From crude and almost laughable little experiments these men did not hesitate to assert universally that any two heavy bodies let fall together descend equally fast and strike the ground at the same moment, without any sensible difference. Now this sixth theorem

is established by the 21 experiments that have their place in tables 1 and 2 in number 13, and on which see number 14, corollary 2.

[Margin: 7th Theorem.]

Of two heavy bodies of the same bulk and figure, but of different species, let fall through the air from the same height at the same moment, the one that is heavier in species, and therefore in the individual, descends more quickly. This is against Cabeo, Arriaga, Mastrius and Bellutus, cited above. But it is not against Baliani, since he admits that of two balls of the same bulk, one of wax and the other of lead, let fall from the height of the fortress of Savona, fifty feet, the wax one was somewhat slower, so that it was about one foot from the ground when the lead one touched the plane beneath. Now our theorem is clear from the experiments reported in the table of number 13, namely experiments 3, 4, 5 and 6, repeated many times. And reasoning a priori plainly teaches it. All the other conditions are equal, and one cannot appeal either to a resistance arising from a more obtuse angle, by which a greater mass of air meets the surfaces, or to a figure less suited to penetrating the medium, since both bodies are of the same bulk and figure. On the other hand, what is heavier in species is heavier in the individual as well, inasmuch as it is compared with a body of equal bulk but of a different species, and therefore lighter in species. It is therefore necessary that the greater heaviness, in species and in the individual, should produce an effect proportioned to itself — that is, should gravitate more and move with a greater impetus the body in which it is naturally implanted. Nor can it be said that the defect of specific heaviness in the one is compensated by an excess of individual heaviness; for then (speaking naturally) what is of the lighter species would have to be of greater bulk, which is against the hypothesis.

[Margin: 8th Theorem.]

Of two heavy bodies of the same species and figure, but of different bulk, and so of different individual heaviness, let fall from the same height at the same moment, the one that is heavier in the individual descends more quickly. This is against not only Cabeo, Arriaga, Mastrius and Bellutus, but also Galileo, in the second dialogue on the System of the World, and Giovanni Battista Baliani, Book 1 of *De motu gravium solidorum ac liquidorum*. Of these, Galileo affirms that two iron balls let fall together from the same height, even were it the concave of the lunar heaven, descend to the earth in the same time; and Baliani, that heavy bodies, whether of the same or of a different species, very unequal in bulk and heaviness, descend naturally through the same space in an equal time and strike the ground beneath at the same indivisible moment of time.

[Margin: The occasion of the errors of Galileo and Baliani.]

The occasion of this erroneous opinion was the too short space that they used: in the places listed above, Galileo admits to having used a height of only a hundred cubits, that is, 150 feet, and Baliani a much smaller height, namely 50 feet. Now when two heavy bodies of the same species, but of different bulk and so of different individual heaviness, are used, a smaller difference appears in their fall. Therefore a greater height is required in these than in the others for

the difference to be evident to the senses, and far greater attention is required to distinguish the sound and the blow of the one from those of the other. Perhaps, too, Galileo denied this inequality so that it should not harm the motion of the Earth, as we shall say in chapter 17, number 12. The theorem proposed, however, is quite clear from the experiments shown in the table in number 13 and gathered there in corollary 2, namely experiments 7, 8, 9, 13, 14, 15, 16 and 21 of that table.

[Margin: 9th Theorem.]

Of two heavy bodies of the same figure and of the same individual heaviness, let fall together through the air from the same height, the one that is heavier in species descends more quickly. This is against Cabeo, Arriaga, Mastrius, Bellutus and Baliani, cited above. What Galileo thought about these is not yet certainly known, for he seems only to have compared balls of the same species together. But on the side of this theorem stand experiment 12 in the table of number 13, and corollary 3 set out in number 14.

[Margin: 10th Theorem.]

Of two heavy bodies of the same figure, but of different species and of different heaviness, both specific and individual, let fall together through the air from the same height, the one that is heavier descends more quickly, whether it is of greater, smaller or equal size. This is against Cabeo, Arriaga, Mastrius and Bellutus; and, as regards the last part of the theorem, about equal size, against Baliani. But the whole theorem is sufficiently proved by the experiments cited in number 13 and in number 14 for corollary 4.

[Margin: 11th Theorem.]

Of two heavy bodies of the same figure, one of which is heavier in species and the other heavier in the individual, let fall together through the air from the same height, sometimes both descend equally fast, sometimes the one heavier in species descends faster, and sometimes the one heavier in the individual. See what we said in number 14, corollary 5, where we also indicated the causes of this variety: above all, the air enclosed within the pores of whichever is less dense or compact; then the size of the sphere, which strikes the air with a more obtuse angle; then the roughness of the surface. As for Baliani's claim in Book 1 *De motu gravium*, that if all hindrances are removed heavy bodies descend equally — because, although one is lighter and the other heavier, yet in the heavier one the greater heaviness must also move a greater matter — this is neither true nor consistent. It is not true, because it conflicts with our experiments. It is not consistent, because if the body is heavier it will also be greater in bulk (for he is speaking of absolute heaviness, heaviness in the individual), and so it will meet hindrance from the quantity of air to be penetrated and from the more obtuse angle with which it tries to strike that air.

[Margin: 12th Theorem.]

Of two heavy bodies of different weight let fall together from the same height, generally one descends faster than the other; and the one that descends faster is always heavier in some respect, namely either in species and in the individual, or in the

individual, or in species. Hence, if one must pronounce absolutely, it must be asserted that the heavier descends faster. This is, as it were, a summary of all the preceding theorems gathered into one, and it is sufficiently established from what was said in number 14, corollary 6. The same is to be said of light bodies in ascent, according to what was said in number 22.

[Margin: 13th Theorem.]

Of two heavy bodies descending unequally from the same height, the difference in speed is not proportional to the difference of heaviness alone, but is much smaller. This is against Aristotle and some Peripatetics on Book 3 of *De caelo*, text 27, where among other things he says of two bodies of unequal bulk: *For the speed of the smaller will stand to that of the larger as the larger body to the smaller body.* Hence, comparing two bodies of the same species, he thought that the one heavier than the other in the individual moves naturally faster in the measure that it is heavier, and so, if one is twice as heavy as the other, it also covers twice as great a space in an equal time. But this, rightly, is refuted by Galileo in Dialogue 2 of the *System of the World*, p. 164 of the Latin edition, and by Baliani in Book 1 of *De motu naturali gravium*, p. 5; and, what is chief, by the most evident experiments that we performed and gathered into a table in number 13. For whether you look at the difference in time or in space, it was never as great as the difference in weight. Thus a clay ball, hollow inside and of 10 ounces, covered the height from the cornice to the lowest base of the Asinelli tower in 4″ 20‴ of the primum mobile, while a clay ball of the same size but of 20 ounces travelled the same height in 3″ 30‴[43]; and when this one was already striking the pavement, the lighter was no more than about 15 feet from the pavement, out of the 280 that made up the height already mentioned. But if the speed of the heavier had been greater in the same measure as its heaviness, the ball of 20 ounces would have descended in half the time of the ball of 10 ounces, that is, in 2″ 10‴[44], and the lighter would have been 140 feet from the pavement when the heavier struck it. So in all the other experiments the excess of the space covered by the heavier body over the space covered by the lighter was found to be far smaller than the excess of heaviness over heaviness. Hence that proportion, which at first sight seemed probable to Aristotle and his followers, vanished entirely once it was brought back to experiment.

[Margin: Why speed does not stand to speed as heaviness to heaviness.]

Since it is difficult to give an a priori reason why the effect, speed to speed, does not keep the proportion that the cause has to the cause, namely heaviness to heaviness, it has come about that not a few of those just named have thought that any two heavy bodies, however much they differ in weight, descend equally of themselves, if the things that retard one of them by accident are removed. But we say that no case can naturally be given in which two bodies are of different weight and yet all the hindrances retarding one of them are removed from them. For the heavier body will either be greater in bulk, so

[43]printed "Tertijs 30‴"; the word fixes the order as thirds
[44]printed "Tertijs 10‴"; the word fixes the order as thirds

that it will bore through the air with a more obtuse angle; or it will be lighter in species, and enclose small portions of air or fire within its pores; or it will have a rougher surface, or be allotted a figure less suited to penetrating the air — and by these the force of the greater heaviness in moving is blunted. But suppose two bodies are given of the same species, bulk, figure and smoothness, and one is nevertheless twice as light as the other in the individual, but, on account of a greater rarity acquired preternaturally or supernaturally, has been allotted an extension and size equal to the other's. Even so, the one that is twice as heavy will not on that account descend twice as fast. Perhaps this is because the principal mover is the very substance of the movable body, which uses heaviness as a merely instrumental cause; and the substance of heavy bodies of the same species requires that they reach their natural place as soon as possible, with a determinate increment of speed indeed, but a very similar one. So the body that is lighter in the individual is moved faster by the force of its substantial principle than it otherwise could be, if bare heaviness alone were considered.

I now come to some selected problems. Their practice is not only desirable in itself, but will also be of use to us for the arguments to be adduced in chapter 17 against the motion of the Earth, or for the motion of the Earth.

Problemata selecta ex praemissis Theorematibus.

Selected problems from the preceding theorems.

[Margin: 1st Problem.]

XXV. *Given the time in which some heavy body, descending naturally, has passed through a given height: to find the time in which it passed through a smaller height, or would have passed through a greater one.*

[Margin: 1st Example.]

The problem will be explained by examples, and its practice taught at the same time. We said in number 12 that a clay ball of 8 ounces descended from the cornice of the Asinelli tower through a space of 280 ancient Roman feet in a time of 4″ 20‴; that is, if you reduce the time to thirds alone, it passed through that space in a time of 260 thirds. Now let someone ask in what time it passed through half of that space, namely 140 feet. To solve this problem from the foundations of theorem 3, let the greater space be to the smaller space sought as the square of the known time is to the square of the time sought; for the root of this square will be the time sought. Now the number of thirds in the given time, 260‴, squared, is 67,600. Let it be, then, as the space 280 to the space 140, so 67,600 to 33,800, the nearest square root of which last number is 184. Therefore such a ball passed through 140 feet in 184‴, and the remaining 140 in 76‴.

[Margin: 2nd Example, for a mile.]

Again, let someone else ask in what time such a ball would pass through a whole mile, which contains 5000 feet. Let it be, then, as the smaller space, which was of 280 feet, to the greater space, that is of 5000 feet, so the square of

the time of 260‴, 67,600, to the square 1207107‴, whose nearest root is 1098‴, that is, 18″ 18‴.

[Margin: 3rd Example, for the semidiameter of the Earth.]

By the same device you will find that such a heavy body, if it descended through a medium such as the air nearest us, would pass through one semidiameter of the Earth, which for us contains 4139 Italian miles, in a time of 70685‴. For as 1 mile is to 4139, so is the square 1207107‴ to the square 4,996,015,873, whose nearest root is 70685‴, which make 19′ 38″ 5‴. In so much time, therefore, the heavy body already mentioned would reach the centre of the Earth, if a well bored all the way there were full of air.

[Margin: 4th Example, for the distance of the Moon.]

But to go further, at least as far as the Moon: since the upper region of the air, and the fire, if there is one, is a less resisting medium, you will readily grant that the ball already mentioned, or at least a larger one, namely of one pound, will pass through the first semidiameter of the Earth, the one nearest the lunar heaven, in 19′, whose square is 361. To someone who asks, then, in what time a clay ball of one pound would descend from the top of the lunar heaven, assumed to be 70 semidiameters distant (granted that no one assigns it so great a distance), I answer confidently that it will descend in 159 minutes of the hour, that is, in 2 hours and 39 minutes. For as 1 semidiameter of the Earth is to 70 semidiameters, so is the square 361, corresponding to the root of 19 minutes, to the square 25,270, whose nearest root gives 159′, that is, 2 hours 39′. Elsewhere, however, in Book 2, chapter 21, and Book 7, section 6, chapter 5, proceeding somewhat differently, we concluded that such a ball would cover the lunar distance in about 3 hours. For the distance of the Sun, of Saturn and of the fixed stars, see the table set out in Book 7, section 6, chapter 5, in which, however, we neglected the small fractions, for the reasons given there.

[Margin: 2nd Problem.]

XXVI. *Given the time in which some heavy body, descending naturally, has passed through a given height: to find another height, smaller or greater, which it would pass through in another given time.* Let the square of the greater time be to the square of the smaller time as the given greater space is to the smaller space sought. Or, if the space sought is to be greater, let the square of the shorter given time be to the square of the longer time as the given smaller space is to the greater space sought.

[Margin: Example.]

For instance: since the clay ball of 8 ounces runs through 280 feet in 260‴, if you ask how great a space it will run through in one hour, that is, in 216000‴, let it be as the square of the number 260, 67,600, is to the square of the number 216,000, the number 46,656,000,000, so 280 feet to the feet sought. They will be 153 308 875 feet, that is, 30 661 775 paces, that is, 30,662 Italian miles. In 24 hours, therefore, whose square is 576, it would pass through 30,662 multiplied 576 times, that is, 17 661 212 miles.

[Margin: 3rd Problem.]

XXVII. *Given the space that the same heavy body has covered in air and in water, and the time corresponding to each space: to find the probable difference between the heaviness, or at least the density, of water and of air.* First, by Problem 1, find in what time that heavy body would cover a space of air equal to the space of water it passed through; then compare the time found with the time in which the same heavy body covered the same amount of space in water. For the more time it used up in the water than in the air, the greater, probably, is the resistance of water than of air, whether that resistance is said to arise from heaviness or rather from greater density — unless the wetness, which together with the density makes water viscous, also helps the resistance that the moving body has to overcome.

[Margin: Example.]

Example. A small lead ball of 4 drachms, or half an ounce, covered for me 280 feet in air in 24 vibrations of the pendulum, but in water it covered 4 feet in 7 vibrations of the same pendulum — that is, there in 4″, here in 1″ 10‴. I ask in what time it would have passed through

280 feet of water? Let it be as 4 feet to 280 feet, so 49, the square of 7 vibrations, to 3430, which is the square of approximately 59 vibrations. Therefore, as 59 is to 24, so, probably, is the resistance and density of well water to the resistance and density of our air, the air nearest the Earth — unless someone would have density stand to density as the square of the time to the square of the time. In that case, in our instance, the density of water would stand to that of our air as 576, which is the square of 24 vibrations, to 3430, which is the square of 59 vibrations.

[Margin: 4th Problem, on investigating the depth of the sea.]

XXVIII. *To explore the depth of the sea, or of any water, with hindrances by accident set aside. First*, take a glass tube of, say, 10 feet, filled with water of the same species as the water whose depth you wish to measure, and set up perpendicular to the horizon. Into it let down a ball of cork, or a gall, D, into whose base a lead hook ABF has been inserted through a loop or rather loose ring, the greater part of the hook being BF; and with the pendulum measure precisely the time in which the whole aggregate of gall and hook reaches the bottom. Then, as soon as the hook has tipped over and freed the ball D to go upward, measure likewise the time in which the ball D rises to the top of the water; and keep each time separately, and also their sum. *Second*, let the same aggregate of ball and hook down into the sea, and measure the time that passes between the letting-down and the return of the ball to the surface of the water. Distribute this sum, like a common profit, to the aggregate of ball and hook, or to the descent alone, by the rule of partnership or by the rule of three, and you will have, distinctly, the time in which the ball with the hook descended to the bottom of the sea. *Third*, then, by the second problem given a little earlier, find the desired depth of the sea. I said *with hindrances by accident removed*: such would be the case if that weight struck some point or hidden rock, or the back

of a fish then swimming beneath, or if the sea were stirred from the bottom by the force of the winds.

Diagram. A small figure set in the left column beside the description of the sounding device. On the left, a dark ball D with a small hook beneath it; on the right, a horizontal bar on a vertical post, the post running down to a small pointed vessel.

- D (above the ball): the ball of cork or gall
- A (left of the hook), c (small letter between A and B), B (right of the hook), F (lower end of the hook): the lead hook ABF, whose greater part is BF
- M (left end of the bar), E (at the post), R (right end of the bar)
- 3 (beside the post)
- G (mouth of the vessel), K (point of the vessel)
- 2½ (beside the vessel)

[Margin: Example.]

Example. Suppose the aggregate of ball and hook has passed through 10 feet of sea water in the time of six vibrations of our smallest pendulum, or 60 thirds of the primum mobile, while the ball rose to the same height in 10 vibrations, or one second and 40 thirds[45]. The sum of ascent and descent, then, is 2″ 40‴, or, resolved into thirds, 160‴. Next, suppose that the ball with the hook, let down into the sea, reached the bottom of the sea and returned to the surface in a time of one minute, or 60″, which are 3600‴. For if 3600‴ are owed to the whole time of 160‴, then to the time alone in which the hook with the ball descended through 10 feet of water, which was 60‴, there are owed 1350‴ — the thirds, of course, in which that hook descended to the bottom of the sea. Finally, as 3600, the square of the time 60‴, is to 1,822,500, the square of the time 1350‴, so 10 feet to 5062 feet, that is, to one Italian mile and 62 feet besides, since a pace consists of five feet. So great, then, will be the depth of that sea. Thus you see the problem of Leo Baptista Albertus [Leon Battista Alberti], which we discussed in Book 2, chapter 5, number 11, corrected and restored in a far nobler way.

[Margin: 5th Problem.]

XXIX. *Given the time in which one heavy body, in natural descent, measures a given height, and the difference of the interval which the other heavy body has covered more slowly than the first: to find the difference of interval that will arise in a given greater time.* Find by problem 2 the interval due to each of the two heavy bodies for the second time, given or assumed; for the difference of these intervals will be the very one you are seeking.

[Margin: 1st Example.]

Example. We said in number 13, in the table at experiment 21, that a small lead sphere of one ounce, let fall from the cornice of the Asinelli tower, touched the pavement of the base, which is 280 feet distant from there, when another

[45]printed "40″. Tertijs"; the word fixes the order as thirds

small sphere of 4 drachms, let fall at the same time from the same place, was 5 feet from the pavement. Further, the one-ounce sphere, while I was then measuring the time, descended in 24 vibrations, or 4″. It is asked how far the half-ounce sphere would have been from the pavement if such motion had continued for three hours, that is, 10800″. First, then, let it be as 16, the square of the time 4″, to the square of 10,800 seconds, which is 116,640,000, so 280 feet to 2,041,200,000 feet, which are 408,240,000 paces, or 408,240 Italian miles. Again, let it be as 16 to 116,640,000, so the 275 feet that the half-ounce sphere covered to 2,006,625,000 feet. Subtracted from 2,041,200,000 feet, these leave a difference of 34,585,000 feet, namely 6,917,000 paces, which make 6917 Italian miles. Further, the semidiameter of the Earth (which for us is 4139 miles) is contained 91 times in 408,240 Italian miles. Therefore, if two of the balls already mentioned, or similar ones of the same species, one of them twice as heavy as the other, were let fall together from a height of 91 terrestrial semidiameters, which is about one and a half times the distance of the Moon, and the medium were such as our air, then when at the end of three hours the heavier struck the Earth, the lighter would still be 6917 Italian miles from the Earth. But if you make the calculation for six hours, that is, 21600″, whose square is 266,560,000, you will find that the one-ounce sphere would pass through 929,210 miles, and the half-ounce one 916,300; their difference at the end of six hours would be 12,910 miles, that is, more than three semidiameters of the Earth.

[Margin: 2nd Example.]

But I should like to weigh another remarkable case, which we discussed in number 13, experiment 12. A lead ball of 2½ ounces covered 56 paces, or 280 feet, in about 4″; and at the moment it struck the pavement, a wooden ball of greater bulk but equal weight, that is, of 2½ ounces, was clearly 40 feet, that is, 8 paces, from the pavement; so the wooden ball had then covered 48 paces. I ask how great the difference of interval would be if each motion had lasted 6 hours. The square of 4 seconds is 16, and the square of the 21,600 seconds that make up 6 hours is 266,560,000. Let it be, then, as 16 to 266,560,000, so 56 paces to 929,210,000 paces, that is, 929,210 Italian miles. Again, let it be as 16 to 266,560,000, so 48 paces to 799,680,000, that is, 799,680 miles. The difference of these miles is 129,530. Therefore, if the balls already mentioned had been let fall together from a height of 929,210 miles, that is, of 224½ terrestrial semidiameters, and the air or medium had been such as our air, then when the lead ball of 2½ ounces had struck the Earth, the wooden one of 2½ ounces would have been 129,530 miles from the Earth, that is, about 31¼ terrestrial semidiameters.

[Margin: 6th Problem.]

XXX. *Given a heavy body that would reach the centre of the Earth from the surface of the Earth in six hours, through a well full of air or water: to find its slowness, that is, in what time it would have to pass through its first pace.* I suppose that the semidiameter of the Earth contains 4,139,000 paces. Therefore, according to problem 1, let it be as 4,139,000 paces to 1 pace, so 466,560,000, the square [?]

of 21,600 seconds, which make up 6 hours, to the square 112¾, whose nearest square root is 10½. Such a heavy body, therefore, would have to use up about 10″ in running naturally through its first single pace, or five feet, that is, 60 vibrations of our smallest pendulum. But such a body will hardly be found; and among many experiments made in water, the body that came, barely, close to being suitable for this was the ebony ball discussed in number 15, experiment 9 or 10, in the small table; for it covered 4⅙ feet in a time of 7″. But this is much more difficult in air.

CAPVT XVII.

Chapter 17.

An & Quomodo per Diurnum simul & Annuum Terrae motum reddatur vnicè aut meliùs ratio Incrementi velocitatis Grauium & Leuium; ideòque hinc talis motus vehementer confirmetur. Qua occasione disseritur de Figura, quam in hypothesi Terrae motae, Grauia & Leuia motu suo naturali describunt, & Argumentum Galilaei pro motu Terrae inde sumptum tandem dissoluitur.

Whether, and how, the diurnal and annual motion of the Earth together gives the one true, or a better, reason for the increment of the speed of heavy and light bodies; and whether such a motion is therefore strongly confirmed from this. On this occasion the figure is discussed that heavy and light bodies describe by their natural motion on the hypothesis of the moving Earth, and Galileo's argument for the motion of the Earth drawn from it is at last dissolved.

I. The Copernicans saw that, with the Earth moving daily and yearly, the line that heavy bodies describe naturally in descending, and light bodies in ascending, cannot really be a straight line perpendicular to the horizon, such as it appears to us. Some of that sect therefore laboured hard to determine the figure of this line. Kepler, adding no proof, and Gassendi, drawing a likeness from the case of a ball let fall from a mover that is meanwhile carried along, judged it to be parabolic, or very close to parabolic, as we have already set out in chapter 4 of this section, in scholia 2 and 3. But Galileo and Boulliau taught that it is circular, or composed of circular lines. Nor did they stop there: from the motion made along such a line they seemed to themselves to adduce a solid and true cause why the motion of heavy bodies appears faster and faster towards the end; and from this they drew an argument, at first sight very strong, for confirming the motion of the Earth. We shall sharpen their argument more than they did themselves, and yet we shall turn the wound back from it upon the Copernican hypothesis. But it is best first to dispose of what Boulliau devises.

[Margin: Boulliau's opinion.]

II. First, then, Boulliau, in chapter 4 of his *Philolaus*, censures the various opinions of those who have tried to bring forward an a priori cause of the ever greater speed of heavy bodies towards the end, but above all of those who take

refuge in a greater gravitation, that is, a second act of heaviness. He says: *Others hold that a descending body acquires greater heaviness*; and he soon carps at this, saying: *A tasteless and insipid reason, labouring under manifest falsity. For heaviness, whatever it may finally be, follows the bulk of the matter, and while that remains the same, the same heaviness remains. From the view of these men, then, it would follow that something of substance could be produced by local motion, which is false.* But, as *Scipione Chiaramonti* rightly answers him in Part 1 of the *Antiphilolaus*, chapter 4, those authors do not mean a new heaviness in first act, acquired through the motion itself, but in second act, which not a few therefore call gravitation, or a downward translative impetus. Having rejected this and the remaining opinions, then, Boulliau concludes: *The reason for the acceleration of the motion of falling bodies therefore depends wholly on the circular motion, which the part must have in common with the whole, and which it would without doubt keep in falling, unless the violence of its state moved it with a violent motion.* He holds, further, that this motion comes about through two opposed circular motions, by which the movable body is kept, to appearance, in the same straight line, and appears unequal in it, although in reality each of the circular motions is equal. To show this he uses Copernicus's demonstration in Book 3, chapter 4, made for the motion of libration and the anomaly of the equinoxes, which we too have set out in Book 3, chapter 29, number 10. But here it must be repeated in summary and applied to this case.

[Margin: A rectilinear motion from two circular ones.]

III. In the following diagram, from the centre A describe the circle BKE and a smaller one, CIDL, whose semidiameter AC is half the semidiameter AB. Let another circle, HGA, be equal to the smaller circle, and let its centre F be carried in the order of the signs along the circumference of the circle CIDL, from C to I. Meanwhile, let some movable body on the circumference of the circle AGH be moved with a motion twice as fast against the order of the signs, the motion of the centre F beginning from C, and that of the other movable body, H, from B. With these posited, Copernicus shows that, as these motions meet each other in opposite directions, the movable body is held in the straight line AB. When the centre F has completed the half-quadrant CF, the movable body H, which was at B, has completed the quadrant HG and is at G; and when the centre F is at I, the quadrant CFI of its circle now being complete, it follows that the movable body, having completed the semicircle HGA, is at A. Hence, if these motions continue in this way, the movable body will be kept in the straight line BAE; and although its motion along that line will appear unequal, in reality it will be equal in the circles already mentioned. So the motion of heavy bodies, which appears to us to take place in a straight line and to be faster and faster, is in truth compounded of two circular and equal motions.

Diagram. Set in the right column beside the construction of paragraph III. A large circle with a vertical and a horizontal diameter; a smaller circle about the same centre; and a third circle, equal to the smaller, passing through the centre and through a point on the great circle at the upper left.

- B (top of the great circle), E (bottom of the great circle)
- K (left end of the horizontal diameter), L (right end of the horizontal diameter)
- A (centre)
- C (on the vertical diameter above A, on the smaller circle), I (left on the smaller circle), D (below A, on the smaller circle)
- H (on the great circle at upper left), G (on the vertical diameter below B), F (near the centre of the third circle)

[Margin: Chiaramonti's arguments against Boulliau.]

IV. Chiaramonti, in that same chapter 4, rejects this doctrine as badly applied to the increment of speed we are dealing with. *First*, because Boulliau wrongly calls the downward motion of heavy bodies towards the centre of the Earth violent, since it is most natural, supposing that they are outside their place. *Second*, because he supposes that KAL is the surface of the Earth, and that a heavy body let fall from the top of the tower, B, has an inclination to the circular motion BHK, but that the points of the arc HG resist it and are carried towards B with a speed double that with which the heavy body would wish to be carried from B towards K; and that from this contrariety, therefore, it comes about that the heavy body falls onto the Earth at A along a straight line, with a motion perpendicular to sense. But the diurnal and annual motions of the Earth are not contrary, since they are in the same direction. Nor can any motion be imagined that opposes the motion of the heavy body: for neither is the air near the Earth moved in a different direction — it moves in the same one — nor does a heaviness resisting the circular motion move through a circle that strives against the first circle. *Third*, he objects against Boulliau the excessive speed that would follow from such a motion. For let the heavy body be at B, and the tower BA be of 10 perches, of which BG is imagined to be the tenth part, that is, one perch, that is, 10,000 of the parts of which AB, the whole sine, is 100,000. For to the versed sine BG, of 10,000 parts, there corresponds the arc BH, of 25° 51′. And from Archimedes' *De dimensione circuli*, the circumference is to the diameter as 22 to 7. Therefore, if the circumference BKE etc. is 360°, and the diameter BE 200,000 parts, the arc BH, which is 25° 51′, will be 45,134 such parts, and its proportion to BG, set at 10,000 parts, will be greater than four and a half times. Now a stone let fall from B passes through the perch BG in a shorter time than two beats of a human artery. But let there be two beats in which the arc BH, namely an arc of 25° 51′, is turned with an equal motion (as Philolaus would have it). The whole circle of 360°, therefore, will be turned in a time of 27 1323/1551 beats, or about 28. And the circumference whose diameter BE is 20 perches is about 63 perches. But a mile contains 333⅓ perches of Cesena; hence, if 63 perches are run through in 28 beats, a mile will certainly be run through by such a movable body in 148 beats, that is, in about two minutes of an hour. Therefore in one hour, by the force of the circular motion, it would cover 30 miles, and in one day 820 miles — a portentous speed, as Chiaramonti calls it, which he denies would suit any bird.

[Margin: Chiaramonti's double error on the speed of heavy bodies.]

But this third attack is frivolous, and it errs in two ways. First, in the Copernican hypothesis: for on that hypothesis, in the motion of birds, besides the motion that appears to us to be their own and only motion, there must also be included the common and circular motion by which they accompany the Earth, if they fly towards the east; and so, on such a hypothesis, they fly past a far greater space than the one that appears to us. Granted, let it be enough for Boulliau if, as far as the apparent motion goes, no more than 10 perches seem to be passed through. Next, he errs outright when he says that a passage through 820 miles made in one day is incredible and portentous. For it is far smaller than the speed that would in reality suit a stone if it were let fall from such a height that one day would be needed to run through it. For from what was shown in chapter 16, number 24, Theorem 3, and number 26, Problem 2, a clay ball of about one pound would pass through 30,662 Italian miles in one hour, and 17 661 212 miles in 24 hours. This is far more wonderful, and yet truer.

[Margin: Our arguments against Boulliau.]

V. Boulliau must therefore be attacked otherwise than by that third argument. First, if any heavy body really covered equal spaces on its circle in equal times, it would strike the Earth with no greater impetus when let fall from a height than when let fall from a low place; and this is against the very many and most manifest experiments set out in chapter 16 from number 6. Second, from a motion ordered through the two circles already mentioned there does not follow the increment of speed that is manifestly apparent in the natural motion of heavy bodies — an increment which we showed in chapter 16, numbers 11 and 12, to follow the odd numbers counted from unity, and which we drove home in number 24, Theorem 3. That it does not follow is easily demonstrated. For according to Boulliau the heavy body B reaches A when the circle CFD, proceeding with equal motion in the order of the signs together with the circle BKE, has completed a quadrant; for then the movable body on the circle HGA has completed a semicircle against the order of the signs. Now let the whole time of descent be divided into four equal parts. In the first time, H, the outermost point of the diameter AFH, will complete a quarter of a quadrant, namely 22° 30′; imagine these degrees contained in the arc BH. Its versed sine BG, therefore, will be 76 of the parts of which the whole sine AB is 1000. At the end of the second time it will complete 45°, whose versed sine is 293; at the end of the third time it will complete 67° 30′, whose versed sine is 617; and finally, at the end of the fourth time, it will complete the quadrant BHK, whose versed sine AB is the same as the whole sine, of 1000 parts. Now let the first versed sine be subtracted from the second, the second from the third, and the third from the fourth: there will remain the spaces covered in each of the four times, as you see in the first column of the following small table.

Spaces covered, separately	Spaces to be covered, separately	Odd numbers
76	76	1
217	218	3
324	380	5
383	532	7

But according to the increment of the odd numbers, which is owed to the speed of heavy bodies, if the space of the first time is 76, the spaces of the other times ought separately to be as you see in the second part of the table. So although the space of the second time, covered by force of Boulliau's circles, is nearly equal to the space to be covered, yet the third falls short of the space owed to the increment of speed, and the fourth much more so. Hence, since the clay ball in our experiments, as I said in chapter 16, number 12, covered 240 Roman feet in four seconds of time, and 15 feet in the first second, then if Boulliau's reasoning held it would have covered no more than 76 feet at the end of the fourth second. This is absurd, and conflicts with the most evident experiments. Third, Boulliau cannot, through the circles already mentioned, give a reason for the increment of speed of light bodies upwards, such as purer air and fire, because these are not carried to the centre of their whole but to its circumference. Let us hear, then, Galileo, who is believed to have come nearer to the truth with a single circular motion.

Galilæi Demonstrationes, quibus conatus est in hypothesi Telluris motae Rationem afferre Incrementi velocitatis Grauium.

Galileo's demonstrations, by which he tried, on the hypothesis of the moving Earth, to give the reason for the increment of the speed of heavy bodies.

[Margin: Galileo's doctrine on the line described by the motion of heavy bodies.]

VI. In the second dialogue of *On the Twofold System of the World*, from page 157 of the Italian, but page 119 of the Latin version, Galileo pronounces the following propositions in the person of Filippo Salviati.

[Margin: Galileo's first proposition.]

The first is this. If the straight motion of heavy bodies towards the centre of the Earth appeared uniform, then, since the circular motion of the Earth towards the east is also posited as uniform, the line compounded of the two motions would be a spiral — namely one of those that Archimedes defined in his book *On Spirals*. And he says that such a line arises when a point moves uniformly along a straight line that is carried round uniformly about one of the line's extremities, fixed as the centre of the circumduction. But since the apparent motion of heavy bodies is uniformly difform, and continually accelerates, it is necessary that the line described, compounded of this motion and the diurnal motion of the Earth, should recede successively, in an ever greater proportion, from the circumference of the circle that the centre of gravity would have described had the stone stayed at the top of the tower. It is necessary, moreover,

that this recession should be slight and very small at the beginning, because the heavy body passes from rest — that is, from the privation of downward motion — and enters upon downward motion, and so necessarily passes through all the degrees of slowness lying between rest and any speed whatever, degrees which he had earlier concluded to be infinite.

[Margin: Galileo's second proposition.]

Second: since the natural descent of heavy bodies from the top of the tower to the centre of the Earth is carried on of itself, as to its own term, he says it necessarily follows that the line of the compound motion recedes from the circumference of the circle described by the top of the tower in such a way, in an ever greater proportion, that it nevertheless ends at the centre of the Earth.

[Margin: Galileo's third proposition.]

VII. Third, on page 160 of the Italian, 121 of the Latin, he asserts that the line already mentioned is circular, or extremely close to circular, because in it the conditions prerequired in the first and second propositions are preserved. On the preceding page he teaches how this circular line is to be drawn. Let A be the centre of the Earth; from it, with the semidiameter BA as interval, let the quadrant BIM etc. of the Earth's circumference be described. Further, let there be the tower BC, whose vertex C describes about the centre A a quadrant of a circle towards the same side, namely the east, towards which the Earth moves by its rotation. Now let the whole interval AC be bisected at E, and from the centre E, with the interval AE, let the semicircle AIVC be described. *Through this*, says Galileo, *I now assert that it can be believed with fair probability that a stone falling from the top of the tower C is moved with a motion compounded of the common circular motion and its own straight one.* For if on the circumference CD some equal arcs are marked, namely CF, FG, GH, HL, LD, and from the centre A straight lines AF, AG, AH, AL, AD are drawn to the ends of those arcs, then the portions of these lines intercepted between the two circumferences CD and BI, namely OF, PG, QH, RL, ID, will always represent for us the same tower CB, carried round by the rotation of the terrestrial globe towards D. Along these the stone, in its fall, will seem to descend with a rectilinear motion to us who, standing at the foot of the tower B, are carried through the arc BI in the same direction with a common and equal motion. Further, the portions of the said lines intercepted between the circumference CD and CI, namely FS, GT, HV, LX, DI, will be the spaces covered apparently downward by the stone at the end of each of the times; and the places in which the stone will be found at the end of

Diagram. Set in the right column beside the construction of paragraph VII. A vertical line C B E A with a right angle at its ends; an outer arc from C leftwards to D (the path of the top of the tower), an inner arc from B leftwards through I to M (the Earth's circumference); straight lines from the centre A to points on the outer arc; and a semicircle from A up through I to C, crossing those lines.

- C (top right, top of the tower), B (right, foot of the tower), E (on the vertical line between B and A), A (bottom right, centre of the Earth)
- F, G, H, L, D (on the outer arc, from right to left)
- O, P, Q, R, I (on the inner arc, from right to left), M (lower end of the inner arc, at the left)
- S, T, V, X (where the semicircle crosses the lines from A, from right to left) those times will be S, T, V, X, I. These points recede from the circumference CD in an ever-increasing proportion, and so the motion of the stone seems to us to be accelerated more and more; and at last this motion, if nothing hindered it, is understood as due to end at the centre of the Earth, A, once the semicircle CIA has been completed.

[Margin: Galileo's fourth proposition, in three members.]

VIII. Fourth, on page 159 of the Italian, 120 of the Latin, Galileo asserts that the natural motion of the stone is in reality circular, although it appears straight to us, and indeed that it runs along the simple circumference of a single circle. Further, that this movable body in falling completes no greater space than if it had stayed at the top of the tower C. For the whole arc CD, which it would have described by staying at the top of the tower, is precisely equal to the arc CI, which it completes in falling; just as, one by one, the arc CF is equal to the arc CS, the arc FG to the arc ST, the arc GH to the arc TV, the arc HL to the arc VX, and the arc DL to the arc XI. From this follows the third member of this proposition, which he himself calls admirable: namely, that the true and real motion of this stone is not accelerated, but is in reality equal and uniform, granted that it appears unequal to us; since to the equal times in which the top of the tower C moves, marked by the equal arcs CF, FG, GH, HL, there correspond real equal spaces CS, ST, TV, VX, XI. *This*, Galileo adds, *frees us from the labour of investigating the causes of the acceleration of this motion, since the movable body, both while standing on the tower and in falling, is always moved in the same way, that is, circularly, with the same speed and a uniform tenor.*

That the arcs already mentioned are equal to one another is, moreover, very readily demonstrated by drawing the line EI from the centre E. For the semidiameter AC of the circle CD is by construction double the semidiameter EC of the circle CIA. Therefore the whole circumference of the first to the whole of the second, a quadrant to a quadrant, and any arc of the greater circumference to any similar arc of the smaller, are in double proportion; for the circumferences of circles are to one another as their diameters, by theorem 5 of Book 11 of the *Collections* of Pappus of Alexandria. Hence any half arc of the circumference CD is equal to a similar arc of the smaller circumference CI. Now the angle CEI, standing at the centre E, is double the angle CAD, which stands at the circumference of the smaller circle but at the centre of the greater, by Proposition 20 of the third book of the *Elements*. Therefore the arc CI, on which the angle CEI stands, is double the arc CD, on which the angle CAD stands; so CD is half of the arc of the greater circle similar to the arc CI, and accordingly the arc CD is equal to the arc CI. By the same reasoning, drawing

straight lines from E to the points S, T, V, it will be proved that the arc CF is equal to the arc CS, the arc CG to the arc CT, and the arc CH to the arc CV. Hence, since the arc CD is divided into the equal arcs already mentioned, FG will be equal to the arc ST, the arc GH to the arc TV, the arc HL to the arc VX, and the arc LD to the arc XI: which was to be shown. This done, Galileo concludes, on page 160, but 121 of the Latin, in these words: *Although I would not now say that the matter stands precisely so as regards the motion of descending heavy bodies, this I do certainly affirm: if the line described by the falling body is not exactly this one, it is nevertheless extremely close to it.* Now let us look at the objections against Galileo: one of them Chiaramonti's, the rest our own.

[Margin: Chiaramonti's objection against Galileo.]

[Margin: But fallacious.]

IX. For Scipione Chiaramonti, in the Italian defence of his *Antitycho*, Part 4, chapter 10, objects to Galileo that it is impossible for a stone in falling to be moved along the circumference CI and yet to represent to us a motion made along a perpendicular straight line; and that whoever says otherwise commits a very great error in mathematics. For, taking the arc CI as one Italian mile and the height of the tower BC as 50 paces, he shows that this arc will have a declination from the horizontal line six times smaller than the channels suited to turning mill-wheels commonly have. But Chiaramonti was certainly deceived. For Galileo never said that the arc CI itself, or its parts, by itself or through its own portions however small, represents to us a perpendicular straight line; had he said so, Chiaramonti's objection would be valid. What he said was that, on the hypothesis of the diurnal rotation, a stone falling from a tower is at every instant of its motion at such a point of the circumference CI that the straight line drawn from the top of the tower, the term from which it fell, through the stone falls on the same point of the Earth over which the stone stood perpendicularly at the beginning of its fall, because the top of the tower and that point of the Earth are moved with a like circular motion towards the east; and so to our eye, remaining at that place on the Earth and consequently carried along with the Earth, the motion seems to be made along a perpendicular straight line. Setting Chiaramonti aside, then, let us come to the more solid objections, devised partly by us and partly by Father Francesco Maria Grimaldi, with whom I have often been accustomed to discuss this hypothesis.

[Margin: Objection[s?] ours and Father Grimaldi's against Galileo.]

X. First, then, I say what I brought against Boulliau. If the motion of heavy bodies falling naturally were in reality equal, and only seemed unequal through a deception of the eye, a body would fall with no greater impetus from a higher place than from a lower one, and accordingly those innumerable effects would not follow which do follow from the more vehement percussion of bodies falling from a higher place, some of which we reviewed in chapter 16 from number 6.

[Margin: First objection.]

[Margin: Inequality of impetus shows an inequality of the motion really made.]

Since, then, touch itself and hearing evidently discern that greater percussion, it cannot be said to be a mere appearance and a mockery of the senses. But that greater percussion necessarily and naturally presupposes a greater impetus, and a greater impetus a greater real increment of speed. Therefore they are not moved equally, but with an ever greater real speed.

[Margin: Second objection.]

[Margin: Heavy bodies descending unequally along the same circle would not appear in the same li[?] … straight.]

XI. Second: by most evident experiments, exhibited before many witnesses most worthy of credit and set out in chapter 16, number 13, and drawn in number 14 into various corollaries, it is established that if two heavy bodies of different weight are let fall together from the same height, the heavier descends faster: if it is heavier both in the individual and in species, as there in corollary 4; indeed, even if it is heavier in the individual but equally heavy with the other in species, as in corollary 2; or if it is heavier in species but equally heavy in the individual. But so that no room is left for any evasion, I shall choose this last case. Of it, in the same chapter, number 13, experiment 12, I related that a wooden ball of 2½ ounces, let fall from the cornice of the Asinelli Tower at Bologna together with a lead ball likewise of 2½ ounces, stood 40 feet, or 8 paces, from the pavement at the base of the same tower when the lead ball, striking the pavement, had already traversed a height of 280 feet, or 56 paces; and so the wooden ball had covered no more than 48 paces in the same time. From this, by example 2 of Problem 5, which is in the same chapter 16, number 29, I deduced that if such balls had been let fall from a height of 929,210 Italian miles, the outcome would have been that at the end of 6 hours the lead ball would strike the Earth, while the wooden ball would still be 129,530 miles from the Earth, that is, very nearly 31¼ semidiameters of the Earth. Such experiments, and similar ones, cannot be saved by the motion of heavy bodies along the circle Galileo determined, or along one insensibly different from it. For, repeating the figure of number 7: if both balls are let fall together from the top of the tower C, and each must reach the centre of the Earth, A, along the semicircular circumference CIA, then at every same moment of time for which the motion lasts each ball must appear — indeed must really be — at the same point of the same circumference. So when the lead ball is at S, the wooden one too is at S, and appears there to our eye remaining at O; when the lead ball is at T, the wooden one too is there; and when the lead ball has struck the surface of the Earth at I, the wooden one too is there and strikes the Earth. Otherwise, if the wooden ball were not at the same points of the same circumference, but at those of another, greater one, drawn nevertheless through the vertex C, this circular line would not end at the centre of the Earth but at some other point below that centre; and this is against the nature of heavy bodies, and against Galileo's second proposition, of which I spoke in number 6. But if the wooden

ball had been, for the whole time of the motion, at the same points of the same circumference as the lead one, it would have descended with precisely equal speed, and would not have stood a full 40 feet from the Earth — which is against a most evident experiment. Hence Father Grimaldi suspected that Galileo, in that same second dialogue on the system of the world, denied for this reason that of two heavy bodies, of however different weight, let fall together from the same term, the heavier reaches the Earth sooner: namely, lest this should harm this motion of his of heavy bodies along the circle already mentioned. But perhaps his occasion for denying it was that he used two balls of the same species but of different weight and different bulk, in which the difference of descent and of percussion is far smaller in appearance than in other comparisons; nor does it show itself evidently unless the bodies are let fall from a notable height, whereas Galileo used no height greater than 100 cubits, as he testifies in the same dialogue.

[Margin: A way of escape is closed to Galileo.]

Nor should you say that that inequality can be defended if the wooden ball is carried round along another circumference, insensibly greater than the circumference CI. For if that happened, both balls would have struck the point I at a sensibly identical moment, and the difference of interval would not have been so sensible as to come to 40 feet. Moreover, if both balls had been let fall from a height of 929,210 miles, and the medium had been of the same density as the air near us, and neither ball had been consumed by heat conceived from the motion, or dissipated before its arrival at the Earth, then when the lead ball had reached the centre of the Earth, A, after 6 hours had elapsed, the wooden ball would have stood 31¼ semidiameters of the Earth from the centre A, as I showed in chapter 16, number 29, at the end. This difference is very notable.

[Margin: Third objection.]

[Margin: The descent of heavy bodies is not of the same rationale everywhere [?].]

XII. Third: the motion of heavy bodies along the circle that Galileo assigned is unfit to save the greatest part of the motions by which heavy bodies naturally descend. This is so both because it saves only the motion of heavy bodies descending through the plane of the equator, and because it does not save even the hour of all motions, but only of those which, because of their lightness or lack of greater heaviness, are so slow that they cannot reach the centre of the Earth except in a time of 6 hours. Scarcely any of these can be found if the descent has to take place through air; and if through water, heavy bodies that descend so slowly are very rare. Such, however, is a ball of the rarer kind of ebony let fall through water, as appears from the problem I gave for this purpose in chapter 16, number 30. But very many heavy bodies, in number and in species, neither descend through the plane of the equator nor are so slow as to need 6 hours to pass through a semidiameter of the Earth, or 4139 miles, as appears from what was said in chapter 16, number 25, example 3, and number 30.

I said, first, that the motion of heavy bodies is not saved unless they descend through the plane of the equator, and so unless the tower from which the stone falls stands on the equator itself. For Galileo's demonstration, brought forward in numbers 7 and 8, requires that the circle along whose circumference CIA the stone is carried round lie in the same plane in which lie both the centre of the Earth, A, and the top of the tower, C, and so too the circle CD described by that same top through the force of the diurnal rotation — as is manifest from the construction of the figure and from the hypothesis on which that demonstration rests. And this cannot happen unless that tower stands on the equator. For if it stands off the equator, under the poles, the descent of the stone will in reality be along a straight line, and so not along a circle; and if it stands on some parallel to the equator, one parallel will be described by the foot of the tower, B, and another by the vertex of the tower, C, and moreover the plane of neither will lie in the plane in which the centre of the Earth is, but in a far different plane. Moreover, Galileo himself, in that second dialogue, page 237 of the Italian, 179 of the Latin, when answering the objections of our Scheiner, acknowledged that this line is circular only on the equator, and that on the other parallels it describes a conical surface. He was prompted, namely, by that question of Scheiner's which stands in the *Disquisitiones*, page 31, and runs as follows: *Why does the centre of a sphere that has fallen under the equator describe a spiral in its plane; under other parallels describe a spiral on a cone; and under the pole descend on the axis, running down a gyral line traced on a cylindrical surface?* To which he answered in these words: *Because, of the lines drawn from the centre to the circumference of the sphere (which are, namely, those along which heavy bodies descend), the one that ends at the equinoctial traces a circle, while those that end at the other parallels describe conical surfaces; the axis, finally, describes nothing else, but remains in its being.* Galileo was therefore wrong, on page 121 of the Latin, but 160 of the Italian, to define universally or indefinitely that this line is circular; nor did he correct this statement of his, as he ought to have, having forgotten, I believe, what he had said.

[Margin: Galileo does not correct[?] his statements, where he ought to from what he had conceded [?].]

I said, second, that not even under the equator is the motion of heavy bodies saved, unless they are so slow that their arrival at the centre of the Earth (if access were given there through a well full of air or of water) needs precisely 6 hours. For if Galileo's demonstration, of which numbers 7 and 8 speak, is to be right, the semicircumference CIA of the circle along which the heavy body is carried round must be equal to the quadrant CD etc. that the top of the tower, C, describes by the force of the diurnal rotation; and so, when the heavy body has reached the centre of the Earth, A, from C through I, having completed the semicircle CIA, the top of the tower, C, must meanwhile have completed a quadrant of the diurnal rotation, that is, in 6 hours. Otherwise, if the heavy body reaches A along the arc CIA either faster or slower than in 6 hours, Galileo's whole demonstration collapses. Since, however, these two

conditions can in reality be joined together — namely, that the place from which the heavy body is let fall be on the equator, and that the body be so slow as to need 6 hours to pass through the semidiameter of the Earth — from this we shall draw a very strong argument against the diurnal motion of the Earth, and so against the annual motion too, which does not stand without the diurnal; and it is the following.

[Margin: Fourth objection.]

[Margin: Nowhere does a heavy body descend along a circle, if the annual motion is admitted.]

XIII. Fourth: not even on the equator, even if the heavy body is such as would reach the centre of the Earth in 6 hours, is it true that the line it describes is circular, or insensibly different from a circular one, unless the motion of the Earth is simply diurnal, about its own unmoved centre. But if the centre of the Earth moves with an annual motion, as Galileo would have it together with Copernicus, the line of the movable body already mentioned will not be circular, but will describe in the space of the world a line very different from a circular one. This is evident. For while in one hour it would have to describe 15° of the circular line by the force of the diurnal motion, the centre of the Earth is meanwhile carried forward in the Great Orb 2′ and 3″. These are nevertheless far greater than 15° of the terrestrial circumference, even if the Great Orb is not as large as the distance of the Sun found by us in Book 3, chapter 7, requires, but only as large as the Copernican distance — that is, if its diameter is only 2284 semidiameters of the Earth, or 1142 diameters of the Earth. For it follows that the circumference of the Great Orb is to the circumference of the terrestrial globe as 1142 to 1, since circumferences are to one another as their diameters, by theorem 5 of Pappus of Alexandria, Book 11 of the *Mathematical Collections*. Therefore one degree of the Great Orb is to one degree of the terrestrial circumference as 1142 to 1. But 2′ 30″ are the 24th part of one degree; hence, dividing 1142 by 24, 2′ 30″ of the Great Orb will be to one degree of the terrestrial circumference as 47 7/12 to 1, and to 15 terrestrial degrees as 47 7/12 to 15, that is, in a greater proportion than triple. Hence in one hour, by the force of the annual motion alone, the heavy body already mentioned will cover in the space of the world a space more than three times greater than it would cover on the terrestrial circumference by the force of the diurnal motion. But if the diameter of the Great Orb is, according to us, 7300 diameters of the Earth, dividing these by 24 gives 304¼; and so the space covered in one hour by the force of the annual motion will be to the space covered by the force of the diurnal motion as 304¼ to 15, that is, more than twenty times greater. Since, then, the circumference of the Great Orb is not parallel to the terrestrial circumference, but passes through its centre in such a way that, because of the inclination of the equator to the ecliptic and the parallelism of the equator with itself, a heavy body following the motion of the centre and of the circumference of the Earth is perpetually in different planes; and since the portion of the Great Orb corresponding to one hour is three times,

indeed twenty times, greater than the portion of the terrestrial circumference corresponding to one hour; it is necessary that the line compounded of both motions should differ notably from a circular one — and much more so if the motion lasts for 6 hours.

[Margin: Fifth objection.]

[Margin: No heavy body descends along a circle, even granting the diurnal motion alone.]

XIV. Fifth: I say that even if some heavy body descended on the equator from the surface to the centre of the Earth in precisely 6 hours, and the Earth moved only with the diurnal motion, the line it describes would still not be circular, but would fall within the circumference of the semicircle. Otherwise the apparent increment of speed would not proceed according to the squares of the times — and yet it does so, not only by our experiments but also by Galileo's experiments and his own admission. To make this manifest, let the figure set out in number 7 be repeated here, and let the quantities of the spaces FS, GT, HV, etc., covered by the heavy body in equal times, be investigated until the vertex of the tower, C, has completed a whole quadrant in 6 hours, and the heavy body the whole semicircle CIA. For the spaces already mentioned will be found to fall short more and more of the quantity necessary for them to keep the proportion of the squares of the times.

[Margin: The way of finding the spaces covered by a heavy body, if it descended along a circular line.]

The way of inquiring into the quantity of the spaces already mentioned will, moreover, be declared very briefly by an example. Let the first arc taken, FC, be of one degree, which the Earth completes by its diurnal motion in 4^{m} of time; for the arc CS, intercepted between the same lines AC and AF, will be double in number of degrees, from what was demonstrated in number 8, that is, of 2°. Therefore the complement to the semicircle, namely the arc SIA, will be of 178°, and its half of 89°, whose sine is 99,984½ of the parts of which the radius EC is 100,000, while the diameter, or greatest of the chords, AC, is 200,000. That sine, doubled, will give the chord AS as 199,969 parts; and this, subtracted from the radius of the quadrant, AC — that is, from AF — of 200,000 parts, will leave the segment FS as 31 parts. In the same way, if the arc CG is of 2°, CT will be 4° and TIA 176°, and its half 88°, whose sine is 99,939; doubled, this will give the chord AT as 199,878, and this, subtracted from the whole radius AG, will leave the space or segment GT as 122 parts; and so for the rest.

Now if the space FS, of 31 such parts, is taken as the first, and as 1, and as the space passed through by the heavy body in the first time, or in the first 4 minutes of time, then the space GT, passed through at the end of the second of the equal times, must stand to the space FS as 4 to 1. For the square of unity, assigned to the first time, is 1, but the square of two, assigned to the second time, is 4. Let it be, then, as 1 to 4, so 31 to another number: one finds not the 122 parts that we said lie in the space GT, but 124 parts. Therefore, if GT, in

order that the proportion due to the squares of the times be kept, is greater than what arises from the circular line, it is necessary that the line which the heavy body describes in descending and keeping the proportion already mentioned should, if the Earth moves with the diurnal motion alone, draw back inward from the line CIA, ever more towards the diameter AC, though it will at last pass through the centre A.

But lest anyone should think that this difference, which is moderate at the beginning, is also moderate and negligible as it goes on, and that the line is therefore insensibly different from a circular one, let him inspect the following table; its explanation, to be sought from what has just been said, will be given beneath it.

[Margin: See the preceding figure.]

Now, to explain the preceding table: note how in it, having divided the quadrant CD etc. into 90°, and the semicircle CIA likewise into 90 pairs of degrees, I traced out the chords of the supplements to the semicircle, which are contained in the second column, and the segments intercepted between the semicircle CIA and the quadrant CD etc., which are given in the 3rd column. In the fourth column there is a continuous series of square numbers beginning from unity; by multiplying the first space, FS, of 31 parts, by these, one obtains the spaces or segments that are due if the proportion of the squares is to be kept. For you will see that at the end of the quadrant from the vertex C, completed in 6 hours, the space covered by the heavy body ought to be 251,100 parts, and yet, if the heavy body has to descend along the semicircle CIA, it cannot be more than 200,000 — namely, as much as AC; and that at the end of the other times too that proportion falls short more and more, whereas it ought either to be kept or rather to increase.

[Margin: Sixth objection.]

[Margin: The motion of heavy bodies is not in reality equal [?], and so not circular either.]

XV. Sixth: the demonstration of the equal motion of the heavy body already mentioned — namely, of one descending on the equator so slowly that it needs 6 hours to reach the centre of the Earth — which we brought forward from Galileo in number 8, does not hold unless the foot of the tower, B, and its vertex, C — that is, the circumference of the terrestrial globe — are supposed to move equally, and A, the centre of the Earth, to be immobile. But if, besides

the diurnal motion, an annual motion of the centre is also given to the Earth, Galileo holds that the compounded motion of any heavy body following the motion of the Earth is unequal in reality, now slow, now fast. He thinks this so true, in this hypothesis, that Galileo founded the cause of the tide of the sea on the inequality of the Earth's motion compounded of the diurnal and the annual, as we have already seen in chapter 14, from number 4 onward.

[Margin: Galileo's inconsistency with himself.]

Galileo therefore contradicts himself when he attributes a real equality to the motion of such heavy bodies, which he does not grant even to the Earth. And granted that this inequality is not the one we experience in the apparent motion of heavy bodies, still another inequality, unknown to sense, is substituted in its place, so that the one manifest to sense is removed — which is a greater absurdity.

[Margin: Objection [?].]

[Margin: It is falsely asserted, universally, that heavy bodies descend along a circular line.]

XVI. Seventh: Galileo errs when he pronounces universally or indefinitely that, in the Copernican hypothesis, the line that heavy bodies describe in their natural descent is circular, or as close to circular as possible. For this is not true even in the plane of the equator, where it ought most of all to be verified, as will be evident from what has been said so far and what is still to be said; and it is much less true outside the equator. To show this to the reader, we shall set out a threefold figure, by which we shall outline this line as best we can. For we cannot represent, in the one plane of this page, the diversity of the planes through which heavy bodies are carried in descending in this hypothesis, nor keep the due proportions, because of the narrowness of the leaves. From this, however, you will better learn what Scheiner indicated very lightly about the line of this motion on a cylindrical or conical surface in the *Disquisitiones Mathematicae*, page 31, and what Galileo conceded at his prompting, as we said in number 12.

[Margin: The first figure, for a heavy body descending in the parallel sphere.]

Let the first figure be for a heavy body let fall perpendicularly above one of the poles of the terrestrial equator, with an imagined spectator of this descent, in the parallel sphere. Let ABCD be the ecliptic, or Great Orb, carrying the centre of the terrestrial globe round with the annual motion from A through B towards the eastern quarter, C, and from C through D to A, the western quarter. For just as the axis of the Earth's ecliptic describes its own cylinder in its annual circuit, so too the axis of the equator describes its own, but one inclined to the cylinder of the ecliptic.

Diagram. The first figure, set in the left column: a cylinder seen obliquely. An upper arc E–M–N–F–S–a–G stands over a lower arc A–D–Z–C, the two joined by verticals E–A and G–C; vertical lines drop from M, N, F, S and a. The line from M carries the marks 1, 4 and 9; dots O, Q, T and Z stand on the verticals from N, F, S and a; H stands above the upper arc. Along the lower

edge run five small circles, the Earth at its successive positions, with centres K, V, B, X and Y, each with a horizontal diameter and lettered I at the left, R at the right, L below and P above (the circle B shows no P).

- E, H, M, N, F, S, a, G: points on the upper arc (H above it)
- 1, 4, 9: marks on the vertical from M
- O, Q, T, Z: dots on the verticals from N, F, S and a
- A, D, C: points on the lower arc
- K, V, B, X, Y: centres of the five circles
- P, I, R, L: the pole, left, right and lower letters of the circles (P on K, V and X; I, R, L on all five)

Now let the Earth be understood as ILRP, and its centre carried by the Great Orb from the point K to the points V, B, X, Y, over an interval of four equal times, to which the equal arcs of the Great Orb KV, VB, BX, XY correspond. Let the terrestrial equator be IR, its axis LP, and its north pole P; and let the axis be produced through the pole P outward, towards the north, by as much as the height of the tower or place from which the heavy body is let fall — say, by as much as KPM. For this line too, carried round with the axis of the equator, will describe the cylinder ACGE, one of whose bases is ABCD and the other EFGH; and at the end of the first of the equal times the tower, which was in the position PM, will be in PN; at the end of the second in PF; at the end of the third in PS; and at the end of the fourth in Za.

Heavy bodies, however, descend naturally in such a way that, if the whole time of the descent is divided into 4 equal parts (as we have assumed here) and the first space is taken as 1, the space covered at the end of the second time is as 4, at the end of the third as 9, and at the end of the fourth as 16 — as is established by our experiments in chapter 16, number 12, and by Galileo's own admission in the second dialogue *On the System of the World*. Let the height PM, therefore, be divided into 16 equal parts, and let there be marked on it the part M1, of one such part, the part M4, of four, and the part M9, of nine parts. Now if a ball heavier than the medium through which it descends were let fall from the vertex M, above the pole P, and the Earth moved with no motion other than the diurnal, about its own centre K, from I to R, and its centre always remained at K, then this ball would certainly descend not only apparently but also really along the same straight line MP, falling perpendicularly on the pole P. At the end of the first time it would have covered the space M1, at the end of the second the space M4, at the end of the third the space M9, and at the end of the fourth the whole space MP, which is 16 of the parts of which M1 is one.

But the centre is carried from K to V, etc., by the force of the annual motion, and the tower or height MP is carried round over the surface of the cylinder, which is to be conceived in the space of the world, on Copernicus's hypothesis. Therefore, when at the end of the first time the tower is at PN, the ball will be seen to have covered the space NO, which is equal to M1, or as 1; at the end of the second the space FQ, or as 4; at the end of the third the space ST, as 9; and at the end of the fourth the space aZ, which is as 16. However, since the eye of

the spectator, supposed to be at the pole P, is likewise carried along with that tower, the ball will appear to him always to be in the same straight line, even though in reality, on this hypothesis, the ball has described on the cylindrical surface the curved line MOQTZ, far longer than the straight line MP and not lying in one plane.

This line will therefore not be a cylindrical section that is a circle — as is the section whose plane cuts the cylinder parallel to the base — nor will it be an ellipse, such as is the section whose cutting plane is not parallel to the base of the cylinder, according to what was demonstrated by Serenus of Antinoë, who is usually published with Apollonius, in Book 1 of the *Sections of the Cylinder*, Propositions 5, 6 and 17. The reason why the points O, Q, T, Z are not in one plane is the proportion of the square numbers. Otherwise, if they were in one plane, the section would be elliptical; but then it would be cut in half at Q by the straight line FP, which is the middle one among five lines standing at equal intervals from one another, and the parts FQ would be 8 of the 16 parts; and the second line, NP, and the fourth, SP, would be cut so that NO would be equal to PT, that is, 7 parts each, as could easily be demonstrated if there were need and we were not hastening on to other matters.

[Margin: The spin owed to a ball descending above the poles.]

It should be noted here, however, that a ball let fall perpendicularly above the pole of the terrestrial equator would, while it descended along the line MOQTZ, at the same time be carried round about its own centre with a spin imitating the diurnal spin of the Earth. I wish it could be observed by an inhabitant under the poles of the world! For from it either the truth of the Earth's diurnal spin would become manifest, if such a spin were discerned on the surface of that ball, or its falsity, if it were not discerned.

[Margin: The 2nd figure, for a heavy body descending in the plane of the equator.]

XVII. Now let the second figure be for a ball let fall from the vertex of a tower standing in the plane of the equator, or in the right sphere. Let A be the centre of the Great Orb; from it describe the arc BDC, divided into four equal parts, Bρ, ρD, DP, PC, corresponding to the four equal times in which the ball let fall from the vertex of the tower is supposed to slide down to the surface of the Earth; and let it be understood that at the beginning of the motion the centre of the Earth is at C, at the end of the first time at P, at the end of the second at D, at the end of the third at ρ, and at the end of the fourth at B. Let the height of the tower be FH, and the terrestrial equator EFG, which, in the four times already mentioned, revolves about the centre C towards the east, from F to E, so that the foot of the tower, F, covers the arc FE, and its vertex the arc HK. Here, if there were no motion other than the diurnal, the ball let fall from the vertex H would have covered at the end of the first time the space LM, as 1 of the parts of which FH is 16, and the tower would be on the line CL. At the end of the second, the tower would be on the line CN, and the space covered by the ball would be NO, namely 4 such parts; at the end of the third,

the tower would be on the line Cm, and the space covered would be mI, or 9 parts; and finally, at the end of the fourth time, with the tower carried to the line CK, the whole space KE, of 16 parts, would have been covered.

But at the end of the first time the centre of the Earth is supposed to have been carried from C to P by the force of the annual motion, and meanwhile the tower, by the force of the diurnal motion, has completed the arc XQ of the equator towards the same side; therefore the tower is on the line QR, and the space apparently covered by the ball is RS, of 1 part. At the end of the second time, with the centre of the Earth brought to D, and the tower completing by the force of the diurnal spin the arc TV, double the arc xQ, the tower will be on the line XV, and the space covered by the ball will appear to be XZ, that is, 4 parts. Then, with the centre of the Earth carried by the annual motion to ρ, and the tower to the line αβ because of the arc Yα completed by the force of the diurnal rotation, triple the arc xQ, the ball will appear to have covered the space βγ, of 9 of the parts of which RS is one. Finally, with the centre of the Earth transported to B, and the tower to the line εθ because of the arc δθ completed by the force of the diurnal spin — indeed quadruple the arc xQ — the ball will appear to have covered the whole space εθ, of 16 parts.

Diagram. The second figure, set in the left column: from A at the foot, radii rise to an arc of the Great Orb carrying five small circles, the Earth at its successive positions, with centres B, ρ [?], D, P and C. Above them an outer arc through ε, β, X, R to H, and inside it a curve through θ, δ, γ, Z and S; from each circle a tower line rises to the outer arc. At the right, around the circle C, lines fan out to K, m, N, L, H, with O, M, I, E, F marked on them and G below.

- A: the centre of the Great Orb, at the foot
- B, ρ [?], D, P, C: centres of the five circles
- R, X, β, ε, H: on the outer arc
- S, Z, γ, δ, θ: on the inner curve
- Y, a, V, T, Q, x: on the circles and tower lines (x stands right of Q)
- K, m, N, L, O, M, I, E, F, G: on the fan of lines about the circle C

Hence the line described by the ball in the space of the world will be the curved line HSZγθ, although to an eye carried likewise along with the foot of the tower from F to the points Q, V, a, θ the ball will appear always to descend along the same straight line, parallel to the tower. Meanwhile the vertex of the tower, H, will describe the curved line HLRXβε. Neither of these will be circular, because it will always come closer to the centre A, from which it is certainly farther when the ball is at H — for it is then distant by the whole aggregate of the semidiameter of the Great Orb, AC, the semidiameter of the Earth, CF, and the height of the tower, FH — than in any of the other positions already mentioned. Indeed, since the plane of the equator, because of the parallelism it keeps with itself, is always carried by the Great Orb, which is inclined to it, to one plane after another, the line HSZγθ cannot lie in one plane, and therefore it cannot be parabolic, hyperbolic or elliptical: for these

lines require that they lie in one and the same plane cutting a cone or a cylinder, actually or potentially. The same thing happens proportionally in the other positions of the tower, granted that we have chosen a single case, namely when it is midnight for that tower.

[Margin: Figure for the oblique sphere.]

XVIII. Now let the third figure be for a heavy body let fall from the vertex of a tower standing in the oblique sphere (or on the circumference of some terrestrial parallel declining from the equator), but standing perpendicularly on the Earth's surface, and so placed that, if it were produced, it would run into the centre of the Earth. Let there be marked, then, the arc ACB, a portion of the Great Orb, on which the centre of the Earth FKEG is first at B; and let the circle of the terrestrial equator, inclined to the Great Orb, be DBE, whose axis KBQ etc. is understood to be produced as far as H. Let the parallel be FQG, on whose circumference the tower GL stands erected perpendicularly to the globe of the Earth; and let the terrestrial equator turn with the diurnal spin from E through B to D, the eastern point, until, a revolution of 24 hours being completed, the point E returns to the original beginning of the revolution. For it is certain in the Copernican hypothesis that the whole globe of the Earth, with all the parallels to the equator, turns towards the same quarter. And just as the semidiameter of the Earth, BG, will describe the cone BGF, whose base is the parallel circle indicated by GQF and described by the point G, which is at the foot of the tower, so the tower GL, joined with the Earth's semidiameter BG, will describe a larger cone, BLM, whose vertex, common with the former, will be the centre of the Earth, B, and its base the circle ML. For the semidiameter of this circle makes a right angle with the axis BH; and therefore, if, while this axis BH stays fixed as a side, the other sides are carried round it until they complete one whole revolution, a cone will be described by them, by definition 18 of Book 11 of Euclid's *Elements*.

Diagram. The third figure, set full width: five hatched globes in a row, each with a cone rising from its centre, and a dotted curve running from the first cone over the tops of the others to L at the far right. The fifth globe, centre B, carries the inclined circle D–B–E, the parallel F–R–Q–P–G, the tower GL and the cone BLM, with the axis dotted down to K.

- Φ, π, [?]: on the first cone and globe (an unresolved sort beside a dot on the globe's rim)
- A, I, C, X, B: centres of the five globes
- x, [?], ω, θ: on the second cone and globe (the unresolved sort beside a dot on the dotted curve)
- ε, η, ζ, ξ: on the third cone (ε at its top, η and ζ within it, ξ at its right edge)
- [?], [?], β, a: on the fourth cone and globe (two unresolved sorts at its top)
- D, E, K: on the fifth globe (inclined circle and foot of the axis)
- M, N, H, O, L: on the top of the fifth cone

- F, V, T, S, R, Q, P, G: on the parallel and the tower lines of the fifth globe

Let us now imagine that the ball let fall from the vertex L reaches the surface of the Earth in four equal times, and that the Earth meanwhile moves with the diurnal motion alone; and so, the arc FG of the parallel being divided into four equal arcs corresponding to the times already mentioned, namely GP, PQ, QR, RF, that the tower is likewise carried first to the line PO, then to the line QH, third to the line RN, and fourth to the line FM. Therefore, since heavy bodies descending naturally pass through spaces that stand to one another in order as the squares of the times, if the height GL is divided into 16 equal parts, of which the one passed through at the end of the first time is OS, that is, 1; the second, at the end of the second time, HT, of 4 parts; the third, at the end of the third time, NV, of 9 parts; and the fourth, at the end of the fourth, MF, of 16 parts, then the tower will indeed describe part of a conical surface, in such a way that the ball, which always appears to be in the same straight perpendicular line, will describe about the surface of the cone MBL the curved line LSTVF; and the proportion of the square numbers does not allow this line to lie in one and the same plane. So even in this case that line will be neither circular, nor elliptical, nor parabolic, nor hyperbolic — even if B, the centre of the Earth, were not meanwhile moving towards A by the annual motion.

Now let the centre B move towards A, the eastern point, into X, by the annual motion, and so carry the cone described by the tower and the Earth's semidiameter to another position. Meanwhile, through the diurnal spin, let the tower have completed the arc aβ and stand on the line βγ: for the ball will appear, at the end of the first of four equal times, to have completed the space γδ, which is taken as 1. Next, at the end of the second time, let the Earth's centre be at C, and the whole cone carried along with it, so that the tower, by the force of the diurnal spin, has completed the arc ξζ, double the arc aβ, and stands on the line εζ: for the ball will appear to have completed the space εη, which will be as 4. Third, let the centre of the Earth be carried by the force of the annual motion to Y, with the whole cone standing on it, and let the tower, through the diurnal rotation, have completed the arc ωθ, triple the arc aβ, and stand on the line xθ: for the ball will appear at λ, having now completed the space xλ, which will be as 9. Finally, at the end of the fourth time, let the centre of the Earth have passed to A by the force of the annual motion, carrying the Earth with it together with the cone already mentioned; and let the tower now have run through, by the diurnal motion, the arc πμ, four times the arc aβ, so that the tower stands on the line μΦ: for then the ball will be on the Earth's surface, that is, at the foot of the tower, μ.

So although the ball will always appear in the same straight line in which the eye stationed at the foot of the tower stands — since the eye is carried by the force of both motions from G to the points β, ζ, θ, μ — in reality it will make the curved line Lδηλμ. This line can be neither circular, since it always approaches more and more closely to its own centre, which is the centre of the

Great Orb; nor elliptical, nor parabolic, nor hyperbolic, since it does not lie in one plane. For it is described about the cone in such a way that it is nevertheless carried into one plane after another, both because of the proportion of the square numbers that it keeps in approaching the Great Orb, and because of the inclination of the terrestrial equator to the Great Orb, the equator remaining always parallel to itself.

[Margin: A warning on correcting the figures.] In the figures already mentioned we drew the centre of the terrestrial globe at its several positions with arcs of the Great Orb between them equal to the arc that the Earth's diameter subtends, so that the figures would not confuse the viewer. Those intervals, however, may be greater or smaller, according to the time of the whole descent of the heavy bodies. And what we have said about the position of the tower that has midnight holds equally for any other position of the tower.

[Margin: Corollaries for the figure of the motion of heavy bodies.] From what has been said it is clear that in no case is the line already mentioned circular, elliptical, hyperbolic or parabolic, since it is not drawn in one plane — which is nevertheless required, as is clear from the sections of Apollonius, Book 1, proposition 4, on the circle cutting a cone; prop. 11, on the parabolic section; prop. 12, on the hyperbolic section; and prop. 13, on the elliptical section; and also from the cylindrical sections of Serenus, Book 1, props. 5, 6 and 17, on the circle and the ellipse arising from the section of a cylinder.

[Margin: The errors of Kepler, Gassendi, Boulliau and others about the figure of the motion of heavy bodies, but above all of Galileo.] Accordingly, these erred: Kepler, who, as stated in chapter 4, scholium 2, described this line as if the Earth's motion were diurnal only, and as approaching too closely, at the beginning of the motion, to the straight perpendicular line; Gassendi, who, as stated in the same place, scholium 4 — namely in the second letter *De motu impresso* — held it to be universally parabolic; Boulliau, in Book 1 of his *Philolaus*, chapter 4, who asserted that it was composed of two circular lines in one plane; and those who, as reported in Chiaramonti, Book 12 of *De Universo*, chapter 21, said that it is like the quadratrix of Nicomedes. But most of all Galileo erred, who in the second Dialogue on the system of the world asserted that it is circular, or as near to circular as can be, and yet ends at the centre of the Earth. Against him, besides these errors, there is also the following objection. Granted, as I said in number 12, he recognised, as if through a lattice, that this line is a spiral about a cone in the parallels of the equator, and in the case above the poles a spiral about a cylinder — but at the prompting and warning of Scheiner, who of all came closest to the truth on this point. We, however, had already drawn the figures already mentioned by our own wit before we had read that passage of Scheiner.

[Margin: 8th objection.] XIX. In the second Dialogue on the twofold system of the world, page 223 of the Italian but 168 of the Latin version, Galileo teaches the following about the pendulum or plumb-line: *"I put that observation of the pendulum before you for this purpose: that you should understand that the*

impetus acquired in the descending arc, where the motion is natural, is of itself able to drive the same ball of the pendulum, by a violent motion, through an equal space in a similar ascending arc — of itself, I say, once all external impediments are removed. I also believe it is understood beyond doubt that, just as in the descending arc the speed continually grows as far as the lowest point of the plumb-line, so too from that same point along the other, ascending arc the speed continually diminishes as far as the extreme and highest point; and indeed diminishes in the same proportion in which it grew at the start, so that the degrees of speed at points equally distant from the lowest point are equal to one another." [Margin: Once inequality of impetus is granted, inequality of motion is wrongly denied.] [Margin: Galileo's doctrine of the speed of descent and ascent of the pendulum along an arc.] *"On this occasion I say that the reason this motion is not perpetual is that in the ascent the heaviness takes away something from the upward-driving impetus; and so the arc of ascent is not precisely as great as the arc of descent, and the heaviness prevails more and more by a contrary impetus, until it destroys that impetus entirely and the plumb-line comes to rest."*

[Margin: And on the motion of heavy bodies through a well as long as the diameter of the Earth.] But Salviati, playing the part of Galileo, goes on and says: *"And from this (reasoning with probability) I think I can believe that, if the terrestrial globe were bored through to the centre, and indeed beyond it as far as the nadir, a cannon-ball would acquire in its descent so much impetus of speed that, once past the centre, it would drive the ball upward through as great a space as the space of its descent; in such a way, that is, that beyond the centre its speed would continually lessen by degrees of decrement corresponding exactly to the degrees of increment acquired in the descent."* So far Galileo, as concerns our subject.

Galileo therefore admits that a heavy body acquires a real impetus, ever greater, and so great that it is able to drive that same ball upward. But if it really moves uniformly along a circle, as follows from his own doctrine given in number 8 and from his own most explicit statement, and the inequality of speed is a mere appearance to the eyes, or to the intervals as viewed, which it seems to pass through in a straight perpendicular line, then it cannot continually acquire an increment of greater impetus, an impetus able to drive upward; or if it does acquire it, the inequality of speed that follows from it by natural necessity is real, not apparent. [Margin: Galileo at variance with himself.] Galileo therefore contradicts himself, and his propositions on page 120, on real uniformity, and on page 168 of the Latin, on the increment of impetus, cannot be reconciled with each other.

Having set out these not untimely remarks on this motion, it is now time to put forward the argument for the Earth's motion that Galileo and Boulliau have built from the motion of heavy bodies, and to dissolve it. Cast into syllogistic form, the argument runs as follows.

[Margin: The argument in form for the motion of the Earth.] XX. *Heavy bodies, descending naturally, acquire by their apparent motion a continual increase of speed. But the reason for this increase is given most readily if the Earth moves*

at least with the diurnal motion; if, however, it is immobile, no reason can be given in which the intellect can rest. Therefore the Earth moves at least with the diurnal motion. [Margin: Proof of the major and the minor.] The MAJOR is clear from many experiments, but chiefly from those set out at length in chapter 16 from number 6. The first, affirmative part of the MINOR is proved thus: if the Earth moves at least with the diurnal spin, the real descent of heavy bodies turns out in fact to be circular and uniform, and the whole inequality of their speed is thrown back onto mere appearance, the eyes falsely judging that they move along the same straight perpendicular line and pass through ever greater spaces in it in equal times — whether they are then said to move along two circles, according to Boulliau's opinion set out in numbers 2 and 3, or along a simple circle, according to Galileo's opinion explained in numbers 7 and 8. The second, negative part of the MINOR is proved from the insufficiency of the reasons that the Peripatetics, or others, have so far adduced for such an increase, which Simplicius in particular reports, in Book 1 *De caelo*, text 88, and others too. For the chief reason usually brought forward is the acquisition of greater and greater gravitation, or impetus, intensifying the earlier impetus. But if this were the cause, heavier bodies would also have to descend faster, and the faster the heavier they are than the others; and so a ball of iron weighing two pounds would have to descend from the same height to the ground in half the time taken by an iron ball of one pound. This is established to be utterly false, as is clear from the experiments set out in chapter 16, number 13, and from theorem 13 of the same chapter.

[Margin: 1st reply.] I reply, first: granting the Major, I deny the first part of the Minor, and its proof. For once the diurnal motion of the Earth is posited, some appearance of an increase of speed is indeed saved by a motion that is in fact uniform; but the other effects are not saved, which presuppose a real increase of a continually greater impetus, and so a speed of motion that is in fact greater and greater. Such are the stronger blow, the louder sound, and the raising of a greater weight, the higher the place from which the heavy bodies fall, according to what was said against Boulliau in number 5 and against Galileo in number 10. Next, Boulliau's two circles do not save the increase of speed according to the odd numbers counted from unity, as we showed in number 5. [Margin: Galileo's many errors gathered into one.] And Galileo's single circle does not save the real increase of the impetus of heavy bodies, which nevertheless had to be saved, even on what Galileo grants elsewhere, according to what was said in numbers 10 and 19. Nor, again, is the unequal descent of two heavy bodies of different weight let fall together from the same height saved, as I showed in number 11. Moreover, that descent along a semicircle is not saved unless the heavy body is at the equator and so slow that it requires exactly 6 hours to reach the centre of the Earth; for once these two conditions are removed — and they are verified in very few cases — the line of the motion already mentioned is not circular, as I showed in numbers 12, 14, 16, 17. Indeed, not even at the equator is that semicircle produced by the motion of a heavy

body, even one so slow that it would reach the centre of the Earth in 6 hours, unless the Earth's motion is diurnal only, with the annual motion of the centre excluded. Since Galileo does not exclude that motion, it makes the fall unequal in reality, and along a line different from a circle; so Galileo again contradicts himself, as I showed in numbers 13 and 15. Indeed, even if the heavy body is at the equator and descends to the centre of the Earth in 6 hours, and the Earth moves with the diurnal motion alone, the line of descent is not circular but notably different from a circle towards the end, as I showed in number 14. Finally, by this hypothesis Galileo cannot save the increase of speed of light bodies that ascend naturally, even above the air bordering the Earth: for these are neither carried to one determinate point as to a centre, nor do they follow the motion of the Earth. Perhaps for this reason he preferred to deny positive lightness, against the experiments adduced in chapter 16, number 3.

[Margin: The objection rejected.] Nor may you say that, granted Boulliau and Galileo have not saved all the properties of heavy bodies descending naturally, they can nevertheless be saved in the hypothesis of the moving Earth, since one can assign the line they describe, and in it the inequality of the parts passed through in equal time, together with the inequality of the blow, the sound and so on, and the inequality of speed of heavy bodies of different weight. For the reply is that this real inequality cannot be saved at the equator, if the heavy body is such that it requires 6 hours to arrive at the centre of the Earth, as I shall demonstrate below. Outside the equator it can indeed be saved by a line such as we described in number 17; but by that line the difficulty of the real increase of the speed of heavy bodies is not removed, but rather increased. For along such a line that unequal motion turns out to be produced along curved lines, of different kinds, about a cone, by a longer path than if, with the Earth standing still, the heavy bodies moved along the simplest straight line, as happens with heavy bodies falling above the poles of the terrestrial axis. And, what is absurd, the same heavy body, its heaviness unchanged and let fall from the same height, is compelled without any necessity to travel in reality a much longer path than if it fell above the poles of the terrestrial axis; and a longer one in one parallel than in another; and, finally, a longer one by night than by day.

[Margin: 2nd reply.] I reply, second: I deny the second part of the Minor, which was the negative one. For a sufficient reason for the increase already mentioned can be given in the hypothesis of the immobile Earth, as will appear in the next chapter, number 10. Nor is it necessary, if the reason is to be sufficient, that the motion downward be the faster the heavier the body is; just as it is not necessary, if the cause of refraction is the inclination of a ray upon a medium of different density, and the inclination of one ray is twice the inclination of another, or the density it falls on is twice as great, that its refraction too be twice the refraction of the other. Or, if the greater distance of a star from the Earth is the cause of smaller refraction and parallax, other things being equal, it is not necessary that the refraction or parallax therefore become half as great because its distance has become twice as great.

[Margin: Corollary against Galileo's boasting.] From what has been said so far, then, it is clear into what shameful errors in geometry and physico-mathematics Galileo fell, who boasted with such great but empty glory that he had found the way by which heavy bodies, descending naturally, are seen to acquire an increase of speed.

CAPVT XVIII.

Chapter 18.

AN & QUOMODO IN HYPOTHESI TERRÆ QUIESCENTIS REDDATUR RATIO À PRIORI, CONTINUI INCREMENTI VELOCITATIS GRAUIUM, & LEUIUM NATURALITER DESCENDENTIUM, VEL ASCENDENTIUM.

Whether, and how, in the hypothesis of the resting Earth, a reason a priori can be given for the continual increase of speed of heavy bodies and light bodies descending, or ascending, naturally.

I. Various opinions on this subject are reported, in the first place by Simplicius on Book 1 *De caelo*, text 88, comment 86; by Franciscus Bonamicus [Francesco Buonamici], Book 4 *De motu*, chapter 37; by the Conimbricenses, Book 2 *De caelo*, chapter 6, question 1; by Zabarella, Book 1 *De motu gravium et levium*, chapter 16; by Chiaramonti, Book 12 of *De Universo*, chapter 30; by Contarenus, Book 1 *De elementis*; and by Pererius on Book 4 of the *Physics*, chapter 3. We must touch on them briefly here, to show that the hypothesis of the immobile Earth does not lack a way of bringing forward an a priori cause for which heavy and light bodies move faster and faster towards the end. Giving that cause is now harder than it was before our experiments and Galileo's. For until then it was not known what proportion they continually keep in such an increase, and so it was enough to bring forward a cause of greater and greater speed. Now, however, it is known — at least by those who have made the experiments, or are willing to make them carefully — that this increase (speaking at least of heavy bodies) follows the progression of the odd numbers counted from unity; so a reason must be given for this proportion too.

[Margin: 1st opinion, Hipparchus's, on the cause of the increase of speed.] II. The *first* opinion was that of *Hipparchus*. He said that if heavy bodies are thrown upward by force, they begin their downward motion when their heaviness begins to prevail over the power impressed by the thrower; but because something of that impressed impetus still lasts, though it is overcome more and more by the innate heaviness, the descent is therefore slower at the beginning and faster at the end. And if heavy bodies have not been thrown upward but let down, there still remains in them something of the force that held them back, which is used up only little by little; and so the motion of heavy bodies is slower at the beginning and faster towards the end. Alexander, in Simplicius, rejects this cause on the ground that heavy bodies are not rarely generated outside their own place, where they were held back by nothing, and yet are still faster towards the end of the motion. I add that if Hipparchus's

reasoning held, heavy bodies thrown downward would always move faster at the beginning than at the end, because of the double motive power downward joined in them — one from the intrinsic power, the other from the extrinsic thrower — the second of which power gradually weakens. But this is not universally true: for sometimes the impetus with which they are sent down is so slack that the increase of speed towards the end of the motion is far greater than near the start. Finally, one who does not simply let a heavy body down, but lets it go downward, entirely ceases to hold it back, and leaves nothing of a retentive quality in that heavy body.

[Margin: 2nd opinion, attributed to Alexander.] III. The *second* opinion, which some attribute to Alexander, held that the cause is that heavy bodies are altered less by contrary qualities the nearer they come to their own place. But an iron ball descending through the air is certainly not altered at all by the air; and if it is altered, it is rather some moisture that it acquires, which grows towards the end; and a glass ball is altered much less in descending through water.

[Margin: [?] opinion, of Themistius and Kepler.] IV. The *third* opinion was that of *Themistius*, on Book 8 of the *Physics*, text 76, who says that bodies move faster at the end for this reason: they are attracted by the places akin to them, to which they are carried. Or that of *Kepler*, in the introduction to the *Commentaries on Mars*, who says that they are drawn by the globe of earth and water through a certain magnetic power. But whether the place attracts only objectively or effectively, it would certainly attract and draw a body akin to it more strongly when the body is nearer than when it is further away, even if it had not been brought nearer by motion from far off. And so, if one ball were let fall from a window 50 feet high at the moment when another ball of the same kind, shape and weight, let fall from a height of 100 feet, had reached that window, they would be attracted equally, being now at an equal distance; and yet the one let fall from the height of 100 feet reaches the ground faster and strikes it with a greater blow.

[Margin: 4th opinion, of Iamblichus, Sirenius and Durandus.] V. The *fourth* opinion, of *Iamblichus* and *Sirenius*, was that this happens from the smaller resistance of the medium, since, that is, a smaller depth of air remains to be passed through; or rather, as *Durandus* says (on Book 2, distinction 14, question 1), because the lower air is the thicker the nearer it is to the Earth, and so, levitating upward less, it resists the downward motion less. But against these stands the case just brought forward, of two heavy bodies equal in kind, bulk, shape and weight, one of which is let fall from a tower 100 feet high, and the other let fall when the first reaches a window 50 feet high: for then an equal depth of air remains to be overcome by each, and yet the one let fall from the hundred-foot height reaches the ground much sooner. Against Durandus in particular there tells the very thickness of the air, which is less apt to give way and to move upward or to the sides. And when a ball heavier than water is let

fall through water of uniform thickness, as we have often done, it still descends faster at the end.

[Margin: 5th opinion, of Contarenus and Burlaeus.] VI. The *fifth* opinion is that of *Contarenus*, Book 1 *De elementis*, and of *Burlaeus* [Walter Burley], on Book 8 of the *Physics*, text 76, who put the cause in the air rushing in from behind to fill the vacuum, rarefied more and more by the motion, and so driving the heavy body downward with greater effort. But if a half-burnt and still smoking material is let fall, or a heavy body with a piece of a lighted candle fixed on top of it, the smoke or the flame is seen for a long time standing upright; so the air does not press on that heavy body from behind. So too with light bodies rising through water: if you hang a thread below one, the thread stays stretched downward and is not driven upward by the water. Moreover, the lower air is not more rarefied on account of the motion completed in the upper parts.

[Margin: 6th opinion, of Zabarella, Pererius and Dandinus.] VII. The *sixth* opinion is that of *Zabarella*, Book 1 *De motu gravium et levium*, chapter 16; of *Pererius*, Book 4 of the *Physics*, chapter 3; and of *Dandinus*, Book 2 *De anima*, in a digression on this motion. Although they grant that the increase of speed is helped by the air rushing in from behind, they refer the chief cause to the air in front, already moved and dispersed in the direction in which the heavy or light body is carried. For just as a moving body moves faster through air already moved in the same direction, and a ship going downstream on a river moves faster, than through unmoved air or wandering water, so it moves much faster through air moved twice, and faster still through air moved three times, and so on.

But against the air from behind enough was said in number 6. Against the air in front there tells the wind, which drives that air crosswise and yet cannot move a heavy body of great weight from its perpendicular motion. Next, it is not numerically the same part of the air that is moved again and again by the descending heavy body, since the air runs in at the sides and around the body to fill the place the body successively leaves; so the air is not rightly said to be moved twice, three times, four times. Universally, against those who fall back on the motion of the air or water in front, there tells the priority of the motion of the heavy body itself. For the air or water beneath is moved because it is driven by the heavy body tending downward, and the air or water is moved faster because that heavy body moves faster. Its increased speed is therefore presupposed before the air or water moves faster, at least by priority of nature and of cause; so the commotion of the air or water cannot be the cause of the greater speed in the descent of heavy bodies. The comparison with the river does not hold here, because the motion of the river is presupposed antecedently to the motion of the ship. Finally, against this opinion tells the slower descent of a lighter ball let fall together with a heavier one.

[Margin: 7th opinion, of Aristotle, Alexander, St Thomas, Albertus de Saxonia, the Conimbricenses, Cabeo, Chiaramonti, Bonamicus.] VIII. The

seventh opinion was that of *Aristotle* and *Alexander*, in *Simplicius* on Book 1 *De caelo*, text 88 — an opinion that Simplicius himself also prefers to the others, on the supposition that such an increase is granted (for in that same place he himself doubts it); likewise that of *St Thomas Aquinas* and *Albertus de Saxonia*, in *Bonamicus*; of Bonamicus himself, in his book *De motu*, chapter 37; of the *Conimbricenses*, on Book 2 *De caelo*, chapter 6, question 1; of *Cabeo*, on Book 1 of the *Meteorologica*, text 17, question 3; and of *Chiaramonti*, Book 12 of *De Universo*, chapter 30. They put the cause in greater and greater gravitation, or in greater accidental gravity, or in the second act of gravity, which by the motion itself becomes more and more perfect in second act — what Aristotle called the apposition of gravity or levity, understand: in second act. For in Book 1 *De caelo*, text 88, he says that if the speed of the elements were increased to infinity, gravity or levity would be increased to infinity; and in the *Mechanics*, question 19, he teaches that if a heavy weight is placed on an axe, it often does not split the body, which the axe nevertheless does split if it is swung from on high by itself, without any other weight, because it takes on some gravity. From this it appears that by the name of gravity he does not mean gravity in first act — for with another weight placed on top, that aggregate already had greater gravity, and yet it did not split the body — but means impetus, and gravity in second act, or a translative quality. Chiaramonti, however, calls the second act of gravity itself motion, which, he admits, can produce another motion by the mediation of gravity; others understand impetus as distinct from motion taken formally.

Since, then, at every moment in which a heavy or light body is outside its place and is prevented by no impediment or contrary mover, it produces some determinate degree of impetus suited to its own gravity or levity, and there is no reason why the earlier impetus should cease, it comes about that, as new and still newer degrees of impetus of the same kind are added, the impetus in the same part of the subject becomes more and more intense, and so the motion becomes faster and faster. But Bonamicus, besides this principal cause, also adds the ever smaller resistance of the medium. This opinion would no doubt satisfy us if a cause had to be assigned only for the continual increase of speed. For what is more consonant with the nature of heavy or light bodies than that, at any instant in which they are away from their natural place, gravity or levity should produce an impetus of the same kind and amount as it produced in the first instant of the motion, and that this should remain so long as it is not destroyed by a contrary impetus, or the body has not reached its natural place?

But from this it would follow that the proportion of this increase goes according to the simple and natural arithmetic progression. For let us suppose, for ease of explanation, that the impetus produced in the first instant of the motion is so great in a given heavy body that by its force the body passes through a single palm in the first and smallest of the equal times. Then, with a second degree of impetus added, equal to the first, it ought in the 2nd of the equal times to pass through no more than two palms, which together with

the first would make 3 palms at the end of the second time. And with a third impetus added, it ought in the 3rd of the equal times to pass through 3 palms separately, which together with the 3 preceding would make six palms; and so on. So the spaces completed in each of the equal times separately would go according to the increase of the arithmetic progression 1, 2, 3, 4, 5, 6; and from these the spaces passed through at the end of the aggregated times would arise in this proportion: 1, 3, 6, 10, 15, 21. And Cabeo, in the place just cited, and Baliani, Book 4 *De motu gravium*, page 110, judged it more probable that the increase goes in this way. But it is now certain to Galileo, to us, and to anyone willing to make the experiment, that this increase is much greater, and indeed follows the progression of the odd numbers counted from unity: so that if in the first of the equal times a heavy body passes through 1 palm, in the second it passes through 3 palms separately, in the third 5, in the fourth 7, in the fifth 9, and so on. From this the spaces aggregated at the end of the times arise according to the order of the square numbers 1, 4, 9, 16, 25. The reason for this increase, therefore, is what is sought.

[Margin: 8th opinion, of a recent philosopher.] IX. The *eighth* opinion, then, was that of a certain recent professor of philosophy, who had been present at some of our experiments and had no doubt at all about the proportion already mentioned. It held that in the first minimum of the duration of this motion gravity produces 1 degree of impetus, by whose force the heavy body passes through one determinate part of the space; that in the second instant, or rather minimum of duration, gravity produces another degree, and the earlier impetus produces another impetus like itself, so that there are three degrees of impetus, and therefore in the second of the equal times a space three times greater is passed through than in the first time; but that meanwhile the older impetus perishes, and so two degrees remain, which produce two more degrees, while gravity always produces its accustomed degree, so that there are five degrees, from which follows a passage through a space five times greater than the first space; and that in the fourth moment the two oldest of these 5 degrees of impetus perish, and the three remaining produce three more, to which gravity, adding its own new degree of impetus, completes 7 degrees, from which follows motion through a space seven times greater than the first; and so on. But this opinion is little in keeping with the natures of things. For why should impetus perish if it has no contrary and the moving body has not reached its place? Or, since all the degrees of this impetus are of the same species, why should so many degrees perish in the very instant in which others, and indeed more of them, are to be produced in their place? For example, why should two of the 5 degrees perish in the fourth instant and three remain, if in that same instant 4 degrees must be produced, which with the three remaining make 7? Is it not less wasteful that only 2 be produced anew, which, added to the five earlier ones, make 7? Certainly it is.

[Margin: 9th opinion, our own, in three parts.] X. The *ninth* opinion, then, and our own, to which we hold until something better occurs to us, is this. At

any instant in which a heavy body is outside its place and the obstacle has been removed, gravity produces one degree of impetus; and that very impetus which was produced by gravity produces another like itself in the instant immediately following, so that all those produced remain and make the earlier impetus more intense. Not all of them, however, produce degrees like themselves at each and every moment, but only once, as soon as they have been produced. If this is so, it follows that in the first instant of the descent one degree is produced by gravity alone; in the second instant (to speak this way for ease) both gravity produces its own degree and the impetus produced by gravity immediately before produces a degree of impetus like itself, and so there are three; in the third instant gravity produces its own and the more recent impetus its own, which, added to the earlier ones, make five degrees of impetus; in the fourth instant gravity begets its own degree and the newest impetus its own, which, joined to the earlier ones, make seven degrees; and so on, two degrees always being produced, one by gravity, the other by the most recently produced impetus. Otherwise, if all the existing degrees each produced their own degrees in every instant, they would exceed their nearest radical principle, which is gravity.

[Margin: 2nd part of our opinion.] If this does not please, let us say that in the first instant, or minimum of time, gravity produces only half of the impetus which it can produce whole in the remaining instants, on account of the difficulty of beginning motion, whatever that difficulty may finally be. Or rather let it be said that in the first instant the heavy body descends by force of an impetus which, before the descent, it had always kept produced in itself, but which was impeded — by a supporting body, for example — from effecting the descent; whereas in descent that heavy body produces for itself, at each instant, a degree of impetus twice as great as that first impetus which it was producing while not descending. Accordingly, if in the first instant it descends, say, a space of one palm by force of the first impetus, in the second instant it will descend three palms — one by force of the same first impetus, which persists, and two by force of the impetus produced in the first instant of the descent — and in the third instant it will descend five palms, because another impetus has now been added, effecting descent through two palms. Proceeding in this way, the progression of the odd numbers beginning from unity will likewise be kept.

[Margin: 3rd part of our opinion.] But suppose someone will not have impetus stand to impetus as speed stands to speed, but holds that an impetus merely doubled, through its union with another impetus equal to it, can have as much force as if it were itself doubled, so that the first two impetuses produce motion as 4 when the first had produced it as 1. Then, surely, three impetuses at the end of the third equal time, each behaving as if it were tripled, would together produce motion as 9, four as 16, and 5 as 25, and so on. If, however, someone says that the cause a priori was the will of the Author of Nature, who could have established another proportion of this increase for heavy and light bodies, but determined on this one as being both beautiful in itself — on

account of the order of the square numbers, which the increments of circles also keep when their diameters grow equally — and suited to the end intended, namely that these bodies should reach their place as soon as possible, yet within certain limits of speed; and that GOD willed to leave traces of his providence in these effects, so that, not finding in nature itself a sufficient cause of them, we should necessarily acknowledge the first cause: such a person would neither be bringing a new mode into philosophy nor summoning God from the machine without any necessity. Certainly he would philosophize much less absurdly than one who had recourse to the motion of the Earth, since that motion is unfit to give the cause of this increase and brings with it many other tangles of spiral motions, as we showed in chapter 17.

Hactenus De Argumentis Pro motu Terræ Excogitatis. Sequuntur Argumenta pro Terræ Immobilitate.

So far, the arguments devised for the motion of the Earth. There follow the arguments for the immobility of the Earth.

CAPVT XIX.

Chapter 19.

Proponuntur Quinque Argumenta ex Incremento velocitatis Grauium ac Leuium contra Terræ motum Diurnum, aut Diurnum ſimul & Annuum.

Five arguments are put forward, from the increase of speed of heavy and light bodies, against the diurnal motion of the Earth, or the diurnal and annual together.

I. It was with the greatest deliberation, and on purpose, that in chapter 16 we set out beforehand so many experiments on the natural descent of heavy bodies and ascent of light ones: we wished to lay down in advance firmer foundations for the arguments against the motion of the Earth that we shall presently bring forward. These arguments will surely have as much physical evidence for those who are willing to try the same experiments, or as much credibility for those who trust our experiments, as the experiments themselves have evidence. But first one axiom, or quasi-axiom, must be set down, which no physicist will deny. It is as follows.

Axiom. The increase of speed of the same heavy body descending naturally from the same height through the same medium, or of the same light body ascending naturally to the same height through the same medium, is such and so great at any place on the terrestrial globe as it is at another place on the terrestrial globe, if all its intrinsic conditions are the same in both.

[Margin: Exposition of the axiom.] To explain the axiom, take as an example the clay ball of 8 ounces which, as was said in chapter 16, number 12, we have often used. By repeated and most certain experiments we found that it descended from a height of 240 feet in a time of 4^s (seconds of time), but in such a way that at the end of the first second it had already passed through 15 feet, at the end of the second 60 feet, at the end of the third 135 feet, and at

the end of the fourth 240 feet — and this in our parallel of Bologna. Galileo testifies that he found results like these, in Dia- logue 2 on the System of the World, at some other Italian parallel of the Equator, I do not know which. I say, then, that if this same ball, keeping all its intrinsic conditions — its gravity, shape, bulk and so on — were let fall from the top of a tower standing at any other place on the Earth's surface, whether at the Equator, or at the poles of the terrestrial globe, or at any other parallel; if the height from which it was let fall were 240 Roman feet, such feet as made up the height we used; and if the medium were the same, namely air of the same rarity and calm: then the increase of speed would be such and so great as we found it in the parallel of Bologna. *Such*, I say — that is, really unequal, or with a real and sensible increase of impetus and speed, if in our parallel it went with a real inequality, or a real and sensible increase of speed. *So great*, moreover — that is, following the order of the square numbers beginning from unity in the spaces completed after equal times — if it has been found by certain experiments to be so great in our parallel.

[Margin: The reason for the axiom.] The *reason* for the axiom is this. Since everything that can concur in determining the increase of speed is the same in both places, and no miracle is supposed to occur (for we are speaking of natural descent), no cause can be soundly assigned why that increase should be real in one place and only apparent, not real, in another, or should follow the proportion already mentioned in one place and not in another. Otherwise no one could gather for himself, from an induction made in some places about the motion of natural bodies or its other sensible effects, first principles that are universal and true in every place — such as this one: every natural body is mobile; every fire is naturally combustive; and so with very many that are commonly held as axioms in physics. This being laid down, now to the arguments.

I. Argumentum à Reali Velocitatis Incremento Grauium contra Motum Diurnum Terræ.

First argument, from the real increase of speed of heavy bodies, against the diurnal motion of the Earth.

II. *Many heavy bodies let fall through air lying in the plane of the Equator would descend to the earth with a real and notable increase of speed, and not merely an apparent one. But if the Earth moved with the diurnal motion only, about its own centre, no heavy bodies let fall through air lying in the plane of the Equator would descend to the earth with a real and notable increase of speed, but only with an apparent one. Therefore the Earth either does not move, or does not move with the diurnal motion only.*

[Margin: Proof of the major.] The MAJOR is proved as follows. Any ball let fall by us through the air in the parallel of Bologna descends to the earth with an increase of speed that is not only apparent, growing according to the order of the square numbers, as we showed in chapter 16, number 12, but also real. This was established from the more violent impact, the louder sound, the

deeper penetration of water, the greater rebound and recoil, the raising of a greater weight, and other similar effects, the higher the place from which the balls were let fall — according to what was said in that same chapter 16 from number 6 on, and, for the raising of a weight and the penetration of water, at number 23, experiments 12 and 13 — and as anyone can easily try for himself. These effects, unless one chooses to be perverse, are a natural sign of an ever greater impetus acquired in the descent, and hence of a real increase of speed following naturally from the greater impetus, so long as there is no impediment retarding its second act. They are, I say, a sign of this as of their cause, just as the same projectile, thrown by an arm that drives it more strongly and therefore making a greater wound or a greater blow on the same subject, is a physically evident sign of a greater impressed impetus — or of a greater commotion of the air, as certain haters of impetus and impressed quality say. Therefore, by the axiom set down above, the same would happen to these balls at the Equator, let fall in like manner through air of the same character; and so the increase of speed there too would be real, and not merely apparent.

III. The MINOR, in which the whole difficulty lies and which requires some mathematics, is proved by first setting out the scheme which we already expounded in chapter 17, number 7. [Margin: Exposition of the figure.] Let there be described, then, from the Earth's centre A the arcs CD and BM, the first passing through the top C of the tower BC, the second through the tower's foot B, the tower standing in the plane of the Equator. Then, the Earth's semidiameter AC being bisected at E, let another arc be described from C towards the same eastern quarter M, which is either the semicircle CIA or at least so great a portion of it that straight lines drawn from A to the arc CD fall upon it, or even cut it. Since the tower BC is supposed to move towards DM by the motion of the diurnal rotation alone, and uniformly — that is, describing with its top and its foot equal arcs in the same circumference in equal times — let the arc CD be divided into any number of equal arcs corresponding to the equal times already mentioned, say into the arcs CF, FG, GH, HL, LD; and to the points of division let the straight lines AF, AG, AH, AL, AD be drawn from the Earth's centre A. Finally, from E, the centre of the smaller circumference, let a straight line be drawn to some point where the circumference CIA intersects one of the straight lines already mentioned, say to the point I.

Diagram. A woodcut set in the right column beside the construction. From the Earth's centre A (foot) the vertical AC rises to C (top right), with E on it about halfway; B stands just below C at the tower's foot. Two concentric arcs run leftward from the top: the outer arc from C through F, G, H, L to D, and the inner arc from B through O, P, Q, R towards M. From C a second curve runs down through S, T, V, X to I, continuing as the semicircle CIA that bulges to the left and returns to A. Straight lines fan from A up to F, G, H, L and D on the outer arc, and a straight line joins E to I.

- C (top right): top of the tower, end of the outer arc

- F, G, H, L, D (outer arc, right to left): the points of division of the arc CD
- S, T, V, X (on the curve from C): the points cut on the small circle by AF, AG, AH, AL
- B (right, below C): foot of the tower
- O, P, Q, R (inner arc, right to left): points on the arc BM
- I (left, where the curve meets the inner arc): the point to which the line from E is drawn
- M (far left): the eastern end of the arc BM
- E (on AC): centre of the smaller circumference
- A (foot): the Earth's centre

[Margin: 1st proposition, for the proof of the minor.] These things marked out, *first* I say that if the Earth moved with the diurnal motion alone, a heavy body let fall from the top C of a tower standing in the plane of the Equator would describe by its natural motion a portion of the line CTI which would be, to all sense, circular, or a portion of a circular circumference. I show it thus. A clay ball let fall by us from the top of the tower C descends to the earth in 4^{s} (seconds of time), and in such a way that at the end of the first second it has passed through 15 ancient Roman feet, at the end of the second 60 feet, at the end of the third 135 feet, at the end of the fourth 240 feet. Therefore, by the axiom set down above, it would do the same at the Equator; and, the same proportion of the square numbers being kept, it would describe in that time a line circular to the utmost fineness of sense. For the spaces completed in the four seconds, namely FS, GT, HV and LX, would be as great as they must be if the line CSTVX drawn through their ends is to be circular; and conversely, if the circular line CSTVX is drawn from the centre E and the size of the spaces FS, GT, HV, LX is investigated, FS is found as 1, GT as 4, HV as 9 and LX as 16, which is the proportion of the squares beginning from unity; or, if the first space FS is taken as 15 feet, GT will be found to be 60 feet, HV 135 feet and LX 240 feet.

The spaces already mentioned are investigated by the method already given in chapter 17, number 14, which is as follows. In one second of time a point on the terrestrial Equator traverses, by force of the diurnal rotation, the arc CF of 15″, and the arcs FG, GH, HL are each equal to it; but the arc CS, since it is described from E, which bisects AC, and is intercepted by the same lines AC and AF, is of twice as many seconds, as we showed in chapter 17, number 8. The arc CS will therefore be of 30″. And since the arc CG is of 30″, the arc CT will for the same reason be of 60″, or one minute; and since the arc CH is of 45″, the arc CV will be of 90″, that is, of 1′ 30″; and finally, since the arc CL is of one minute, CX will be of 2′. The complements will therefore be: AIS, 179° 59′ 30″; AIT, 179° 59′ 0″; AIV, 179° 58′ 30″; and AIX, 179° 58′ 0″. The chords of these, taken in order from the doubled sines, will be: AS, 19 999 999 947 parts, of which the diameter or greatest chord is 20 000 000 000; the chord AT, 19 999 999 788 such parts; the chord AV, 19 999 999 524 parts; and the chord AX,

19 999 999 154. If these chords are subtracted from the greatest chord AC, to which the radii AF, AG, AH, AL are equal, there remain the spaces FS of 53 parts, GT of 212, HV of 476, LX of 846. But the proportion between these is exactly the same as between the squares 1, 4, 9, 16. For if one makes: as the first space FS, 1, is to 4, so is 53 to another, GT will come out at 212 parts. Again, if one makes: as FS, 1, is to 9, so is 53 to another, HV will come out at 476 parts; and finally, if one makes: as FS, 1, is to 16, so is 53 to another, LX will come out at 846 parts. Therefore, if a curved line is described continuously through the ends of the lines completed by that ball, keeping the proportion of the squares in the spaces, that line will be circular; and conversely, if it is circular, those spaces or segments intercepted between that circular line and the arc CD will have the proportion already mentioned. Since, then, that heavy body travels by a single line and path, and by no other than the one that the ends of the completed spaces describe, that line will be circular. The same will happen if the time of descent does not exceed 4^{m} (minutes of time), and so if the whole arc CL does not exceed one degree, as will be plain to anyone who examines the chords and the complements of the chords to the greatest chord. We have chosen, moreover, to set the numbers already mentioned before the eyes in the synopsis of a single small table; for it, look at the preceding figure, which is also placed on page 399.

Arcs	Arcs	Arcs, complements	Chords, of which AC is 20 000 000 000	Residual spaces	Proportion of the spaces
CF 0′ 15″	CS 0′ 30″	AIS 179° 59′ 30″	19999999947	FS 53	1
CG 0′ 30″	CT 1′ 0″	AIT 179° 59′ 0″	19999999788	GT 212	4
CH 0′ 45″	CV 1′ 30″	AIV 179° 58′ 30″	19999999524	HV 476	9
CL 1′ 0″	CX 2′ 0″	AIX 179° 58′ 0″	19999999154	LX 846	16

[Margin: 2nd proposition, for the proof of the minor.] IV. *Second*, I say that the arcs CS, ST, TV, VX are each equal to the arcs CF, FG, GH, HL, and so are equal among themselves, just as the latter are equal among themselves and correspond to equal times. For the circumference CD has as its semidiameter the straight line AC, which is twice as great as AE, the semidiameter of the smaller circumference CI, since by construction its centre E bisects AC. Now by theorem 5 of Book 11 of the *Mathematical Collections* of *Pappus of Alexandria*, the circumferences of circles are to one another as their diameters, or as their semidiameters. Therefore, just as a quadrant whose semidiameter is AC equals two quadrants of a circumference having as semidiameter AE, which is half of AC, so the arc CF, which is of 15″, is equal to the arc CS, which is of 30″; and for the same reason the arc FG is equal to the arc ST, the arc GH to the arc TV, and the arc HL to the arc VX, in true and absolute length, because the former are each of 15″ and the latter of 30″. That these arcs are of 30″, and

of twice as many units of arc as the arcs CF, FG, GH, HL, has already been shown in chapter 17, number 8; and it is easily proved by drawing straight lines from E to the points S, T, V, X, as EI was then drawn to the point I. For by the 20th of the third book of the *Elements*, the angles at the centre E turn out double the angles formed at the circumference at A by the same lines; but the angles at A are at the centre of the circumference CD and measure it, just as the angles at E measure the arcs of the circumference CI. Hence, if the angles at E, made by the same straight lines, are double the angles at A — the angle BEI, for instance, is double the angle BAI, that is CAD — the arc CI too is of twice as many units of arc as the arc CD, and so with the rest. These things having been shown first, the minor is now to be proved.

[Margin: Proof of the minor.] The MINOR, then, is proved. For the ball spoken of in the proof of the major would describe at the Equator, by its descent, a line circular to the utmost fineness of sense, as we showed in number 3; and this granted, it would pass through equal arcs in equal times, as was shown here in number 4. Therefore it would not descend with a real inequality, or with a real increase of speed — if, that is, the Earth moved with the diurnal motion alone. This is what was to be demonstrated in the minor. The MAJOR having thus been demonstrated physically and the MINOR physico-mathematically, it follows that either the Earth does not move at all, or it does not move with the diurnal motion only.

[Margin: 1st reply of the Copernicans, but a trifling one.] V. The Copernicans might perhaps reply that the impetus by force of which a heavy body descending from a higher place makes a greater impact does indeed grow continually insofar as it comes from the principle moving it downward, namely from gravity; but that it does not grow insofar as it comes from the principle moving it forward towards the east, being instead equal, or produced equally and uniformly, as the uniformity of the diurnal motion requires, to which the heavy body must be attuned in its forward motion; and so from the greater impact one cannot argue a real increase of impetus with respect to that other effect, namely a greater speed in the real descent along the circular line already mentioned. But this reply, though necessarily devised from the nature of the Copernican hypothesis that is to be defended, is nonetheless, taken absolutely, trifling. For it is sufficiently established by induction that a mobile body, by force of an impetus coming either from within or from without, is moved, by priority of nature, before it strikes another body towards which it is moved, and that impact necessarily presupposes the local motion of the striker; and that if a greater impact arises as the impetus grows, a greater or swifter motion also precedes it by some priority, so that the same impetus, of itself, naturally and with impediments removed, effects these two effects, namely motion and impact; and that just as there cannot be impact without previous motion, so there cannot be greater impact without greater motion arising from the increase of impetus. Indeed, a greater impetus is ordered of itself and primarily to swifter motion, and secondarily, or as it were incidentally, to the impact

on a body that impedes further motion. Grant, then, that the impetus of a heavy body descending along a circular line would not grow by force of the common principle moving it forward towards the east: still, it would have to grow by force of gravity, and by its increase cause a swifter motion along the path by which it really descends before it caused a greater and greater impact. Nor can any rational physical cause be assigned that would allow this impetus to grow insofar as it is percussive while it tends downward, and yet would impede its increase insofar as it is really motive downward, and so impede the increase of speed. And conversely, if anything can physically impede the increase of impetus as motive, by inhibiting it, or by tempering it and holding it in perpetual uniformity, by that very fact it would also impede the secondary effect that depends on the primary by physical necessity, namely the greater impact. Since, then, the impact is manifestly greater the higher the point from which the heavy body falls, it is also manifest and physically evident that a greater and greater speed preceded, not only apparently but really; but this could not precede if the uniformity of the Earth's diurnal motion is supposed; therefore the supposition of this motion is false and absurd.

[Margin: 2nd reply for the Copernicans.] Secondly, someone might perhaps reply that the motion of descending heavy bodies, insofar as it is forward on account of imitating the diurnal and the annual terrestrial motion, is not uniform, because it does not take place at the same distance from the centre of the Earth and of the annual orb, but at a smaller and smaller distance; and so it completes arcs of circles that are indeed similar to one another in equal times, but smaller, that is, of fewer paces or feet. Hence, by force of the principle that of itself moves circularly, the motion of descending heavy bodies is retarded insofar as it is motion, granted that it is not diminished insofar as it is percussive. [Margin: But useless.] But this reply is of no help either, for the dilemma already stated always holds. Either it retards the real motion so as to reduce it to perpetual uniformity — and then, by the necessity by which impact follows the vehemence of the motion it comes from, the impact would be rendered uniform from whatever height it took place — or it does not reduce it, but still leaves it, if not in its former inequality, at least in a very notable one; and then the motion too, though not with so great an inequality as otherwise, would in fact have a notable one. In reality, however, it would not notably diminish the inequality of heavy bodies, because in the figure to be set out at number 9 the semidiameter of the Earth's orb CF is 25 870 000 Roman feet, nor much greater or smaller on the Copernican reckoning; while the semidiameter of the annual orb, according to Copernicus, is 29 543 740 000 Roman feet, from what is to be said in the table at the end of number 13. Hence the whole of AF is 29 569 610 000. [Margin: See the figure to be set below at number 9.] Now the Asinelli tower, from whose height we let heavy bodies fall, namely FH, is 240 feet; therefore the whole of AH is 29 569 610 240. Now in one second of time, by force of the circular diurnal motion, 15″ of the Equator are passed through, to which 1875 ¼ feet correspond; by force of the annual motion, 2‴

28′′′′ are made (as many, that is, as the mean motion of the Sun would make), which is, according to Copetnico [?], 5965 feet, as will be clear shortly from the same table. Therefore the motion compounded of the diurnal and the annual, corresponding to one second of time, is 7840 ¼ feet; by this, namely, a point on the surface of the terrestrial Equator, say the point F, is carried in one second of time to X. Now let it be done: as the semidiameter AF, of 29 569 610 000 feet, is to FX, of 7840 ¼ feet, so is the semidiameter AH, of 29 569 610 240 feet, to another; and the arc HE will be found to be 7840 and 7 394 284 160/29 569 610 000 feet, which is insensibly greater than the arc FX. Much less sensibly, then, do the arcs HE and FX differ from each other; and yet the inequality of the motion of heavy bodies in their descent from the tower already mentioned is as great as that between these numbers, 15, 60, 135, 240, from what was said in chapter 16, number 12. Therefore, since the diurnal motion together with the annual is retarded, on account of the variation of the circles, by not even a quarter of a foot, the whole of that inequality which comes from the principle moving downward is left intact as far as whole feet are concerned, and still goes according to the numbers 15, 60, 135, 240. From this one might rather argue that, if the path along which the heavy body actually descends is rendered equal by the principle moving it forward circularly, retarding the principle that of itself moves it downward unequally, then this circular principle must be called very unequal of itself, and must intend a motion very different from the diurnal and annual motions, which are feigned to be equal of themselves.

[Margin: 3rd reply for the Copernicans.] Thirdly, the Copernicans will reply by taking refuge in the familiar example of the ship, as in the last little boat left from the shipwreck of their hypothesis. They will say that it can happen, on the hypothesis of a standing Earth, that while a ship is carried towards the East, a ball let fall downward from the top of the ship's mast, having at the same time received the ship's impetus from the mast, really falls along a curved line to the foot of the mast in such a way that it makes a greater impact the higher the mast is; and yet its motion, really, and as it would be observed by someone standing on the shore, would always be equal. [Margin: But insufficient.] But this reply can neither be established by any experiment a posteriori nor be made persuasive by any reason a priori. For if the ball's motion were blunted in such a way that, though it would of itself have been unequal, it were rendered always equal, then the impact made from any interval whatever would also be equal. But because this experiment is not easy in practice, we ourselves will suggest to the Copernicans an easier way of testing the effects arising from the motion of one and the same body from two principles, one of which moves it along a straight line, unequally of itself, the other along a circle, and equally.

Let the figure set out at number 3 be repeated here. In it let AC be a beam hollowed out lengthwise in the manner of a channel, or troughed, and floating on still water in such a way that the end A is held immobile, as though at the centre of the motion, while the other end, C, can be carried round with an equal and uniform motion from C through G to D. Let there be, besides, some

ball at C, connected by a small cord to a large weight hanging from A under the water, so that it can be drawn along the trough of the beam; and let the depth of the pond be so great that the weight does not reach the bottom of the water when the ball has come from C to A — that is, let the depth of the water be greater than the length of the beam AC. First, then, with the beam at rest, let the weight be released downward from A, and let the time in which the ball moves from C to A be measured with the pendulum, which we have often mentioned in measuring seconds of time; at the same time let the impact the ball makes on some body placed at A be carefully observed; and let the same be done when the ball comes again from E to A, which is a path shorter by half. Then, the ball having been brought back again to C, at the same instant at which the weight is released from A and the ball begins to move from C, let the end C of the beam begin to be carried round equally towards D; and let the time in which the ball C reaches A be measured, and the impact noted. For it will appear that the impact is greater when the ball comes from C than when it comes from E while the beam was at rest, and that the time from E to A exceeds half the time spent from C to A. When the beam is carried round equally, however, an inequality will indeed be observed in the impacts and times already mentioned, but not so great a one, because the transverse motion blunts the motion along the straight line CA that would otherwise follow of itself — and the more so, the swifter the transverse motion of the beam. But if the speed of the circular motion is precisely so great that the motion of the ball released both from C and from E turns out really equal, at least to sense — whether its real path runs along the circle CSTI or not — then the impact too will be as great, to sense, for the ball released from C as for the one released from E, and the time spent from E to A will be half the time spent from C to A. All this will be brought about still more easily if the beam AC is so inclined to the plane of the horizon that the ball runs freely down to A, the immobile end, while meanwhile the other end, C, raised up, is carried along a circle parallel to the horizon. And from this the Copernicans will learn that an impetus which of itself would grow unequally cannot be restrained to equality without the inequality of the impact being impeded too. Finally, it is manifest from other, more certain experiments that the same heavy body, if let fall straight down, moves more swiftly than if let fall obliquely — as in the experiments of Class II adduced above in chapter 16, number 22, compared with others in which the same ball was let fall perpendicularly downward — and in rivers, one branch of which flows down through a straight channel and the other through meanders and a less steep channel.

Applicatio eiusdem Argumenti ad plurima Corpora Grauia.

Application of the same argument to very many heavy bodies.

VI. We have used the example of the clay ball of 8 ounces because we employed that ball in particular most frequently, it being more easily obtained in view of the number of such balls needed for repeating the experiments rather

often, since for each of them a ball of its own was required, to be substituted in place of the previous one once that was broken or bruised. Yet although we have used it, the argument made holds nonetheless for the greatest part of those heavy bodies which are so much heavier than our air that they can overcome its fluctuations, made by an ordinary breeze, without disturbance of the proportion already mentioned. For such bodies are either heavier in species than the clay ball or not much lighter, so that they descend from a height of 240 feet either in a shorter time than 4^{s} or in one not much longer. Nor would you find any that requires one whole minute of time to measure out so small a height by natural descent. For a leather playing-ball and an orange are not fit to overcome the customary commotion of our air without fluctuating somewhat in their descent, as we have found more than once, and I say the same of certain wooden balls of a lighter kind; and yet these very balls reached the ground from a height of 280 feet, namely from the crown of the Asinelli tower, in a shorter time than 8^{s}. Therefore all bodies (and they are surely very many) that are fit to overcome the fluctuation of the air without disturbance of the proportion due of itself to the increment of speed descend from a height of 240 feet in a shorter time than 8^{s}. And yet, even if they required a whole minute of time for it — the time in which a point of the Earth's surface, by force of the diurnal turning, passes through 15′ of the Equator or of a parallel of the Equator — the argument would still hold. For within the first minute of the first degree of this motion, the line described by the heavy body on account of the diurnal motion alone is circular to the utmost fineness of sense, from which it would follow that its motion is in fact equal, as we showed in number 4. That the line is circular will be plain to anyone who investigates the chords, and from them the spaces that are the complements of the chords, in the way we taught in chapter 17, number 14, and in this chapter at number 3. So that this may be more evident, we shall investigate it at this place. Let the whole time of descent of the ball, then, est [?] a height of 240 feet, be 60^{s}, which make one minute. This minute, divided accordingly into four equal times, namely into periods of 15^{s} of time each, would require for each of them 3′ 45″ of the Equator; but for the sake of abundance and ease let there be 4′ in each of the arcs CF, FG, GH, HL of the figure set out earlier, for there will be twice as many minu- tes, namely 8′, in the arcs CS, ST, TV, VX; hence the arc CT will be of 16′, CV of 24′ and CX of 32′. Their complements, then, will be AIS, 179° 52′; AIT, 179° 44′; AIV, 179° 36′; and AIX, 179° 28′. From their halves the right sines will be found; these, doubled, will give the chords of the arcs already mentioned, and the chords, subtracted from the greatest chord AC, will leave the spaces passed through at the end of the equal times, in parts of which AC is taken, as above, as 20 000 000 000 — as can be seen in the following small table.

Arcs: arc	Arcs: ′	Arcs: arc	Arcs: value	Complements to the semicircle: arc	Complements to the semicircle: value	Halves of the complements
CF	8′	CS	0° 16′	AIS	179° 52′	89° 56′

Arcs: arc	Arcs: ′	Arcs: arc	Arcs: value	Complements to the semicircle: arc	Complements to the semicircle: value	Halves of the complements
CG	16′	CF [?]	0° 32′	AIT	179° 44′	89° 52′
CH	24′	CV	0° 48′	AIV	179° 36′	89° 48′
CL	32′	CX	1° 4′	AIX	179° 28′	89° 44′

Sines of the halves	Chords: chord	Chords: value	Segments or spaces: segment	Segments or spaces: value	Proportion of the spaces
9999993231	AS	19999986462	FS	13538	1
9999972923	AT	19999945846	GT	54154	4
9999939076	AV	19999878152	HV	121848	9
9999891692	AX	19999783384	LX	216616	16

Now let it be done: as the first space FS, 1, is to the second, GT, 4, so 13,538 to another, and you will find 54,156. Again, as FS, 1, is to HV, 9, so 13,538 to another, and you will find 121,842. Finally, as FS, 1, is to LX, 16, so 13,538 to another, and you will find 216,608. The spaces found from the chords subtracted from the greatest chord, then, fall short of those found by the proportion due to the square numbers by 2 parts in GT, but exceed them by 6 parts in HV and by 8 parts in LX — parts of which the whole AC, that is, the Earth's semidiameter, is 20 000 000 000. Further, the Earth's semidiameter, as we showed in Book 2, chapter 7, contains 4139 modern Italian and Bolognese miles, that is, 4 139 000 paces, or 20 695 000 feet, or 248 340 000 inches. Let it be done, then: as 20 000 000 000 is to 8 parts, so 248 340 000 inches to another; and you will find not one whole inch, or a finger's breadth, but this fraction of a single inch, 198,632/2000000, that is, nearly a tenth part of an inch. Hence LX would differ at most by one tenth part of a finger taken in breadth from the space it ought to have if the line CSTVX were geometrically circular, and HV and GT by much less. Therefore, if a heavy body did not require a whole minute of time for its descent from a height of 240 feet, it would still describe in its descent a line circular to sense at the Equator, according to what was said in number 3, and would consequently move in fact equally, according to what was said in number 4. The argument already mentioned therefore holds for all bodies so heavy that they do not require a time longer than one minute of time for natural descent through a height of 240 feet. Of this kind is the greatest part of heavy bodies, namely those suited to descending through our air without sensible fluctuation, or without such fluctuation as would move them off a straight line perpendicular to sense.

Applicatio Argumenti eiusdem ad Grauia extra Aequatorem posita.

Application of the same argument to heavy bodies placed outside the Equator.

VII. We have used the argument made so far supposing that the heavy body descends in the plane of the Equator, because the demonstration of the real

equality of motion, which would necessarily follow from the circular motion, has greater evidence if the line of motion lies in one and the same plane, as the nature of a perfectly circular line requires. Yet it has its own physical evidence, sufficient for inferring the same equality, in places outside the Equator too — and the more truly, the less those places are distant from the Equator. For outside the Equator heavy bodies, in descending, do describe (once the diurnal motion of the Earth is admitted) the curved line of their motion on the surface of a right cone that has its vertex at the centre of the Earth and its axis coinciding with the axis of the Equator, and that motion begins from the periphery of the conical base, as we showed in chapter 17, number 18. Even so, within the time of 4^{s} of time in which, in the preceding argument, we suppose the ball to have descended from a height of 240 feet, the revolution of that cone is so small with respect to its transverse magnitude, or the thickness of the cone taken near its base, that to sense it is just as if the motion took place on a plane surface; nor can that slight deflection from one plane to another be so great as to produce a real inequality of motion that is sensible, and as great as the impact proves, together with the other similar effects that indicate a real increase of impetus. But lest anyone think this was said out of a certain careless complacency, let us undertake the demonstration of what has been said — and indeed one adapted to a parallel declining 45 degrees from the Equator, such as is very nearly the one in which we made our experiments and Galileo made his, so that from this, as from a middle case, judgement may be made of the others.

In the following diagram let there be the cone ABC, whose vertex is at the Earth's centre B, and let BM be the axis coinciding with the axis of the Equator. Let the base of the cone be the circle AECD, turned towards the viewer of this page in an upright position for ease of demonstration, although by the laws of perspective it ought to be represented in oblique view, as an ellipse. Let the parallel of the Equator in which the foot of the tower stands be FHG, and the tower itself GC. From its top, or a window, C, let a ball be let fall and descend to the point H of the Earth's surface along the curved line LH in a time of 4^{s} of time, in which the point C, by force of the diurnal turning, completes the arc CK, which is of one minute, since it lies in a circle parallel to the Equator; for the arc of the Equator corresponding to 4^{s} of time is that great.

Diagram. A circle (the base AECD of the cone) drawn upright, with D at its top, A at its left and C at its right, and its centre M; from A and C two straight lines converge downward to the vertex B at the Earth's centre. A vertical line runs from D through M to E at the foot of the circle. A line from M rises to the upper right, with P marked on it; lines run from M towards C. O and K stand near the lower right of the circle, with L on the circle's lower right arc. Below the circle a horizontal line F–H–G crosses the cone; a dotted line drops from K to H, and straight lines run from C and from L down to H.

- D (top of circle): D
- P (upper right, inside circle): P
- M (centre of circle): M

- A (left end of circle): A
- C (right end of circle): C
- O (inside circle, lower right): O
- K (inside circle, below O): K
- L (on lower right arc): L
- E (foot of circle on the vertical): E
- F (left end of horizontal line): F
- H (middle of horizontal line): H
- G (right end of horizontal line): G
- B (vertex at foot): B

Its half, namely the arc CL, is of 30″. The second sine [Sinus Secundus] of this arc, PC, equal to the straight line MO, is 9 999 999 894 of the parts of which the radius ML is 10 000 000 000. If you subtract the sine PC from this, there remains the versed sine, or sagitta, OL, of 106 such parts. But so that the quantity of the arc CLK, and of the line OL by which the arc CLK departs from the straight line COK, may be known in parts taken determinately, it must be recalled that the Earth's semidiameter contains 20 695 000 Bolognese feet and its diameter 41 390 000, as I said in number 6, towards the end. The result is that the circumference of a great circle is 129 964 600 feet, for from what was said in Book 1, chapter 4, the diameter is to the circumference as 100 to 314; and therefore one minute of the Equator contains 6020 feet. But because we suppose the circle AECD to decline 45° from the Equator, the arc CK, by the problem of Io. Antonius Maginus [Giovanni Antonio Magini] and Iosephus Moletius [Giuseppe Moleti] on Book 1, chapter 20, of Ptolemy's *Geography*, and the ta- ble given there in Moletius, will be 42″ 25‴ of the Equator. Now the periphery AECD is to the periphery of the terrestrial Equator as 42″ 25‴ is to 60″; and since circumferences are to one another as their diameters, or semidiameters, and conversely, therefore as 60″ is to 42″ 25‴, so is the Earth's semidiameter to ML, the semidiameter of the parallel. Let it be done, then: as 1 minute, or 60″, is to 42″ 25‴, so 6020 feet to another; and the arc CLK will come out at 4219 feet. Again, let it be done: as 60″ is to 42″ 25‴, so the 20 695 000 feet of the terrestrial semidiameter to the feet of the semidiameter ML, 14 441 500. Finally, if one makes it: as the radius ML, of 10 000 000 000 parts, is to the versed sine OL, of 106 parts, so 14 441 500 feet to another, the sagitta OL will be found to be 0 153/1000 feet, that is, about a 6½th part of a foot. Hence the arc CLK, which is 4219 feet, does not deflect from the straight and plane line COK, where it deflects most, by more than two inches of a foot; and these, in an arc of 4219 feet, or 844 paces, or in the circular periphery of nearly one mile, are not a sensible portion. Therefore, if a heavy body descending from C went along the arc CLK in a time of 4^{s} of time, it would not decline from the plane surface by more than 2 inches of a foot, or 3 fingers' breadth. But it goes along LH, which departs less from the plane surface and comes closer to the straight line CLG lying in the same plane; it therefore deflects still less from the plane surface, although in geometric rigour it goes along a conical surface.

Nor does this conflict with what was said in chapter 17, number 18. For there we argued against Galileo, who pronounced universally that the line of motion of heavy bodies is circular, without restricting his proposition to a heavy body that completes its descent in 4 seconds, and who, besides the diurnal motion, supposed the annual motion of the Earth and spoke of the whole semicircle continued down to the centre of the Earth.

II. Argumentum contra motum Terræ Diurnum simul & Annuum, à Reali Incremento velocitatis Grauium desumptum.

II. An argument against the diurnal and annual motion of the Earth taken together, drawn from the real increase of the speed of heavy bodies.

VIII. I see that the argument made so far tells only against the Semi-Copernicans, who attribute only the diurnal turning to the Earth, and whom I reviewed in chapter 2. But the Copernicans could ascribe the real inequality of the descent of heavy bodies to the annual motion of the Earth combined with the diurnal — granted that Galileo, who asserts both motions, denies this inequality, as we said in chapter 17, number 8. Our weapons must therefore be aimed against both motions together, namely by the following argument.

Many heavy bodies, let fall through the air that lies in the plane of the Equator, would descend to the earth with a real and notable increase of speed, growing equally, at whatever time of day they were let fall. But if the Earth moved with the diurnal and the annual motion together, some of those many heavy bodies, let fall through the air that lies in the plane of the Equator, would not descend with a real and notable increase of speed, growing equally, when let fall at any time of day whatever. Therefore the Earth does not move with the diurnal and the annual motion together.

[Margin: Proof of the major.] The MAJOR was proved in number 2. For here nothing else is added to the major of that argument except that the increment of speed grows in the same way at whatever time of day the heavy body is let fall downward. This is sufficiently established from our experiments, especially those with clay balls, made in the morning, in the evening and around midday; for we always obtained the same proportion of the square numbers, and the same impact, the same raising of a weight and the same penetration into the depth of water, with the same ball let fall from the same height. And the same will be established for anyone who does not neglect these experiments.

[Margin: 1st part of the minor is proved.] IX. The MINOR is proved as regards the qualifiers *real* and *notable* increase. For by force of the precisely diurnal motion, the descent of the clay ball of 8 ounces through 240 Roman feet in a time of 4^s of time would be really equal, granted that it is apparently unequal, and the increment of speed would turn out to be in fact none, or negligible, as was shown from number 2 to number 5; and this demonstration was applied in number 6 to very many heavy bodies. By force of the annual motion too, the motion of that ball would be equal, without any difference worth attending to, because the annual motion of the Earth's centre within 4^s of time is entirely equal, and in each second makes $2''' 27'''' 51^v$, just as the Sun

does on the hypothesis of a moving Sun; [Margin: The annual motion of the Earth, in a time of 4 seconds, would be entirely equal to sense.] and the top of the tower from which the ball is let fall describes in this time a line differing insensibly from a circular one, while the ball already mentioned meanwhile describes arcs equal to the arcs described by the top of the tower, without any notable difference, or any worth attending to, as we shall show shortly.

[Margin: Explanation of the figure.] In the following diagram, describe from A, the centre of the annual orb, the arc BC, on which let the centre of the Earth, carried from C to B, the eastern point, be at C at the beginning of the ball's descent; at the end of the first second of time at P; at the end of the second at D; at the end of the third at Q; at the end of the fourth at B. And on the straight line AH, produced from A, let there be the tower, or height, HF, of 240 feet, so that its top H, at the interval AH, describes in a time of 4^{s} of time the arc HG, similar to the arc CB — such an arc as it would describe by force of the annual motion of the Earth alone.

Diagram. An upper arc running from K at the left through G, M, L and E to H at the right; below it a second arc through B, Q, D, P and C, along which five overlapping circles are strung. Straight lines rise from the vertex A at the foot of the figure through B, Q, D, P and C to the upper arc, with V marked on the right-hand line. A curve through marked points runs from H down through R, S and T towards O near K; I and O stand at the left near K, and F at the upper right below H. Below T, between the first two circles, a sort is printed turned on its side; it reads as Z or N according to the direction of turning.

- A (vertex at the foot): A

If this happened, the ball let fall from H would appear at R at the end of the first second of time, having completed the space ER, which is as 1, and the tower would be at EX; at the end of the second second the ball would be at S, having passed through the space LS, as 4, and the tower at LY; at the end of the third the ball would be at T, having passed through the space MT, as 9, and the tower would be at MZ; finally, at the end of the fourth second the ball would be at O, having completed the space GO, of 16 parts of which ER is one; and the tower would be at GO, and the path of the ball would be HRSTO. In reality, however, in geometric and astronomical rigour, according to the hypothesis of Copernicus, the tower FH also moves in the Equator towards P with the diurnal motion, completing in a time of 4^s of time one whole minute of the Equator. Hence at the end of the fourth second it is not at GO but a little further east and more inclined, say at KI, having completed, namely, the arc IO of one minute; and therefore the top H has described not the arc HG but the arc HK. [Margin: 1st step of the demonstration.] I say, however, that it has described, to sense, or without any difference worth attending to, an arc similar, and indeed equal, to the arc HG and coinciding with it; and hence that the tower KI can be taken as standing in the position GO, and in the preceding times at MZ, LY, EX, just as if it had not been inclined at all by force of the diurnal turning. To show this, I produce the straight line KI to B, and join K to the centre A by the straight line AK. For in the triangle KAB, besides the angle ABK of 179° 59′, as being the complement of the angle KBG, which measures the arc OI of one minute passed through by the tower in a time of 4^s, the side BK is given, made up of the height of 240 Roman feet and the Earth's semidiameter BI; and BI, from what was said in Book 2, chapter 7, is 5174 ancient Roman miles, that is, 5 174 000 Roman paces, namely 25 870 000 geometric feet. Hence the whole of BK is 25 870 240 feet. Further, from what was said in Book 3, chapter 7, the mean distance of the Sun from the Earth is 7300 terrestrial semidiameters, that is, in Roma- n feet 188 851 000 000. Joining, then, BG (which is as great as BK) and AB, the whole of AG comes to 188 876 870 240 Roman feet, and each of AH, AE, AL and AM is as great. Now if, following the laws of triangles, you use a radius, or whole sine, of 12 figures, as in Pitiscus's great *Canon*, and you make: as the sum of the sides AB and BK is to their difference, so the tangent of the half-sum of the angles adjacent to the base AK (a half-sum of 30″) is to another number, you will find the tangent of the angle of 0° 0′ 29″ 56‴ 40⁗. Added to the half-sum already mentioned, that is, to 30″, this angle gives the angle AKB, 59″ 56‴ 40⁗; subtracted from the same half-sum, it leaves the angle BAK, 3‴ 20⁗.

[Margin: 2nd step.] With these angles obtained, if again by the rules of trigonometry one makes: as the sine of the angle AKB is to the given opposite side AB, so the sine of the angle ABK is to the opposite side AK, the side AK will be found to be 188 876 870 238 7/10 Roman feet. Therefore the line AK,

by which the top of the tower stands distant, at the end of the ball's descent, from A, the centre of the Great Orb, is very nearly equal to the line AG and to the others, AM, AL, AE and AH, each of which is 188 876 870 240 Roman or geometric feet. Nor does it differ from them except by 1 3/10 feet, a tiny difference entirely negligible in respect of the radius AG, which is of more than 180 000 000 000 feet. Indeed, even if AK differed from AG by the whole height of the tower IK, that is, by 240 feet (which is nevertheless impossible, since the tower has described only the arc OI, which is of one minute), that difference could still be disregarded. Therefore, if AK is equal to sense to AG, much more are the remaining straight lines drawn from A to the arc HK equal to the same straight lines produced to the arc HG. So the arc HG can be taken for the arc HK without any appreciable difference, and the arc HK as an arc perfectly circular, so far as our purpose goes; and the position of the tower at the end of the descent can be taken just as if it were at OG, or on the line AG, and much more, at the preceding times, as if it were on the lines AE, AL and AM. Further, in a time of 4 seconds of time the centre of the Earth (whose motion is as great as the mean motion of the Sun) runs through the arc CB, $9''' \; 51'''' \; 24^{v}$; and the top of the tower runs through very nearly as much from H to G; and HK, described from its own centre, is of the same number of sexagesimal parts.

[Margin: 3rd step.] Now let AH be bisected at V, and from the centre V, at the interval VH, let a circular arc HO be described through the top of the tower H. It will be of twice as many sexagesimal parts as the arc HG, namely $19''' \; 42'''' \; 48^{v}$; and any arc of it will be of twice as many sexagesimal parts as any arc of the periphery HG cut off by the same straight lines drawn from the centre A. Hence, as regards absolute length, the whole arc HG will be equal to the whole arc HO, and the arc HE to the arc HR, EL to RS, LM to ST and MG to TO. All these proportions are evident from what was demonstrated with a similar figure in number 4 of this chapter. I chose, moreover, a position of the tower opposite the Sun, in the night hemisphere, because in such a position there is a danger of a greater inequality in the increase of speed [?], as I shall say in number 12.

[Margin: 4th step.] XI. Finally I say that the ball mentioned above, let fall from H, describes in a time of 4 seconds the circular line HRSTO, to sense, equal to HG or HK; and hence, from what has just been said, that in equal times it completes arcs as great as those the point H travels over on the arc HG, that is, equal to sense. For at the end of each of the four seconds the ball appears in the perpendicular of the tower, that is, at EX, LY, MZ and GO; and, as to appearance, from what was proved in chapter 16, number 12, the first space completed by the ball, namely ER, is as 1, the second, LS, as 4, the third, MT, as 9, and the fourth, GO, as 16. And these same spaces, keeping this proportion, lie between the circular line HG and HO, if the former is described with a semidiameter twice as great as the latter (as we supposed in the construction), so long as the first arc HK does not exceed one minute, as is evident from what was demonstrated a posteriori by the tables of sines and chords in number 3.

Since, I say, these things are so, and the ball already mentioned describes only one line in its descent, it follows that it describes the circular line HRSTO, and therefore moves equally to sense, without any notable real increase of speed.

XII. But some scruple might still remain in someone's mind on account of the appendage added to the annual motion by the diurnal motion of the Earth; and from it one might suspect some notable inequality in the motion of heavy bodies, and a great one, which, although it would be imperceptible with astronomical instruments, would nevertheless in absolute terms amount to many miles, or paces, or feet; and one might suspect that from it arises that more vehement impact, and the real increase of impetus made manifest by that very impact. [Margin: The second [?] part of the minor [?] is proved [?].] We shall show that not even in this way is that inequality notable, or so great that the more vehement impact could be ascribed to it: indeed, that sometimes it will be none at all, sometimes even with a decrease, and for the most part negligible and insufficient to defend the experiments of a real increase of the impetus of heavy bodies — an increase that comes from the more vehement impact, the higher the place from which they descend. We shall use the figure we used in Book 7, section 5, chapter 3, for the stations and retrogressions of the planets. For, from Galileo himself in Dialogue 4 on the System of the World, according to Copernicus the orb of the terrestrial globe stands to the Great Orb as an epicycle to an eccentric; and the points of the Earth's surface, and the bodies that complete the diurnal turning along with it, become as it were stationary twice every day, are in a manner retrograde for almost the whole day, and as it were direct for the whole night, so far as concerns that addition of motion which the diurnal motion makes to the annual. Let there be understood, then, described from the centre E, the arc LDK of the Great Orb, carrying D, the centre of the terrestrial globe ALCK, towards the eastern quarter L; and let the point A on the periphery of the terrestrial Equator, or a terrestrial body placed there, move towards L, completing the whole turning ALCKA in 24 hours.

Diagram. A circle set in the right column, with R and A at its top, F and B on its upper left and H on its upper right. A nearly horizontal arc crosses it from L at the left through P, a second lettered point, S and D near the centre, and O, to K at the right; G stands at the lower left, V, T, I and C along the lower edge, M at the lower right. Straight lines from points on the circle converge downward in a long cone to E at its foot. The letter just right of P is a capital with a bowl and a tail that reads as R or Q; the I beside T stands hard against T and may be a stroke of the drawing.

- R (top of the circle): R
- A (top of the circle): A
- F (upper left): F
- B (upper left, below F): B
- H (upper right): H
- S (centre, left of D): S

- D (centre): D
- L (left end of the horizontal arc): L
- P (on the arc, right of L): P
- R [?] (right of P): R or Q [?]
- O (on the arc, right of centre): O
- K (right end of the horizontal arc): K
- G (lower left): G
- V (lower edge): V
- T (lower edge): T
- I [?] (against T): I [?]
- C (lowest point of the circle): C
- M (lower right): M
- E (vertex of the cone, at the foot): E

[Margin: 1st case.] First, it is evident that around the point L, at which the Sun, placed at E, rises, and around K, at which it sets, the diurnal motion neither adds anything to nor takes anything from the annual motion of the centre D. So if the descending ball, completing along with the Earth a small part of the diurnal turning within 4 seconds of time, that is, running through one minute of the Equator ALCK, is very near the morning place L or the evening place K, its motion is as equal as the annual motion itself, and is not varied at all by the diurnal.

[Margin: 2nd case.] Second, since over the whole arc KAL the motion is compounded of the annual motion of the centre D and the diurnal, which drives towards the same quarter as the centre, the diurnal adds to the mean annual motion in such a way that it adds more and more from K through H to A, and most of all at A, but less and less from A to L. Conversely, because over the whole arc LCK the diurnal motion tends towards the contrary quarter, it subtracts from the annual motion, yet in such a way that it subtracts more and more from L to C, but less from C to K. Hence it comes about that, although any terrestrial body always moves forward in cosmic space, it nevertheless really moves unequally (if we wish astronomical rigour to be kept): it is swifter than the mean motion of the centre on the arc KAL, and swiftest at A, the point of midnight, but slower on the arc LCK, and slowest around C, the point of midnight [?]; and in this way it imitates the direct motion and retrogradation of the planets, and the inequality of the prosthaphaereses that the epicycle imposes on the eccentric.

[Margin: 3rd case.] Third, from what has just been said it follows that over the whole left arc ALC the inequality of the annual motion produced by the diurnal is one of decrease, because on the arc AL the diurnal motion adds continually less and less to the annual, while from L to C it subtracts more and more. Conversely, on the right arc CKA, the inequality is one of continual increase of the mo- tion, because from C to K the mean annual motion is diminished less and less, and from K to A it is increased more and more. And so the first two parts of the proposition asserted at the beginning of number 12

stand established: namely, that sometimes the diurnal motion introduces no inequality into the annual motion, as at the points L and K; and that sometimes it introduces one in such a way that it is rather with a decrease of speed, as on the arc ALC. There remains to be proved the third part, concerning the very slight inequality that the diurnal motion adds to the annual, even if it is considered in paces or feet.

XIII. Before we show this, however, we need to know in advance how many paces or feet a point placed on the terrestrial Equator is carried forward in each second of time by force of the diurnal motion, and the centre of the Earth by force of the annual motion. Both of these depend on the paces and feet contained in the semidiameter of the Earth and in the semidiameter of the Great Orb. For when these are doubled, the diameter is had; and if one makes: as 100 is to 314, so the diameter to another number, the circumference is had. Divided by 360, this gives the paces or feet contained in one degree; these, divided by 60, give the paces or feet of one minute; and so, by continued division by sixties, the number of feet contained in one second, third or fourth becomes known. Therefore, if it is known through how many sexagesimal parts of a degree the centre of the Earth is carried forward by force of the annual motion in each second of time, and likewise a point of the terrestrial Equator by force of the diurnal motion, the number of feet passed through by force of each motion will at once be known. It must therefore be supposed, from what was said in Book 2, chapter 7, that the semidiameter of the Earth contains 5 174 000 ancient Roman paces, that is, 25 870 000 feet; and that the semidiameter of the Great Orb, from what was said about the mean distance of the Sun in Book 3, chapter 7, contains 1142 semidiameters of the Earth for Copernicus, 3381 for Kepler, and 7300 for us. Further, from the tables of the primum mobile, any point of the Equator passes through 15″ of the Equator in one second of time; and from the tables of the mean motion of the Sun, according to what was said in Book 3, chapter 17, the centre of the Earth passes through 2‴ 27⁗ 51ᵛ in each second of time. With these suppositions made, you will learn the rest from the following small tables, in which, as regards terrestrial measures, we follow only our own opinion.

Of the Earth	Ancient Roman miles	Roman paces	Roman feet
Diameter	10348	10 348 000	51 740 000
Circumference	32512	32 512 000	162 560 000

We shall, however, apply these measures to modern Italian miles in another way in chapter 22, from number 1; but here we chose them so as to use the geometric foot, which is the ancient Roman foot, just as we used it in observing the descent of heavy bodies.

XIV. Taking up again now the figure of number 12, let us suppose that the plane of the terrestrial Equator (although it is in reality inclined to the plane of the Great Orb) is nevertheless in the same plane; for it will not be difficult to judge what happens to it when it is inclined to that plane. And since the clay ball mentioned above descends from a height of 240 feet in 4 seconds of time, let this time be divided into four parts, and, with the ball supposed at G at the beginning of its motion, let there be for the single seconds four equal arcs GV, VT, TI, IC, each of which, from what was said a little before, is of 15″, but of 1875 1/4 feet, from the first part of the preceding small table. Let the points of these divisions be joined to the centres D and E by the straight lines DG, GE; DV, VE; DT, TE; DI, IE. The task now is to find the four angles at E. This will not be difficult. For in the triangle EDI there are given the angle EDI, measuring the arc CI, of 15″; the semidiameter of the Earth, DI, as 1; and the semidiameter of the Great Orb, ED — for me 7300 of the parts of which DI is 1, but for Copernicus 1142. Therefore the angle DEI will not remain hidden. Similarly, in the triangle EDT there are given DT, 1, and DE, as above, and the angle EDT, of 30″. Hence the angle DET will become known; and when DEI is subtracted from it, IET will remain. In a similar way the remaining angles at E will be found, since the angles EDV, 45″, and EDG, 60″ or one minute, are known. So let one make: as the sum of the two given sides is to their difference, so the tangent of the half-sum of the angles at the base; and

the tangent of the angle to be subtracted from the half-sum already mentioned will come out, so that the angle sought at E remains. [Margin: Summary of the rule.] Or, if you are used to the shortcuts of logarithms, join into one sum the residue of the logarithm of the sum of the given sides, the logarithm of the difference of the same sides, and the mesologarithm of the half-sum of the angles at the base; for the result will be the mesologarithm of the angle to be subtracted from the half-sum already mentioned, so that the angle at E is left known. By this method we found the angles written below.

[Margin: 1st small table.]

Angles	Copernicus ″″	Copernicus ᵛ	Us ″″	Us ᵛ
CEI	59	0	56	0
IET	55	0	52	0
TEV	51	30	48	30
VEG	48	30	45	30

The arc CI, however, which is viewed from E in a direct position, is 1875 1/4 feet, as I said in the first part of the small table of number 13; and these feet the diurnal motion takes away from the annual, which for me is 28,555 1/4 feet, from the last part of the small table of number 13, when the point I runs through the arc IC. The remaining arcs, IT, TV and VG, are viewed more and more obliquely, and they subtract fewer feet from the annual motion the smaller the angles they subtend. Therefore, if one makes: as the angle 59 is to 55, so 1875 1/4 feet to another number, we shall have very nearly the feet that the diurnal motion subtracts from the annual on the arc TI; and so for the rest. Let there be, then, for these four arcs a second small table, both in the Copernican measures and in ours, between which the Keplerian lie midway.

[Margin: 2nd small table.]

Arc	Copernicus: feet	Copernicus: difference	Us: feet	Us: difference
CI	1875 1/4		1875 1/4	
IT	1748	127	1741	134
TV	1637	111	1624	117
VG	1542	95	1523	101

Therefore, if we subtract these arcs from the annual motion corresponding to one second of time, which is, as I said, 28,555 1/4 feet, we shall have the equated annual motion of the terrestrial points when they are not more than one minute distant from the point C, in which position the differences are greatest and the inequality is greatest, just as also at the point A. But, extending the trigonometric calculation from the point C up to the arc six minutes distant from the point C, I find that the differences now come out so equal that they do not differ by one whole foot, as is evident from the following small table, compiled from our measures.

[Margin: 3rd small table.]

Arc of distance from the point C	Differences of the arcs in feet	Arc of distance from the point C	Differences of the arcs in feet
0′ 15″	✠	3′ 15″	26
0′ 30″	134	3′ 30″	25
0′ 45″	117	3′ 45″	25
1′ 0″	101	4′ 0″	24
1′ 15″	87	4′ 15″	24
1′ 30″	75	4′ 30″	24
1′ 45″	64	4′ 45″	23
2′ 0″	54	5′ 0″	23
2′ 15″	45	5′ 15″	23
2′ 30″	37	5′ 30″	23
2′ 45″	31	5′ 45″	22
3′ 0″	27	6′ 0″	22

It is evident, then, as I said, that over almost the whole diurnal circle the diurnal motion of 4 seconds of time introduces into the annual no sensible or notable inequality. For, apart from the arcs of 6 minutes before or after the points A and C, the difference of the additions or subtractions does not reach one whole foot; and yet the difference of the impacts is proportioned to the difference and inequality of the apparent increase, which amounts to many feet. For in the first second the ball already mentioned completes 15 feet, in the second 60 feet, in the third 135 feet, and in the fourth 240, as has often been said — proportioned, I say, after its own kind, so that the impact from a height of 60 feet is much greater than from 15, and from 135 than from 60, and so on. Of this distinction we gave a sufficient specimen in chapter 16, number 23, in class 12 of the experiments.

Applicatio eiusdem 2. Argumenti ad Plurima corpora Grauia, etiam extra Aequatorem.

Application of the same 2nd argument to very many heavy bodies, outside the Equator as well.

XV. Argument 2, which rests on the clay ball of 8 ounces, holds for most heavy bodies of the same bulk that are heavier than it, and so descend from a height of 240 feet in a time no greater than 4 seconds of time, according to what was said in number 6. It holds, moreover, in very many, indeed in almost all, places outside the Equator. For neither does the diurnal motion, in so small a time, carry the ball sensibly round outside the same plane, as I showed in number 7; nor does the annual motion, likewise in so small a time — 4 seconds of time — transfer the same ball into planes so different that, by reason of them, the ball already mentioned could acquire as notable a real increase of speed as the impact it makes demonstrates when it is let fall from a higher place. For although in that much time the centre of the Earth runs through 28 2/5 ancient Roman miles, according to our measures set out at the end of number 13, at the foot of the last table, since in each second it runs through 7 1/10 miles,

nevertheless the plane through which the ball began to descend, following the parallelism of the Equator, declines uniformly from its former position.

III. Argumentum Contra Motum Diurnum Terræ.

III. An argument against the diurnal motion of the Earth.

XVI. *A heavy body the same in species and in number, retaining the same gravity, bulk, density, shape and other intrinsic conditions, and let fall from the same height through the same medium, descends naturally with an equal increase of real speed, over whatever part of the Earth it is let fall. But if the Earth moved with the diurnal motion only, a heavy body of this kind would not descend with an equal increase of real speed when let fall over whatever part of the Earth. Therefore the Earth either does not move, or does not move with the diurnal motion only.*

[Margin: Proof of the major.] The MAJOR is evident from the axiom set out at the beginning of the chapter, and it cannot be denied except by someone who now wishes to defend the presumed hypothesis of the Earth's motion, which is in dispute here. For he has no other reason for denying this axiom; nor has he proved from better-known things that his hypothesis is in fact so, but only that it is possible, with the astronomical experiments saved.

Diagram. Set in the right column. An upper arc runs from E at the left through M, N, F, S and a small italic a to G at the right, with H above it; a lower arc runs from A through D to C, and vertical lines join the two arcs. On the line falling from M, the small figures 1, 4 and 9 stand beside dots; O, Q and T stand beside heavy dots on the next three verticals, and Z beside a dot near C. Along the foot, five circles are strung from A to C, each lettered: the first with P above, I to the left, K at the centre, R to the right and L below; the second with P, V at the centre, R, I and L; the third with B at the centre, R, I and L; the fourth with P, I, X at the centre, R and L; the fifth with Y at the centre, I, R and L. Letters standing between two circles are assigned to the nearer one.

- E (left end of the upper arc): E
- H (above the upper arc): H
- G (right end of the upper arc): G
- M (upper arc): M
- N (upper arc): N
- F (upper arc): F
- S (upper arc): S

- P, X, R, I, L (fourth circle): P, X, R, I, L
- Y, I, R, L (fifth circle): Y, I, R, L

[Margin: Proof of the minor.] The MINOR is proved by repeating figure 1, which we set out in chapter 17, number 16. For in it a ball let fall from the top M of a tower, standing perpendicularly above either pole of the terrestrial Equator, would in fact descend along the perpendicular line MP, and would imitate the turning of the Earth by no other motion than the turning of its parts about its own centre of gravity; but the centre itself, along with the heavy body, would descen- d straight down; for it would not be carried anywhere else by force of the annual motion, which we do not suppose in this argument. Therefore the increase of speed, and of the spaces completed in equal times, would in reality be such as it appears to those who test and observe it: namely, following the series of the square numbers beginning from unity. In the first second the space completed would be M1, as one; at the end of the second, M4, as four; at the end of the third, M9, as nine; and at the end of the fourth, MP, as 16.

By contrast, the same heavy body let fall at the Equator would indeed move unequally as to appearance by force of the diurnal motion alone, but equally as to the real space traversed in four seconds of time, as we showed in Argument 1, number 3, and also applied to the other parallels of the Equator in number 7. Therefore, if the Earth moved with the diurnal motion only, the same heavy body, its intrinsic conditions remaining the same, let fall from the same height — say of 240 feet — through air of the same rarity and stillness, would not descend with an equal increase of real speed above every place of the Earth whatever.

[Margin: A threefold reply to argument 3.] XVII. The opponents may perhaps reply, first, that air as rare cannot be found under the poles of the world as far away from that region; next, that the Earth attracts heavy bodies along a straight line, because the magnetic virtue pours itself out along the length of the terrestrial axis; and lastly, that in heavy bodies there are two virtues: one of moving themselves downward through a lighter medium, and this they are left to exercise in every place; the other of following the diurnal motion of the Earth, on the hypothesis that they have been let fall above a place of the Earth that is turned by the diurnal motion, and that this second virtue is not exercised in act from the centre of gravity of the bodies if they are let fall above the terrestrial poles, because the poles do not share in the diurnal turning. Hence, they would say, other things are not equal: on account of the first of these disparities the Minor can be denied, and on account of the other two the Major can be denied or distinguished — conceded, indeed, if heavy bodies are either

drawn extrinsically by the Earth in the same way in every place, or exert the same intrinsic motive virtue of their own in second act, but denied otherwise.

[Margin: The reply is rejected.] But as to the first: the air under the poles of the world can never naturally be so thick as to retard notably the motion of descending heavy bodies, and to impede that real increase of the spaces traversed in equal time according to the proportion that the squares of the times have. Or, if you prefer, transfer this argument to a heavy body descending through water, which is of the same density in every place, and so on. As to the magnetic force, we already rejected it in chapter 18, number 4, from partnership among the motive causes in this case, because otherwise it would snatch nearer bodies faster and more vehemently, with greater collision and impact, than more remote ones, which is contrary to manifest experiments. The third part of the reply, however, has no foundation from elsewhere or from better-known things, but only from the mere fiction of this hypothesis, namely of the diurnal motion of the Earth. It is just as if one said that outside the poles bodies move with the Earth because the Earth moves, but above the poles they do not move with the Earth because those points of the Earth do not move. That would be rightly said if it were already known from elsewhere that the Earth moves in reality, and not merely that it can move with most of the celestial phenomena saved. Therefore, to assert this motion as a fact, that other virtue would have to have been known beforehand by some physical experiment — just as in these bodies we have recognised an active virtue of tending either upward or obliquely, or at least a passive virtue of not resisting such motions if they are drawn towards the part where there would be danger of a vacuum. Physicists acknowledge that virtue not without reason, because of the common good of the universe, which prevails over the other virtue that moves towards the body's own good. But in our case, whose good does this virtue of going round and following the motion of the Earth serve? Not that of the heavy body itself, for it is better for it to arrive straight, and by the shortest possible route, at the place owed to its nature. Not that of the universe, or of another, better body, for that circuit of heavy bodies confers no benefit on anything. Nor can any other good be imagined here except the agreement of the parts in motion with their whole; [Margin: A notable objection [?] against [?] those who assert [?] the motion of the Earth.] and on account of that same agreement we likewise say that heavy bodies ought not to move in a circle, since neither does the Earth move. Since, then, the force of each argument taken a priori is equal, each for its own hypothesis, it must be discerned from elsewhere which of the two agrees in reality with experiments and reasons a posteriori; nor should a reason be thrust forward that is no better known than the reason for the contradictory hypothesis — a point very much to be noted. Here, however, we suppose that the other arguments for the motion of the Earth have already been solidly resolved, as in truth they were.

IV. Argumentum contra motum Diurnum simul & Annuum Terræ.

IV. Argument against the diurnal and annual motion of the Earth together.

XVIII. This argument is exactly the same as Argument 3, if to the Minor you add the hypothesis of the annual motion as well, and in the conclusion exclude the annual motion as well. For outside the poles of the world heavy bodies, by force of both motions, would move without a real and notable increase of speed along a curved line whose nearly equal parts would be traversed in equal times — or at least parts not so unequal as are the parts of the straight line along which they would move above the poles of the Earth, as is clear from what was said for Argument 2. For here that portion of the path which would have to be traversed outside the poles by force of the diurnal motion would cease, and only that portion would have to be traversed which is supposed to be run through by force of the annual motion; for at the poles the diurnal motion is nothing.

V. Argumentum contra motum Terræ Diurnum simul & Annuum, à motu Leuium desumptum.

V. Argument against the diurnal and annual motion of the Earth together, taken from the motion of light bodies.

XIX. All the arguments made so far hold in their own way for light bodies ascending upward by natural motion, perpendicularly as to appearance; for they too acquire a real increase of impetus, as has already been proved by our own experiments in chapter 16. But the argument would be more evident if we had some body so light that it did not share the nature of earth and water — as glass spheres full of air do share it, and artificial fires, and fiery rockets thrown upward, and smoke, vapours, little clouds and the like, in which some earthy or watery matter is always mixed. But if we had a purely aerial or fiery body that ascended perpendicularly upward, so that such an ascent could be observed with the eyes, we should at once be certain that the Earth does not move with the diurnal motion — at least if it still persevered in perpendicular ascent beyond our own air. For a body of this kind ought not to follow the diurnal or annual motion of the Earth, as not being akin to it; so if the Earth moved, the body would certainly be left behind by it in aerial space, and its ascent could not appear perpendicular to us, but would appear oblique towards the West. Conversely, if it appeared perpendicular, that would be a sign that the whole Earth, and the part of it in which the observer stood, remained unmoved. Yet the greater the probability that such an ascent has, from reason a priori, in purely aerial corpuscles and in exhalations — even if it cannot be noticed by the eyes, except perhaps in some comets — the more probable is the immobility of the Earth than its mobility. But the remaining arguments brought forward above give us, for whom the experiments of the real increase of impetus are established, physical evidence of the immobility of the Earth.

CAPVT XX.

Chapter 20.

Proponuntur Argumenta sex à motu Rectilineo & Perpendiculari Grauium Leuiumque contra Diurnum simul & Annuum motum Terræ. Quorum pleraq. Physicè sunt euidentia.

Six arguments are proposed, taken from the rectilinear and perpendicular motion of heavy and light bodies, against the diurnal and annual motion of the Earth together. Most of them are physically evident.

I. Very ancient and very celebrated is the subdivision of simple local motion into motion towards the centre of the universe, motion from the centre, and motion around the centre; or into circu- lar motion, which belongs to the celestial bodies; straight motion downward, which suits heavy bodies; and straight motion upward, which suits light bodies — whether they are elementary or mixed, but inanimate, or have not been allotted any other motion by a soul. [Margin: The three species of simple local motion, from Aristotle.] Aristotle gives this division at the very beginning of Book 1 of *On the Heavens*, chapter 2, or texts 5 and 6, in these words: "Every motion that takes place with respect to place, which we call locomotion [latio], is either straight, or circular, or mixed from these; for these two alone are simple. The cause is that among magnitudes too these alone are simple, the straight and the circular. Circular motion, then, is that which takes place about the centre; straight, that which is up and down. By 'up' I mean motion from the centre, and by 'down' motion towards the centre. Hence every simple locomotion must be either from the centre, or towards the centre, or circular." Then in chapter 3, or text 17: "Let heavy, then, be that which is naturally borne towards the centre, and light that which is borne from the centre; heaviest, that which underlies all things that are borne downward, and lightest, that which stands above all things that are borne upward." He repeats this in Book 4, text 26. With this foundation laid, among the other arguments by which he establishes the immobility of the Earth in Book 2 of *On the Heavens*, chapter 13, text 101, he has this one: "It is manifest, therefore, that the Earth must be at the centre of the universe and immobile, both for the reasons stated and because weights thrown violently upward are borne back perpendicularly to the same place, even if that force should throw them to an infinite distance."

[Margin: Copernicus's teaching on the distinction of straight and circular motion.] II. But Copernicus, in Book 1 of the *Revolutions*, chapter 8, tried to overturn this Peripatetic teaching as contrary to his hypotheses. He holds that the motion of heavy and light bodies is compounded of the straight and the circular, and so is not a simple motion; that in it the circular predominates per se, as perpetual and as suited to a body already sound, that is, set in its own place, while the straight belongs to it per accidens, as to a sick body and one in disorder, being placed outside its own place; and that straight motion does

not exist in reality, but is distinguished from the circular only in thought. Let us pick out his own words. First he says: "We must admit that the motion of falling and rising bodies is twofold in comparison with the world, and altogether compounded of straight and circular." Then, having said that not only earthy things but fiery ones too, inasmuch as they are kindled from earthy matter, follow the nature of their whole, that is, are carried round with the Earth, he adds: "Therefore what they say, that the motion of a simple body is simple, is verified above all of the circular, so long as the simple body remains in its natural place and in its unity; for in its place there is no motion other than circular, which remains wholly within itself, like a body at rest. Straight motion, however, comes upon those things that wander from their natural place or are thrust out of it, etc. Nothing is so repugnant to the order of the whole and to the form of the world as to be outside its own place. Straight motion therefore happens only to things that are not in a right condition, and are not perfect according to nature, while they are separated from their whole and *diserunt* [?] its unity." At last, after a few remarks on the unequal motion of heavy and light bodies, slow at the beginning but swifter as it proceeds, and on the uniformity of circular motion, he concludes: "Since, then, circular motion belongs to wholes, but to parts straight motion as well, we can say that the circular remains with the straight as 'animal' remains with 'sick'. Indeed, the fact that Aristotle distributed simple motion into three kinds — from the centre, to the centre, and about the centre — will be thought merely an act of reason, just as we separate the line, the point and the surface, although one cannot subsist without another, and none of them without body." So far Copernicus.

[Margin: Galileo's teaching on straight and circular motion, against Aristotle.] III. Galileo, however, with far more tunnels, from the very beginning of Dialogue 1 on the two systems of the world, has laboured to undermine and overturn the foundations of Aristotelian motion already mentioned. First he says that the helical line drawn around a cylinder seems to be counted among the simple lines. He reproaches Aristotle for taking the simplicity of motion merely from the simplicity of the line, and so handing down a defective teaching, since among simple motions he counts as straight only the motion that takes place up and down — whereas motions can be straight, and therefore simple, even if they take place not up or down but forward, backward, to the right or to the left, provided only they come from a moving principle — and for acknowledging the motion that takes place in a straight line by a heavy or light body as compounded in a qualified sense. Then he says that straight motion cannot exist in a well-ordered world: both because it befits only things that are disordered and placed outside their own place, and because straight motion is infinite by its nature, since a straight line is of itself infinite and indeterminate; and nature, as Aristotle agrees, does not of itself undertake things that cannot be completed, such as infinite motion is. Besides this, he approves Plato's speculation about straight motion at the beginning of the world: that through it the bodies that were in Chaos might acquire a determinate degree of speed,

the motion being afterwards converted into circular motion, intended per se. In circular motion, moreover, each point of the circumference is a beginning and an end. Further, he denies that Aristotle has sufficiently proved that heavy bodies move to the centre of the universe from the fact that they move to the centre of the Earth, or downward; for, he says, those two centres are not one and the same, and the centre of the universe is an imaginary point, destitute of all virtue. Again, he carps at the Peripatetics because they attribute to the whole Earth, as natural to it, a straight motion downward to the centre of the universe — a motion it never had, but is supposed it would have if it had been placed outside that centre — whereas they call præternatural the circular motion of fire in its orb, which they themselves grant it in reality.

In Dialogue 2, moreover — pages 119 and 132 of the Italian, but 90 and 99 of the Latin version — he sets out Aristotle's argument for the rest of the Earth, taken from the perpendicular descent of heavy bodies, or from the falling back of projectiles to the same place from which they were thrown upward perpendicularly along a straight line. He denies that this argument holds unless the Earth is supposed to be at rest. For unless this is supposed, so long as we are uncertain whether the Earth moves or not, we are also uncertain whether the descent of heavy bodies takes place along a line that is really straight and perpendicular, or along a curved and oblique one; since it is certain that, if the Earth moves, the descent must take place along a curved line, or one mixed of straight and circular. Aristotle, he says, ought not to have denied that motion to heavy bodies falling downward, since he granted it to fire, which tends straight upward of itself but is carried round circularly by the motion of the heaven. He also adduces the example, repeated so often, of the stone that falls from the top of a ship's mast to its foot whether the ship moves or is at rest — but if it is at rest the descent is rectilinear, while if the ship moves the descent becomes in reality curvilinear and transverse. We said more about these matters in the scholia of chapter 4. Notwithstanding these points, we shall show that the argument of Aristotle, Ptolemy and others for the rest of the Earth holds good. It can be framed as follows.

[Margin: 1st form of the argument.] IV. Heavy bodies left to themselves, through air or through water, descend of themselves to the Earth along a straight line falling perpendicularly on the Earth; and heavy bodies thrown upward along a straight line perpendicular to the Earth fall back of themselves to the same place from which they were thrown, along the same straight line, likewise falling perpendicularly on the Earth. But if the Earth moved with the diurnal turning of 24 hours alone, or with the annual motion as well, they would not descend, nor fall back to the same place, along a straight line perpendicular to the Earth. Therefore the Earth moves neither with the diurnal turning of 24 hours nor with the annual motion.

I chose to frame in this way the argument that Aristotle indicated to us briefly above, in *On the Heavens* 2, chapter 13, text 10 [?]. Not only do his interpreters accept it at that place, but so do Petrus Alliacensis, question 3 on the *Sphere*,

conclusion 3; Clavius on chapter 1 of the *Sphere*, page 96 in my copy; Tycho in the *Epistolae Astronomicae*, page 167; Scheiner in the *Disquisitiones Mathematicae*, from page 30; Chiaramonti in the Italian defence of the *Antitycho*, part 2, chapter 3; and most of the physicists and cosmographers. In the Major I added the qualifier "of themselves" [per se], to exclude the impediment that might arise per accidens from the wind or another mover knocking the descending body sideways. In the Minor I expressed the turning of the Earth as the one the Copernicans posit, namely the one completed wholly in 24 hours; for otherwise, if the revolution were much slower, it could be imagined so slow that it would not physically alter the straightness of the descent of heavy bodies falling in a very short time. With these things set out, the Major and the Minor must be proved. We shall show the Minor first, because we shall dispatch it more briefly; and almost the whole difficulty lies in the Major.

[Margin: Proof of the Minor.] V. The MINOR, then, is proved as follows: in the time in which heavy bodies usually descend, or fall back to the same place, the Earth, by its diurnal turning towards the East, and much mo- re by the annual motion, would withdraw the place on the Earth's surface above which the heavy body had been let fall, or from which it had been thrown perpendicularly upward, from the place in cosmic space where it was when the heavy body was first released or thrown — and that far and notably. Therefore, for that heavy body to appear always on the same perpendicular straight line, and to fall back apparently to the same place, it would have to depart from its former straight line and descend in such a way as to move transversely, following the former place of the Earth — and indeed along a curved line, striking the Earth obliquely in reality. This is evident from the figures set out in chapter 17, numbers 16, 17 and 18; and from the admission both of Copernicus and Galileo, in the passages cited in numbers 2 and 3, and of Kepler, Gassendi and Boulliau, who teach that this motion is in reality curvilinear, as was said in chapter 4, scholia 2 and 4, and chapter 17, number 3. Hence that descent, or falling back, would indeed seem in appearance rectilinear and perpendicular to the Earth, but in cosmic space it would in reality be curvilinear, and would strike the Earth obliquely.

[Margin: Proof of the Major [?].] VI. The MAJOR is proved as follows. A thing must be asserted to be such when it is physically evident, and is not established to be false from a higher light, or from more evident, or at least more certain, principles. For to deny it, or to assert its opposite, it is not enough that the opposite is possible, or has certain congruences, or perfections desirable under some aspect. But that heavy bodies left to themselves, or thrown perpendicularly upward, descend or fall back along one and the same straight line perpendicular to the Earth is in itself so physically evident that it is not established to be false from a higher light — that is, neither from more evident nor even from more certain principles. Therefore such motion must be asserted to be straight, and consequently it is straight. We have, moreover, included in this proof two propositions which seem themselves to need further proof.

[Margin: Proof of the proposition [?].] The first is that a thing must be asserted to be such when it is so physically evident that it is not established to be false from principles of a higher light, which produce greater evidence or certainty; and that, to deny it, it is not enough that the opposite is possible or has certain congruences. This proposition is manifest from the whole of physical science, which would otherwise perish if it were not true, since the whole of that science rests on first principles drawn from sensations duly had. But sensations are not duly had, nor fit to generate physical evidence, if they are found by other sensations, equally or more manifest, to be deceptive and in need of correction. So it is when, having drawn a stick out of water, we see and confirm by touch that it is straight, though it had previously appeared bent; or when, while the ship is running, we see from the bank or the shore that a stone let fall perpendicularly from the top of the mast describes in the air a curved line striking the bottom of the ship obliquely, though to us, or to others carried along together in that ship, it seemed to descend along a straight and perpendicular line; or when we prove that the Sun, which looks a foot across to us, is not a foot across, from the distance of the Sun found through eclipses or lunar dichotomies, and so through other, more certain sensations. Therefore, since the senses per se — that is, usually, indeed always, if they are applied in the due manner — present objects to us such as they are in reality, or reveal other things through which we can correct the deceptiveness of other sensations, possession stands on the side of the sensations, and the presumption [?] must be made in their favour, so long as the opposite is not proved from the principles of a superior light: whether of the Catholic Faith, which has certainty without evidence, or of Metaphysics, Mathematics, or a science subalternate to Mathematics and Physics, but one in which the principles of mathematics predominate.

[Margin: The 4 degrees of natural evidence.] At this point I think it should be recalled to memory — or even brought to the notice of those who perhaps never learned it — that there are four degrees of evidence in the natural sciences, corresponding to the four total natural sciences (taking "natural" as opposed to "supernatural"): namely Metaphysics, Mathematics, Physics and Moral science. These are nevertheless reduced to three, because metaphysical and mathematical evidence have the same force. Metaphysical and mathematical evidence is that which makes a proposition so evident that it is altogether impossible for the matter to be otherwise, the first principles of Metaphysics and Mathematics being kept. These principles are most absolutely true, and rest on this axiom, the most manifest of all: "It is impossible for the same thing to be and not to be"; or on axioms arising from it next, or very near, such as are very many divisions of beings — as when we say, "Every being is either corporeal or incorporeal; either substance or accident; either finite or infinite," etc.; or when we say, "Every whole is greater than its part," or, "If from equals you take away equals, the remainders are equal." For these are so true that not even by divine power could they fail to be true.

The second evidence is physical: that which makes a proposition so evident that it is impossible for it not to be so, the first principles of Physics being kept — that is, the mode of being and operating of natural things and causes — even though it is not repugnant to the principles of Metaphysics or Mathematics, or to the absolute power of God, for it to be otherwise. In this way it is evident that every heavy body left to itself tends downward; that all fire burns; that daily, in the torrid and temperate zones, the Sun rises above the horizon and always moves in a circle; that every animal is mortal, indeed will die; that an eclipse of the Sun happens only at new moons; that some substance proper to it underlies every accident; and so of similar things — even though, if God wills, as at times he has willed, these things can be otherwise. For the axe-head floated on the water at the command of Elisha, and the body of St Peter on the sea at the bidding of Christ; the fire of the Babylonian furnace did not burn the three youths; the Sun stood still at the command of Joshua; at the Saviour's death the Sun suffered an eclipse by the Moon while the Moon was at the full; and daily, in the most holy Sacrament of the Eucharist, physical accidents are found without the proper substance of the bread and wine. Evidence of this kind, therefore, is not altogether absolute, but has implicitly annexed to it a certain hypothesis and a tacit limitation: namely, if Nature exists and operates in its accustomed manner, the manner owed to it; or if the mode of being and operating of natural causes as such is what is considered.

Moral evidence, finally, is when, the principles of prudence being kept, the matter cannot be otherwise, even though it is repugnant neither to the principles of Metaphysics nor to those of Physics for it to be otherwise. In this way it is evident that Rome, or the Ocean, exists to someone who has never seen them, but has heard from the constant report of honest men that both are to be found. Moreover, physical and moral evidence persists, and has the force of determining the intellect to assent, so long as it has not been established from divine revelation, or from the principles of Metaphysics or Mathematics, that the opposite is true. In the same way the probability of an opinion also remains for as long as its opposite has not been evidently known.

With these things laid down, I said that what is so physically evident that it is not established to be false from the principles of a higher light must be asserted; otherwise that evidence ceases, because the tacit condition on which it rested ceases. I said, however, that to deny that something is, which has been manifest by such evidence, it is not enough that the opposite is possible, or has some congruences in favour of its real existence. Otherwise we could assert the real existence of all things that are possible and that, if they existed, would certainly have some goodness and perfection — which is erroneous, even if we had a sign of the existence of neither of two contradictories. How much more erroneous, then, is it to deny that something is such, when we have sufficient signs of it, and to deny it because its opposite has certain congruences and desirabilities and is not otherwise impossible? Are not the equality of the lunar month, the uniformity of the motion of the Moon and of all the planets, and configurations

of the fixed stars according to regular figures possible — indeed, do they not have great and desirable congruences? Certainly they do. Would anyone therefore dare to deny that some lunations are shorter and others longer? Or, if you refer this to an apparent inequality, what of the figures of the stars? Must they too be called regular in reality, and irregular only optically? If anyone dares to say so, let him go on, by all means, and rub his brow still harder, and affirm that in reality there is no summer, no winter, no pains, no diseases, no death, but that these only appear — on the ground that a temperate and equable state of the weather and of the humours, and an immortal life, are possible and more desirable entities. For it is no more evident that there is summer and winter, etc., than that the natural descent of heavy bodies is rectilinear and perpendicular to the Earth. But if you say [?] that, in the examples listed, the appearance of those things cannot be joined with the privation of their real existence, or at least not without a miracle, I too shall say that the appearance of the straight motion of heavy bodies cannot be joined with the real privation of straightness without a miracle. And in the controversy over the notion and definition of a miracle I shall have as my supporters all the best theologians, who recognise so great a miracle in the motion of the whole Earth and in the rest of the Sun that they deny this motion could be produced naturally even by the whole of angelic power. We ought to adhere to them rather than to the Galileists and the rest of the Copernicans, for whom the Sun stands still and the Earth is turned round without any miracle at all. Finally, it must be noted that the proposition "Heavy bodies descend either along a straight line or along a line that is not straight" (which alone the adversaries concede to be evident) is evident metaphysically — understand: on the supposition that they descend. Here, however, we require and defend only physical evidence.

[Margin: Proof of the 2nd proposition.] VII. Secondly, in the proof of the Major we said that it is physically evident that heavy bodies left to themselves, or thrown upward to the perpendicular, descend and fall back along one and the same straight line falling perpendicularly on the Earth; and that it is evident in such a way that the falsity of this straightness cannot be proved from any higher light, or from more certain principles. For it is established by the experiments of all ages and places that this motion appears straight — not to some people or at some times straight and to others or at other times not straight, but to all people and always straight. Nor does any authority of God oppose this appearance; rather, it supports it in the highest degree by the very fact that it very often affirms to us that the Earth is immobile. Finally, no reason drawn either from Metaphysics or from Mathematics certainly and evidently resists the straightness of this motion. This is clear both from the solution of the arguments adduced for the motion of the Earth from chapter 5 to chapter 19, and from the admission of the Copernicans, who openly concede that on either hypothesis — that is, of the Earth unmoved or moved — all the phenomena can be saved. And indeed Galileo, in Dialogue 2 on the system of the world, page 81 of the Latin, says most expressly: "And this motion of 24 hours, as regards

this first appearance, in no way prevents its belonging as well to the Earth alone as to the whole rest of the world except the Earth. For the same appearances would be seen in the one position as in the other." From no effect, therefore, can it be proved that the Earth moves, and hence that the descent of heavy bodies is not, as it appears, rectilinear and perpendicular with respect to the Earth. And let this suffice for the Aristotelian argument. Let us hear, however, the reply of the Copernicans.

Responsio Copernicanorum ad 1. Argumentum, eiusq. Inualiditas.

The reply of the Copernicans to the 1st argument, and its invalidity.

VIII. The Copernicans reply, however — Rothmann in Tycho's letters, page 185; Galileo in Dialogue 2 on the system of the world; and Gassendi in Letter 2 of *De motu impresso a motore translato*, pages 80 and 106 — by distinguishing the Major. They concede it if it is certain from elsewhere that the Earth does not move and that our senses are not deceived in judging the rectilinear motion of heavy bodies, or if the motion of the Earth is not common both to us who observe the motion of the heavy bodies and to the heavy bodies themselves; otherwise they deny the Major. And they press the example of a man who did not know of the motion of the ship in which he is carried, and who would therefore judge rectilinear the fall of a stone let fall from the top of the mast, or the descent of a ball let fall through the water of a vessel enclosed in that ship — a fall that, because of the ship's motion, would in reality be curvilinear in the space of the world, even though it would not be recognised as such, because the eye observing that motion is carried along together with the ship. And Gassendi, although he indeed suspends his assent, nevertheless adds certain things there which, to use Chiaramonti's words, would take away altogether the criterion of sense — that is, the power of judging that rests on sensations — however rightly the sensitive power were disposed, the object duly presented, and the medium such as not to disturb the sensation. [Margin: Gassendi's dissertation against the deceptiveness of the senses.] For Gassendi says: "Now the globe of the Earth is the one into which we were transported as if asleep, or rather in which we were born without thinking of it. But from the time we opened our eyes, and contemplated besides this globe another, namely the Sun, in the same expanse, as it were, or space of the world as the Earth, the question has been to which of these globes rest belongs, and to which motion. We, for our part, unhesitatingly pronounced that rest undoubtedly belongs to the Earth and motion to the Sun. Pythagoras, Plato, Aristarchus and other ancients, and likewise Copernicus, Galileo, Kepler and many more recent men, warned that perhaps we are deceived, and that the Sun is at rest and the Earth moves; we nevertheless held out against them. And we became the more obstinate the more attentively we observed that the parts of the Earth are not drawn away from one another, but that that mountain is always to the north, this city to the south, that river to the east, this island to the west; and that we meanwhile run about upon the Earth just as we run about through the house or city in

which we were born — so that, just as neither the house runs about through the city, nor the city through the province or the Earth, so the Earth itself also does not seem to run about through the spaces of the world. Such indeed is our imagination from our birth onward; nor do we notice that the Earth is perhaps like a ship, and that it may happen that, being on the Earth, we are deceived just as that inland man is while he is on a ship. For what will be the difference? Or what the reason for a difference? And what the way of distinguishing truth from error? I do not, indeed, say that the Earth therefore moves and the Sun is at rest; but I do say that better reasons must be sought than those drawn from sense itself. And if we had never had experience of the deceptiveness of our sight, we would seem excusable, and could object that nothing is more manifest or more certain than sight, and that, once faith is withdrawn from the eyes, nothing is worthy of belief. But since experience has taught us that sight is deceived so greatly, and that faith is not always to be placed in the eyes — and this above all when motion is in question — what else can be answered than that both sight and the other senses must be corrected by reason?" So Gassendi, with a declamatory elegance of style indeed, but one that strikes nothing, and does not even prick Aristotle.

[Margin: The reply offered is rejected.] IX. For the reply and the distinction already mentioned are worth nothing. Physical evidence does not require that we be certain from elsewhere that the Earth is at rest and that our sense is in no way deceived; it requires that sense is not deceived once every application of the power, and every examination of the medium and of the object naturally possible to us, has been made. Otherwise one would have to proceed to infinity from one sensation to another and yet another, with a perpetual fear of error; or, if this certainty had to be sought from other principles that presuppose no sensation, it would no longer be physical certainty but metaphysical, mathematical or theological — which would be demanded here unseasonably and unskilfully. The example of the man observing the fall of a heavy body in a ship, moreover, is no parallel. For neither all men nor always are ignorant that the ship moves, and natural means are given of detecting that ignorance, and so of correcting the deceptiveness of sense. By contrast, no natural means is given by which we could certainly and evidently detect that the Earth moves, and we with the Earth, and hence that sense is deceived in judging the rectilinear motion of heavy bodies. On the contrary: from the more vehement percussion when they fall from a higher place, we have an argument from the sensations themselves that the increase of speed is real, and hence that the Earth does not move, as is clear from the preceding chapter. The a priori reasons for the motion of the Earth drawn from certain congruences, moreover, have already been abundantly resolved from chapter 5 to chapter 19; and in the motion of the Earth there is no lack of many other absurdities, just as in its rest there is no lack of very many utilities, and of congruences with the end intended by God and desirable to us. Therefore, even if the weights of the a priori reasons were equal on both sides, there will always be this disparity: for the rest of the Earth

and the rectilinear motion of heavy bodies there stands the universal sensation of all men at every time and place, whereas for the curvilinear motion of heavy bodies and the motion of the Earth there is no sensation, nor can there be. And on him who asserts that sense is deceived lies the burden of proof — and indeed of a very strong one; otherwise all tribunals will award the suit to so many eyewitnesses.

II. Argumentum à Breuitate & Compendio itineris Grauium Leuiumq. naturaliter ad suum locum properantium.

II. Argument from the brevity and shortness of the path of heavy and light bodies hastening naturally to their own place.

[Margin: Form of the 2nd argument.] X. The nature of heavy and light bodies requires that, if they are outside the place owed to them, they reach it, once impediments are removed, by tending to it along the shortest possible path. But if the Earth moved with the diurnal motion alone, or with the annual as well, neither heavy nor light bodies placed outside the place owed to them would reach it by tending along the shortest path, however completely the impediments were removed. Therefore the Earth moves with neither the diurnal nor the annual motion.

[Margin: Proof of the MINOR.] The MINOR is proved first, because there is no controversy about its truth, nor can the adversaries deny it, if the path a body would have to traverse on the hypothesis of the moving Earth is compared with its path on the hypothesis of the Earth at rest. For if the Earth does not move at all, heavy and light bodies left to themselves tend to and reach their own place along a straight line perpendicular to the place they tend to, and no path can be shorter than that. But if the Earth moves with the diurnal motion alone, and much more if it moves with the annual motion too, the heavy bodies must turn aside from the straight path downward, following the Earth and its motion: both the diurnal motion, so that they fall on the point above which they were let fall perpendicularly or thrown upward — a point already withdrawn from the former perpendicular by the turning of the Earth — and the annual motion, so that they do not fall outside the whole Earth. They must therefore describe by their motion a transverse and curvilinear path, such as we sketched in chapter 17 from number 16. And the same must be said of light bodies tending upward, for these too must appear, to an eye carried along with the Earth, to lie on the same straight line drawn perpendicularly from the Earth's surface. Thus, for example, take the clay ball which, as stated in chapter 16, number 12, we observed to descend from an apparent height of 240 feet in a time of 4^s. If it followed only the diurnal motion of the Earth, so as to fall on the same place above which it was let fall, it would have had to run through at least 7527 Roman feet, had it been at the Equator — namely as many as are contained in one minute of the Equator, according to what was said in chapter 19, number 13, in the first part of the table; for one minute of the Equator turns in every 4 hour-seconds. And if it followed besides the annual motion of the

Earth, then, since the centre of the Earth runs through 2‴ 28⁗ of the annual orb in each hour-second — that is, 9‴ 52⁗ in every 4 seconds — it would have had to pass, by the force of this motion alone, through at least 23,860 feet, or 4772 Roman paces, that is, 4 4/5 miles, if we follow the Copernican diameter of the Great Orb; but if we follow ours, it would have had to traverse at least 142,760 Roman feet, or 28,552 paces, that is, 28½ ancient Roman miles, as may be gathered from the table of chapter 19, number 13. These distances exceed the shortest, perpendicular path of 240 feet by a very long interval.

[Margin: Proof of the MAJOR.] The MAJOR is proved because in inanimate bodies, whose motion is not determined by a soul, Nature takes the short way, and does not do through more what it can do through fewer. The Copernicans indeed use this axiom — or rather abuse it — to attribute the simplicity and unity of the diurnal motion to the Earth alone, and to deny it to the fixed stars and the planets. Moreover, that very increase of impetus by which heavy and light bodies move faster and faster towards the end of their motion is an argument of a nature that aims at the shortest and most expeditious path, so that they may reach their own place. We must, however, hear the reply the Copernicans could devise.

[Margin: The 1st reply to Argument 2, of little strength.] For one can reply, first, by distinguishing the Major: conceding it comparatively — with respect to the place of their whole, to which they seek to be joined, that place being meanwhile carried along, and supposing that they imitate the motion by which their place is moved; for under these conditions they cannot be carried by a shorter path — but denying it absolutely, or when the comparison is made with the place over which they hung perpendicularly, or on which they stood, when they were first let fall. But who does not see that this has been invented out of the necessity of the hypothesis of the Earth's motion? Since that hypothesis is disputed, it ought not to be presumed as certain; rather, the controversy must be settled from other, better-known things. And it is better known that the nature of these bodies requires a priori — indeed, if we rest on the observation and testimony of the senses, it is also better known a posteriori that it pursues — the joining of the parts with their whole, and their restoration to their own place by the shortest path. Surely it would be better for them to be united with it at once along the straight line, and afterwards, if it moves circularly, to move with it.

[Margin: 2nd reply.] The second reply is to concede the Major if the brevity of the path of elementary bodies does not presuppose multiple motions and paths of the celestial bodies, and to deny it if it does. Now if the brevity of the path of heavy and light bodies along the line perpendicular to the Earth is kept, the diurnal and annual motion of the Earth must be transferred from the Earth to the stars; and it seems that the simplicity of the celestial bodies, as being simple, should be favoured rather than that of the elementary bodies. On the hypothesis of the immobile Earth, however, the foundation drawn from the sensations always prevails, on account of which both the rest of the Earth

and the diurnal motion of the stars are reasonably asserted; and the hypothesis of the moving Earth lacks this foundation. Besides, we have already shown, in chapter 6 from number 11 to 15 and in chapter 9 from number 1 to 5, that more motions are multiplied if the Earth moves, even counting the necessary motions of the stars, than if it is at rest.

III. Argumentum à Simplicitate motus Grauium & Leuium.

III. Argument from the simplicity of the motion of heavy and light bodies.

[Margin: Form of the 3rd argument.] XI. Species of motions, or diverse inequalities and diverse degrees of speed in the same mobile body, are not to be multiplied without necessity. But if the Earth moved with the diurnal or also the annual motion, species of motions, and diverse inequalities and degrees of speed in the same mobile body, would be multiplied in heavy and light bodies without necessity. Therefore the Earth moves with neither motion. [Margin: Proof of the MAJOR.] The MAJOR is used by the Copernicans to substitute one single diurnal and one single annual motion of the Earth for the many other motions of the fixed stars and planets that would have to be admitted if the Earth were immobile, as is clear from chapter 6, number 14, and chapter 9, number 2; and it rests on these axioms: "God and nature do nothing in vain," and likewise, "Entities are not to be multiplied without necessity." The MINOR is easily shown from the different figures of motion that heavy bodies would describe in descending if the Earth were turned with both motions, or at least with one of them — figures we sketched after a fashion in chapter 17, numbers 16, 17 and 18. [Margin: How varied, unequal and nowhere constant the motion of heavy bodies would be, if the Earth moved.] For if a heavy body were let fall above the poles of the terrestrial Equator, and the Earth moved with the diurnal motion alone, the descent would take place along a straight line perpendicular to the Earth; but if it moved with the annual motion as well, the body would describe a curved and oblique line on a cylindrical surface. If it were let fall on the parallels of the Equator, it would describe a curved line about a conical surface — and indeed the surface of a cone that varies, or is carried by the annual motion to different places; but if at the Equator, the line would be described in nearly the same plane, as we showed in the same place. Added to this, in following the diurnal motion of the Earth, heavy bodies would have to traverse more path in the same time at the Equator than on the parallels, since on the parallels the motion of the parts of the Earth's surface is slower. So the same heavy body, let fall above different places of the Earth, would descend by different paths and with very different degrees of speed. Besides this, it would acquire another inequality from the different times of the same day, at which the diurnal motion would sometimes add to the annual, sometimes subtract from it, and sometimes neither add nor subtract [?] anything, according to what was said in chapter 19, number 12. The same must be understood, proportionally, of the ascent of light bodies. Moreover, no necessity appears for multiplying so many varieties of motion, since with the

Earth at rest all the celestial phenomena and all the experiments on elementary motions are saved.

[Margin: A reply of no great strength.] The Copernicans will reply by denying the Minor. For there is a necessity — not indeed a posteriori, from sensations or phenomena, but a priori — that motions not be multiplied in the heavens without necessity; and in an equal contest between celestial and elementary bodies, multiplicity of motions must be allowed to the elementary rather than to the celestial bodies. For through it, since it presupposes the motion of the Earth, very many other motions are dispensed with, which would otherwise have to be acknow- ledged in the heavens, if they are excluded from the Earth. But in reality there are more motions in the world if the Earth moves than if it is at rest. For in the heavens motions are not really multiplied; rather, there is in each body a single diurnal motion, though it is slower in some and swifter in others. Besides, the disparity always prevails, on account of the physical evidence of the motion of the celestial bodies and of the rest of the Earth.

IV. Argumentum à Termino motus Grauium ac Leuium, ad quem tendunt.

IV. Argument from the term of the motion of heavy and light bodies, to which they tend.

[Margin: 4th argument, an enthymeme [?].] XII. If the Earth moves with the diurnal motion, no reason can be given, antecedent to the hypothesis of the motion or rest of the Earth, why heavy and light bodies tend to the term they tend to, rather than to another of the same or even of better condition for terminating that motion. But such a reason can be given if the Earth does not move. Therefore the hypothesis of the immobile Earth is to be preferred to the hypothesis of the mobile Earth. About the consequence there seems to be no doubt, at least if other things are equal. [Margin: Proof of the 1st part of the antecedent.] The first part of the antecedent is proved by taking a single example, so that a judgement can be made about the others. Above some rock placed at the Equator, let there be a glass sphere, which is thrown from there straight up to the perpendicular, or at any rate is let fall from a tower above that rock. It is certain from observations that this sphere will fall on that rock, unless per accidens it is violently pushed elsewhere, or pulled back, or impeded. Let there be, moreover, at the terrestrial Equator, a lake or pond, distant from the rock already mentioned towards the west by so many paces that, if the glass sphere in reality descended by a straight path and did not follow the turning of the terrestrial rotation, it would fall into the lake or pond. Granting the diurnal turning of the Earth, I ask why that glass falls on the rock. Suppose you say this happens because that glass shares in the motion that the whole Earth has, since it is an earthly body, and therefore must move towards the same part as the Earth and about the same centre about which the Earth moves. Then this reason is not antecedent to this disputed hypothesis about the motion of the Earth, but presupposes it — and presupposes it in such a way that, even if its

contradictory were supposed, namely the privation of motion in the Earth, the glass would nonetheless fall on that rock. So the motion of the Earth can no more be adduced as the cause of the descent upon the rock than its rest can. If you say this happens so that the sphere may be united with its whole, or be better preserved there, or on account of the kinship the glass sphere has with the rock, or because it is drawn magnetically to it by the Earth, you give no satisfaction. For it has no greater kinship with the rock than with the water of the lake or pond; nor is it better preserved there than here, since it is rather broken by the rock; nor is there in the rock a mass of glass having the character of the whole. But if the character of the whole lies in the whole terraqueous globe, the sphere will be united with its whole, or drawn by it, no less if it falls into the water than if it falls on the rock. Besides, as Scheiner rightly argues in the *Disquisitiones Mathematicae*, page 30, if there were a globe of water about the centre of the Earth, and the land about this globe, a clod of earth placed at that centre would nevertheless not rise to its whole, but would remain there: therefore heavy bodies do not descend so as to be united with their whole, but so as to lie beneath bodies lighter than themselves. The objection has greater force, however, if the clod is at a distance from the centre, lest they say that it does not move because the centre does not move either. If you say that the sphere falls on the rock so that its motion may always appear to us on the same straight line, you invent a cause arbitrarily; for our sight is not the end of that fall. And then what will you say of a drop of rain falling on sand or on burning coals? So, whichever way you turn, you can devise no solid cause of the fall already mentioned that is antecedent to the hypothesis of the motion of the Earth.

[Margin: Proof of the 2nd part of the antecedent.] XIII. The second part of the antecedent is proved. The cause why a heavy body falls back to the place over which it hangs perpendicularly is not an appetite for uniting itself to its whole (otherwise a stone, for example, let fall down a well would have to unite itself to the side of the well dug in the earth), but that the parts of the universe in the elementary system may return as soon as possible to their own place, and their order with respect to position be restored — namely, that the heavier lie beneath the lighter and the lighter stand above the heavier. This cannot happen as soon as possible, nor by a shorter [?] path, than along the line perpendicular to the Earth, that is, the line tending straight to the centre of all heavy bodies. For although this centre is a point, and is not of itself either the mover or the terminator of the motion of all heavy bodies, it is nevertheless directive of it, as that towards which, if they tend, it is certain they will return most quickly to the place owed to them in the order of the universe. In the same way a standard is not a sign under which all the soldiers can gather, as in a place or covering able to hold them all, but is directive of their motion; and the Cynosure is not the harbour of those who sail, but directive of their navigation. For even if the whole Earth had burst apart into various parts, those parts would flow together again to the centre, not so as to be at the centre,

but so as to lie beneath lighter bodies; and for this they needed some common point that would objectively determine their shortest and surest path. Similarly, lighter bodies must recede from the centre of the heavier, on the supposition that about this centre, especially on a straight line, there are heavier bodies not impeded from descending beneath the lighter ones; and for this reason they are said to move from the middle. Hence it is no obstacle that Kepler, in the Introduction to the *Commentaries on Mars*, insists that the centre of the Earth is a mathematical point and nothing, and so can move heavy bodies to itself neither effectively nor objectively. The words of this author are these: "A mathematical point, whether it is the centre of the world or not, cannot move heavy bodies either effectively or objectively, so that they approach it. Let the physicists prove that this power belongs to a point, which is neither a body nor is understood otherwise than through relation alone. It is impossible that the form of a stone, in moving its body, should seek a mathematical point, or the middle of the world, without regard to the body in which that point is. Let the physicists prove that natural things have a sympathy for what is nothing." But we do not say that they tend to the centre without regard to the body whose centre it is; on the contrary, we suppose that heavier bodies are placed all around it, and that heavy bodies tend to these so as to lie beneath lighter ones, and so to be co-ordinated with them in the universe. Nature, and God the Geometer, have used this centre as a term towards which the heavier bodies, and from which the lighter, are to be carried — not, however, as a term to which, and in which, they are to be placed; just as a centre is used by one who describes a circumference on which certain things are to be placed. It is false, therefore, that the centre does not move objectively and in the manner of a sign, or even of a term of relation and order. As for what Kepler adds in the same place — "Heavy bodies (even if we place the Earth at the centre of the world) are not borne to the centre of the world as to the centre of the world, but as to the centre of a round kindred body, namely the Earth" — this we admit so far as it goes. But it follows from this that this centre is the term from which their distance in a round body is to be measured, and that their direction is to be taken along a line that is a radius or semidiameter of the round body; for this line alone is what, by its revolution about the centre, constitutes a round body. And hence the motion of heavy and light bodies naturally descending or ascending must take place along a line perpendicular to the round surface of the terrestrial globe; and this cannot happen, with the phenomena and the falling back to the same place saved, unless the Earth is at rest.

The Copernicans could reply, however, that the consequence of the enthymeme is true if other things are equal, or if a suitable reason can be given for the many phenomena that appear in the heavens on the supposition of the Earth's immobility; and that otherwise it is not true. And so they seem in some fashion able to escape the force of this argument, and to be held by it only within the bounds of probability. Yet the foundation drawn from the sensations always prevails, and the hypothesis of the moving Earth lacks it.

V. Argumentum à sphæra catenulis appensa & deorsum ab Angelo dimissa.

V. Argument from a sphere hung on little chains and let fall downward by an angel.

XIV. If an angel hovering over a point of the Earth let fall downward a metal sphere, but one tied to a chain, holding back the other end of the chain, that sphere would tend straight towards the Earth and would stretch the chain along the perpendicular above the former point of the Earth. But this could not be if the Earth moved. The Copernicans will reply by denying the Major: for the sphere would tend towards the east with an oblique motion, and so would drag the chain with it. Or, if the angel's force in holding back the chain were greater, it would indeed come to rest at last, but inclined towards the east.

VI. Argumentum à Linearum & Figurarum, Mensurarumq. confusione.

VI. Argument from the confusion of lines, figures and measures.

XV. I bring this argument under the title of this chapter because it has a great affinity with what was said about the straight line described by the motion of heavy and light bodies. For just as it is physically evident that these bodies describe a straight line in their descent or ascent, so it is evident to architects that they describe a straight line with a plumb line stretched out and let down; and to practical geometers that they draw a straight line with the help of a ruler or a stretched thread, a circular periphery with the help of compasses, and a right angle with the help of a square or of the problems of practical geometry, and from there construct various rectangular figures. But if the Earth moved, these things would not be such in reality in the space of the world, but only optically, or apparently, on the board, the paper, the wall, and so on; nor would vision be continued along one and the same straight line. Nor could someone who had run towards the East, or had drawn furrows with a plough, truly say that he had run through three miles in one hour, or had finished ploughing one iugerum in one day. For he would have measured out much more space in the world, especially if the Earth moved with the annual motion as well: besides the apparent motion, he would in addition have completed the motion that the Earth meanwhile completed by its own motion. But all these things, however foreign they are to common sense and however paradoxical to the common view, the Copernicans will deny are absurd to an intellect that knows the reasons for which they assert the motion of the Earth.

CAPVT XXI.

Chapter 21.

CAPVT XXI.

PROPONUNTUR ARGUMENTA QUATUORDECIM EX MOTU CORPORUM ELEMENTARIUM VERSÙS QUATUOR MUNDI CARDINES, SEU PLAGAS QUATUOR VENTORUM PRINCIPALIUM, CONTRA MOTUM DIURNUM TELLURIS. QUÆ MULTÒ MAGIS MILITANT CONTRA ANNUUM DIURNO CONIUNCTUM: EX QUIBUS QUINQUE SUNT PHYSICÈ INSOLUBILIA.

Fourteen arguments are proposed, taken from the motion of elementary bodies towards the four cardinal points of the world, or the regions of the four principal winds, against the diurnal motion of the Earth. They militate much more against the annual motion joined to the diurnal. Of these, five are physically insoluble.

I. The arguments that are commonly made, or could be made, against the diurnal motion of the Earth, taken separately or joined with the annual, are almost innumerable, if the motion of bodies, whether animate or lacking a soul, towards the East is compared with their motion towards the poles or towards the West. But they are reduced to fewer, because most of them differ only by reason of their subject, while the form and the ground of the difficulty are the same: namely, that from the turning of the Earth towards the East it seems to follow that the motion of terrestrial, aquatic and flying bodies turns out swifter towards the East, slower towards the West, or even at times impossible, while towards the poles it behaves in a middle way; and since these consequences do not answer to the experiments, this motion must therefore be counted among false hypotheses. [Margin: Buchanan's poem against the turning of the Earth.] Buchanan touched elegantly on many of these points in book 1 of his *Sphere*, composed in verse, in these lines:

> Even the birds, swimming through the air with the gentle oarage of their wings, would lament their woods snatched away by the swift turning of the Earth, and their nests with their tender brood, and perhaps with their dear mate; nor would the turtle-dove dare to entrust itself alone to the West Wind, lest, as the Earth fled, it should weep for its marriage carried far away and mourn its widowed love in long grief. What of when the light-armed Persians first join battle with the Medes, and the army stands against them with equal arms — the pole standing still and the ground fleeing — while the missile iron flies suspended in the empty air? The one side, running against [?] the weapons, would put itself upon them; the other would never suffer wounds, for the weapons, carried away from the enemy by the turning of the Earth, would fall in vain beside their master's footsteps. What of when the Earth, driven on, twists itself always towards the West, if the blue levels of the sea lie sluggish and unmoved in their lazy pools? Meanwhile, must not either a great part of the Earth float upon the waters, the compact of nature broken — so that the light wave, carrying heavy rocks on its flood, does not give way, and the water does not bore through the high mountains, though before it could not be taught to carry even the smallest pebbles? Or, if the Earth, solid and unbroken, should resist

the waves, the watery part of the sea would daily overwhelm a part of it, and night would always look upon the land that the Sun had just seen, sunk in the strait and squalid with shapeless sand.

But let us treat this matter seriously, with arguments selected from the motions of these things.

I. Argumentum à pendentibus vel meantibus in Aere versùs Occidentem.

I. Argument from things hanging or travelling in the air towards the West.

[Margin: Form of the 1st argument.] II. If the Earth moved with the diurnal turning, or also with the annual translation, clouds hanging in the air, and rising smoke, and birds, however much they hold themselves suspended or fly towards the East, would appear always to be carried towards the West. But this is against manifest experience. Therefore the Earth does not move with the diurnal turning, and much less with the annual translation. The MINOR is clear to those who observe; the MAJOR is proved. For the part of the Earth on which we stand while observing the things already mentioned would snatch us away towards the East with a far swifter motion than any wind could drive the clouds, or any impetus from within could drive the birds, towards the East. For, from what was said in chapter 19, number 13, a point of the terrestrial Equator would pass in one hour-second — that is, in about one beat of the pulse — through 15″ of the terrestrial circumference, namely 376 Roman paces; and in one hour through 15 degrees, that is, 1355 ancient Roman miles. This is roughly the argument of Ptolemy in book 1 of the *Great Construction*, chapter 7; of Petrus Aliacensis, question 3 on Sacrobosco's *Sphere*, conclusion 3; of Clavius on chapter 1 of the *Sphere*, page 196 in my copy; and of Scheiner in the *Disquisitiones Mathematicae* from page 30. But it is worth transcribing Ptolemy's words here: "They think that nothing can resist them if they suppose the heaven immobile and the Earth revolving daily from west to east about the same axis." Against them he adds: "For it escapes them that, as far as the appearances in the stars are concerned, nothing perhaps prevents someone from thinking that things are so; but from the things that happen around us and in the air this will seem quite ridiculous. Why? Because they cannot deny that the revolution of the Earth, if it turned in this way, would be simply the swiftest of all the motions about it, since it would complete so great a revolution in so short a time; so that the things that are not in it would always appear to move with a single motion contrary to the Earth. Thus neither clouds nor anything else among things flying or thrown would ever appear to be carried towards the east; but the Earth itself would outrun them all, and would so resist their motion towards the east that all the rest, left behind, would appear to advance towards the west. For even if they say that the air is likewise carried round with the Earth at equal speed, the things that form in that air would nonetheless always be left behind by the motion of both, etc."

[Margin: Copernicus's reply to Argument 1.] Copernicus, however, replies very briefly, implicitly denying the Major, in book 1, chapter 8, in these words:

"What then shall we say of the clouds and the other things hanging in the air in whatever way, or settling, or tending upward to the heights? Only that not merely the Earth with the watery element joined to it moves in this way, but also no small part of the air, and whatever things have kinship with the Earth in the same way. Either the neighbouring air, mixed with earthy or watery matter, follows the same nature as the Earth; or the motion of the air is acquired, and it shares it from the Earth through contiguity, with perpetual revolution and without resistance." And a little below: "We must admit that the motion of falling and rising things is double, by comparison with the world, and altogether compounded of straight and circular. For since the things that are pressed down by their own weight are especially earthy, there is no doubt that the parts preserve the same nature as their whole." That is, they move with a double motion: one common to them and to all things akin to water or earth, about the centre of the Earth, about which the Earth and the water turn — a motion we cannot perceive, because we are carried along with the Earth; the other their own, and this alone we can notice. Therefore, if clouds, smoke, birds and so on do not use their own motion, they will seem to us, who are carried round together with them, to stand still and hang in the air, because they are nevertheless carried round towards the east by the common motion; but if they move with their own motion towards the west or the east, this motion alone will appear, separated from the motion common to them and to us. This reply also holds for things hanging or travelling in the very thin air above the Peruvian and other mountains, where air fit for breathing is said scarcely to be found: for those hanging bodies too, being of an earthy or watery nature, share the common circular motion towards the east. Their own motion towards the west, moreover, is nothing other than a certain subtraction and diminution of the common motion towards the east, as Galileo rightly explains in Dialogue 2 on the system of the world, page 136 of the Latin. He adds that if flies, butterflies and similar flying creatures are shut up in the larger cabin of a decked ship, and there is a vessel full of water there with fishes in it, then whether the ship stands still or runs, the same proper motion of the flying and swimming creatures will appear in either case; and that the same therefore happens with the proper motions of bodies, whether the Earth stands still or moves.

II. Argumentum à motu difficiliori versùs Occasum, & faciliori versùs Ortum futuro.

II. Argument from the motion that would be harder towards the west and easier towards the east.

[Margin: Form of the 2nd argument.] III. If the Earth moved with the diurnal motion, it would be harder to walk, swim or fly towards the West than towards the East. The consequent is false, and against common experience. Therefore the antecedent is false too. So argue Petrus Aliacensis on the *Sphere*, question 3, conclusion 3, and Scheiner in the *Disquisitiones*, page 31. They prove

the Major because the air too would have to move towards the East together with the Earth: therefore things walking, swimming or flying towards the West would feel the air coming against them, and that most rapidly, and would be driven back by it towards the East; so that to make any progress towards the West they would need far greater force and effort. About the Minor there is no controversy, for in itself, and as a rule, this difficulty is not felt.

[Margin: Reply to Argument 2.] The reply, however, is to distinguish the Major: it is conceded if the bodies walking, swimming or flying had, besides their own motion, no motion common to them, to the Earth and to our air, circular towards the East — a motion by which they would be carried towards the East prior in nature to being driven there by the air. But if they had this motion, as they are supposed to have it, the Major is denied.

III. Argumentum à rebus præsertim fluidis in Ortum obuertendis.

III. Argument from things, especially fluid ones, that would be turned towards the east.

[Margin: Form of the 3rd argument.] IV. Granting the diurnal turning of the Earth, the vanes of towers, the hair of women who have left it undressed, the flames and smoke of fiery bolides (or their radiant tails, and those of comets), threads tied to balls and thrown into the air, the sails of ships, the leaves of trees, the ears of grain in open fields, and smoke rising from chimneys and furnaces, would all be turned perpetually towards the East. The consequent is false; therefore so is that from which it would follow, namely the turning of the Earth. And it is much more false that the Earth moves with the annual motion on top of the diurnal, because the effects already mentioned would follow much more.

[Margin: Reply to Argument 3.] The reply is, as above, to concede the Major if the bodies already mentioned did not move towards the East with a motion common with the Earth, circular, and of equal speed; otherwise the Major is denied.

IV. Argumentum à Dissipatione multarum rerum in Aere.

IV. Argument from the dispersal of many things in the air.

[Margin: 4th argument.] V. If the Earth and the water, and with them all earthy and watery bodies, moved with the diurnal turning towards the same part of the world at equal speed, lead bullets would melt in the air from the excessive heat conceived from so rapid an impetus; water rising from the pipes of fountains would be scattered into imperceptible drops, and any cloud into mists; flames in the open air would be extinguished; the sound of bells would either be scattered or be heard more easily and more quickly in the western part; no fragrance of odours could be perceived by those to the east, since they are carried away very swiftly towards the East; and finally, the atoms we see flitting in a ray of the Sun would float off, scattered elsewhere. But we see none of these things follow. Therefore neither the Earth, nor the water, nor these bodies with the Earth or the water, move with the diurnal turning.

[Margin: Reply to Argument 4.] The reply is to deny the Major, if the air moves with equal speed and towards the same region of the world as the bodies already mentioned, as the asserters of the Earth's motion suppose it to move; for then the friction and resistance of the air, on account of which those effects would otherwise follow, cease.

V. Argumentum à Bombardæ globo exploso in Occidentem & in Orientem.

V. Argument from a cannon ball fired towards the west and towards the east.

VI. This argument is very celebrated, and is supported by the experiments of William, Landgrave of Hesse [William IV of Hesse-Kassel], and of Tycho. On these we must hear first of all Tycho himself, in the *Letters*, book 1, page 189: "For, that these things may be understood more clearly," he says, "an iron ball fired obliquely from the largest cannon, which they call a cartaun, scarcely reaches the ground, spent by its motion, within two minutes of time; and in that time it would have to be rolled round twenty thousand greater paces by the diurnal motion in the parallel of Germany, if the Earth were subject to the diurnal motion. For so Rothmann himself told me: that his Prince had once made a trial in firing a ball from a very large cannon (though not for this reason, but only to test the space and time of the ball's advance)." [Margin: The Landgrave's experiment on the time and space of the fall of a cannon ball.] Kepler adds, in book 1 of the *Epitome of Copernican Astronomy*, page 108: "The Landgrave and Brahe measured the time that elapses while a great cannon ball, driven out by the force of the fires, flies across through the air before it strikes the ground: they found it to be two minutes, and the space of its passage a great German mile." And from this Hérigone took it, when he says in tome 5, page 625, that the ball already mentioned had travelled four Italian miles in the air in that time before it struck the ground. But to return to Tycho: in that place he suggests to us his argument against the motion of the Earth, beginning with these words: "And what, I ask, will happen if an iron ball, or a lead one, or even a stone one, is fired from a larger cannon directed towards the east, and from that same cannon, placed in the same spot towards the west, and raised on both sides at equal angles with the horizon with respect to the former inclination? Is it to be thought possible that the ball, fired on both sides with the same quantity and force of powder, would cover just as much space on the ground, on account of the natural knowledge of motion by which any ball formed of earthly things would accompany the whole Earth? Where, then, will that most violent motion remain, aroused against nature by the gunpowder — a motion which is surely in some way a rival to that other natural motion, however very swift, by which the Earth would have to be turned round in a circle?"

[Margin: Tycho's argument from a cannon ball against the motion of the Earth.] After this he adds that there are three motions in that ball: one by which, by reason of its gravity, it would tend to the centre of the Earth along a

straight line, if it were not impeded; a second by which, through its consent with the Earth, it would imitate exactly the circulation of the whole Earth, if it were not impeded by its gravity; and a third, violent, from nitre mixed with sulphur and set alight with charcoal, by which it is driven to where it would not otherwise go naturally. With these laid down, he argues thus. If that third motion, produced by the gunpowder, has so much force that it impedes for a long time the natural descent of the ball intended by gravity — and impedes it so far that the ball is carried down towards the Earth only after a long space has been crossed, and only after two minutes of time — by what privilege will the second motion, by which that ball is said to imitate the circulation of the Earth, not be impeded by that violent third motion? Is it because the second motion is natural? But the first, intended by gravity, is natural too. Is it because the medium is different? By no means, for it is the same thin air, and it resists the violent motion no more. If, then, the violent motion impeded the second motion as well, some difference would appear in the motion and fall of the ball fired towards the East, compared with one fired towards the West; and yet none appears. "For experience testifies," Tycho says there, "that a ball of the same size and weight, fired in the way we have described, in turn, by the force of gunpowder of the same quantity and strength, leaves behind it very nearly the same space of the Earth's surface whether it is shot towards the east, with the same inclination of the same cannon, as I said, or towards the west — especially when the air is fairly calm and nothing per accidens furthers or retards this impulse or that. And yet, on account of the Earth's diurnal motion (if there were one), most rapid as it would be, the ball fired towards the east could by no means measure out so much space of the Earth's surface, since the Earth would somewhat outrun it by its own motion; while for the one fired in like manner towards the west, the Earth would then withdraw some of its surface by its own motion, and so increase the space intercepted." After this he narrates the Landgrave's experiment, which I reported at the beginning, and finally concludes: "By this single argument I think it sufficiently shown that the Earth has no proper motion from west to east, until he" — namely Rothmann, with whom he was disputing about this — "or someone else shows clearly, by invincible reasons, how it can happen that that excessively violent motion of which I spoke is not impeded at all by those two natural motions that he assumes, or even does not disturb them by any trace." Tycho's argument, therefore, reduced to the laws of the syllogism, runs as follows.

[Margin: Form of Argument 5.] VII. If the Earth were subject to the diurnal turning, the same ball from the same cannon, fired in the same way, would pass through less space when sent towards the East than when sent towards the West. But the same ball from the same cannon, fired in the same way, does not pass through less space towards the East than towards the West. Therefore the Earth is not subject to the diurnal turning. The MINOR is certain from the experiments asserted by Tycho. The MAJOR has been proved by the discourse of Tycho quoted above.

[Margin: 1st Reply, Gilbert's, to Argument 5.] William Gilbert replies, in book 6 of *De magnete*, chapter 5, by having recourse to the magnetic effluvia of the Earth, which draw the cannon ball round in the same way both towards the east and towards the west. For after saying that some people doubt how the balls of a larger culverin, shot with a similar quantity and vigour of gunpowder, and also with equal direction and altitude through the same air, could be shot an equal interval from one fixed place towards Eurus and towards the west, if the Earth moves towards Eurus, he adds: "But those who bring forward arguments of this kind are deceived: they do not notice the nature of the primary globes, such as the globe of the Earth is, and the combination with their own globes, even if the parts are not joined to them by solid parts. The Earth, however, does not move with its diurnal revolution by a separation of its more solid circumference from the bodies poured round it; rather, all the effluvia poured round it, and the heavy bodies in them, driven by force in whatever way, proceed uniformly together with the Earth by a general coherence." He adds, moreover, that gravity is an appetite by which the parts desire to cohere with their primary globes, and that they move with them; and that for this reason bodies are neither accelerated nor retarded on account of the diurnal revolution of the Earth. And he finally concludes that a projectile thrown with equal force towards Eurus and towards the west covers an equal distance on either side, even if the diurnal turning proceeds, just as a man's twenty paces make an equal interval both towards the east and towards the west. "In no way, therefore," he says, "is the diurnal motion of the Earth refuted by the illustrious Tycho Brahe with such arguments."

[Margin: 2nd Reply, Kepler's, to Argument 5.] Kepler, himself also an asserter of magnetic attractions, replies in clearer words, in the *Epitome of Copernican Astronomy*, book 1, page 134, beginning with these words: "Let the same judgement, then, mutatis mutandis, be passed on cannon balls as well. A great ball, lasting two minutes of one hour in its flight through the air, crosses towards the west through one German mile on the ground; meanwhile the ground beneath the Equator comes to meet it through eight miles. So, with respect to the space of the world, the ball is still carried away towards the region opposite to the violent motion, namely towards the east, by seven miles; and the firing in the opposite direction does it no other good than to use up the eighth mile and make the ball follow towards the east more slowly. The powder cannot shake the ball entirely out of the hands, as it were, of the Earth; it always stays fast, entangled in the drawing power." He could not have pictured the case of a ball fired towards the west in clearer formulas. He goes on, then, about the same ball fired towards the east: "Conversely, the ball sent towards the east is advanced in the same interval of time, by the rapt motion of the Earth itself, through 8 miles, and itself adds a ninth, since it is fired violently likewise towards the east. Thus, whether it is fired towards the east or towards the west, it is always carried towards the east; only this one a little more than that one. But this compounded space of the world has nothing to do with the

space on the ground that men can measure. That space is nearly the same on either side, because the force is the same, and because the magnetic bonds from which the ball is, as it were, snatched away and carried further are the same on either side." He adds, however, that if some slight difference were to exist, the opportunity of testing it by experiment would be lacking. "For who," he says, "will make me certain of the same force of powder in each firing, and of the other circumstances being the same on either side?"

[Margin: 3rd Reply, Hérigone's.] The reply of Pierre Hérigone in tome 5, page 625, however, is not so clear, and assumes other measures: namely, that the cannon ball already mentioned, fired at the Equator towards the west, moves towards the east in two hour-minutes through 26 Italian miles, and strikes and overturns walls because the motion of the walls, by the force of the diurnal turning, is faster than the cannon ball's motion towards the east; yet in such a way, he says, that if the ball stood altogether immobile, it would strike them more violently.

But replies of this kind are worthless, since they do not even touch the force of Tycho's argument. For Tycho does not hold that both motive powers of the ball are compounded in such a way that the elongation of the ball from the term of its motion turns out in reality such as one would have to understand it to result if each power produced its whole motion separately, or even successively. Rather, he contends that the powers already mentioned must be joined in such a way that one of them is nonetheless broken and tempered: namely, if the motive power towards the east would by itself have carried the cannon ball through 8 miles, then, when the impetus of the kindled powder, motive towards the west through 1 mile, comes upon it, it is weakened, and is not understood in fact to carry the ball, for its part, except through, for example, 7 ½ miles.

[Margin: 4th Reply.] The reply, however, is to deny the Major, because a greater space would rather appear to be traversed towards the East than towards the West, since towards the East the natural motion of the diurnal turning carried out by the ball would conspire with the motion from the kindled powder, which would then be by no means violent. Towards the West, on the other hand, the violent motion from the kindled powder, although it would blunt the motion produced by the diurnal turning, would nonetheless be blunted by it, and indeed more so, as by the stronger.

VI. Argumentum ab eiusdem Bombardæ globo prope polos, & in diuersis Parallelis explosæ.

VI. Argument from a ball of the same cannon fired near the poles and in different parallels.

VIII. A second argument of Tycho's is contained in the same *Letters*, at the end of page 189 and the beginning of page 190, in this discourse: "I add this too: that if, about the poles of the Earth, where the diurnal motion (if there were one) ends in rest, the same testing were made with a musket towards any part of the horizon in the manner described before, the outcome would be in

every way the same as if it were made midway between the two poles, at the Equator, where the motion of the Earth's circumference would have to be most rapid; just as also, in any horizon, if a ball is fired towards the east and the west in like manner, it covers the same space as one fired towards the south and the north with a similar impulse — whereas, if the Earth had any diurnal motion, that motion would regard the west and the east, but not likewise the south and the north. Since, then, these things happen uniformly everywhere, etc." Let this now be the form of the argument.

[Margin: Form of the 6th argument.] If the Earth moved with the diurnal motion, a ball fired in like manner from a cannon or a musket would pass through a notably different space when it was sent near or towards the poles than when it was sent in the parallels nearer the Equator, or towards the south or the north. But this is against the experiments. Therefore the Earth does not move with the diurnal motion. The MINOR seems to be established by the experiments themselves, if faith is placed in Tycho. The MAJOR is proved because, if the ball were fired towards the poles along the plane of the same meridian, less variation would be brought upon it by the diurnal motion than if it were fired now towards the east, now towards the west; and if in the parallels nearer the pole, the ball would be carried more slowly with the Earth, and if in those nearer the Equator, more quickly with the Earth, other things being equal, as is supposed.

The usual reply is to deny the Major, or to distinguish it: conceding it of a difference of real space in the space of the world, and denying it of a difference of apparent space, that is, of space that falls under our measurement. But in fact the argument holds, and this reply is worthless, according to what was said towards the end in connection with the preceding argument.

VII. Argumentum à globo item Bombardæ sumptum, & à Scopo, quem versus Orientem & versùs Occidentem feriret.

VII. Argument taken likewise from a cannon ball, and from the target that it would strike towards the east and towards the west.

[Margin: Argument against the diurnal motion of the Earth, falsely attributed to Tycho by Galileo.] IX. I am surprised that Galileo, in the second Dialogue on the System of the World, mentions Tycho's cannon more than once and yet does not set out Tycho's own argument, but one different from Tycho's, which he expounds as follows on page 131 of the Latin edition. If cannon shots were fired at an eastern target and the Earth moved, they would strike above the target; if at a western one, they would strike below the target. For the eastern parts of the Earth are continually depressed by the diurnal motion below the tangent parallel to the horizon, and conversely the western parts are raised; this is why the western stars are seen to become lower. Consequently, shots aimed along that tangent at an eastern target, which is meanwhile depressed while the ball runs along the tangent, ought to come out higher than they should, and western shots lower than they should, since the target has meanwhile been

raised. But this variation of aim is not confirmed by experiments; therefore it is a sign that the Earth does not move. To this argument, however, I draw from Galileo a twofold reply, which I will bring forward after the argument has been reduced to form.

[Margin: Formula of the 7th argument.] If the Earth moved with the diurnal motion, or even with the annual, a ball from the same cannon, fired either towards the east or towards the west [?], would be cheated of striking the target at which it was aimed. But it is not cheated. Therefore the Earth does not move with the diurnal motion. The MINOR is assumed as certain from observation. The MAJOR seems established by the reasoning of Galileo just quoted. Therefore, etc.

[Margin: 1st Reply, from Galileo.] Galileo's first reply, roughly, is to deny the Major. Even if the eastern target were continually depressed below the tangent by the force of the diurnal motion — if we speak of the first tangent, immobile in the space of the world — the cannon ball nevertheless, before it bends downward by the force of gravity, runs along one moving tangent after another, a tangent that is continually inclined, just as the whole length of the cannon is inclined by the force of the diurnal motion; and it does not cease to look towards the same target. Conversely, the axis of a cannon pointed towards the west is raised by the force of the diurnal motion, and along its length one must conceive one raised tangent after another, no less than for the western target. So in neither case would an aim that was otherwise duly taken be cheated of its effect.

[Margin: 2nd Reply.] Galileo's second reply does not indeed deny the Minor, but calls it into doubt. There he corrects certain Copernicans who, with excessive liberality, indulge their opponents and grant them certain experiments as true and certain, although they have never been performed. Among these he suspects this one can be counted: namely, whether shots towards the east come out higher than they should, and shots towards the west lower than they should. Indeed, he is convinced that this has never been tested by anyone, and that the experiment cannot easily be made: for no gunner will be found so skilled that he would claim to be able to hit the target itself with every shot, or not to miss the target by more than one cubit, if he has to fire from a distance of about 500 cubits or more. Further, if the Earth moved, the error due to that motion could not be greater than one cubit; and so in this experiment, however often repeated, the motion of the Earth could not be convicted of falsehood, since an error just as large can occur while the Earth is at rest. [Margin: The time in which a cannon ball strikes the target.] To prove this by a rougher calculation, he supposes that a shot from a larger culverin is made on the equinoctial line itself, where the greatest variation will arise because of the very swift motion of the equinoctial parts of the Earth, at a target 500 cubits distant towards the west. And he says it is certain that the culverin's ball reaches the target very quickly, in no longer time than a traveller takes to complete two paces, which he affirms to be less than one second of time. For if a traveller covers three Italian miles,

that is, 9000 cubits, in one hour, or 3600^{s}, then in one second he covers two and a half paces; so a single second of time is more than enough for the cannon ball's motion as far as the target. In so small a time, by the force of the diurnal revolution, 15″ of the Equator rise; and consequently the western target and horizon, in that circle whose semidiameter is supposed to be 500 cubits, will be raised by 15″. Now, from the tables of sines, the chord of an arc of one minute is less than 30 parts of which the radius is 100,000; therefore the chord of 15″ is less than 15 parts of which the semidiameter is 200,000. Therefore it will be less than four hundredths of one of those parts of which the semidiameter is 500 cubits. So the raising of the target, and the error of the ball due to the diurnal motion of the Earth, would not exceed four hundredths of one cubit, or about one finger's breadth; and it cannot be established by such an experiment whether the Earth is at rest or moves. Here, moreover, I have neither the leisure, nor is it useful, to correct Galileo's reasoning and calculation; I note only that he confused the chord with the sine of an arc of one minute. For the sine of this arc is 29 parts of which the radius is 100,000, so the chord is not 30 such parts but 58.

VIII. Argumentum à Bombardæ globo nunc in Septentrionem, nunc in Orientem Occidentemue exploso, per P. Franciscum Mariam Grimaldum excogitatum contra Motum Diurnum & Annuum Terræ.

VIII. Argument from a cannon ball fired now towards the north, now towards the east or west, devised by Father Francesco Maria Grimaldi against the diurnal and annual motion of the Earth.

[Margin: Father Grimaldi's theorem against the motion of the Earth.] X. So long as we look at the apparent spaces that bodies usually traverse, the arguments drawn from them against the Earth's motion do not have so manifest a force. But if we consider the increase of real percussion and impetus, somewhat stronger weapons against its motion are supplied to us from that source, as is clear from what was said in chapter 19. From this, then, it seemed possible to take another argument, resting on the impacts of cannon balls. Let it be supposed first — for the sake of explanation, not of necessity — that the ball of a very large cannon, that is, one weighing 60 or 80 pounds, reaches straight to a target 250 paces distant in the time of two beats of the human artery, or about two seconds of time, which those skilled in this art would readily grant. And in the following figure let the mouth of the cannon be A, aimed at the eastern target B, which is distant by the interval AB of 250 paces. Now if the Earth, with its kindred bodies, were not moved with a common motion towards the east, the ball from A would reach the target B in a time of 2^{s}. But because both are carried with equal motion by the diurnal turning, and in two seconds complete 30″ of the Equator — that is, 752 Roman geometric paces, from the first small table of chapter 19, no. [?] 13, set out above — let the chord of this arc be AC, taken as a nearly horizontal line, along which the mouth of the cannon A is understood to be carried over to C, and the target from B to D,

each having completed 752 paces. For the target D will be distant from the mouth C by the interval CD of 250 paces, as before, and the ball I, fired from A, will strike it. Now let the cannon PA be aimed towards the northern target E, so that the cannon is in the position AQ, and let the interval AE be 250 paces,

Diagram. A woodcut in the right column illustrating Grimaldi's cannon argument. A horizontal cannon lies with its breech at P and its mouth at A; a second cannon hangs vertically from A down to Q. To the right of A a ball stands at B, on a dotted line running to a second horizontal cannon whose mouth is at C; from C a further cannon hangs vertically down to R. A dotted vertical rises from A to a ball at E; a solid curve rises from A through K towards G, and a dotted straight line runs from A through H towards G; a dotted vertical rises from C to L, just below G. Above G stands N over a circled ball F, and a dotted line runs from G out to M. To the right of C stands a pair of balls labelled I and D.

- P (left, breech of the horizontal cannon): P
- A (mouth of the left horizontal cannon): A
- Q (foot of the cannon hanging from A): Q
- B (ball to the right of A): B
- C (mouth of the right horizontal cannon): C
- R (foot of the cannon hanging from C): R
- E (ball above A): E
- K (on the curve from A): K
- H (on the dotted line from A): H
- L (top of the dotted vertical from C): L
- G (upper right): G
- N (above F): N
- F (circled ball beside G): F
- M (end of the dotted line from G): M
- I, D (pair of balls right of C): I, D

that is, exactly equal to the interval AB; and let everything else be equal as well — namely, the cannon cooled, the same ball, the quantity and quality of the gunpowder of the same measure and kind, the inclination or elevation of the cannon, the temper of the air, and so on — so that in the same time of 2^s the ball from A could reach E along the straight line AE, if the Earth stood still. But since the Earth is posited to be carried at least by the diurnal motion, and with it every heavy body akin to it, then certainly, when the cannon has been carried over into the position CR, having completed the 752 paces of the interval AC, the target too will have been carried in its parallel to N, and the cannon ball to F, where it will strike the target, having completed, as far as appearance goes, only the interval CF of 250 paces. In reality, however, it will have completed in the space of the world a much greater path, namely AKF, whose chord AHL will be 825 paces. This will be clear from the laws of triangles if, in the triangle ACF, right-angled at C, in which AC of 752 paces and CF of 250 paces are given, the base AHF

is sought; and in the same operation the angle AFC will be found to be 70° 35′, to which the angle NFM is equal.

With these suppositions, it seems that the cannon ball would strike the northern target N with a far weaker blow and a feebler percussion than the eastern target D, so that the breaking of a wall, or the pushing away of another ball set up as the target, would be notably less; and this difference would easily have been observed, or could be observed. For two causes would concur to weaken the impetus of a ball sent towards the north. [Margin: 1st cause of the weaker impetus towards the north.] *First*, the impetus of the ball on its exit from the mouth of the cannon A would be impressed all at once, and would be of such a kind in itself, and so great, that if the Earth were immobile it would strike the target B just as well as E, along the straight line AB or AE, at an equal interval of 250 feet. But both the Earth and the ball are posited to be carried towards the east; and while the ball strives towards E, the diurnal motion prevails, so that it deviates and is twisted away from the straight line AE and drawn along the curve AKF towards F (because at the beginning this motion is swifter, and the ball is carried beyond the straight line AHF which it would describe if the motion were uniform). It is therefore necessary that its impetus be broken and greatly weakened, since it is resisted by the diurnal motion and is forced to go by the longer and oblique path AKF, when otherwise it would go by the straight and shorter path, along AE, to E. This happens in the same proportional way as when someone drops a lead ball down a tube standing perpendicularly on his hand and very swiftly carries the tube sideways: the impetus and descent of the ball would certainly be greatly retarded and weakened, and in its fall it would strike the hand beneath with a much smaller blow than if it had been allowed to fall from the same height through a tube that was not moved.

[Margin: 2nd cause weakening it towards the north.] *Second*, although to the eye at C the cannon ball would seem to strike the target N at the point F along the line FN, in reality it would strike it with a very oblique blow along the track LM. The line of direction along which the impetus, twisted by the force of the diurnal motion away from the straight lines AE and FN, would be spread would be AHL — indeed it would be a portion of the curve AKF, declining from the straight line CF still more than by the angle AFC, which we found above to be 70° 35′. Hence it would come about that the ball would strike the target not with its point G, which is foremost in the motion and is carried, like the head of a battering ram, along the straight line LG, but with its lateral point F, which declines from the real path of the impetus LGM — the path it would run through in the space of the world, and along which it would strike every obstacle standing in that path. So, striking not straight at F but with a fleeting, as it were, and very oblique contact, which would rather deserve the name of rubbing or grazing than of a blow and a wound, it would scarcely strike the target N. And if beside N there were another target at G, placed to the right towards the Greek wind, the ball would strike that one with

a much greater impetus, even if neither the cannon nor the ball were aimed at it, since it would be driven against it according to the real direction of its impetus; and there it would break through a wall with greater ruin. And if the target N and the target G, equal in all other respects, could be pushed away, the target G would be driven much further — say, through the space GM — than the other, say through a space equal to FN. For we commonly see in the game of billiards, or with leather balls struck with rackets, how much weaker the blow and the push are if one ball is struck by the other with a contact that slips away as if along a tangent, or if the ball is caught on a slicing, slanted racket and sent back, than if the diameter of one ball strikes straight against the diameter of the other with its full impetus, or the leather ball is caught and sent back by a perpendicular meeting. For these two causes, then, which would weaken a northward blow compared with an eastward or westward one, and which nevertheless do not in reality weaken it, it seems clear that the Earth does not move with the diurnal motion, and much less with the annual, which would weaken that blow more. Let the argument now be put in form.

[Margin: Form of the 8th argument.] If the Earth moved with the diurnal motion, or even with the annual, the blow of a cannon ball fired towards the north or towards the south would be much weaker than towards the west or towards the east. The consequent is false; therefore so is the antecedent from which it follows. What is said of the cannon ball, moreover, holds for many other projectiles. The MAJOR seems sufficiently proved by the preceding reasoning. The MINOR is assumed as certain from an experiment that very skilled gunners can perform, who aim so surely that they are able to stop up the mouths of enemy cannons with their balls; for they would at some time have observed this difference, or could observe it.

[Margin: Reply of the Copernicans.] The Copernicans will perhaps reply by denying the Major. For, they will say, the motion of the cannon ball, insofar as it comes from the kindled powder, has of itself its direction towards the target, which from the very beginning, by the kind of motion impressed on it, it intends to strike straight; and although it is carried along an oblique path, nevertheless, because the target is carried along with it with equal motion and velocity (even in the very brief, almost momentary, time in which it is struck), it comes about that the percussion is finally made directly. Just so, if an eye looking through a narrow tube at the flame of a candle placed towards the north is carried by a ship towards the east together with the candle, it will see the flame with a direct gaze; a ball on a gaming table, likewise carried by a ship towards the east and pushed against a ball to the north of it, will strike that ball directly; and finally a hammer, driven by the arm of a sailor carried towards the east against the ship's mast standing to the north, will strike through the mast directly towards the north — however much the ball and the hammer are in reality snatched sideways by the ship's motion and run through an oblique path aimed by two principles of motion mixed together. [Margin: Weakness of the reply.] The reply, however, is good as to the straightness of the percussion,

but weak as to its vehemence, which would be diminished and enfeebled all the more, the more the motion snatching the ball or the hammer sideways resists the impetus produced at the beginning. For we are certain from very many experiments that a motion once impressed, and moving towards one part, is weakened and diminished by an impetus that moves not only towards the contrary part but also towards a different part, that is, sideways. It is true indeed that in the example of billiards and of the hammer, because of the brevity of the path, the difference between percussions made once with the ship unmoved and again with it in motion is not so notable; and much less in the case of the hammer, whose impetus is restored by the arm as by a conjoined principle, even though this restoration is not noticed.

IX. Argumentum Nostrum contra motum Terræ Diurnum simul & Annuum, ab ictu & percussione maiore globi versus Orientem, quàm versus Occidentem proiecti.

IX. Our own argument against the diurnal and annual motion of the Earth together, from the greater blow and percussion of a ball thrown towards the east than of one thrown towards the west.

XI. This argument proceeds in a way altogether contrary to Tycho's, adduced in number 7; for it runs as follows. [Margin: Form of the 9th argument.] If the Earth moved with the diurnal or even the annual motion, the same ball, pushed with the same force over the same distance, once at an eastern target and again at a western one, would strike the eastern target with a stronger blow than the western. The consequent is false; therefore so is the antecedent. The MINOR is most certain from experiments: both with billiards, in which we push ivory balls on a gaming table against another ball that is unmoved and equally distant, now towards the east, now towards the west; and with many other similar projectiles. The MAJOR is proved because the impetus of a ball thrown towards the east would not be retarded by the diurnal or annual motion of the Earth, but would rather be helped by it, and would in turn assist it, since both strive towards the same region. Conversely, the impetus of a ball sent towards the west would retard or blunt the impetus moving towards the east, and con- versely would be blunted by it, since they tend in contrary directions (granting that the impetus of the diurnal and annual motion together is much stronger), and so the one resists the other — not absolutely, but in a certain respect. So, if a clay ball of an ounce, shot by a crossbow downward from the top of a tower at a target of clay 30 feet distant, strikes and pierces the clay with a far greater blow, and penetrates it further, than if the same ball were driven by the same crossbow upward against a clay target of the same softness, also 30 feet distant, the reason is plainly that in the former case, besides the impetus impressed by the crossbow, there is also an impetus produced by gravity, which by itself would strike the clay in a headlong fall, and each helps the other; in the latter case, by contrast, the impetus produced by gravity resists the impetus impressed by the crossbow and blunts it more and more. [Margin:

No suitable reply.] To this argument I certainly find no solid reply, nor one that is persuasive while the natures of things are preserved. For the examples that could be brought forward, on the hypothesis of a standing Earth, of projectiles sent now towards the east, now towards the west, over the deck or planks of ships while the ship is always carried towards the east, either have an uncertain or unobservable difference of percussion, because of the brevity of the path, or fall short of perfect likeness and do not include two intrinsic impetuses which in one case help each other and in the other blunt each other by mutual resistance.

X. Argumentum à Contrarietate Motuum.

X. Argument from the contrariety of motions.

[Margin: Form of the 10th argument.] XII. If the Earth moved with the diurnal motion, or even with the annual, the same mobile body would be moved at the same time with two contrary motions. But it is physically repugnant for the same mobile body to be moved at the same time with two contrary motions. Therefore the Earth moves with neither the diurnal nor the annual motion. The MAJOR is proved because it is manifest that many bodies really move towards the west; but if the Earth moved towards the east, then, for many other experiments to be saved, those same bodies would have to be moved meanwhile towards the east by a certain motion common to all terrestrial and watery bodies — and this is exactly what Copernicus and his followers assert. Therefore they would be moved at the same time towards different regions and termini: by their proper motion they would approach that very western terminus from which they would meanwhile be receding by the common motion; or, while approaching the eastern terminus by the force of the common motion, they would recede from it by the force of their proper motion. The MINOR is proved because it is impossible for the same thing at the same time to approach and recede with respect to the same terminus, since recession has annexed to it the privation of approach to the terminus from which the recession is made, and a privation and a form cannot be physically exercised together.

[Margin: 1st Reply to Argument 10.] The first reply, however, is to deny the Major in the sense in which the Minor is true, that is, of two motions truly and really contrary [?] in relation to termini fixed and immobile in the space of the world. For even if, comparing the terminus a quo on the surface of the earth or the water with the terminus ad quem which bodies tending westward would apparently approach, they would seem to recede from the eastern terminus a quo, yet in reality they would always approach the eastern terminus fixed in the space of the world. For the common motion of the Earth's diurnal revolution, and much more of its annual revolution, is swifter than the proper motion of any body tending towards the west — granted that, because of this proper motion, the approach towards the east would be diminished, an approach which would otherwise be greater if there were no motion at all towards the west. The reply will become clearer [?] by an example. Let a traveller on the Equator go forward for one hour towards the west, departing

from some column and covering three thousand Roman paces on the surface of the earth. In the meantime the diurnal turning of the Earth will snatch him towards the east, just as it does the column; but it will snatch the column in such a way that in the space of the world it rolls it towards the east through 15°, that is, through 1,355,000 paces, whereas it will snatch the traveller in such a way that it rolls him through only 1,352,000 paces, or 1352 Italian miles — the 3 miles that the traveller has meanwhile covered being subtracted. He covered them not by receding towards the west from the fixed place of the world in which the column stood, but by receding towards the east from that fixed place less than he would have receded had he let himself be snatched by the common motion alone, without any proper motion of his own. See the figure and its exposition in Section 2 of this Book, chapter 3, scholium 1.

[Margin: 2nd Reply [?].] Galileo replies, second, in the second Dialogue on the System of the World, page 200 of the Latin edition, by turning the argument back. For if these two motions are denied to the Earth, two contrary motions must be attributed to the celestial bodies; in whatever way, then, they can be reconciled in the heaven, in the same way they can be reconciled on the Earth. He adds, moreover, that if any fatigue were to be feared, it should rather be feared for the starry sphere than for the Earth, since the sphere would have to carry much greater bodies than the Earth does.

XI. Argumentum à Multiplicatione motuum eiusdem speciei minimè necessaria.

XI. Argument from the wholly unnecessary multiplication of motions of the same kind.

[Margin: Form of the 11th argument.] XIII. Motions are not to be multiplied without necessity. But if the Earth moved with the diurnal, or even the annual, motion, innumerable motions would be multiplied without necessity. Therefore the Earth moves with neither the diurnal nor the annual motion. The MAJOR is established by an axiom received by all, and so insisted upon by the Copernicans that on this very ground they try to take the diurnal motion away from the fixed stars and the planets and transfer it to the Earth alone, and to accomplish the motions of the epicycles of the five lesser planets by the single motion of the Great Orb. The MINOR is proved because, to save the phenomena of sublunary motions, each and every terrestrial and aquatic body — among which there are innumerable mixed bodies, some animate, some inanimate — would have to have, besides its own proper motions, a common motion by which it would revolve with the Earth daily and yearly towards the east. But all these motions can be avoided, with every phenomenon whatever saved, if the Earth is at rest, as the Copernicans openly concede; and so they are multiplied without necessity.

[Margin: Reply.] The Copernicans, however, could reply either by turning the argument back, or by distinguishing the Major: conceding it if, by not multiplying motions in sublunary bodies, a multiplication of motions of the

same kind in the celestial bodies could be avoided, and otherwise denying it. But in the sense in which they will concede the Major, they will deny the Minor. For if the diurnal motion is not conceded to the Earth and its kindred bodies, it will have to be conceded to the innumerable fixed stars and to all the planets. Likewise, if the annual motion through the Great Orb is not attributed to the centre of the Earth and to the whole elementary system together with the lunar heaven, it will have to be attributed to five distinct epicycles of the lesser planets, or to other circles or ellipses equivalent to them. Since, therefore, these two motions must be multiplied in one set of bodies or the other, and no necessity appears for multiplying them in the celestial rather than in the subcelestial bodies, the reason for attributing them to the one rather than to the other must be sought from elsewhere. Let this, then, be the twelfth argument.

XII. Argumentum à Multiplicatione motuum in ijs corporibus, in quibus maius est fundamentum eos multiplicandi, & minor multiplicatio fit.

XII. Argument from the multiplication of motions in those bodies in which there is a greater ground for multiplying them and the multiplication is smaller.

[Margin: Form of the 12th argument.] XIV. If the diurnal and annual motion is to be attributed to one set of bodies or the other, it is rather to be attributed to those in which a greater ground appears and the multiplication is smaller, than to those in which a lesser ground appears and the multiplication is greater. But a greater ground appears for attributing the diurnal and annual motion to the celestial bodies, and in them the multiplication would be smaller than in the Earth and the remaining bodies. Therefore it is rather to be attributed to the celestial bodies. The MAJOR is evident. The MINOR is easily proved, because we have a sufficient ground for the diurnal and annual motion from phenomena and observations manifest to the senses; nor is there any repugnance to the contrary, nor any argument for asserting that the senses are deceived in these matters. Next, if the diurnal motion is attributed to the celestial bodies, it is attributed only to the eighth sphere, by whose single motion the fixed stars can be moved, and to the seven planets with the 4 companions of Jupiter and the 2 of Saturn — that is, to 14 bodies in all. And if the annual motion is attributed to the Sun, and the motion proportional to it to the 5 planets in their epicycles, it is attributed to only six bodies; or, if here too you add the companions of Saturn and Jupiter, it is not attributed except to 13 bodies. But if the diurnal and annual motion is attributed to sublunary bodies, a motion is attributed to them that rests on no observation perceptible to the senses, that is, on no a posteriori ground obtained through the senses. The diurnal motion would have to be attributed to the Earth and to absolutely all the sublunary bodies situated below the upper region of the air, which are far more than 14 both in number and in kind; and the annual motion not only to all sublunary bodies but also to the Moon itself and to the lunar heaven. [Margin: No reply to Argument 12.] To this argument I see not even the shadow of a solid reply — unless the Copernicans, abandoning and scorning the ground taken from the senses, have

recourse to congruences a priori. But since the greatest of these congruences consists in avoiding a multiplicity of motions, they cut their own throats with their own sword: they fall into a far more numerous multitude of motions, and meanwhile undermine the foundations of physics, that is, sensations.

XIII. Argumentum à Destructione motuum, qui apparent, & Substitutione motuum, qui non apparent.

XIII. Argument from the destruction of the motions that appear, and the substitution of motions that do not appear.

[Margin: Form of the 13th argument.] XV. If the diurnal motion, or the annual as well, is attributed to the Earth, the motions that appear are destroyed without necessary reason, so that none of them really exist; and in their place motions are substituted that never appear. But that is absurd. Therefore, etc. The MINOR is self-evident. The MAJOR is proved because both the diurnal and the annual motion of the Earth, and of the other bodies that imitate it in these motions, is greater than the proper motion of any of them. From this it follows that the proper motion which appears in these bodies towards the west is not really a motion, since by it the body does not approach the same fixed point towards the west; it is only a diminution of the greater motion towards the east, as was said in the reply to argument 10. The diurnal and annual motion of the Earth and its kindred bodies, on the other hand, which is substituted as the real one, in no way appears.

XIV. Argumentum à Multiplici Inæqualitate ac difformitate motus in eodem mobili absq. necessitate.

XIV. Argument from the manifold inequality and nonuniformity of motion in the same mobile body without necessity.

[Margin: Form of the 14th argument.] XVI. If at least the diurnal motion is conceded to the Earth, a motion unequal and nonuniform with innumerable variety must be attributed to the same mobile body, without any necessity. But this is unfitting. Therefore, etc. The MINOR is certain in itself. The MAJOR is evident, because the same terrestrial body, even when separated from the earth — say a cannon ball shot towards the east, or a cloud, or a bird — must move faster at the Equator than in the next parallel, faster in that one than in the following one, and so on for all the others without limit, as many as can be described up to the poles. Hence, if a bird flies from the Equator towards the poles, straight or obliquely, then even though its flight is uniform to appearance, or even faster and faster, it must in reality move continually slower and slower, so as to adapt itself to the slower and slower motion of the parallels. This would certainly happen more often, and in more bodies, than if the diurnal motion were attributed to the fixed stars. The Copernicans do not deny that this happens without necessity; [Margin: No reply.] and they cannot reply to this argument except by saying that this variety follows from their hypothesis, whose foundations they have not in sensations but in ideal reasons

and in certain congruences. But among the greatest of these congruences is the one they so often inculcate, that simplicity and uniformity of motions be established — and this they violate far more numerously, by attributing it to so many sublunary bodies. And so the reply comes to nothing and destroys itself. If you wish to know the inequality of the motion of terrestrial bodies to a definite measure — as they stand either at the Equator or in other parallels, and as they move about noon or about midnight — run through the small tables to be given in the following chapter at the end of number 1, especially 5, 6 and 7.

†

CAPVT XXII.

Chapter 22.

Proponuntur Argumenta Quinque sed inualida ab Impetu & Velocitate nimia Telluris & Cognatorum Corporum, si mouerentur motu siue Diurno solùm, siue etiam Annuo, & vtriusque motus Mensuræ hac occasione traduntur alia ratione quàm factum sit capite 19. numero 13. vt hac fortasse aliquibus magis satisfiat.

Five arguments are proposed, but invalid ones, from the impetus and excessive velocity of the Earth and its kindred bodies, if they moved either with the diurnal motion alone or with the annual as well. On this occasion the measures of both motions are given by another method than was done in chapter 19, number 13, so that this one may perhaps satisfy some readers more.

I. Before we discuss the effects that the velocity of the moving Earth would produce, that velocity itself must be set out in determinate parts of space known to us, which the Earth would traverse in one hour, or in one minute of an hour, or in one second. For this we need four elements, or foundations, for constructing the following Table. [Margin: 1st foundation of the following tables.] The first is how many miles are contained in the diameter and in the greatest circumference of the Earth, such as the Equator is; on this question we reported a great many opinions in Book 2, chapter 7, at the end of scholium 9. Now the authors who dispute about the motion of the Earth, most of them, together with the Germans and some seamen, assign 60 Italian miles, or 15 German, to one degree of the terrestrial Equator, and 1720 German miles to the diameter of the Earth — so Tycho, Longomontanus, William Gilbert, Mästlin, Metius [Adriaan Metius], Hérigone, Scheiner and, for the most part, Kepler. We, on the other hand, found by exact measurement 72 ¼ Italian miles of this Bologna measure in one degree of the Equator, and 8278 for the diameter of the Earth; close to this come Gassendi, who assigns 73, very many seamen, who assign 70, most of the Arabs, and also Fernel and Snel, who assign about 68 Italian miles to it, as we said in the same place. Since that is so, we shall construct the table according to only these two opinions, namely that of 60 Italian or 15 German miles, and that of 72 ¼ Italian. [Margin: 2nd foundation of the table.] The second thing we need is how many minutes on the Equator

correspond to one degree of the parallel equally distant on either side from the Equator and from the poles of the Equator, that is, declining 45 degrees; and likewise how many correspond to one degree of an almost smallest parallel, that is, distant by a single degree from the pole and declining 89 degrees from the Equator — so that a judgement can be made of the rest from the middle and the extremes. Now, by the problem given by Giuseppe Moletti and Giovanni Antonio Magini on chapter 23 of Book 1 of Ptolemy's *Geography*, and by the table constructed by the same Moletti, to one degree of the parallel declining 45° there correspond on the Equator 42′ 24″ 35″ [?]; but to one degree of the parallel declining 89° there corresponds on the Equator 1′ 2″ 51‴. [Margin: 3rd foundation of the table.] The third thing we need is the semidiameter of the Great Orb, which doubled gives the diameter. Hence, if one makes, as 100 is to 314, so the given diameter to another number, the circumference of the Great Orb is obtained, according to the rules given in Book 1, chapter 4; the circumference divided by 360 gives the size of one degree, a degree divided by 60 gives that of one minute, and a minute subdivided by 60 gives the size of one second. Among the opinions on the semidiameter of the Great Orb — that is, on the mean distance between the Sun and the Earth — there are several, reported by us in Book 3, chapter 7, at the end; but it will be enough to follow two that are, as it were, the extremes, and one in the middle. The first is that of Copernicus, who puts that distance at 1142 terrestrial semidiameters, and many use this figure in the present controversy; the second is ours, by which we assign 7300 semidiameters of the Earth to this distance; the third, as it were midway between these, was Kepler's, who finally assigned 3381 terrestrial semidiameters to it. Now if, with the Germans and many others, we assign 1720 German miles, or 6880 Italian, to the diameter of the Earth, then in the diameter of the Great Orb, which for Copernicus is 2284 semidia- meters, it will be 3928 480 German miles, or 15 713 920 Italian. For Kepler, for whom that diameter is 6762 terrestrial semidiameters, it will be 11 630 640 German miles, or 46 522 560 Italian. For us, for whom that diameter is 14,600 terrestrial semidiameters, it will be, according to our opinion on the diameter of the Earth, 120 858 800 Italian miles of Bologna. From these the rest will be derived, as can be seen in the table. [Margin: 4th foundation.] The fourth and last thing we need is how many degrees or minutes some one point of the Equator traverses on its own in one hour, one minute, or one second of an hour by force of the diurnal revolution, and likewise how many minutes of the circumference of the Great Orb the centre of the Earth traverses in one hour, or one minute, or one second of an hour, so that we can apply to them the corresponding number of miles. For if a point of the Equator, or the point corresponding to it in another parallel, is in such a position that the Sun apparently rises or sets for it, the diurnal motion will add nothing to the annual motion and take nothing from it; but if it is at the point of midnight, the diurnal motion must be added to the annual; and if at the point of noon, subtracted — so that in this way the

velocity of the parts of the earth becomes known from the composite motion. On these foundations, then, the following Tables rest.

I. TABVLA.

Table I.

Table I	Copernicus, Tycho, Mästlin, Kepler, Longomontanus, Gilbert, Scheiner, Hérigone, etc.: German miles	Italian miles	Paces	Ours: Italian miles	Paces
Diameter of the Earth	1720	6880	✠	8278	
Circumference of the Earth	5400	21600	✠	26010	
Equator: degree 1	15	60		72 ¼	
Equator: minute 1	0 ¼	1		1 204/1000	
Equator: second 1	0	0	16 ⅔	0	20 1/15

Parallel declining 45°: minute 1	0	0	706 11/12	0	852 ¾
Parallel declining 45°: second 1	0	0	11 47/60	0	14 ¼
Parallel declining 89°: degree 1	0	1 1/20		1 ¼	
Parallel declining 89°: minute 1	0	0	17 ½	0	20 5/6
Parallel declining 89°: second 1	0	0	0 ⅕	0	about ⅖

II. TABVLA.

Table II. A terrestrial point traverses:

Table II	Copernicus, Tycho, Mästlin, Kepler, etc.: German miles	Italian miles	Paces	Ours: Italian miles	Paces
In 1 hour, 15 degrees; therefore, at the Equator	225	900		1087 ½	
In the parallel declining 45°	157 ½	636 ¼		767 ½	
In the parallel declining 89°	about 4	15 ¾		18 ¾	
In 1 minute of an hour, 15 minutes; therefore, at the Equator	3 ¾	15		18 6/100	
In the parallel declining 45°	2 65/100	10 604/1000		12 791/1000	

Table II	Copernicus, Tycho, Mästlin, Kepler, etc.: German miles	Italian miles	Paces	Ours: Italian miles	Paces
In the parallel declining 89°	0	0	262 ½	0	312 ½
In 1 second of an hour, 15 seconds; therefore, at the Equator	0	0	250	0	301
In the parallel declining 45°	0	0	175 ¾	0	213 ¾
In the parallel declining 89°	0	0	3	0	5

III. TABVLA.
Table III.

Table III — Great Orb	Copernicus: German miles	Copernicus: Italian miles	Kepler: German miles	Kepler: Italian miles	Ours: Italian miles
Diameter	3928 480	15 713 920	11 630 640	46 522 560	120 858 800
Circumference	12 235 427 ⅕	48 941 708 ⅘	36 520 209 ⅗	146 080 838 ⅖	379 496 632
1 degree	33987 11/36	135 949 2/9	101445 1/36	405 780 1/9	1054 157 14/45
1 minute	566 27/60	2265 13/15	1690 ¾	6763	17569 3/10
1 second	9 13/30	37 11/15	28 1/6	112 ⅔	292 ⅚

IV. TABVLA.
Table IV. The centre of the Earth traverses in the Great Orb:

Table IV	Arc traversed	Copernicus: German miles	Copernicus: Italian miles	Kepler: German miles	Kepler: Italian miles	Ours: Italian miles
In 1 hour	2′ 28″	1397 ¼	5589	3607 1/6	14428 ⅔	43338
In 1 minute	2″ 28‴[47]	23 3/10	93 2/15	60 7/60	240 7/15	722 3/10
In 1 second	2‴ 28 [?]	0 23/60	1 33/60	1	4	12 1/30 [?]

Compounding, therefore, the diurnal motion of some point on the surface of the Earth with the annual motion of the centre, the space and the velocity come out as below.

V. TABVLA.
Table V. If the Sun rises or sets for a point of the Earth, that point of the Earth traverses the miles written below:

Table V	Copernicus: German miles	Copernicus: Italian miles	Kepler: German miles	Kepler: Italian miles	Ours: Italian miles
1 hour	1397 ¼	5589	3607 1/6	14428 ⅔	43338

[47]so printed (the figure is confirmed); the series wants 28‴

Table V	Copernicus: German miles	Copernicus: Italian miles	Kepler: German miles	Kepler: Italian miles	Ours: Italian miles
1 minute	23 3/10	93 2/15	60 7/60	240 7/15	722 3/10
1 second	0 23/60	1 33/60	1	4	12 1/30

But if it is midnight at some point of the Earth, that point traverses a space compounded of the diurnal and the annual space, that is:

VI. TABVLA.

Table VI.

Table VI	Copernicus: German miles	Copernicus: Italian miles	Kepler: German miles	Kepler: Italian miles	Ours: Italian miles
1 hour, at the Equator	1622	6488	3832	15328	44425 ⅕
In the parallel declining 45°	1555	6220	3765	15060	44105 ½
In the parallel declining 89°	1401	5604	3611	14444	43356 ¾
1 minute, at the Equator	27	108	75 ⅛	300 ½	740
In the parallel declining 45°	26	104	70 ⅗	182 ⅖	735
In the parallel declining 89°	23 ⅗	93 ⅗	49 ⅖	197 ⅗	723
1 second, at the Equator	0 23/93	1 33/60	1 1/16	4 ¼	12 301/1000
In the parallel declining 45°	0 25/93	1 32/60	1 1/20	4 ⅕	12 214/1000
In the parallel declining 89°	0 22/93	1 31/60	1 3/4000	4 3/1000	12 5/1000

Conversely, if it is noon at some point of the Earth, the diurnal space must be subtracted from the annual, and so that point traverses the miles written below.

In the parallel declining 89°	0 24/93	1 33/60	0 3997/4000	3 997/1000	11 995/1000

I. Argumentum ab Inertia Telluris ad omnem motum, præsertim, circularem, & tam celerem.

I. Argument from the inertness of the Earth to all motion, especially circular motion, and motion so swift.

[Margin: Form of the 1st argument.] II. The Earth is the heaviest and densest of all bodies; therefore it is naturally incapable of any motion, especially circular. The antecedent is denied by no one of sound judgement. The consequence is proved because heaviness was given to bodies so that, in proportion to their heaviness, they should tend towards the centre of the universe along a straight line, and rest there once they have reached their place. Therefore, if the earth is the heaviest of all bodies, it must occupy the centre of the universe with its own centre, and rest there; and if it were removed from it, it would return to it naturally by no other motion than a rectilinear one. This is the sum of the argument and of its proof, which the Peripatetics hold implicitly, in other words, together with Aristotle, *De caelo* 2, chapter 13, and Tycho in his *Epistolae Astronomicae*, page 147. But the Copernicans, and Galileo first of all, will easily deny the consequence of this argument, as is clear from their foundations set out above in chapter 20, numbers 2 and 3. For they will say that heaviness is not a force of tending towards the centre of the universe, but an inclination which parts have to be united with their wholes and their primary globes; that rectilinear motion does not belong to those parts except apparently, whereas in reality circular motion alone belongs to them, and per se; that if they are outside their place, a curved motion belongs to them, mixed of the circular and of another striving towards the straight, but not straight; and that to the primary globes of the world themselves, of which kind the Earth is, circular motion about the centre of the world belongs per se. Hence, if the Earth were placed at the centre of the world, it would withdraw from there along some curve to the periphery of the Great Orb, and thereafter continue its circuit along that periphery. Kepler, moreover, in Book 1 of the *Epitome of Copernican Astronomy*, page 108, denies that the whole Earth can be called heavy insofar as

it is whole, since there is nothing outside it that attracts it — granted that he attributes to the Sun a force of attracting the Earth and the other planets, or of driving them round; and he adds that the motion which must be attributed to the fixed stars, if it is denied to the Earth, is much faster.

II. Argumentum à nimia Velocitate Terræ, quàm nullum mobile versùs Orientem assequi posset.

II. Argument from the excessive velocity of the Earth, which no mobile body moving towards the east could overtake.

[Margin: Buchanan's argument against the motion of the Earth.] III. George Buchanan painted this popular argument in poetic colours, in Book 1 of his *Sphaera* set in verse, in these lines:

Picture in your mind the Pole standing still, its body unmoved, its fires sluggish; and the Earth rolling itself round in a circle, and through thrice eight hours of shadow and of light closing its perpetual round along its own tracks. This force of its course swift arrows could not equal, nor the wings of birds, nor the blasts of the wind, nor the stones that the violence of sulphurous flame drives out whenever the heat shut up in the hollow bronze rages.

[Margin: Form of the 2nd argument.] The argument can therefore be framed thus. If the Earth revolved towards the east with the diurnal motion, or the annual as well, no elementary body moving towards the east could reach the places of the earth it was heading for — at least near the Equator. But this is contrary to manifest experiments. Therefore the Earth moves with neither the diurnal nor the annual motion. [Margin: Proof of the Minor.] The MINOR is evident: for birds flying to their nest, ships sailing to an eastern harbour, and arrows and the balls of muskets and of cannon aimed at an eastern target, all get there.

[Margin: Proof of the Major.] The MAJOR is proved by comparing the velocity of the Earth set out in the tables given above, in number 1, with the natural velocity of any bodies whatever, especially near the Equator. For by the diurnal motion alone the Earth — that is, a point of the earth at the Equator — traverses 301 paces in one second of an hour, that is, in about one beat of the human pulse; whereas not only no ship or bird, but not even the ball of a larger culverin, covers more than about 125 paces in one second. And if a portion of the annual motion is joined to the diurnal, there is no need to restrict the argument to a body at the Equator: for even when the motion is least, that is, about noon, a point of the earth traverses very nearly 12 Italian miles in one second, whether it is at the Equator or near the Pole, as is clear from the last cells of the 7th Table, set opposite one second of an hour.

The reply, however, is to deny the Major, because birds, ships, arrows, cannon balls and all bodies of this kind are moved not by their proper motion alone, as appears to us, but also by the common motion with which the earth moves, even though this does not appear to us; and this motion is as great as the Earth's. Therefore, carried along by an equal motion, they can reach an

eastern place and target by their own proper motion, which they add over and above the common one. [Margin: Reply to Argument 2.] So, at any rate, the Copernicans.

III. Argumentum ab ingenti Sonitu, Verbere Aeris, & Vento perpetuo.

III. Argument from the enormous sound, the beating of the air, and a perpetual wind.

[Margin: Buchanan's argument against the motion of the Earth.] IV. George Buchanan likewise did not pass over this argument, when he sang in Book 1 of the *Sphaera*:

Do you not see, when boys shake their little rattles in the right hand, or when an arrow, loosed from the whistling string, flies; or when the wind, let out from the throat of the bellows, fans the panting fire in the furnaces? Do you not see with what a murmur the air hisses and groans to be split? If, then, at a slight impulse the air, struck, roars with a sound and bellows back, what sound shall we imagine there would be, what murmurs, while the Earth, driven headlong, twists itself round in a circle, and so many forests at once, and the steep summits of mountains, cleave the indignant air, and tear it, and [?] it?

Simplicius raises exactly this objection against Salviati, that is, against Galileo, in Galileo's Dialogue 2 on the system of the world, Latin page 186, in the person of a certain author: "The author goes on to show that in the doctrine of Copernicus one has to deny the senses and the most powerful sensations. That would be the case if we, who feel the breath of even the lightest breeze, could not feel the onslaught of a perpetual Wind striking us with such velocity that it flies across more than 2529 miles an hour — for that is the space the centre of the earth traverses by its annual motion in one hour along the circumference of the Great Orb, as he himself carefully computes. But, says the same author, in Copernicus's opinion the surrounding air is moved with the earth, and yet the motion of the air, swifter than any wind, is not felt; instead, unless something else intervenes, there is the greatest calm. What, then, is a true deception of the sense, if this is not a deception?" Finally, Kepler raises similar objections against himself in Book 1 of the *Epitome of Copernican Astronomy*, page 137, with this little question: "If the Earth were revolved with this very swift motion, would a perpetual wind be felt from the direction opposite to the motion?" The replies to these will be brought forward shortly, once the argument has been put into form, in this way:

[Margin: Form of the 3rd argument.] If the Earth revolved with the diurnal motion, or with the annual as well, a perpetual wind blowing towards the west would be felt by us, and the air, dashed against mountains, towers and the leaves of trees, would give out an enormous sound and whistling. But neither is felt by us or by any mortal. Therefore the Earth revolves neither with the diurnal motion nor with the annual. The MINOR seems certain from daily experience, when the air is calm and no winds blow from elsewhere. [Margin: Proof of the Major.] The MAJOR is proved thus. Either the air around us is not moved with the earth at equal velocity — and then, as we and the mountains

and forests are carried eastward and go to meet the unmoving air, the result would be exactly as if the air ran against us, the mountains and the forests, all at rest, with equal velocity. Or the air too is moved with the earth at equal velocity — and then in one hour, by force of the annual motion, it flies through 5589 Italian miles for Copernicus, 14,428 ⅔ for Kepler, and 43,338 for us, as is clear from number 1, table 4. How, then, can so rapid a motion of the air — by day towards the east, by night towards the west, by force of the annual motion — not be felt by us?

[Margin: 1st reply to Argument 3.] The Copernicans' first reply is to deny the second part of the Minor, namely that no mortal feels a perpetual wind or breeze blowing towards the west. For Galileo, Dialogue 4, page 327, and with him Gassendi in his second letter *De motu impresso*, holds that within the Tropics a perpetual breeze and wind are felt, and that for this reason sailing westward is quicker than sailing eastward — as we said elsewhere, in chapter 4 at the end of number 6 and in its scholium 5, and in chapter 7, number 4. But, they hold, it is not felt to be as vehement as the velocity of the terrestrial motion would otherwise require, because the air moves together with the earth towards the east, but somewhat more slowly, since by its fluidity [fluxibilitas] it does not entirely comply with the earth's motion. This reply, however, supposes that the rapture of the air towards the east comes from contact with the earth; otherwise, if it came from an intrinsic principle, its fluidity would be no obstacle to its moving with the earth at equal velocity. On page 138 of the *Epitome of Copernican Astronomy*, Kepler first puts forward a similar reply drawn from other effects, answering that question about the perception of a perpetual wind thus: "This could be conceded of the highest summits of the mountains; and in this cooling a cause could be sought for the perennial snows even under the torrid Zone, and likewise for the coldness of the east winds, the pleasantness of the morning, and the like — provided that both the lower mountain country and the valleys hidden among their summits, which animals inhabit, were safe, and the air in them were undisturbed and quiet through this exterior friction, and there were freedom in it for the bubbling vapours to rush in every direction. But it is not necessary for us to concede what is objected." He therefore brings forward another reply, which we shall add at once.

[Margin: 2nd reply to Argument 3.] The second reply, with the Copernicans, is to deny the Major. For the whole of the air that is in the lowest and middle region of the air, being full of terrestrial and watery vapours and exhalations, is moved eastward at equal velocity with the earth by the intrinsic force of the motion common to them and to the terraqueous globe; and we likewise, and the mountains, and the forests with their leaves, are moved the same way. Therefore, "just as we do not feel the blow of a spear pursuing us if we avoid it by fleeing at equal velocity," says Galileo, page 187, Dialogue 2, "so neither do we feel the blow of the air, since we are carried in the same direction with it at equal velocity." Kepler, moreover, in Book 1 of the *Epitome of Copernican Astronomy*, page 38, says that the ethereal aura, which is not moved with our air,

is so many times thinner than our air, which animals breathe, that the friction against the ethereal aura over a thousand miles in one hour is more tranquil, and so less perceptible, than the friction of a man's face against the air as he walks half a mile through it in one hour. So, on page 108, he had said: "The ethereal aura, through which the highest ridges of the mountains are carried, is thinner not merely eightfold but almost infinitely many times than the air through which a leaden ball is carried. Therefore the passage of the ridges through the aether is very many times more tranquil than that of an iron ball through the air." Kepler therefore holds that the air enclosed within the ordinary mountains is moved with the earth, being watery, and that the ethereal aura begins at the highest ridges of the mountains; and that, although it is not moved with the motion of the earth, it cannot, because of its thinness, produce blasts or winds that are very perceptible, much less a great sound and crash.

IV. Argumentum à Concussione ac ruina ædificiorum, & Proiectione corporum infirmiter Terræ adhærentium.

IV. Argument from the shaking and collapse of buildings, and from the flinging off of bodies weakly attached to the Earth.

[Margin: Buchanan's argument against the motion of the Earth.] V. This argument, such as it is, belongs to a great many writers, against both motions of the earth but especially the diurnal; among them Buchanan, in Book 1 of the *Sphaera*, sings thus:

So if the Earth, driven with so swift a motion, went into the West, and came back again into the East, it would shake all things together with it, and with a vast crash the unforeseen slaughter of a sudden collapse would overwhelm temples, houses, and cities, even with their wretched citizens.

[Margin: And of Clavius.] Clavius, too, says it explicitly, in Book 1 on the *Sphere*, page 196 in my copy: "If the Earth," he says, "were turned about the axis of the world with such speed that it completed its circuit in the space of 24 hours, as some people fable, all buildings would collapse and could by no means stand for long; and there is no one who does not see that this is entirely false. Nor is the reply of some people valid, who say that buildings do not collapse because of the excessive speed of the motion, just as water contained in a vessel does not flow out if the vessel is swung round very swiftly. It is not valid, I say, because the whole impetus of the water is impressed towards the lower parts of the vessel, not towards its mouth; but the impetus is impressed on buildings towards the outermost parts of the earth, etc." The true cause, however, why the water does not fall in that case is that the impetus impressed on the water and the vessel together, which moves them in a circle, is greater than the one that the heaviness of the water, moving it downward, produces; and this impetus, continued very swiftly in a circle, carries the upper parts of the water to another place, in which they are no longer above the air.

Galileo and Kepler raise this same argument against themselves and solve it: Galileo in Dialogue 2 on the system of the world, from Latin page 139 to 148,

but in the Italian from page 184 to 213; Kepler in the *Epitome of Astro-* nomy*, pages 156[48] and 137; *Philolaus*, part 1, chapter 6; and Redemptus Baranzanus [Redento Baranzano], part 1 of the *Uranoscopia*, page 111. But before all of these, Copernicus, Book 1, chapter 7, where he too attributes this argument to Ptolemy. [Margin: Copernicus's [?] against himself.] Copernicus's words are: "For the motion would have to be most violent, and its speed unsurpassable, that carried the whole circuit of the earth round in 24 hours. But things set going by a sudden whirling seem altogether unfit for coming together, and rather, if united, to be scattered, unless they are held together by some firmness of cohesion. And long ago," he says — that is, Ptolemy, whom he had named a little before — "the earth, scattered, would have fallen out of the very heaven, which is quite ridiculous; and all the more would animals, and any other loose weights, by no means remain unshaken." He replies to this objection in chapter 8. [Margin: Ptolemy's argument against the motion of the Earth.] Ptolemy's words, in Book 1 of the *Almagest*, chapter 7, had been: "If one single motion, common to the other heavy bodies, also belonged to the Earth itself, it is clear that because of so great an excess in its turning, proportionate to its magnitude, it would outrun them; and, leaving behind in the air the animals and the other weights, it would itself very swiftly fall out even beyond the heaven itself." Chiaramonti subscribes to this in the *Antiphilolaus*, parts 1 and 6. Let the argument now be gathered into form, as below.

[Margin: Form of the 4th argument.] VI. If the Earth went round with the diurnal motion, or with the annual as well, all buildings would be shaken and would fall, and the other things that stand on the earth's surface but cohere with it not very firmly would be shaken off by its whirling and flung away. But neither happens. Therefore the Earth goes round neither with the diurnal nor with the annual motion. The MINOR is evident: for we do not experience perpetual landslides or earthquakes, but only rarely, and those from some cause other than the whirling of the whole earth. The MAJOR is proved from the very rapid whirling of wheels. For things placed on their circumference that do not cohere very firmly with it are thrust off and flung far away. So mill wheels standing half out of the water wet the places nearby with a spray of flung drops; so the wheels of carts driven fast push off the mud sticking to them; and boys, setting a stone in the notch of a reed as in a pair of tongs and swinging the reed round, throw the stone a long distance. Much more, then, would the Earth eventually shake buildings and bring them down, and not only shake fruit and leaves from the trees but thrust off the animals creeping over it, and ships, and the stones lying in the beds of torrents left without water, and sands and the like — by as much as its whirling is faster than the whirling of any wheel.

[Margin: Reply to Argument 4.] The Copernicans already named, however, reply by denying the Major, and against its proof, drawn from a similar case, they deny the parity. For bodies placed on wheels are not moved of themselves,

[48]so printed; the same work is cited below at page 136

or with a velocity equal to the wheel's; and the impetus impressed on them by the wheel follows the straight line tangent to the wheel at the point where those bodies are and from which the impetus leaves, even if, by reason of their own heaviness, they then decline downward from the straightness of that tangent. The same is to be said of the stone thrust out of the notch of the reed. But all heavy bodies, whether fixed firmly in the earth, like buildings, or weakly, like sands, ships, the stones of torrents, and the leaves and fruit of trees, are moved with the common motion and at equal speed with the earth, in an entirely uniform manner; and they neither strike against anything nor are shaken by a reciprocating agitation to and fro. In the same way, not even cups full of wine are overturned if a boat is carried down a river very rapidly but at uniform velocity; nor do the Antipodes fall down, because they strive towards the centre of the earth with an equal concert. If anyone wants more about the cause for which bodies placed on wheels are thrust off, let him consult Galileo in the places cited a little earlier, and Niccolò Cabeo, Book 1 on the *Meteorologica*, text 17, question 8, where he denies that bodies thrust off in this way move along the tangent of the circle at the point from which those projectiles are torn away, because heaviness inclines those projectiles downward and twists them away from the straightness of the tangent.

V. Argumentum ab impetus Sensatione futura in nobis, si moueremur cum Terra.

V. Argument from the sensation of impetus that would arise in us if we were moved with the Earth.

VII. Before I had read the seeds of this argument in Kepler, Book 1 of the *Epitome of Copernican Astronomy*, page 136, it had long seemed to me impossible that any animal, and we above all, should not feel in ourselves, and in all the organs and vessels of our body, an impetus impressed either by the earth or by our common motive faculty, if we were carried round together with the earth at so great a velocity as we set out in the tables given in number 1; yet the comparison with those who are carried in a ship seemed to remove this suspicion. Father Francesco Maria Grimaldi had not read Kepler in that place either; and yet he too, while we were discussing this matter, asserted to me that, just as someone falling from a window, even if he falls straight along the perpendicular and has his eyes closed, feels himself slipping downward, so we too would feel our motion and impetus if we were turned with the earth in so headlong or so very rapid a whirling. Not much later, rereading the already mentioned passage of Kepler on another occasion related to this one, I came across this very objection, framed in this question: [Margin: Kepler's argument against the motion of the earth, and the reply.] "But surely we would at least feel this motion in our bodies, even with our eyes closed?" To which he replies at once: "Not at all. For not even in ships is the motion always felt when they run on uniformly, although there natural bodies are carried by their heaviness not to the ships as ships, but beyond the ships, outward and downward to the

lands beneath, which are at rest with respect to the river, while the ship carries them across this line. How much less shall we feel the motion of the Earth, we who are attracted by the heaviness of our bodies nowhere else than to the moving earth on which we stand; and therefore we are not carried outside the line of natural attraction, since that line accompanies us as we are carried along together." So much from Kepler, and it is almost enough; but for the sake of the natural philosophers and the logicians I must solve this very argument reduced to the rules of the syllogism.

[Margin: Form of the 5th argument.] If the Earth, and we with the Earth, were carried eastward at equal velocity, it could not be that we should not at some time feel this motion in ourselves. But we never feel such a motion. Therefore neither the Earth, nor we with the Earth, are carried eastward at equal velocity. About the MINOR I do not think anyone has any doubt. The MAJOR is proved because, in falling downward, or in leaping upward and falling back downward, we nevertheless feel, even if we close our eyes meanwhile, the impetus impressed on our bodies, either upward by the soul or downward by heaviness. Therefore, likewise, whether the Earth and the Air, of a terrestrial or watery nature, carry us eastward, or whether there is in our bodies a common faculty and force of going round in a circle and following the Earth, we should nevertheless at length feel this very impetus with some sense, at least with the common sense, since it is received in us subjectively and perhaps emanates from us effectively.

[Margin: Reply to the 5th argument.] The reply, however, is to deny the Major, on the ground and by the comparison Kepler has just brought forward. What is brought forward to confirm the Major is weak and involves a disparity. For in the cases cited we feel the motion and the impetus precisely because neither the air nor the earth moves with us with the same motion upward or downward. So it happens that, if not with our eyes, at least by touch, we feel ourselves leaving one place and acquiring another; and in a leap upward there is a struggle between the impetus upward from the soul and the impetus downward from heaviness. But in the common motion eastward nothing of the kind happens, and we have no indication of this common motion, or of a new place acquired through it, whether we compare the place we occupy with the fixed Stars or with other things — understand, as long as we are not moving with a proper motion, for that one does appear to us. Nor should it seem surprising that there is some faculty in us which exercises its act without our feeling it; for the vital faculty does this perpetually in concocting and digesting food.

CAPVT XXIII.

Chapter 23.

CAPVT XXIII.

Proponuntur ac Dissoluuntur Quatuor Argumenta sumpta ex Stellarum Ortu & Occasu, siue in aperto, siue ex puteo visis, & ex Solis Vmbris Solstitialibus, aut Eclipsi in morte CHRISTI.

Four arguments are proposed and refuted, taken from the rising and setting of the stars, whether seen in the open or from a well, and from the solstitial shadows of the Sun, or from the eclipse at the death of CHRIST.

I. Up to this point the arguments against the motion of the Earth have been sought from what appears in elementary bodies; now they are to be drawn from the celestial phenomena — but these, in the end, we shall acknowledge to be weak. They are not to be despised, however, lest they should seem to be rejected unheard and without cause.

I. Argumentum ab Occasu apparenti Siderum.

I. Argument from the apparent setting of the stars.

[Margin: Form of Argument 1.] If the Earth moved with the diurnal motion, the western mountains would seem to us to rise rather than the stars to descend below the horizon, and the eastern mountains to descend rather than the stars to rise above the horizon. But observation shows otherwise: the mountains in both quarters appear motionless, and the stars appear to rise from the East and to descend into the West; indeed, it is from this that the one part of the heaven is called the East [Oriens] and the other the West [Occidens]. Therefore the Earth does not move with the diurnal motion. [Margin: Kepler's reply to Argument 1.] So Kepler objects to himself in Book 1 of the *Epitome of Copernican Astronomy*, page 129. But he replies at once by denying the consequence of the Major. For ascent, he says, is judged by sight from the leaving behind of the plane on which we stand, and from the approach of a thing to the vertex, towards which a man's stature is raised upright. Now it is the mountains themselves that form the visible plain for us, and they do not approach the vertex, because as far as they advance, so far the line on which the spectator's stature stands erect advances with them, and the vertex too lies on that line. So the vertex, as far as sight goes, is always equally distant from the extremities of the ground on which the spectator stands, that is, from the outermost mountains. The mountains therefore cannot be seen to rise, even though in the hypothesis of the moving Earth they truly do rise.

[Margin: Empty corroboration of Argument 1.] If you press the argument and say that the mountains must at least seem to move, if not to rise or descend, the reply is to deny this consequence too. For if they seemed to move, it would certainly be by no other motion than one of ascent or descent; so, for the very reason that they do not seem to rise or descend, they will not seem even to move. Virgil's line holds good here:

We sail forth from the harbour, and lands and cities recede,

although it is the ship that really recedes. So those who sail downstream, if they are not already aware of their own motion and the ship's, will think that

the shores and mountains nearby are coming to meet them against the current; and so in similar cases.

II. Argumentum à Fixis Stellis ex Puteo spectatis.

II. Argument from the fixed stars viewed from a well.

[Margin: Form of Argument 2.] II. If the Earth, rather than the Firmament, moved with the diurnal whirling, then we, looking from the bottom of a well at some fixed star standing over our vertex, could not see it for as long as we actually do see it; instead, carried eastward together with the well, we would lose sight of it in a single beat of the artery. The consequent is false; therefore so is the antecedent from which it follows. This, namely, is how Bartholomaeus Mastrius and Bonaventura Bellutus argue, together with Alexander Tassonus [Alessandro Tassoni], in disputation 4 *On the Heavens*, question 4, article 3, number 117. They try to prove the consequence of the MAJOR from the fact that the mouth of a well is no wider than one ell — as small a space as the Earth traverses with its diurnal whirling in the twinkling of an eye — while from the bottom of a well we can see no more of the heaven than what is comprised under the angle made at the centre of the eye by two lines drawn from the eye through the outermost edges of the well into the heaven. Since, then, the space of the heaven comprised by the said angle is far greater than the mouth of the well, they infer from this that the same star can be seen from the bottom of the well for so long a time, and that the Fixed stars, rather than the Earth, move with the diurnal motion. But these authors are to be forgiven, as men little devoted to Geometry, since even some friend of ours or other, by no means lightly versed in Geometry, thought that this argument had demonstrative force against the motion of the Earth, and tried to add weight to it with his calculations. For they say that in one second of an hour, or roughly one pulse of the human artery, the Earth, by force of the diurnal whirling, traverses under the Equator a great many paces, let alone a single ell, which is the width of a well; and that therefore the whole width of the well would at once withdraw from the space lying beneath the celestial space that contains the fixed star, etc. Nor, however, is it necessary to go down into a well; it is enough to watch the stars passing by from a very long tube, or from the far end of some portico closed on all sides, through a window.

[Margin: Reply to Argument 2.] The reply, nevertheless, is to distinguish the consequence of the Major. It is conceded if the eye and the bottom of the well were at the centre of the Earth and the mouth of the well were not much wider than three hundred of our paces; or if the eye and the bottom of the well were near the surface of the earth, but the visual angle made by straight lines drawn from the eye through the opposite edges of the well did not comprise more seconds in the heaven than fifteen of the circumference described from the eye itself. Otherwise, the consequence of the Major is denied. As to its proof, it is conceded that a point of the earth's surface traverses more paces in one beat of the human artery, that is, in very nearly one second of an hour —

especially in the parallels near the Equator — than the usual width of a well; but the consequence is denied. For the measure of the time for which a Star stays in view of an eye placed at the bottom of the well is not the physical quantity of the well's width, determined in paces or other measures known to us, nor its proportion to the physical quantity of the whole terrestrial circumference. It is an optical quantity, namely that of the visual angle, relative to the arc of the circumference described from the centre of the Earth; for that circumference is the one whose entire revolution measures the diurnal time of 24 hours. Hence, if the eye is at the centre of the earth, the measure of that time, or of the star's duration in view of an eye placed at the bottom of so deep a well, is the arc of the circumference, terrestrial as well as celestial, comprised by two straight lines drawn from the eye through the opposite edges of the well; and in this case I say that, if the star is to remain in view for a longer time than one second of an hour, or one beat of the human artery, the mouth of the well must be wider than three hundred of our paces. But if the eye is near the surface of the earth, the measure of the said time is not the arc of the circumference of the terrestrial globe comprised by the edges of the well, because that arc is not described from the eye as its centre; it is a celestial or terrestrial arc similar to the arc comprised by the visual angle, that is, by the lines drawn from the eye through the opposite edges, if the doubled parallax of the star is subtracted from it. And in this case I say that, if the star is not to remain in view of an eye placed at the bottom of the well for more than one second of an hour, such an arc and angle must not comprise more than 15″. Although these things can easily be understood by those skilled in Geometry, it is nevertheless worth the effort to help both them and others with a diagram and with some problems — very opportune ones — taking the occasion from this argument.

III. From the centre of the Earth, A, describe BCD, the semiperiphery of the celestial Equator, and beneath it ELF, the semicircumference of the terrestrial Equator, in whose plane let there be the well aSOb. Through its bottom describe from A the semicircumference GIK, which the eye I, placed at the bottom of the well, is supposed to describe while it is moved with the Earth by the diurnal whirling about the centre A, towards B, the eastern point; and let the width of the well be the straight line SO, subtending the arc SLO. Now since the walls of wells and of all buildings built to the perpendicular, and the perpendicular lines of the walls, meet at A, the centre of the Earth, then if a well is imagined dug right down to the centre of the earth, the well will be ASO. Let there be such a well, then, and the eye placed at A. For, the straight lines ASP and AOQ having been produced from A through the edges of the well, S and O, as far as the heaven: as soon as the eastern edge of the well has come to S, if a star is at P on the line ASP, the eye will begin to see it, and will be able to see it until the edge O of the well has come to S. I said, moreover, that a star cannot be seen by an eye placed at the centre of the Earth for longer than one second of an hour if the mouth of the well, OS, is not wider than

three hundred paces. This I shall demonstrate with the help of the following problem, so that the benefit may be more general.

Diagram. A semicircle on the diameter BD with centre A, the Earth's centre, and two smaller concentric semicircles within it. Straight lines run from A and from a point I above A out to the outer arc; small star marks stand beside M and P on that arc. A short arc above I carries the letters of the well's mouth; the italic letters a and b stand either side of I.

- M, P, C, Q [?], N (along the top of the outer arc, left to right): points of the celestial Equator; star marks beside M and P
- V (left end of the outer arc)
- R, [?], S, L, O, X (along the small arc above I, left to right)
- a, b (italic, either side of I)
- I (the eye at the bottom of the well)
- T, H (left, near the inner arcs)
- B, E, G, A, K, F, D (along the diameter, left to right)

I. Problema. Data temporis mora, quo Stella ab oculo in fundo putei existente in centro Terrae sub Aequatore videri poterit, & data insuper semidiametro Terrae, Inuestigare Latitudinem oris putei, ad talem moram necessariam.

Problem I. Given the stay of time for which a star can be seen by an eye at the bottom of a well at the centre of the Earth, under the Equator, and given also the Earth's semidiameter: to find the width of the mouth of the well needed for such a stay.

IV. From A, the centre of the Earth, let the perpendicular ALC be drawn, bisecting the arc SLO, the chord SO and the angle SAO, by propositions 9, 10 and 11 of Euclid's first book. For there arises the rectilinear triangle ALO, right-angled at L, in which are given the base AO, the semidiameter of the earth, and the angle OAL. This angle is half the angle OAS, which subtends the arc OS, known from the given stay of time converted into degrees of the Equator. Therefore, by the laws of Trigonometry, the side OL will not remain hidden, in the units in which AO is known; and OL doubled will then give the chord OS, that is, the required width of the well.

EXEMPLVM.

Example.

[Margin: Example for a stay of one second.] Let the stay of the time already mentioned be one second of an hour. From the tables of the primum mobile the arc OS corresponding to it is 15″; its half, the arc OL, is 7½″, and the angle OAL is just as large. Now since, from what was said in Book 2, chapter 7, the Earth's semidiameter AO is 4139 Bologna miles, AO will be 4,139,000 Bologna paces. From these data the side OL is found to be 150 paces. Therefore the required width of the well, OS, is 300 paces.

Now imagine the eye at the bottom of the well, at I, equally distant from the sides Ob and Sa, and let the straight lines ISM and ION be produced from I

through the edges O and S of the well as far as the heaven. They will intercept the arc MCN, much greater than the arc PCQ intercepted by the visual angle SAO. Therefore the eye I will see the star — which rises for it earlier, from M — with a stay longer than that with which the eye A sees the star rising at P, by as much as the arc MCN of the Equator is greater than the arc PCQ, each arc being converted into time. But if this time, in this position of the eye too, is to be no greater than one beat of the human artery, or one second of an hour, then, as I said, the depth IL of the well and the narrowness of its mouth OS must be such that the angle MIN does not comprise more than 15″ of the Equator — at least if the star is a fixed star, or lacks sensible parallax. Let us suppose, then, that the depth of the well is at least 100 paces, or 500 feet, although hardly any well is usually found that exceeds 100 cubits, that is, 150 feet; and let the stay of the star in view of the eye I be one second of an hour; and let it be proposed to find the width of the well beyond which it cannot go, that stay being given. This will be found by the following Problem, with an example added as well, as you see.

II. Problema. Data mora stellae sub aspectu oculi in fundo putei eam spectantis, & in Aequatore existentis; data insuper putei profunditate: Inuestigare Oris putealis latitudinem, illi morae congruentem.

Problem II. Given the stay of a star in view of an eye that watches it from the bottom of a well and is situated on the Equator, and given also the depth of the well: to find the width of the well's mouth that agrees with that stay.

V. In the preceding figure, since the arc MCN is given from the time of the star's stay in view of the eye I, converted into degrees of the Equator, the angle MAN, from which that arc has been described, is also given. And when AIC is produced, bisecting the angle MAN just as it bisects SIO, the angle CAN will be known, since it is half the angle MAN. Now let the straight lines AM and AN be produced from A. For in the triangle AIN, the angle ANI, which is the parallax of the star, and the angle NAI, taken together, are equal to the external angle CIN, by proposition 32 of the first book of Euclid's *Elements*. So if the parallax N is known and is added to the angle NAI, the angle CIN, that is LIO, will be known, in the small rectilinear triangle LIO, right-angled at L, in which the depth of the well, IL, is given. Therefore, by the canons of triangles, the side LO will become evident, and doubled it will give the required width of the well, OS.

EXEMPLVM.

Example.

Let the given stay of the star be 1 second of an hour, to which on the Equator there corresponds the arc MCN, that is, the angle MAN, of 15″. So half of this angle, CAN, is 7½″; and the angle CIN, that is LIO, is just as large, to every subtlety of sense, if the angle N, or the parallax, is supposed insensible, as it is supposed in the fixed stars. Now, in the triangle LIO, let the depth of the well,

or the side LI, be given as 100 paces, or 500 feet, that is, 6000 inches. From this, and from the angle LIO of 7½″, the side OL will come out at 21⅘ inches. So the whole width of the well, OS, will be 43⅗ inches, that is, 3 feet and 7⅗ inches. But if it is greater, the star will stay in view of the eye I for a longer time than one second of an hour.

III. Problema. Data Latitudine & Profunditate Putei sub Aequatore, Inuestigare temporis moram, qua stella videri poterit ab oculo in fundo putei collocato.

Problem III. Given the width and depth of a well under the Equator: to find the stay of time for which a star can be seen by an eye placed at the bottom of the well.

VI. In the triangle LIO of the preceding figure, right-angled at L, the depth of the well, LI, is given as one side about the right angle, and LO as the other, since it is half the well's width OS. Therefore the angle LIO will become known by Trigonometry. When the parallax of the star, if there is any — that is, the angle ANI — is subtracted from it, the angle IAN will be known, by proposition 32 of Euclid's first book; this is the angle CAN, which measures the arc CN of the Equator. Doubled, it will give the arc MCN, which, converted at last into time, will show the stay of the star in view of the eye I.

EXEMPLVM.

Example.

Let the depth of the well, LI, be given as 100 feet, and the width SO as 4 feet, and so the half-width LO as 2 feet. Then, by the laws of right-angled triangles, the angle LIO will be 8′ 50″; and CAN will be just as large, if N, the parallactic angle, is insensible, as it is in the fixed stars. So the whole angle MAN, that is, the arc MCN, will be 17′ 40″, to which there corresponds a time of one minute and very nearly 11 seconds, that is, about 71 pulses of the human artery. When these have elapsed, the star M, which began to be seen by the eye I under the edge S, will set for it under the edge O, having by then been carried to N by the force of the diurnal celestial revolution. But if it is the Earth that turns, the edge O of the well will in that much time have been carried with the well towards T, the eastern point, through so great an arc of the terrestrial circumference that through it a straight line, namely IM, can be drawn from the eye to the fixed star at M, now supposed motionless. For the size of this arc, consult the following Problem.

IV. Problema. Data Putei Profunditate ac Latitudine, Inuestigare arcum circumferentiae terrestris Aequatoris, qui vi diurnae vertiginis transire debet ab ortu ad occasum stellae, respectu oculi in centro putei spectatum. Et si nota fuerit quantitas vnius Gradus Aequatoris terrestris in pedibus aut passibus &c. Determinare in his mensuris quantitatem praedicti arcus.

Problem IV. Given the depth and width of a well: to find the arc of the circumference of the terrestrial Equator which, by force of the diurnal whirling, must pass over between the rising and the setting of a star, considered with respect to an eye at the centre of the well. And, if the quantity of one degree of the terrestrial Equator in feet or paces etc. is known: to determine the quantity of the already mentioned arc in these measures.

VII. Let the time of the star's stay in view of an eye placed at the bottom of the given well be found by Problem 3, and from it the arc of the Equator corresponding to that time; for the required arc of the terrestrial circumference will be similar to it. Thus if, of the well SabO, the depth LI and the half-width OL are given, and from them the angle LIO, then the angle CAN is given, provided that the parallax N, if there is any, has been subtracted from the angle LIO. This doubled will give the angle MAN, which measures both the arc MCN and the arc ZLX, because each is described from the common centre A and intercepted by the same two straight lines AZM and AXN, drawn from that same centre A. Now that the arc ZLX is known, if an arc equal to it is taken from the edge S towards T, you will have the arc ST; and the point T will be the one to which the eastern edge S will have been carried after the said time. Taking, then, towards the right the arc TR, determined by the chord TR equal to the well's width OS, R will be the western edge; and the line drawn through R from the eye H, now carried here, will fall on the star M as it sets for the eye H. Finally, if one makes: as 60′ is to the paces or feet contained in one degree of the terrestrial Equator, so are the minutes of the arc found, ZLX or TRS, to another number, the said arc will be known in these measures too.

EXEMPLVM.

Example.

Let the width of the well be 4 feet and its depth 100 feet, as in the example of Problem 3. Then, from what was said there, the arc MCN will be 17′ 40″. Therefore ZLX and TRS will each be 17′ 40″ as well. Now, from what was said in Book 2, chapter 7, one degree of the terrestrial Equator holds 72,500 Bologna paces, that is, 362 500 feet. Therefore, as 60′ is to 362 500 feet, so is 17⅔′ to 46 319 feet. Hence, although the said well is 4 feet wide, the same star will nevertheless stay in view of an eye placed at its bottom until an arc of the terrestrial circumference of 46,319 feet has passed, if the well is 100 feet deep. [Margin: Error in geometry of the authors of Argument 2.] From this it is gathered how badly those men sinned against Geometry who thought that the star must vanish from the eyes as soon as as much of the terrestrial circumference has passed as the width of the well.

III. Argumentum ex Vmbris Gnomonum sub Tropicis in diebus Solstitialibus.

III. Argument from the shadows of gnomons under the Tropics on the solstitial days.

[Margin: Form of the 3rd argument, and the reply.] VIII. If the Earth moved with the diurnal motion, gnomons erected under the Tropics on the solstitial days would cast sensible shadows, except at the single moment of noon. But this is contrary to the experiments and observations made at Syene and other places under the Tropic of Cancer, and reported by Strabo, Pliny the Elder and others. Therefore etc. The reply, as above to Argument 2, is to deny the Major, for the same reason. For since gnomons erected perpendicularly on the surface of the earth converge on the centre of the earth, the two outermost ones, which, if produced into the heaven, would touch the edges of the Sun, subtend a similar arc both on the surface of the earth and in the heaven of the Sun, namely about 30′, which require two minutes of time of the diurnal revolution. For that much time, therefore, throughout the whole space contained between the two outermost gnomons already mentioned, no sensible shadow of them appears, whether the Sun moves with the diurnal motion while the Earth with its gnomons stands still, or the Earth moves while the Sun stands still. For, as I said, the arc is similar, and either arc is the measure of a time that has the same proportion to the whole day as that arc has to its whole circumference. Further, on Syene in particular and other places under the Tropic of Cancer, and on no midday shadows being seen on the day of the solstice, Cleomedes can be consulted, Book 1 of the *Cyclical Theory*, chapter 10; Strabo, Book 17; Pliny the Elder, Book 2, chapter 75; Ptolemy, Book 4 of the *Geography*, chapter 5, in the 3rd table of Africa; and Macrobius, *On the Dream of Scipio*, Book 2, chapter 8.

IV. Argumentum ab Eclipsi Solis visa in morte CHRISTI.

IV. Argument from the eclipse of the Sun seen at the death of CHRIST.

[Margin: Form of the 4th argument.] IX. The eclipse of the Sun at the death of CHRIST was total, and lasted as such for three hours. But if the Earth turned with the diurnal whirling, it would not have lasted total for three hours. Therefore the Earth does not turn with the diurnal whirling. The MAJOR is certain from the Gospel, where it is said that darkness came over the whole earth from the sixth hour until the ninth hour. The MINOR is proved because the Earth's very rapid whirling would have completed 45° in those three hours, and would have withdrawn the whole of Palestine under another quarter of the heaven, between which and the Sun the Moon would not have been interposed. And it is confirmed from the 5th letter of Dionysius the Areopagite to Polycarp, which we reported in Book 5, chapter 18, number 3, where he describes the motion of the Luminaries in that eclipse from East towards West. From this Tannerus, *De caelo*, question 9, and Inchofer [Melchior Inchofer], chapter 7 of the *Tractatus Syllepticus*, infer that the diurnal motion belongs to the Luminaries; but if the Earth too had been endowed with a diurnal motion, it would have carried Palestine away from a position suitable for seeing the Eclipse twice as

fast, since the Luminaries would be meeting it with their own motion and going of their own accord to meet the terrestrial revolution.

[Margin: Reply to Argument 4.] The reply is to deny the Minor. That miraculous eclipse was not total, and of three hours, by force of the diurnal and common motion (although, had it been by force of that motion, a miracle could have been worked in that motion too), but by force of the Moon's proper motion compared with the Sun's proper motion. This motion was varied supernaturally in the Moon: the Moon was drawn back from the Full Moon, and from diametral opposition to the Sun, to Conjunction with the Sun, and was kept beneath it, between it and Palestine, for three hours — which could have happened in just the same way whether the Earth moved or not. But the rest that concerns this miracle we have pursued diligently in that chapter 18 of Book 5.

CAPVT XXIV.

Chapter 24.

Proponuntur ac Dissoluuntur Quatuor Argumenta contra Terrae motum Diurnum & Annuum ex Principio & simplicitate huius motus sumpta.

Four arguments against the Earth's diurnal and annual motion, taken from the principle and the simplicity of this motion, are proposed and refuted.

I. Aristotle, in Book 2 of *De caelo*, chapter 12, had censured certain of the Ancients, especially Anaximander, who, though concerned with why the whole Earth does not move downward but rests at the centre of the World, had given no reason from the Earth's own nature, nor any reason why its parts are carried to the middle of the world; and he himself laid down that one must first inquire whether it moves, and then where it rests. Accordingly, in chapter 13, text 96, he tries to show that the earth by its own nature moves with neither motion. For, repeating what he had related in chapter 13, he says: "For, as we have said, some make it one of the stars, while others, placing it in the middle, say that it is rolled and moved about the middle and its own poles." And he adds at once: [Margin: Aristotle's 1st argument against the motion of the Earth.] "But that this is impossible is evident, taking as a principle that, if it is carried, whether it exists in the middle or outside the middle, it must be moved by this motion violently; for this motion is not the Earth's own, since then each of its particles would have this motion; but in fact they are all carried in a straight line to the middle. Therefore, since this motion is violent, or beyond nature, it cannot be everlasting; but the order of the World is everlasting." His argument, then, reduced to the rules of the syllogism, is as follows.

I. Argumentum Aristotelis ex Violentia motus.

I. Aristotle's argument from the violence of the motion.

[Margin: Form of the 1st argument.] II. If the whole Earth moved, either with the annual and diurnal motion together or with the diurnal motion alone,

its motion would be violent or preternatural; but a violent or preternatural motion ought not to be attributed to the whole Earth. Therefore etc.

The MAJOR is proved because neither motion would come from a natural principle of the Earth itself. For if the circular motion, whether of translation or of the whirling alone, were natural to the whole Earth, it would be natural to its parts as well. But it is not natural to the parts of the Earth; therefore not to the whole Earth either. That it is not natural to the parts is proved because none of them moves in a circle, either by whirling or by translation; rather, when let go, they are carried downward along a straight line perpendicular to the middle. The MINOR is proved because a motion that is not everlasting ought not to be attributed to the Earth, which is part of the World, since the order of the World in its other parts and motions — namely in the heaven of the world, in generations, etc. — is everlasting. But if a violent or preternatural motion were attributed to the Earth, it would not be everlasting; for nothing violent is perpetual.

[Margin: 1st reply to Argument 1.] The Copernicans will reply, first, by denying the Major. To its proof they will concede that circular motion is natural both to the whole Earth and to its parts, as long as the parts are joined to their whole; but if they are separated, they will say that the motion natural to them is one mixed of circular and straight, or some other like it, according to the shape of motion required, so that by tending downward they fall back on the point of the Earth above which they were let go perpendicularly — on which enough was said in chapter 17. And where it is said in the proof of the Major that circular or quasi-circular motion does not belong to the parts, they will deny it. To the proof of this statement, taken from the apparent straightness of the downward motion of heavy bodies, they will concede that their motion as it appears to us is rectilinear, but will deny this of the real motion, which takes place in the space of the world. [Margin: Objection against the reply.] Against this reply, however, the Aristotelians will object that it is absurd to abandon sense and, in Physics, to destroy the motion that appears so as to substitute a motion that neither appears nor can appear — and this for certain fitting reasons, but by no means necessary ones.

[Margin: 2nd reply to the argument.] Second, the Copernicans will reply to the Minor by denying it as to its second part, concerning preternatural motion; or they will turn the argument back against Aristotle, who attributes to fire a circular motion from outside, owing to the diurnal revolution of the heaven, and so a preternatural one, and yet a perpetual one. Therefore a motion in a circle can also be attributed to the parts of the earth, if they are drawn magnetically by the whole globe of the Earth, as Gilbert, Kepler, Galileo and Gassendi hold; and indeed to the whole Earth as well, if it too is drawn round by the Sun's whirling about its own centre, as Kepler holds.

II. Argumentum à Simplicitate motus debita Telluri.

II. Argument from the simplicity of motion owed to the Earth.

III. Our Scheiner uses a very long sorites and heaped-up questions in the *Disquisitiones Mathematicae*, from page 31 to 35, to which Galileo tries to reply in Dialogue 2, from page 175 to 182 of the Latin, but from page 232 to 240 of the Italian. But since Scheiner, at last, on page 35, gathers what he had said before into three Enthymemes, I shall report them in order with the replies that Galileo in part, and other Copernicans in part, have suggested from their hypotheses. His first argument is of this kind:

[Margin: Scheiner's 1st enthymeme against the motion of the Earth.] "The Copernican motion of the Earth removes from the Universe the simple motion of things upward and downward; therefore it is not to be admitted." The Antecedent is plain, because on the Copernican motion of the Earth heavy and light bodies must naturally descend or ascend to their place in such a way that they describe a line that is not, indeed, perfectly circular, but quasi-circular, and varying according to the different parallels, as is plain from the figures brought forward in chapter 17, numbers 16, 17 and 18. The Consequence is proved because it is evident from the perpetual experience of the senses that a simple motion along a straight line, upward and downward and falling perpendicularly on the Earth, belongs to heavy and light bodies.

The Copernicans reply by denying the Antecedent as regards the motion that is apparent and evident to sense; for the hypothesis of Copernicus too represents this motion as rectilinear. In this sense they concede the Consequence; but they concede the Antecedent of the real line of this motion, against which there is no experience of sense, since sense stands towards it merely negatively and is directed only to the apparent motion.

III. Argumentum ab Incommodis Principij huius motus, quodcumque illud assignetur.

III. Argument from the difficulties of the principle of this motion, whatever principle is assigned.

[Margin: Scheiner's 2nd enthymeme.] IV. Scheiner's second argument, on the same page 35, which for us here is the 3rd, is this: "The Copernican motion of the Earth necessarily introduces into all things, those carried from the centre as well as those carried to the centre, some circular motion, whose principle, however — whether natural or not natural, whether internal or external — cannot be assigned without innumerable absurdities. Therefore the motion of the Earth is not to be admitted." Yet the very many absurdities he listed earlier militate only against an external and non-natural principle, which the better Copernicans do not assign; and not even Kepler, or the others who acknowledge magnetic tractions by the earth, think that parts of the earth placed outside their place are drawn by the terrestrial globe unnaturally, but naturally, with an inclination concurring in them to receive the traction passively. Let us hear, then, what he brings against those who assign this principle as natural and intrinsic. He says that, if circular motion is natural to the Earth, the straight motion, which certainly appears in those bodies, cannot be natural, since these

motions differ from each other in species. Moreover, if the whole earth together with the water were annihilated, no hail or rain would fall from a cloud along an apparent straight line, but would only be carried round naturally — which he affirms is contrary to experiments and to reason. Finally, if beneath the earth, about the Earth's centre, there were a sphere of air, and a stone were placed at the centre of the earth, the stone would have to rise naturally from that centre to the rest of the earth, and afterwards turn with it, so as to be joined in this way to its whole and to imitate its circular motion — which likewise seems absurd, since that stone ought to remain beneath the air and at the centre. Therefore the motion of the Earth or of its parts is not from an intrinsic principle, nor natural.

[Margin: Reply to Argument 3.] Galileo, nevertheless, would reply by denying the Antecedent. To its proof he will say that the principle of this motion is natural and intrinsic, and that nothing prevents the same thing being the principle of a motion really circular and apparently rectilinear, because by it the eye too is carried round in a circle, and so cannot see the motion except always on the same straight line. Next, if the terraqueous globe were annihilated, it is uncertain what miracle would happen in the rest of the elementary sphere, granted this miracle; perhaps, however, the hail and rain would either descend with the rarefied air to fill the vacuum, or would really go round in a circle about the place where the globe of the Earth had been, or, because they would not know that the Earth had been annihilated, would descend just as they do now as far as that centre which had formerly been the Earth's centre. Lastly, the stone would remain at the centre of the Earth, because that is the centre of heavy bodies, about which, or towards which, they tend so as to be united in this way to their whole, yet in such a way that, if they are not impeded, they tend to the place where all the parts of the globe conspire to arrange themselves equally around it. That stone, however, would turn about its own centre and the Earth's.

IV. Argumentum à Peruersione motus recti terrestris pro quasi violento habiti, & circularis pro naturali.

IV. Argument from the perversion by which the Earth's straight motion is held to be quasi-violent, and the circular motion natural.

[Margin: 4th argument, from Scheiner.] V. Scheiner's third argument, on that page 35, is of this kind: "The Copernican motion of the Earth makes straight motion accidental to heavy bodies, and quasi-violent, and on the contrary makes circular motion necessary and natural; to things most diverse in nature it gives one nature of moving; it calls a stone up from the centre of the earth of its own accord; the same stone lest it fall downward from the vault, it holds suspended by the mere love with which it longs to dwell with its whole, etc. All of which are contrary to reason and experience. Therefore the motion of the earth is not to be admitted."

[Margin: Reply.] The reply is to deny the Major as regards the claim of violence in the apparent straight motion. For this motion too is natural, though secondarily, because it belongs to a body that is out of order and tending to its own place, whereas circular motion belongs to a body already set in its own place. As for the stone held suspended outside the centre of the earth, in a terrestrial vault above air spread round the centre of the earth, so that no other terrestrial body were at the centre: the Major holds, according to what was said about the terminus ad quem of the motion of heavy bodies in Argument 4 of chapter 20, number 12. For the stone could not be torn away from its whole except violently, since the character of the whole [ratio totius] would not be at the centre. What the Copernicans nevertheless try to reply was stated in the same place.

INTERROGATIONIBUS, & QUAESTIUNCULIS MULTIS SCHEINERI DE PRINCIPIO HUIUS MOTUS, SATISFIT HAC OCCASIONE EX COPERNICANORUM HYPOTHESI PRAECIPUÈ GALILAEI.

On this occasion the many questions and petty queries of Scheiner about the principle of this motion are answered from the hypothesis of the Copernicans, chiefly of Galileo.

[Margin: 1st question.] VI. This circular motion of heavy and light bodies — from what principle does it come? Internal or external? If external, does God excite it by a continuous miracle? Or an Angel? Or the Air? And this last, indeed, many assign. But against this is, etc.

[Margin: Reply.] The reply is that it comes from an internal principle, and much less from the Air, since the Air itself is carried round together with the globe of the Earth and Water.

[Margin: 2nd question.] If the highest part of the Air is not moved with the diurnal motion of the Earth but is exempt from it, how then would heavy bodies let fall through it be carried round in a circle?

[Margin: Reply.] The reply is, 1, that no one has yet made this experiment — whether heavy bodies let fall through the highest region of the air move in the same way as those let fall through our own air. Secondly, that heavy bodies are carried round not from outside but by an intrinsic force of following and imitating the motion of their primary globe.

[Margin: 3rd question.] If this circular motion comes from an internal Principle, this principle is either an accident or a substance. If the first, of what kind is it? For no quality of local motion around [qualitas locomotiva circum] seems to have been recognized so far. And even if there were one, how, after all, would it be found in things so contrary? In fire as in water? In air as in earth? In living things as in things lacking a soul?

[Margin: Reply.] The reply is that it is an accident, whose effect we cannot recognize through the senses, because we too are moved together with the Earth; but if we were outside the elementary world, we should see this circular motion. Further, contrary motions do not belong to things diverse and contrary: that is, downward motion does not belong to light things, nor upward motion

to heavy ones, just as the motions that depend on a soul do not belong to inanimate things. But motions that are not contrary but common — such as circular motion, which even on Aristotle's testimony can be mixed with straight motion — can belong to diverse and contrary natures, just as downward motion belongs to innumerable bodies differing in species.

[Margin: 4th question.] If the Earth stood still by the will of God, would the other things be rotated or not? If the latter, it is false that they are whirled round by nature; if the former, the earlier questions return. And it would surely be strange that the gull could not hover over its little fish, the lark over its little nest, the crow over a snail and a rock, even when it wished to.

[Margin: Reply.] The reply is, 1, that it is uncertain what God would will to be the case with these things if he performed that miracle. Secondly, that if no other miracle took place than the stopping of the earth, the remaining bodies akin to the earth — which are accustomed to be led by a blind impulse, and therefore neither understand nor sense the privation of motion brought about in the Earth — would continue in their motions. Nor could those animals then hover over the bodies already mentioned, because these bodies are supposed to be checked together with the Earth, while the animals themselves would be carried round by natural necessity, unimpeded by God. Thirdly: suppose that the Earth, which Scheiner sets standing still, were suddenly snatched elsewhere by a divine miracle together with the bodies adhering to it, while the gull, the lark, etc. hovered over the bodies already mentioned and were moved by no motion of their own; then they certainly could not hover over them. Just so, in the hypothesis of Copernicus, they could not do so if the Earth were stopped by a miracle and this miracle did not take place in them, but their natural principle were allowed to move them round.

[Margin: 5th question.] How does it come about that these things, so various, move only from west to east, parallel [?] to the Equator? That they always move and never rest?

[Margin: Reply.] The reply is that this happens exactly as, in the opposite and Ptolemaic hypothesis, the fixed Stars move from east to west, describing lines parallel to the Equator as regards the diurnal motion, and that without cessation.

[Margin: 6th question.] Why are the higher ones swifter and the lower ones slower? [Margin: Reply.] The reply is: because, by the common law of circles described from the same centre, if all revolve in the same time, the parts more remote from the centre are carried through greater circles and are therefore swifter, since they complete a greater space in the same time. But this seems to assign a geometrical rather than a physical reason.

[Margin: 7th question.] [Margin: Reply.] Why are those nearer the Equinoctial carried in a greater circle, and those more remote in a smaller one? The reply is that this happens in the same way as, in the contrary hypothesis, the Stars nearer the Equinoctial move in greater circles than the more remote ones; and they would do so even if they moved of themselves and not

with the motion of the eighth sphere, so as to keep the laws and proportion of the diurnal revolution. But the stars have this from an Intelligence, or from their own nature, granted a natural motion by which they transfer themselves to such a position in the sphere; heavy bodies, however, do not have it from their own nature that they should demand to be now above one parallel, now above another. And so the reply does not satisfy equally.

[Margin: 8th question.] Why would the same ball, under the Equinoctial, revolve as a whole about the centre of the earth in the greatest circuit and with incredible speed, but under the pole about its own centre, in no circuit and with the utmost slowness? For in its descent above the poles along a straight line it would cover a far smaller space in the same time than if it descended in the plane of the Equator.

[Margin: Reply.] Galileo replies, on page 236 of the Italian and 178 of the Latin, that this happens in imitation of the Fixed stars, which would do the same if the diurnal motion were attributed to them and one star at the Equator were compared with a star fixed at the pole of the Equator. So the ball, because it imitates the motion of its primary globe, is carried round, if it is placed at the Equator, just as the terrestrial Equator is; if it is above the poles, it is not carried round, just as the pole is not, which is supposed immobile as regards the diurnal motion.

[Margin: 9th question.] Why does the same thing — a lead ball, for example — if it has once gone round the earth describing a great circle at the Equator, not travel round the same earth along a great circle wherever it is placed, but, when moved outside the Equinoctial, is driven in smaller circles?

[Margin: Reply.] The reply is that the same thing happens to it, as regards the diurnal circuit, as would happen — indeed, according to Ptolemy, already does happen — to the fixed stars, which were once at the Equator and afterwards lay on parallels of the Equator. But see the reply to Question 7.

[Margin: 10th question.] If circular motion [latio circularis] is natural to heavy and light bodies, what kind is the motion that takes place along a straight line? For if it is natural, how is the motion that goes round also natural, since it differs in species from the straight? If it is violent, how does it come about that a fiery missile flying upward lifts its sparkling head away from the earth and does not instead whirl round, since the upward motion is the weaker and violent one, and the circular motion the stronger and natural one? Why do falling thunderbolts not trail their tail according to the rule of circular motion, which is natural to them, but rather according to the course of the violent one, so that they stretch it upward?

[Margin: Reply.] Galileo replies that it has been said countless times that this circular motion is natural and intended primarily and of itself, whereas the straight motion — or rather the one mixed of straight and circular — is natural on the supposition that the bodies are out of order and outside their own place. Further, that we do not notice motion of this kind because it is common to us.

[Margin: 11th question.] Why does the centre of a sphere let fall under the Equator describe a spiral in the Equator's plane? Under other parallels describe a spiral on a cone? Under the pole describe a straight line coinciding with the axis, while the sphere itself, with its outermost point, runs along a spiral line traced on a cylindrical surface?

[Margin: Reply.] Galileo replies that this happens because heavy bodies descend along lines drawn from the centre to the circumference of the sphere; and lines of this kind, as the earth is moved by the force of the diurnal whirling, describe a circle at the Equator, while those that end at parallels describe conical surfaces; the axis itself, however, describes nothing, but remains within itself. Galileo therefore concludes, on page 179 of the Latin and 237 of the Italian, that from all these petty queries of Scheiner he can gather nothing that carries any weight against the motion of the Earth; and rightly. For had Scheiner looked more deeply into the Copernican hypothesis, he could have answered himself, and so have refrained from many, if not all, petty queries of this kind.

CAPVT XXV.

Chapter 25.

Proponuntur & Soluuntur Vndecim Argumenta contra Solum Annuum Terrae motum; & primò illa, quae Aristoteles & eius in hoc sectatores sumpsere ex loco Telluri in Mundo debito, spectata ipsius natura, & loco ac motu Grauium ac Leuium ipsi debito. Et Colliguntur selecti Aristotelis Textus ad id spectantes, cum explicatiunculis, vbi opus est.

Eleven arguments against the annual motion of the Earth alone are proposed and solved; and first those that Aristotle and his followers in this matter took from the place owed to the Earth in the World, having regard to its nature and to the place and motion of Heavy and Light bodies owed to it. And the selected Texts of Aristotle bearing on this are collected, with brief explanations where needed.

I. So far we have dealt with the arguments that militate against the Earth's diurnal motion only, or against the diurnal and annual motions together; from here on we deal with those that could be devised, either by others or by us, against the annual motion alone. First there present themselves the arguments of the Peripatetics and of many others, derived from the nature of heavy and light bodies and from that motion of theirs by which they seek their right seat in the universe. These Aristotle first of all hurled against certain Pythagoreans in Book 2 of *De caelo*, chapters 12 and 13; Ptolemy, *Almagest* Book 1, chapter 7; Alfraganus, differentia 4; Cleomedes, *Cyclical Theory* Book 1, chapter 9; Albert the Great, *De caelo et mundo* Book 2, tract 1, chapter 7, and *De natura loci* tract 1, chapter 3; Johannes de Sacrobosco in the *Sphere*, chapter 1, and Clavius there, page 135; Petrus Aliacensis, question 3 on the *Sphere*; Maurolycus [Francesco Maurolico], *Cosmographia* dialogue 1, page 10; Barocius, *Cosmographia* Book 1, page 35; Blancanus in the *Sphere*, Book 4, chapter 1; Scheiner in the *Disquisitiones Mathematicae*, page 35; Fortunius Licetus [Fortunio Liceti] in his disputations on

the single centre of motion; Io. Elephantutius on the structure of the universal orb; Chiaramonti, *De Universo* Book 12, passim; and, lest we neglect the Poets, Georgius Bucanhanus in Book 1 of the *Sphere*. There he first describes the opinion of the Pythagoreans, who lived at Tarentum and Croton and said that Fire is at the middle of the universe and that the Earth, with another, opposite Earth, turns about it, in these verses:

[Margin: Buchanan's verses on the position of Fire and Earth in the Universe.]

> Nor lighter was the error, on the place of earth and wave, of those same sages who dwelt within the lofty walls of Croton and in Spartan Tarentum: for nature encloses nothing in the whole of its body purer or better than the living seed of flame, etc. To this, then, by far the worthiest seat seemed the secret inner shrine of the orb, the recess of the middle, from where, as from a sacred sanctuary, it might pour itself out into every part — as, if it is lawful to compare great things with small, the HEART, fount of blood and of life, which quickens the sluggish limbs in all living creatures, spreads from the cavern of the breast its vital heat through the other members. Next after fire, for them, the Earth is set; and yet they did not establish this one alone, but also an Antichthon, an earth opposite to it, rolling its eternal circuits round the fire.

Having set this out, he at once rejects them, saying:

> Perceive how far these things depart from true reason: for since heavy bodies have one force of moving of their own accord, so as to flee the vaults of heaven and flow into the middle centre of the world, it must be that the Earth, lowest, settles of its own accord, and, poised in the empty air at the middle station of the world, shapes itself into a sphere.

II. These arguments are taken chiefly from Aristotle, Book 2 of *De caelo*, chapters 12 and 13, as we shall soon see. Further: Aristotle's arguments are touched on lightly by some, and by certain people are even cited unfaithfully, or enfeebled; their force must not be dissembled by us, but brought out in its full extent; and the text is neither always so clear in itself, nor translated so clearly from Greek into the Latin tongue, that it could not seem obscure to some. It will therefore be worth the effort to transcribe here his selected texts that bear on this matter, with a very brief paraphrase where needed, so that from them we may extract the thread of Peripatetic doctrine and the force of the arguments, like a kernel from its shell.

[Margin: Texts of Aristotle selected for this controversy.] Accordingly Aristotle, in Book 2 of *De caelo*, chapter 12, text 72, proposes the questions to be treated in that and the following chapters, saying: "It remains to speak of the Earth: where it is placed, and whether it is among the things that are at rest or among those that move; and of its shape." And shortly afterwards he says: [Margin: *De caelo* 2, text 72.] "While most of those who say that the whole

heaven is finite say that it lies at the middle, those who live around Italy and are called Pythagoreans say the contrary: for they say that Fire is at the middle, and that the Earth is one of the stars and, being carried in a circle about the middle, produces night and day." That is, it is carried round the centre of the universe by an annual motion in such a way that it nevertheless also produces the alternations of night and day by a diurnal whirling. He goes on in the same text and relates of the same men: "Moreover, they invent another earth opposite to this one, which they call by the name Antichthon, not seeking the cause from the things that appear to sense, but rather striving to drag the appearances towards certain opinions and reasons of their own, and trying to adorn these" — that is, with the colours of certain congruences. [Margin: Text 73.] For he adds in text 73, as if divining what was afterwards to be invented by the Copernicans: "To many others too it will seem that the middle ought not to be assigned to the Earth, since they take their argument not from the things that appear, but rather from reasons. For they think that the most honourable region is owed to the most honourable thing; and that Fire is more honourable than Earth, and the Boundary than the intermediate parts; and that the Extremity and the centre have the character of a boundary. Reasoning from this, therefore, they hold that it is not the Earth that is set at the middle of the sphere, but rather Fire. Further, the Pythagoreans add this reason too: that it is most fitting that what is most principal in the universe be guarded, and that the middle of the world is most apt for this (which they accordingly call the prison of Jupiter), and that this region therefore belongs to Fire." The Copernicans, however, understood by this most honourable and most principal Fire the Sun itself.

But the Philosopher, at once, in text 74, criticizes the Pythagoreans and the others who differ in this way on two counts. First, that they use an equivocation and confuse the middle of magnitude, such as the centre of a sphere and of the world, with the middle of the thing and of its nature, which is not always the same, as is plain in animals: for in them the middle of the animal and the middle of the body are not the same. For whether the brain is the principal part of the animal, in which the soul exercises the common sensations, or the heart, in which lies the principle of the vital operations, neither is at the middle of the body's magnitude, that is, of the organic body; and in us, indeed, the heart is much nearer the head than the feet — an example Aristotle does not indeed state, but it is enough for him to have pointed to this. Secondly, between the two extremes of a sphere, namely the centre and the surface, he says that the surface is the more honourable, because it has the character of the end and of the container, the centre that of the finished, or of what is bounded and contained by another. With this explanation set out first, you will better understand the words of text 74, which run thus: [Margin: Text 74.] "As if the middle were said simply, that is, in only one way, and the middle of magnitude were the same as the middle of the thing and of its nature. And yet, just as in animals the middle of the animal and that of the body are not the same, so too, and much more, must it be judged of the whole heaven and world. For this reason, then,

they ought not to have been perturbed about the places of the universe, nor to have brought that guard, namely Jupiter's, to the centre, but to have sought what sort of thing the middle of the thing is, and where by its nature it is apt to be. For a middle of this kind is a principle, and more honourable. But the middle of place resembles the extreme more than the principle: for the middle of place is that which is bounded, while what bounds is the end; and the end and the container are more honourable than what is bounded, for the latter is matter, whereas the former is the substance of its constitution." After this, in text 75, he hints at the opi- nions of certain people about the motion of the earth, and among other things these words are worth noting: [Margin: Text 75.] "Those who deny that the earth is placed at the middle say that it moves in a circle about the middle, and not only this earth but also the Antichthon." And shortly afterwards he says that some, from the fact that in the celestial phenomena no notable variation appears to us who observe them from the surface of the earth, although we are distant from the centre of the Earth by a whole semidiameter, thought that everything could appear to us just the same whether the Earth is at the middle of the Universe or not. For this is the sense of those words: "Since the Earth is not the centre, but is distant from the centre by the whole of its hemisphere, they think nothing prevents the Phenomena from turning out in the same way if we did not live at the centre of the world as if the Earth were at the middle of the world; for not even now does anything notable happen to us, who are distant from the centre by half the diameter." Finally, he closes text 75 by relating the opinion of Plato, or of Timaeus, about the Earth at the centre of the world, but turned round by a whirling about its own centre and an immobile axis: "Some say that, while lying at the centre, it is rolled and moved about the pole that is always immobile, as is written in the *Timaeus*." That is, about the pole of the axis of the terrestrial Equator.

[Margin: Texts 76 and 77.] Further, in text 76 he sets out the opinions on the shape of the Earth, and in text 77 he brings forward a most weighty question, one worthy of our understanding, saying: "For perhaps it would be the mark of a rather irrational mind not to wonder how a small particle of earth, if it is raised and released, is carried downward and will not rest, and the larger part always moves faster; whereas the whole earth, if one imagined it raised and then released, would not be carried downward but, great as its weight is, would rest? And again, if someone took hold of its particles and withdrew the whole earth before they fell, they would nonetheless be carried downward with nothing resisting." From these doubts, he says in text 78, various solutions arose. Xenophanes of Colophon said that the whole Earth is not carried downward because it has an infinite root below, by which it is supported; Thales of Miletus said that it floats on the waters. [Margin: Text 79.] Him Aristotle criticizes in text 79: as if the water itself did not need another body to support it, and as if the whole earth, being heavier, ought not to descend through the water, seeing that any part of earth released descends through water. [Margin: Text 80.] Hence in text 80 he observes that some philosophize only so far as satisfies themselves,

and rest content with the reasons that first occur to them, as long as they have nothing to say against them. But he warns that one who philosophizes rightly must behave otherwise, and adds that golden admonition: [Margin: Aristotle's admonition for philosophizing rightly.] "Therefore one who is to inquire well must be fit to raise objections by means of the objections proper to each genus; and this comes from having considered all the differences."

[Margin: Texts 81, 82, etc.] Next, in text 81, he relates the opinion of Anaximenes, Anaxagoras and Democritus, who attributed a broad shape to the Earth so that it could not be carried downward; these he attacks from text 82 to 85. In that text he reports Empedocles as saying that the Earth is not carried downward because it is prevented by the most rapid revolution of the heaven, in the way that water in a cup swung swiftly round cannot fall, up or down. [Margin: From text 86 to 89.] Against him he presses several objections from text 86 to 89, where this is to be noted: "Or is it that heavy and light are not determined by the whirling either, but that, heavy and light things existing beforehand, the former come to the middle, while the latter rise above because of the motion?"

[Margin: Text 90.] Then, in text 90, he relates the opinion of Anaximander, who said that the whole Earth is not moved because, since it is at the middle, there is no reason why it should be carried to one side rather than another, since all regions of the world are, for the whole earth, downward in one respect and upward in another, and so none is more upward than downward. [Margin: Text 91.] This, he says in text 91, is said wittily indeed, but not truly; otherwise any body whatever, once placed at the middle of the world — whether it were earth, fire, air or water — would rest there perpetually, since the reason Anaximander adduced is not proper to the Earth itself; and moreover a reason should have been given why the parts of the earth are carried to the middle. [Margin: Text 92.] So in text 92 he says: "For it seems not only to remain at the middle but also to be carried to the middle: for where any particle of it is carried, there the whole must also be carried; and where something is carried according to nature, there it must also remain according to nature." [Margin: Text 93.] Further, in text 93, he says that it is absurd to ask why the Earth remains at the middle and not to ask why fire remains at the extremity: "For if the extreme place belongs to that by its own nature, it is plain that some place must belong to the Earth too by nature." The remaining points with which he presses Anaximander sharply can be read in texts 94 and 95, with which chapter 12 is completed.

III. In chapter 13, however, Aristotle, in texts 96 and 97, first determines whether the Earth moves, and tries to show that it does not move — a priori, indeed, in text 96, from the nature of the whole Earth, which, however, he investigates from the motion of the parts of the earth. He begins text 96 thus: [Margin: Text 96.] "Let us say first whether it has motion or remains still. For, as we said, some make it one of the stars, while others, placing it at the middle, say that it is rolled and moved about its own middle and pole. That this is

impossible we shall try to make plain, beginning from this first argument: that if the earth, whether it exists at the middle or outside the middle, is moved, it must be moved violently with a motion of this kind; for it does not belong to the earth itself by nature — otherwise each one of its particles would have this motion; but in fact they are all carried along a straight line to the middle. Therefore, since this motion is violent and beyond nature, it is not possible for it to be everlasting; but the order of the World is everlasting." [Margin: Text 97.] Afterwards, in text 97, he adds an argument a posteriori from the double motion of the Planets, which he says would have to belong to the Earth too if it moved, and yet could not be in it with the phenomena saved; but this argument belongs to chapter 26. He then goes on to other arguments from the motion of heavy bodies to the centre of the Universe, and in text 98 says: [Margin: Text 98.] "Moreover, the motion of the parts and of the whole itself according to nature is to the middle of the universe; for this is why it is placed, and even now exists, at its centre."

To prove this he needed the solution of two questions: the first is whether heavy bodies are carried to the centre of the Earth; the second, whether they are carried to the centre of the Earth insofar as it is the centre of the Earth, or insofar as it is the same, in subject and in reality, as the centre of the Universe. He solves the latter first, saying in text 99: [Margin: Text 99.] "But someone might doubt, since the middle of both is the same, to which of the two the things that have weight, and the parts of the earth, are carried according to nature: to the centre or middle of the Earth as it is the middle of the Earth, or as it is the middle of the Universe? I say, accordingly, that they must be carried to what is the middle of the Universe; for fire and whatever light things are carried to the parts contrary to those to which heavy things tend are carried to the middle of the extreme containing place." That is, towards the highest surface of the heaven, which is the universal place. "But it happens that the same middle belongs to the Earth and to the universe together; for they are carried to the middle of the Earth too, but accidentally, insofar as the Earth has its own middle at the middle of the Universe." In these two [?] texts Aristotle seemed to Galileo and Kepler to assume what is in question, namely that the centre of the Earth and that of the universe are the same; on this, more later.

Meanwhile the Philosopher solves the second question easily in text 100, by saying: [Margin: Text 100.] "That they are also carried to the middle of the Earth is shown by this sign: weights carried towards it move along lines that are not parallel but at similar angles; therefore they are all carried to one middle, which is indeed the middle of the Earth." Or, as Ptolemy argues in Book 1, chapter 7, all weights fall perpendicularly on the Earth's surface, and everywhere make right angles on both sides with the Tangent to the globe of the Earth at the point above which they are released; and so it comes about that the lines of all plumb-lines, and of walls raised to the perpendicular, converge at the centre of the Earth.

From what has now been said in texts 98, 99 and 100, Aristotle concludes in text 101 in this way: [Margin: Text 101.] "It is plain, therefore, that the Earth must be placed at the middle of the Universe, and be immobile." But someone could object that from the propositions already mentioned, if they are granted, it follows only that the earth does not move with a motion of translation, and does not follow that it does not move with a motion of whirling about the immobile centre of itself and of the universe. So he adds in the same text 101: "And for the causes stated, and because weights violently thrown upward are carried back along the perpendicular to the same place, even if that force should throw them to infinity. That it therefore neither moves nor lies outside the middle is plain from these things." Then, going back, he gathers from the natural rest of the earth that the motion of heavy bodies and of parts of the Earth receding from the middle is violent, and concludes from this that the motion of the whole earth receding from the middle is much more violent. Accordingly, in text 102 he argues thus: [Margin: Text 102.] "Moreover, the cause of rest is plain from what has been said. For indeed if the earth is by its own nature disposed to be carried from every side to the middle, as fire too appears to be carried from the middle to the extremity" — that is, carried by its own nature — "it is impossible that the motion of any particle of it by which it moves away from the middle should not be violent; for one motion belongs to one body, and a simple motion to a simple body, and not contrary motions." That is, two contrary motions do not belong naturally to one simple body, such as the Earth is. "But the motion away from the middle is contrary to the motion toward the middle. Therefore, if it is impossible for any particle of earth to move away from the middle" — understand: naturally — "it is evident that it is still more impossible for the whole Earth too" — namely, to move away from the middle of the universe; "for to the place to which the part is disposed by nature to be carried, the whole too is disposed by nature to be carried. Hence, if it is impossible for it to be moved except by a stronger force, it must necessarily move [?] in the very middle."

[Margin: Text 103.]

Lastly, in text 103 he confirms this position of the Earth by another argument, from the celestial Phenomena, which turn out just as if the Earth were in the middle; but these, like text 97 too, belong to the arguments to be proposed in chapter 26. And he concludes chapter 13 with his customary recapitulation: "So much, then, has been said about the Earth itself: about its place, its rest and its motion, and how they stand." For in chapter 14 he deals with the Figure of the Earth, and with that finished he completes Book 2 of *De caelo*. In Book 3 he treats of the Generation, number and difference of the Elements. And in Book 4 he deals with Heaviness and Lightness, and with which of them belong to the individual elements, and in what degree. Since this doctrine is very useful for understanding better Aristotle's arguments for the place of the Earth, we shall reduce it to the briefest compendium, selecting those points that bear most on this question.

SELECTA QUASI IN EPITOMEN, EX LIBRO 4. DE CÆLO.

Selections, as it were in an Epitome, from Book 4 of De caelo.

[Margin: Texts 1 and 2.]

IV. In text 1 of Book 4 of *De caelo*, then, he says that he will treat of the Heavy and the Light: what each is, what their nature is, and why they have these powers. In text 2 he supposes that the Heavy and the Light can in some way be moved naturally, but he observes that no name has been given to their actuality, unless one thinks that propensity or inclination to motion is a name suited to it. He adds that Heavy and Light things have within themselves something like incitements to motion, and that all authors use their powers, namely heaviness and lightness, yet few have given any determination about them.

[Margin: Text 3.]

In text 3 he says that the Ancients discussed only what is lighter or heavier than another, as bronze is heavier than wood — that is, what is light and heavy comparatively, and not what is simply and absolutely heavy or light.

[Margin: Text 4.]

Now note the words of text 4: "For the former" — that is, Light things — "are always disposed by nature to be carried from the middle, and the latter always toward the middle" — that is, heavy things. "Of these, that which is carried from the middle we say is carried upward, and that which is carried toward the middle, downward. For it is absurd not to think that in the heaven" — that is, in the World, which he often names in this way from its more important part — "there is something that is up and something else that is down, as certain people hold. For they say that there is not one thing up and another down, if it is alike on every side and anyone can walk everywhere with his feet set opposite to his own." So Timaeus held, as Simplicius reports on this text. "We, however, call up the very extremity of the Universe, which is up both in position and first in nature."

[Margin: The distinction of up and down established.]

[Margin: Text 5 explained.]

In text 5, from the fact that the heaven has not only an extremity but also a middle, he concludes that there is an up and a down, provided that the heaven is spherical on every side. Otherwise, if only a single hemisphere is supposed, whatever is its middle will not have the character of down. For then one of the two extremes will be the earth itself, and the middle will be something lying between the heaven and the earth; and so the notion of a middle in the universe is not enough to establish the difference of position called down, unless the universe is spherical. With this paraphrase you will now understand this text, which is otherwise obscure to many. It runs: "Since there is an extremity of the heaven and a middle, it is clear that there will be both an up and a down, as many also say, but not adequately. The cause of this is that they think the heaven is not alike on every side, but that there is only a single hemisphere, the

one above us. But those who think that it is such all round, and that the middle stands alike toward the universe, will call the one up and the middle down."

So far, then, is it from following that the position of up and down is abolished, because the earth can be walked about all round, and feet can stand at different times on a quarter opposite to themselves, or because each person can become his own Antipode, that Aristotle rather establishes that position from this very fact.

[Margin: Text 6.]

Having established it, he repeats in text 6 his definition or description, saying: "We call simply Light, then, what is carried upward and to the extremity; and simply Heavy what is carried downward and to the middle. But light relative to another, or Lighter, is that which, of two heavy things equal in bulk, is carried upward by nature more swiftly than the other." Here corrupt texts have "downward" in place of "upward."

[Margin: Text 8.]

Having determined these points, in texts 8 and 9 he presses the Platonists, who in the *Timaeus* defined the heavier as "that which consists of more of the same parts, and the lighter as that which consists of fewer, as a larger piece of lead is heavier than a smaller one, and bronze than bronze," and likewise for two other individuals of the same species. In this they would not have erred had they defined only what is heavier in the individual; but in this way, he says, nothing is determined about heavy and light taken simply. He adds: "In the same way they say that lead is heavier than wood too."

[Margin: Text 9.]

He shows in text 9 that this is absurd: first, because fire would be now lighter, now heavier, according as it consisted of more or fewer parts, and so the simply Light would be abolished; second, because a larger fire, being heavier, would be carried upward more slowly than a smaller one. And yet Fire is always light, and simply light, and the larger it is, the more swiftly it is carried upward.

[Margin: Text 10.]

When in text 10 he denies that what consists of fewer triangles is light and that what consists of more is heavier, he alludes to Plato in the *Timaeus*, who assigns the Cube to Earth, the Icosahedron to Water, the Octahedron to Air and the Pyramid to Fire, as Simplicius notes there.

[Margin: Text 11.]

Next, in text 11 he censures those who defined Heavier things by the multitude of their planes or by greater bulk, as though bulk consisted of indivisible planes. But many things are heavier than others and yet smaller in bulk, as bronze is heavier than wool.

[Margin: Texts 12 to 20.]

Leucippus and Democritus, as Simplicius reports here in commentary 4, attributed the cause of heaviness to the solidity of the atoms and the cause of lightness to the interposition of the void; from text 12 to text 20 he therefore harries them with many objections. The chief of these is that there could be

gold and earth containing more void within them than some fire, and yet they would not for that reason turn out lighter; and that the void is not moved and does not need a place upward, since it is itself rather a place, if its existence is admitted.

[Margin: Text 22.]

In text 22 he takes it as an axiom that each natural body is carried naturally to its own place and flees from the contrary place, insofar as the place is such. For as in other changes there is a passage from one contrary to the other that is intended of itself — in Generation, for example, to the form; in alteration to the quality; in augmentation to the quantity of the substance — so in natural locomotion the mobile body must tend to its own place, insofar as it is its place. He therefore censures certain of the Ancients who said that Heavy and Light things are carried down and up because they are carried toward what is like them. For although it is true that in the place to which they are carried there are things of a like nature — namely, that in the place to which earthy things are carried there is earth, and in the place to which airy things are carried there is air — nonetheless the formal terminus of the local motion of Heavy and Light things is the place, insofar as it is such a place in the universe as befits them. This he confirms as follows: "For if someone were to move the Earth to where the Moon now is, each of its parts would be carried not to it, but to the place where it now also is." Let the Copernicans note this, who say that heavy and light things are carried to their wholes not by reason of place but because of kinship in nature.

[Margin: Text 23.]

Yet Aristotle grants in text 23 that the intermediate elements are also carried toward things like themselves, for another reason: water, he says, is like air, and air like fire. But this he denies of the extreme elements.

[Margin: Text 24.]

And in text 24 he teaches again that this likeness is not the formal terminus of the local motion of heavy and light things, but the place itself, up and down, insofar as it is such: just as what is curable, if it is changed as curable, is moved toward health and not toward whiteness, even supposing whiteness were found joined with health. "To ask," says the Philosopher, "why fire is carried upward and earth downward is the same as to ask why the curable, if it is moved and changed insofar as it is curable, tends to health and not to whiteness." This doctrine he confir- [Margin: Text 25.]

ms in text 25: when air comes from water, three changes intervene — Generation, terminating at the substantial form; alteration, terminating at the qualities; and at once locomotion to the place above water. Granted, then, that air is more like air than water, it is still not carried to air because it is like it; for this likeness consists in a quality, which it has already acquired by force of the alteration. It therefore ascends upward to such a place insofar as this place is owed to the lighter body. He therefore concludes that each of these is carried to its own place insofar as such a place is owed to them in the universe.

[Margin: Text 26.]

With these points subtly argued, in texts 26 and 27 he defines the Heavy and the Light, both simply and relatively, with this new formula: "First, then, it has been defined, as seems right to everyone, that the simply heavy is what sinks beneath all things, and the Light what rises above all things."

[Margin: Text 27.]

And in text 27: "Heavy and light relative to another are those in which both are present: for they rise above some things and sink beneath others, as air and water do; for neither of these is simply light or heavy," etc.

[Margin: Texts 28 and 29.]

And in text 28 he teaches that the cause of heaviness and lightness in composite or mixed bodies is a greater or lesser participation in the qualities and differences of the elements. At once, in text 29, he gives his opinion on the things that participate in heaviness, in these words: "It happens, therefore, that the same things do not appear heavy and light everywhere, because of the difference of the primary bodies. For example, in air a piece of wood weighing one talent will be heavier than lead weighing one pound, but in water it will be lighter. The cause is that all things have heaviness except fire, and all things have lightness except earth," etc.

[Margin: Text 30.]

And in text 30: "For in its own region everything has heaviness except fire, even air itself. A sign of this is that an inflated skin pulls more" — namely, it pulls down the scale-pan, or the hand that holds it up — "than an empty one." And he concludes this text thus: "Hence, if something has more air than earth and water, it may be lighter in water but heavier in air; for it does not rise above air, but it does rise above water."

[Margin: Text 31.]

Next comes text 31, in which, defining once more, he says: "I call simply light what is always naturally disposed to be carried upward, and heavy what is always naturally disposed to be carried downward, when not hindered."

[Margin: Text 32.]

Against certain people who say that all things have some heaviness, he affirms that there are some things that are simply light and have no heaviness; and in text 32 he proves this from the fact that fire rises above all things and sinks beneath none of the elementary bodies — yet it would sink beneath them, he says, if it had any heaviness. But his opponents would say that it sinks beneath none because all things are heavier than fire.

[Margin: Text 33.]

And in text 33 he confirms that there is a middle in the Universe, to which heavy things are carried and from which light things are carried, because there is no motion downward to infinity; and he adds this confirmation: "Further, fire appears to be carried upward at similar angles, and earth and everything that has heaviness downward. Hence they must be carried to the middle. Whether

this happens accidentally toward the middle of the Earth or toward that of the Universe, since their centre is the same, is another discussion."

[Margin: Text 34.]

Aristotle goes on, and from text 34 onward proves the same proposition — namely, that there are a simply Heavy and a simply Light — by two most fitting reasons. For if there is both something that sinks beneath all things and something that rises above all things, and there is a middle and an extremity in the universe to which certain bodies are carried simply, is it not reasonable that there should be a simply Heavy and a simply Light?

[Margin: Text 39.]

I pass over the following texts for now, since they do not bear much on our matter, and come to text 39, in which I would have these propositions noted above all others: "If it is withdrawn, there is motion into what comes next below: air into the region of water, and water into that of earth. But upward, into the region that belongs to fire, air will not be carried when the fire is removed, except by force — just as water is drawn upward by the contiguous upper surface if someone draws it upward faster than the water is carried downward; nor will water be carried into the region of air, except by force." And a little later: "As earth is not carried upward, so neither is fire carried downward when the air is removed" — understand: except by force, by something drawing it in order to fill a void — "for it has no heaviness in its own region, nor has earth lightness." Texts 40 and 41 do not bear on our matter, nor do the remaining four, that is, 42, 43, 44 and 45. In the last of these, however, he teaches that the shapes of bodies do not produce the Heavy and the Light, and so are not motive downward or upward; but that, motion from Heaviness or from Lightness being supposed, they contribute to a greater or lesser speed. With these premises laid down, we must come to the arguments.

I. Argumentum pro Telluris loco in centro Vniuersi.

Argument 1, for the Earth's place at the centre of the Universe.

V. "The centre of the Earth is where the terminus is to which all Heavy things naturally tend of themselves. But a terminus of this kind is the centre of the Universe. Therefore the Earth is at the centre of the Universe."

The MAJOR is proved as follows. On the one hand, the centre of the Earth is where the terminus is to which all Heavy things are carried. For, released all round and from any place whatever, they are carried along straight lines that are not parallel to one another but converge in one point, and so fall perpendicularly on the convex surface of the terraqueous globe — that is, they make right angles on both sides with the straight line touching the terrestrial globe at the point of contact; and this happens everywhere on earth. Hence Aristotle, *De caelo* Book 2, text 100, and Ptolemy, *Almagest* Book 1, chapter 7, rightly conclude from this that all Heavy things are carried to one point, which lies within the Earth equally distant from the convex surface of the terrestrial globe; and such a point is the centre of the Earth. On the other hand, if not

some heavy things only, nor only at some times, but all heavy things and always are carried to one and the same terminus, and that naturally and from within, it follows that this is the terminus to which they are carried not accidentally but of themselves. Therefore the centre of the Earth, in reality and in fact, is that terminus to which all heavy things naturally tend of themselves.

[Margin: First proof of the Minor.]

The MINOR is proved, first, by an exclusive proof, one that excludes the centre of the Earth. For even if the Earth were not where it is, but were annihilated or moved elsewhere, Water would nonetheless, with the Earth removed, descend into the place where the Earth had been; and if the Water in turn were removed, Air would take the place of the water by natural descent. So teach reason, supported by experiments — not these indeed, but similar ones — and Aristotle, *De caelo* Book 4, texts 22 and 39, already cited above. For we see that when a part of the earth on which water lay is removed, the water descends into the place where that part of the earth was, and air descends into the place where the water was. And the account is the same for the whole element and for the part, and for a motion of the same species, from the same principle and to the same terminus, as the Philosopher taught more than once, especially in *De caelo* Book 2, texts 96 and 102, already cited. Nor should you say that the air and water would then descend to fill a void, and so not naturally but by force and by attraction. For both water and air itself have some heaviness, as Aristotle proved by the experiment of the skin, *De caelo* Book 4, text 30; they would therefore rush down by the force of their innate heaviness, and not by attraction, to fill the void and at the same time to occupy the place owed to the heavier body. Therefore in that case the centre of heavy things would not be the centre of the Earth, since the Earth would either not exist or exist elsewhere. Hence, if the centre of Heavy things can be separated from the centre of the Earth, the centre of the Earth is not of itself the terminus to which Heavy things are carried of themselves insofar as it is the centre of the Earth, but accidentally. Aristotle does not indeed state this proof, but he conveys it implicitly in the texts already mentioned.

[Margin: Second proof of the Minor.]

Second, the Minor is proved by an inclusive proof, which is Aristotle's, *De caelo* Book 2, text 99. For the terminus to which heavy things are carried of themselves is the terminus from which light things are carried to the opposite terminus, since along the same line, making similar angles everywhere, the former descend and the latter ascend, as is said in the same place and in *De caelo* Book 4, text 33, cited above, and as is evident by experiment. But Light things are carried toward the outermost surface of the universal place that contains the middle of the world, that is, toward the outermost surface of the heaven; and indeed by a perpendicular ascent, and at angles, with respect to the celestial surface, like those that heavy things make in descending at the surface of the earth (if we abide by the judgement of the senses, as we must so long as nothing is established to the contrary, whether by evidence or by higher authority).

Therefore the terminus from which light things recede is the middle or centre of the world; and so the same is the terminus to which heavy things are carried of themselves. I have chosen to set out Aristotle's argument in this way so that its force might show itself as fully as possible. Yet two distinguished Copernicans, Galileo and Kepler, report it in other, almost equivalent words, though they answer it differently.

[Margin: The same argument propounded by Galileo and solved.]

VI. For Galileo, in Dialogue 1 on the *System of the World*, Italian page 26, Latin page 20, brings in Simplicio arguing thus with Salviati: "In the second place you call into doubt whether the parts of the Earth move, as Aristotle affirms, toward the centre of the World — as though he had not demonstrated this conclusively by contrary motions, when he argues in this way: The motion of heavy things is contrary to the motion of light things. But the motion of light things, as is apparent, tends directly upward, that is, toward the circumference of the World; therefore the motion of heavy things tends straight toward the centre of the World; and it happens accidentally that it tends toward the centre of the Earth, since these centres coincide by chance." From Galileo, in the same place, I gather a threefold reply to this argument.

[Margin: Galileo's first solution.]

The first is the one by which he implicitly denies the Minor of the argument proposed by Simplicio. For although fire tends straight upward to a circumference greater than the terrestrial circumference — such as the concave of the Lunar heaven, to which Aristotle more than once grants that Fire tends — it does not follow from this that this circumference is the circumference of the Universe or of the highest heaven, or concentric with the World. Nor can this be affirmed unless it is presupposed that the centre from which we see light things ascend is the same as the centre of the World, and so that the centre of the terrestrial globe is the same as the centre of the World. But this is the very thing we are in doubt about, and about which Aristotle himself raised a doubt in text 99 of the second book of *De caelo*. Hence Galileo asserts that Aristotle, by supposing the very point in question, manifestly commits a paralogism.

[Margin: Aristotle accused of paralogism by Galileo, and defended by Chiaramonti, but not sufficiently.]

But Chiaramonti, *De Universo* Book 12, chapter 22, defends Aristotle. He says that in that text 99 Aristotle did not intend to prove that heavy things are carried downward — for this he supposed from common sense and from a most widely received axiom, that heavy things are carried downward to the lowest place of the world and that this is the centre of the universe — but intended to prove that heavy things are carried to the centre of the Earth not of themselves and insofar as it is the centre of the Earth, but insofar as it is the centre of the World. Yet granted that he did not want to prove that heavy things tend downward, he did want to prove that heavy things tend to the centre of the universe, from the fact that they tend of themselves to the point from which light things recede by ascending straight upward. And he supposed this point

to be the middle of the universe because he supposed the circumference to which light things are carried to be the circumference of the World. That he should suppose it to be this circumference rather than that of some other sphere eccentric to the world arose from nowhere else than from a preconceived opinion that the circumference of the World was described from the centre from which light things recede and to which heavy things tend — that is, from the centre of the Earth. Hence it is that, without any further demonstration, he asserted in *De caelo* Book 2, text 98, and *De caelo* Book 4, text 33, already cited, that the centre of the Earth and the centre of the Universe are the same. Therefore, although Aristotle in *De caelo* Book 2, text 101, concluded that the Earth is in the middle of the World, yet since he proved it only by supposing that its centre is the same as the centre of the World, he seems to have supposed what was in dispute — and what he himself, a little before, in text 73, had related was denied by the Italian Pythagoreans.

[Margin: Galileo's second solution.]

Second, Galileo, in the same place and in the person of Sagredo, holds that, even if it were granted that the circumference which fire seeks in a straight line is the circumference of the World, it still does not follow from this that heavy things descending along the same line tend to the centre of the World, unless that line is supposed to be produced as far as the centre of the World and to be traversed in its whole length by their descent. For from any point within a circle, even one far from the centre, a straight line can be drawn toward the circumference, indeed produced as far as the circumference itself; and along that line ascent and descent can take place without passing, in the descent, the point already mentioned, and so without reaching the centre.

[Margin: Third solution.]

Third, Galileo, on the following page and in the person of Salviati, denies that heavy things are carried of themselves to the centre not of the Earth but of the Universe. For it is uncertain whether the Universe has a centre, and where it is, because of the infinity, or at least the vastness, of the world beyond what we see, and because the centre is a nothing, devoid of every faculty; whereas the centre of the Earth is certain, and heavy things are carried to it in order to be united with their whole and to take refuge with their universal mother.

[Margin: The centre of the World unfit to terminate the motion of heavy things of itself.]

This objection — that the centre of the World is unfit to move and attract by way of an end, or to terminate the motion of heavy things of itself — is pressed also by Kepler, *Epitome of Copernican Astronomy* Book 1, page 95, and by Gassendi, Letter 2, *De motu impresso*.

VII. Kepler, moreover, in the *Epitome of Copernican Astronomy* Book 1, page 99, sets out Aristotle's argument thus: "Aristotle proved that the motion of heavy things tends to the centre of the World from the fact that the motion of light things is toward the surface of the World, since the motions of heavy and light things tend toward contrary quarters."

[Margin: The same argument propounded by Kepler and solved, but insufficiently.]

To this argument he appends a reply that suffers from a greater fault than Aristotle's argument seems to suffer from. For he says that heavy and light are not said absolutely but only comparatively. Otherwise, if fire and smoke were absolutely light, they would fly off from the Earth as far as the outermost heaven; yet clouds of smoke, once they have passed the lowest region of the air, rest suspended. This, he says, is a proof that they do not of themselves, by their own nature, seek the outermost parts of the World, nor even flee from the centre of the earth, but are pushed by heavier things and give way to them — as one of the two pans of a balance, though heavy, seeks the higher place because it is drawn by the other, heavier one. With this said, he concludes: "Therefore it is false that light things seek higher places of themselves; false that they seek the very surface of the World."

[Margin: Five faults in Kepler's solution.]

But this reply errs in many ways. First, it is false that there is nothing absolutely heavy or light. For what of itself lies beneath all things in the elemental sphere is absolutely heavy, and what rises above all things is absolutely light; and there is in the elemental sphere some body that of itself sinks beneath all things, and a body that rises above all things. Second, it is false that, if there were something absolutely light, it would reach as far as the outermost heaven; for it would be enough for it to reach above all the other elemental bodies that are heavier than it, or less light. Third, he wrongly takes clouds of smoke as an example of simply light things, since they retain something of watery heaviness, and so do not reach even the highest region of the air, and are heavier than pure air. Fourth, from the suspension of clouds he wrongly infers that neither these nor light things as a whole move upward of themselves and from within, but that they are thrust out by the heavier parts of denser air. For we have arguments from elsewhere that show physically a positive lightness and an upward motion of light things of themselves and from within, as we have taught elsewhere; and at any rate that thrusting-out ought not to have been taken as certain in order to exclude the earth from the centre of the World, since it is less certain than the point at issue. Fifth and last, he wrongly attributes to Aristotle the saying that light things seek the outermost surface of the World; for Aristotle said only that they tend toward the outermost surface of the World — and if someone says that he will sail toward Africa, it does not follow that he wants to arrive in Africa. Therefore the first and second solutions of the Aristotelian argument brought forward by Galileo (for the third will be questioned below) are more solid than Kepler's. Now we must answer the same argument as proposed by us.

[Margin: Our reply to Argument 1.]

VIII. I reply, then, to Argument 1, proposed at number 5, by granting the Major and denying the Minor. And to its First proof it can be replied on behalf of the Copernicans that, if the whole Earth were moved elsewhere, all heavy

things too would be carried there — indeed, that the whole elemental sphere would be moved there with the Earth, unless some new miracle were worked in the matter. But if the Earth were removed entirely, or annihilated, then the heaviest of the remaining elements would succeed into its place, and its centre would then become of itself the centre of heavy things — not insofar as it is the centre of Water, but insofar as it is the centre of the body that would then be the heaviest in the World, or at least insofar as it is the centre at which the heaviest body of all, namely the Earth, ought naturally to exist. But it does not follow from this that the centre of the Earth, at least when the Earth exists, is not of itself the terminus toward which all heavy things move and from which all light things move. So too the outermost surface of the eighth sphere, as the highest of the celestial spheres, is for Aristotle of itself the universal place of all visible things; granted that, if it were destroyed and Saturn's Sphere remained, this sphere would then become the most universal place, containing all things.

[Margin: Reply to the second proof of the Minor.]

To the Second proof of the Minor I deny the Consequence. For granted that light things, from anywhere on earth, are allowed to be carried along a line falling perpendicularly on the outermost surface of the World, it does not follow from this that they are carried to that surface of themselves, but accidentally, insofar as it is exterior to and concentric with the sphere of the elements, to whose outermost surface light things tend of themselves. Hence, if light things tend of themselves to the outermost surface of the elemental sphere, they also recede of themselves from its centre; and therefore heavy things are carried of themselves to the centre of the elemental sphere, not insofar as it is the same as the centre of the World, but insofar as it is the centre of the elemental sphere. Moreover, the order of the Elements requires that the centre of the elemental sphere be the centre of the Earth first, by a certain priority of foundation and of nature, rather than of the other bodies. Therefore the terminus per se to which heavy things are carried, and from which light things are carried, is with better reason the centre of the Earth as Earth than the centre of the universe as it is the centre of the universe. Next, neither the Pythagoreans nor the Copernicans would grant that light things ascend, from anywhere on earth, at right angles formed on the very surface of the outermost heaven in geometrical rigour, but only to sense: both because they say that the whole Great Orb, along which they carry the Earth's centre around, is like a point relative to the vast sphere of the Fixed stars; and because the curved line along which they say light things really ascend is not perceived by us, carried along as we are with the Earth.

II. Argumentum pro Identitate centri Terræ cum centro Mundi ex Perpendiculari Ascensu Leuium versùs Cælum vltimum.

Argument 2, for the identity of the centre of the Earth with the centre of the World, from the perpendicular ascent of light things toward the outermost heaven.

[Margin: Form of Argument 2.]

IX. Light things, released from any point whatever of the convex surface of the terrestrial globe, ascend along a line that is not only straight but also falls perpendicularly both on the convexity of the earth and on the concave of the celestial hemisphere seen by us, that is, of the visible World. Therefore they ascend from the middle of the World. But the same middle from which they ascend is the middle of the Earth. Therefore the middle, or centre, of the Earth and of the World are the same. On the MINOR the Pythagoreans and Copernicans agree with the Peripatetics, nor do experiments allow it to be doubted.

[Margin: Proof of the MAJOR.]

The Antecedent of the MAJOR is proved both by the authority of Aristotle, already adduced, *De caelo* Book 2, text 99, and *De caelo* Book 4, text 33, taken together, and by the experience of the eyes. For, placed anywhere on earth, we see a whole hemisphere of the highest heaven, that is, of the visible World, and we see light things ascend straight toward it in such a way that the line of ascent, produced in imagination, makes equal angles on both sides: mixtilinear angles with the circumference passing through our zenith, but rectilinear — indeed right — angles with another straight line, conceived as touching the convex surface of the outermost heaven at the point on which the straight line of the ascent of light things falls. The Consequence of the Major is proved because it is impossible for a smaller sphere to be inscribed within a larger in such a way that, from any point whatever of the convexity of the smaller sphere from which perpendiculars are drawn to the surface of the larger, a hemisphere of that larger sphere can be seen — unless they are concentric; indeed, unless the smaller is so small that the whole of it can be reckoned as the physical centre of the larger. This is easily evident from Geometry.

[Margin: Reply to Argument 2.]

I reply. Grant that the World is finite and spherical, and that what we see of it is reckoned by everyone as a hemisphere (for the common people, ignorant of the fallacies of sense and of Optics, reckon the upper parts of the World to be a vault, or the arched roof of an oven, depressed in the middle and nearer to us than its extremities resting on the horizon). These things being granted, I say, I concede the whole Major physically and optically, that is, as to the appearance to the senses. First, because the distance of the highest heaven is so great that not only the globe of the earth but also the great orb, in which either the Sun or the Earth is carried, is like a point, so that no inequality of the angles already mentioned can be discerned. Second, because, if our senses themselves are supposed to be carried along with the Earth, they cannot discern this common motion of heavy things made along a line that is in fact curved, but are compelled to see them always appearing on the same straight line. But I deny the Major as to astronomical rigour, according to which the question now is whether the Earth is at the centre of the World, or is as far from it as the Sun is from the Earth; for it can be that far away with the phenomena already mentioned preserved.

III. Argumentum ex Termino formali motus Grauium & Leuium.

Argument 3, from the formal terminus of the motion of heavy and light things.

[Margin: Form of Argument 3.]

X. Heaviness and Lightness were given to bodies by God and by Nature so that, if they are outside their own place, they may return to it — not so that they may be joined to their own wholes similar to themselves, but so that they may tend [rendant] [recte: tendant] to their proper place in the World insofar as it is a place: heavy things downward, light things upward. Therefore they have their determinate place in the World. Therefore the Earth and all Heavy things are carried to the centre of the World, and Light things from the centre of the World. The Antecedent was proved most acutely by Aristotle in *De caelo* Book 4, texts 22, 23 and 24, reported above. The first consequence is proved because the motion of heavy and light things as such is not spontaneous, as in animals, nor free, as in men, but is determined by nature; and so they are said to be moved by what generates them, because whatever generates them co-generates in them a principle that determines them to one mode of acting and of moving themselves. Therefore, if their local motion is determinate, their proper terminus, namely a place in the World, is determinate too. The second consequence is proved because every other place outside the centre of the World is, by its own nature, indeterminate and indifferent with respect to heavy and light things; for no reason appears why heavy things ought to tend toward that place rather than toward another place in the World.

[Margin: Reply to Argument 3.]

I reply by granting the antecedent (which, however, Copernicus, Gilbert, Kepler and Galileo deny, maintaining that heaviness and lightness are nothing other than an inclination of the parts to tend to their primary globes, or to kindred bodies similar to themselves), and by denying both the first Consequence, if by a determinate place is understood a fixed and immovable place, and the second. For if the centre of the Earth is naturally carried along the circumference of the Great Orb, any points whatever of that circumference are determined for that office at their own moments of the year; and from this is taken the reason why, at such a time of the year, heavy things ought to tend to such a point in the World rather than another.

IV. Argumentum ex Negatione Descensus totius Telluris deorsum.

Argument 4, from the denial of a descent of the whole Earth downward.

[Margin: Formula of Argument 4.]

XI. If the centre of the Earth is not at the centre of the World, no adequate reason can be brought why the whole Earth is not carried either downward or toward that region of the world toward which the parts of the earth placed outside it are carried; but a reason can be brought if it is at the centre of the World. Therefore the centre of the Earth is at the centre of the World. The Antecedent is proved because all the other reasons that others have tried to adduce are sufficiently refuted by Aristotle, *De caelo* Book 2, chapter 12, from

text 77 on. Otherwise there is no reason why the Earth, placed outside the centre of the World, should rest in one part of the World rather than in another, and not be carried where its parts are carried; for, from *De caelo* Book 2, texts 96 and 102: "Where the parts are carried by their nature, there the whole too is naturally apt to be carried." On the other hand, if it is at the centre of the World, it will be equidistant from every region of the World, and so there will be no reason why it should be carried toward one region rather than another; and accordingly it will remain there unmoved.

[Margin: Reply of Kepler and Gassendi.]

Kepler, in the *Epitome of Copernican Astronomy* Book 1, page 102, and Pierre Gassendi, Letter 2, *De motu impresso*, page 113, reply by denying the antecedent. The cause, they say, is that the whole Earth, insofar as it is whole and compacted of parts already united to itself, is not heavy: because there is nothing outside the earth that attracts it magnetically, says Kepler; or because, as Gassendi says, heaviness is an affection not of the whole Earth but of the parts torn away from it. For the globe of the earth, considered in itself as a whole, does not need a motion by which to betake itself into its own place, from which it never goes out, since it is itself its own place. For this motion, he says, unites the parts and gathers them into one; and so, both on the side inhabited by us and on the side of the Antipodes, and on every side, they conspire toward the same point; but it is not a motion that gathers the Earth together with some other body. But this reply does not satisfy. For if by the name of heaviness is understood the act of gravitating itself, the question is about this very thing: why it does not gravitate toward a place that can be designated outside itself. If, on the other hand, heaviness in first act is understood, the parts do not acquire it from the separation itself, or from what separates them from their whole; for often such a separating agent is unfit for this — as fire hurling the rocks of Vesuvius upward, or a cannon hurling its ball. Therefore they are presupposed to have had it even when they adhered to the Earth; and so the whole Earth, consisting of similar parts, has heaviness. And rightly does Aristotle say, *De caelo* Book 2, text 77: "Perhaps it would be the mark of a more irrational mind not to wonder in what way a small particle of earth, if it is raised and released, is carried and does not want to rest, and a larger one always faster; whereas if someone were to release the whole Earth after raising it, it would not be carried at all; but now so great a heaviness is at rest." And in *Meteorologica* Book 1, chapter 4, he said: "In the middle, then, and about the middle is what is heaviest and coldest."

[Margin: The weight of the whole Earth wrongly investigated by Chiaramonti.]

Admittedly, I do not approve the attempt of Chiaramonti, in *De Universo* Book 12, in the appendix to chapter 13. By weighing a cube of our own pounded earth, he thought that from its proportion to the cubes contained in the globe of the earth he could come close to the weight of the whole Earth. I do not approve it, not only because within the Earth there are many waters and many caverns, as he himself admits, but because the cube of earth

he used, however much it was pounded and compressed, was much lighter than a cube of pure Earth, such as is found in the bowels of the earth. This is proved from the following. He says there that the cube was one inch of the foot of Cesena high — he shows the figure of that foot there in a linear diagram, and it is two inches of the ancient Roman foot — and that the earthen cube weighed 7½ ounces. Yet a lead cube of this kind, which, by his own concession in the same chapter 13, must be lighter than an equal cube of pure Earth, weighs two pounds and more. Therefore, by multiplying by 7½, as he does, the inch-cubes that are in the mass of the earth, we do not come close to the true weight of the whole Earth — although he says that the whole Earth weighs 2711,787,896,857,350,340,085,118 pounds.

[Margin: Second reply to Argument 4.]

A better reply, then, can be made with the hypothesis of the Copernicans preserved: by denying the Antecedent, and saying that the cause why the whole Earth, though very heavy, is not apparently carried along a straight line toward the centre of the World is this — that it is determined by its nature to a circular motion about the centre of the World, so that it must always stay equidistant from it, while its parts gravitate only toward the centre of the Earth itself.

V. Argumentum ex Translatione, aut Dissipatione Telluris in alienum locum.

Argument 5, from the transfer or the dispersal of the Earth into a foreign place.

XII. If the whole Earth were transferred to where the Moon now is, heavy things would not be carried to it, but to the centre of the World. And if the whole Earth were divided into particles that were carried off elsewhere, they would return nowhere else than to the centre of the World. Therefore the centre of the Earth and that of the World are the same. The Antecedent is gathered from Aristotle, *De caelo* Book 4, text 22; therefore, etc.

[Margin: Lunar waters adhering to the Moon, from Kepler.]

Galileo will reply, in Dialogue 2 on the *System of the World*, Latin page 181, by denying the Antecedent; for he says that, if the aggregate of heavy things were transposed to any place whatever, the parts separated from the whole would flow together there. But Kepler would deny the same antecedent much more strongly, since in the *Epitome of Copernican Astronomy* Book 1, page 100, he affirms that there are waters on the Moon, and heavy ones at that, and yet they do not fall to the earth, much less to the centre of the World, because they are kindred to the Lunar globe and cohere with it — by the Magnetic force of the Lunar globe, to be sure; and so he denies that all heavy things flow together to the centre of the Earth.

VI. Argumentum ex Loco debito Grauissimo & Infimo Corporum.

Argument 6, from the place due to the heaviest and lowest of bodies.

[Margin: Form of Argument 6.]

XIII. To the heaviest and densest of bodies the lowest place in the World is due. But the Earth is the heaviest, densest and lowest of Bodies, and the lowest place of the World is its centre. Therefore the Earth's centre must be at the centre of the World.

[Margin: Reply to Argument 6.]

The reply is by conceding the Major concerning the lowest place in relation to the elemental system, that is, in that part of the World which consists of heavy and light things; in this sense the Copernicans deny the second part of the Minor. But absolutely, and in relation to the system of the universe, they will deny the Major, and in this sense they will concede the Minor.

VII. Argumentum ex Definitione Grauium & Leuium.

Argument 7, from the definition of heavy and light things.

[Margin: Form of Argument 7.]

XIV. If the Earth were not at the centre of the Universe, the commonly received definition of heavy and light things would not be good. But the consequent is absurd; therefore so is that from which it follows; and so the Earth is at the centre of the Universe. The MINOR is evident. The MAJOR is proved: for the definitions of these handed down by Aristotle in *De caelo* Book 4, and commonly received, are three, but because the terms are equivalent they conspire into one. For in text 6 it is said: "Simply, then, we call light what is carried upward and to the extremity, and heavy simply what is carried downward and to the middle." Next, in text 26: "Let the first thing be defined as it seems to everyone: that heavy simply is what lies beneath all things, and light, what rises above all things." Finally, in text 31: "I call simply light what is always naturally apt to be carried upward, and heavy, what is always naturally apt to be carried downward, when not prevented." Now from the first definition, and from *De caelo* Book 4, text 4, to be carried downward and to be carried to the middle of the World are the same; and nothing can lie beneath all things unless it is at the centre of the Universe. Therefore, if the Earth, which is simply heavy, is not at the centre of the Universe, the definition of things simply heavy and light will not stand.

[Margin: Reply to Argument 7.]

The reply is by denying the Major. As to its proof: if by the middle is understood the middle of the Elemental system, that is, of the aggregate of heavy and light things as such, it is conceded that Aristotle's definitions can be commonly received. Yet even so they are not received by the Platonists, who, on the testimony of Aristotle himself in *De caelo* Book 4, texts 8 and 9, defined heavy as what consists of more of the same things and light as what consists of fewer, or heavy as what consists of more triangles and light as what consists of fewer; nor by those who distinguished heavy things by the full and light things by the void, or by more voids — namely Democritus and Leucippus, whom Aristotle nevertheless presses from text 12 to text 20 of *De caelo* Book 4; nor, finally, by the Copernicans, who hold that heaviness is an inclination to

tend to its own whole, and that lightness consists in a lesser heaviness. But if by the middle is understood the centre of the Universe and of the whole World system, it is denied that those definitions must necessarily be received, except by those who presuppose from elsewhere that the centre of the elemental system is the same as the centre of the World; for by those who do not suppose this, but either deny it or call it into dispute, they need not be admitted. And for the essential coordination of heavy and light things it is enough that the Heaviest lies beneath all things, the Lightest rises above all things, and the heavier lies beneath the lighter, along a straight line drawn from the centre of the elemental sphere.

VIII. Argumentum à Destructione Leuitatis positiuæ.

Argument 8, from the destruction of positive lightness.

[Margin: Form of Argument 8.]

XV. If the centre of the Earth and of the elemental system is not at the centre of the World, positive lightness is taken away and is resolved into a privation of greater heaviness. But this is absurd; therefore, etc. The MINOR is evident from the experiments and reasons adduced in chapter 16, numbers 3, 4 and 5.

[Margin: Proof of the Major.]

The MAJOR is proved, first, by the consent of the Copernicans, who with Copernicus, Book 1, chapter 8, deny that there is any positive lightness — as Kepler denies it in the *Epitome of Copernican Astronomy* Book 1, page 99, Galileo in the treatise on the things that float on water, and Gassendi in the Letter *De motu impresso*, pages 118 and 119. It is proved, second, by reason. For granted that the globe of Earth, Water and Air can be the place to which heavy things tend by their heaviness, even if this globe is transferred — since they have, after all, a centre toward which to direct their motion and descent, namely the point that is on the circumference of the annual orb — yet no place can be assigned to which light things may gather by ascent as to their own, since they are forced to leave it at once; nor is there a place in the space of the world toward which they ought by their nature to strive through an intrinsic principle of motion.

[Margin: First reply to Argument 8.]

I reply, first, by denying the Major. For the place of light things — of elemental fire, say, if there is such a thing — is a portion of the elemental sphere situated between the concave of the Moon and the highest region of the air; and particles of fire carried up there adhere to it no less than particles of earth adhere to the earth. And just as particles of earth, although through the transfer of the elemental system they lose, in the space of the World, the place that the whole earth also loses — that is, the remote place, or, as others call it, the mathematical place — do not, however, lose the pro- ximate and physical place, so neither do the particles of fire, although the elemental system is carried around elsewhere together with the Lunar heaven.

[Margin: Second reply, but a frivolous one.]

Second, not a few will reply by denying the Minor, with Epicurus, Democritus and Leucippus, whom Copernicus followed implicitly, Book 1, chapter 8, but explicitly Galileo in the treatise on the things that are borne on water, Kepler in the *Epitome of Copernican Astronomy* Book 1, page 99, and Gassendi, Letter 2, *De motu impresso*, page 118. For they said that lightness consists in the mere privation of greater heaviness; that Fire is called lightest because it is the least heavy of all — that is, Gassendi adds, because it is drawn by the Earth least of all bodies; and that the things we call light do not ascend upward by the force of an intrinsic principle, but are thrust upward by heavier things striving to occupy the lower place due to them. To confirm this he adduces certain things that suggest there is a twofold lightness: one, which he attacks with such light arguments; the other, the very lightness of the arguments.

[Margin: Gassendi's objections against positive lightness.]

First, he says, fire does not burn in a fireplace if the room is so closed that no air can enter through any little chink. But if the fireplace is open, why does the air that is in the room not thrust the fire upward? (For if the fire is carried upward in this case, the experiment would be void.) If you say it is because so great a rarefaction of the air cannot take place so suddenly as to fill as much space as the flame occupied, then the cause why the fire does not ascend is not a lack of thrusting-out, but the difficulty of filling the void. Second, he says that the feet of someone sitting at a fire are warmed in front, while the heels are cooled, as colder air runs to the heels on its way toward the fire. But grant that the experiment is true: from where do you prove that the air runs up in order to thrust out the fire, and not rather in order to succeed into the place of the flame flying upward? Third, he says that fire burns more vehemently if the logs lie on an iron grate rather than on the ash itself. Yet this happens not because the air underneath pushes the fire upward — for thrusting-out cannot of itself be the cause of a greater fire, since it supposes that the whole fire that is to be thrust out already exists — but because the proximate material of the ignition, and the flame itself, require rarefaction all around, and on that side this is impeded by the ash. Fourth and finally, he says that the furnace of the Chymists which they call the blast furnace [flatuoſam], without other bellows, by the air alone coming in from below, fans and inflames the coals standing above it. But who would doubt that the wind can drive the subtler parts and spirits of the fire, and force them into the pores of the coals in such a way that, united, they act more strongly and inflame the coals? Yet they will do the same even if they come in not from below but from above, as when we kindle coals lying underneath with a fan. So let these arguments go, and any lighter than these that have been devised in vain against the lightness of bodies.

IX. Argumentum à Confusione Grauium cum Leuibus, & vicissim.

Argument 9, from the confusion of heavy things with light things, and the reverse.

[Margin: Form of Argument 9.]

XVI. If the Earth is outside the centre of the World, nothing will be absolutely heavy or light; the same thing that is called heavy will at the same time have to be called light, and what is light, heavy. The consequent is unfitting; therefore so is the Antecedent from which it follows.

The MAJOR is proved because, while what is called heavy descends toward the earth, it will nevertheless at the same time recede from the middle, that is, from the centre of the universe; and what is called light, while ascending from the Earth, will approach the middle of the world. But what is carried from the middle is light, and what is carried to the middle is heavy; therefore the same thing will be at once heavy and light.

[Margin: Reply.]

I reply by denying the Major and its proof. For in the opinion that places the Earth outside the middle of the World, those definitions that distinguish heavy things from light things by approach to the middle of the World are not valid.

X. Argumentum à Fine motus Grauium & Leuium.

Argument 10, from the end of the motion of heavy and light things.

[Margin: Form of Argument 10.]

XVII. Heaviness and Lightness are implanted in inanimate bodies so that they may rest in their own place and not easily be moved away from it; or, if they have been removed from it, may return to those places in such a way as to rest there. Therefore the centre of the Earth, and of the whole elemental sphere, is not outside the centre of the World. The Antecedent is proved, first, from the Philosopher, *De caelo* Book 2, text 92, where it is said: "For where any particle of it — that is, of the Earth — is carried, there the whole too must be carried; and where something is carried according to nature, there it must also remain according to nature." Next, by reason. For by this the end of the motions that are in animate things or in celestial bodies is distinguished from the end of the motion that is in the elements and in inanimate mixed bodies: motion is given to animate things so that by spontaneous motion they may acquire for themselves something beyond what they have from birth; to celestial things, so that they may be moved not by acquiring something for themselves but for the sake of others; but to the Elements and to inanimate things motion is given for neither purpose, but precisely so that they may retain and recover the place due to them in the Universe. The Consequence is proved because, if the Earth is placed outside the centre of the world for some cause — above all so that through its motion many phenomena of the Sun and of the five lesser Planets may be more easily explained — then, if it moves, neither it nor the remaining elements retain their place in the World any longer, but change it perpetually.

[Margin: Reply to Argument 10.]

The reply is by conceding the Antecedent concerning the motion of heavy and light things as such; and in this sense the Consequence is denied. For when the Earth is carried around along the annual orb, they do not change place

by gravitation and levitation, that is, insofar as they are Heavy or Light; for once they have arrived at their own Physical place, they remain in it — granted that they change their Mathematical place through the circular motion, which belongs to the Earth not as a heavy thing, but insofar as it is supposed to be a kind of Planet.

XI. Argumentum à non necessaria Multiplicatione Centrorum, & Situs eorum.

Argument 11, from the unnecessary multiplication of centres and of their positions.

[Margin: Form of Argument 11.]

XVIII. Centres of systems in the World are not to be multiplied without necessity, and much less are the finite positions of centres to be multiplied to infinity. But if the Earth's centre is not the same as the centre of the World, then without necessity not only are the centres of systems multiplied, but also the finite positions of centres, to infinity. Therefore, etc. The MAJOR is certain from the axiom repeated so many times above, and admitted by the Copernicans themselves. The MINOR is proved because it follows from this that the centre of the system of the whole World is really different from the centre of the system of the Elements, which is the same as the centre of the Earth; and because the centre of the Earth is supposed to move perpetually, it also perpetually acquires one position after another, to infinity. But these things happen without necessity, since, once the identity of the centre of the elements with that of the World is posited, all the phenomena can be saved.

[Margin: First reply to Argument 11.]

The reply is, first, by denying the Minor. For in the opinion of the Copernicans the necessity is not indeed a posteriori, nor drawn from what appears to sense, but a priori, on account of that very axiom which is used in the Major — namely, that the centres of the Planetary system should not be multiplied; that is, that the Sun's centre, or the centre of the annual orb, should not be posited as different from the centre of the World.

[Margin: Second reply.]

And so the reply is, second, by retorting the argument, and putting this Minor under the Major of Argument 11: But if the Sun's centre, or the centre of the Great Orb, is not the same as the centre of the World, the centres of the systems of the World and of the Planetary system are multiplied without necessity. If, however, this necessity is proved from elsewhere, then this argument will be better framed against the Copernican hypothesis than against the opposite one.

CAPVT XXVI.

Chapter 26.

CAPVT XXVI.

Proponuntur ac Dissoluuntur Quinq. Argumenta contra Annuum Terrae motum & situm extra Vniuersi centrum, ex Situ deorsum & Peruersione systematis Mundani.

Five arguments against the annual motion of the Earth and its position outside the centre of the Universe, drawn from its downward position and from the overturning of the system of the World, are proposed and resolved.

I. Argumentum à Differentia situs Sursum ac Deorsum.

Argument 1, from the difference between the upward and the downward position.

[Margin: Form of Argument 1.]

I. From whatever part of the Earth's circuit the heavens are viewed, everyone judges that the Heavens are up and the Earth down. But this judgement cannot stand unless they judge that the Earth is at the centre of the World. Therefore, by the common judgement of mankind, the Earth is at the centre of the World. The MAJOR is proved not only by the authority of Sacred Scripture — which we are not yet dealing with here — which says in Proverbs 25: "The heaven above and the earth beneath; therefore let thy words be few"; and in Deuteronomy 4: "Know therefore this day, and consider it in thy heart, that the Lord himself is God in heaven above and in the earth beneath, and there is no other"; and in Isaiah 6: "Look upon the earth beneath." It is proved also by the common consent of very many wise men, so much so that Aristotle said in *De caelo* 4, text 4: "For it is absurd not to think that there is something in the World that is up, and something else that is down." The MINOR is proved because, in whatever part of the earthly circuit they are, people judge that what is simply down is the point about which the circumference of the heavens appears to be described, and which seems to be equally distant from the highest heaven. Therefore they judge that point to be the centre of the World.

[Margin: Reply to Argument 1.]

The reply is by conceding the Minor of the centre of the World taken Physically and as to appearance, and denying it of the centre taken Mathematically, or according to Astronomical rigour. For the distance of the highest heaven is so great in comparison with the Earth's distance from the centre of the World that, in the Copernican hypothesis, the latter vanishes against the former, and the whole Great Orb, along which the Earth is carried around, is like a point relative to the highest sphere.

II. Argumentum ex ratione Infimi.

Argument 2, from the nature of what is lowest.

[Margin: Form of Argument 2, and reply.]

II. The lowest place is owed to the lowest of the bodies of the World. But the Earth is the lowest not only of the elements but of all bodies, and the centre of the World is the lowest place. Therefore, etc.

Kepler, in the *Epitome of Copernican Astronomy*, Book 1, page 101, and Gassendi, in Letter 2, *De motu impresso*, page 113, reply by denying both the

Major and the Minor: for places need not correspond to bodies in nobility, nor is the Earth less noble than the Moon and perhaps than certain other Planets. And indeed the Sun is nobler than Saturn, Jupiter and Mars, yet not higher in place.

It might, however, be replied that the Earth, taken together with men and the other living creatures, is not the lowest, and so the Minor would be denied. Gassendi, for his part, says that nothing in the World is absolutely lowest or highest, but only relatively to the position of a living creature, and above all of man, whose highest part is the head and lowest the feet. Hence the part that hangs over our crown is called highest, and what lies beneath our feet lowest; so that what is for us the Nadir and the bottom of the heavens is for our Antipodes the Zenith and the top of the heavens. Nor does what is in the middle at once have the character of lowest, as is plain in the navel of the human body.

III. Argumentum à nimia Licentia collocandi Tellurem vbilibet.

Argument 3, from the excessive licence of placing the Earth anywhere one likes.

[Margin: Form of Argument 3.]

III. If the Earth is not at the centre of the Universe, everyone will be free to place it wherever he wishes in the Universe. The consequent is absurd. Therefore, etc.

[Margin: Reply.]

The reply is by denying the Major. For no one will be free to place the Earth in a position from which the whole hemisphere of the heavens does not appear to us, to sense, on every side. With this phenomenon preserved, however, it will be permitted. For, as Gassendi notes in Letter 2, *De motu impresso*, page 115, the distance of the Fixed stars is so great that we judge them all to lie in a single surface with the Planets and with one another. From this he infers that if we were on the Moon or on the Sun, the heavens would nonetheless appear spherical to us, and their hemisphere on every side. He adds that, just as the Ptolemaics admit that the Planets revolve around the Earth and yet do not say that their orbs are concentric with the Earth, so it does not follow that, because we see the heavens turn around the Earth, we therefore know where the centre of the heavens is; and that centre may be many semidiameters of the Earth away from the Earth.

IV. Argumentum à situ Inferni loci seu Inferorum.

Argument 4, from the position of Hell, the place of those below.

[Margin: Form of Argument 4.]

VI. If the Earth is not at the centre of the World, the place of the damned would not be Hell [Infernus], nor would all who are banished there descend into Hell; rather, the place of the damned would be in the heavens. But these things are absurd. Therefore, etc. The MAJOR is proved because those who were carried towards the centre of the Earth, at about noon, would recede from

the middle of the world — that is, from the Sun, or from the centre of the Great Orb, which is close to the Sun — and so would ascend rather than descend.

[Margin: Reply.]

The Copernicans will reply by flatly denying the Major. For Hell, the place of the damned, is understood relatively — both to the surface of the Earth, on which men live as wayfarers [Viatores], and to the highest region of the Empyrean, in which the blessed [comprehenſores] dwell; the damned recede from both in going down to Gehenna. Nor, they will say, is it absurd that the damned are in the Planetary heaven — but not in the Empyrean heaven; nor must that saying of CHRIST, "I saw Satan like lightning falling from heaven," necessarily be understood of the Planetary heaven, but of the Empyrean heaven. But as for the sacred authorities concerning the place of the Earth, they must be treated seriously below.

5. Argumentum à Peruersione Systematis Elementaris ac Planetarÿ, numerique Planetarum.

Argument 5, from the overturning of the Elementary and Planetary system, and of the number of the Planets.

[Margin: Form of Argument 5.]

V. If the Earth moves along the Great Orb around the Sun, as the Copernicans imagine, the whole system — not only the elementary but also the Planetary — is overturned and thrown into disorder, against the common sense not so much of the crowd as of the wise; and this without any necessity. Therefore the Earth does not move along the Great Orb, etc. The Antecedent is proved because it is the common sense of the wise that all the Elements and elementary bodies lie below all the heavens and are distinct from them no less in place than in nature and condition; that the Moon is the lowest of all the Planets; that the Sun and Moon are the two chief Luminaries and the primary Planets; and finally that the Sun is higher than the Moon but lower than Saturn, Jupiter and Mars. But the Copernicans place in the heavens, and among the Planets, not only the Earth but also the whole Elementary sphere, and with them all mixed bodies, animate and inanimate, so that by their account even beetles and ants are now, as it were, secondary little planets. The Moon they insert between the heaven of Mars and that of Venus, and make it a secondary Planet, the Earth's companion. Finally the Sun, cast out of every heaven and struck off the whole number of the Planets, they set motionless at or near the centre of the World. All these things they invent compelled by no necessity of the celestial or elementary Phenomena, but merely in pursuit of certain ideas and intelligible congruences.

[Margin: Reply to the Argument.]

The Copernicans reply by conceding the Antecedent in all its parts, except the denial of necessity. That denial is proved only of a necessity taken from the experience of the senses; but they will say that they were compelled to it by a necessity a priori, from archetypal and Ideal causes, and so as not to

admit other absurdities into the system of the World — such as they consider Retrogradation and Station, the double inequality of the motion of the Planets, and the superfluity of epicy- cles, and of Librations. Or they will say that this very necessity is not indeed absolute, but only from the supposition of what is better in itself and what seems more worthy of God, the Maker and Founder. Therefore, although the argument as framed has very great force with those accustomed to the Peripatetic manner of philosophising, with minds of the Platonic school, which contemplate intelligible Ideas rather than the images of things received through the senses, it is not of such weight.

CAPVT XXVII.

Chapter 27.

PROPONUNTUR AC DISSOLUUNTUR NOUEM ARGUMENTA SUMPTA EX CAELESTIBUS PHAENOMENIS, & PRAECIPUÈ EX ECLIPSIBUS, & AB EUIDENTIA MOTUS SOLIS, CONTRA MOTUM TELLURIS ANNUUM.

Nine arguments against the annual motion of the Earth, taken from the Celestial Phenomena, and chiefly from Eclipses, and from the evidence of the motion of the Sun, are proposed and resolved.

I. To show that the globe of the Earth is at the centre of the heavens and of this visible World, many arguments are commonly brought forward, drawn from what appears to us of the heavens and the celestial bodies. On these see Aristotle, *De caelo* 2, chapter 13, texts 97 and 103, and his interpreters there; Ptolemy, *Almagest* Book 1, chapters 5 and 6; Cleomedes, *Cyclical Theory* Book 1, chapter 9; Alfraganus, difference 4; Sacrobosco in the *Sphere*, chapter 1, and Clavius on it, from page 135 to 143; Maurolycus [Francesco Maurolico], dialogue 1 of the *Cosmographia*, page 9; Barocius, *Cosmographia* Book 1, page 33; Blancanus in the *Sphaera*, Book 4, chapter 1; Liceti in the disputations *De Terra unico centro motus*; and Georgius Bucanhanus, Book 1 of the *Sphere* — with whose verses, it seems, we should make our prelude:

[Margin: Bucanhanus's verses for the Earth's position in the middle of the World.]

> Nor is it hard to know this by sure signs. If the earth stood less far from the eastern gate than from the Tartessian bound that receives the weary axles, then Phoebus, when he put forth his head bright with flashing rays, would show a larger orb as he rose in the morning, and a smaller one again as night came on. Why should I tell of the stars, both those that glide along the same perpetual track and those that, with unequal steps, wander constantly through the liquid fields of heaven? When they travel nearer, they will seem to us of greater bodily size; while they are farther off, they will show a face smaller in proportion to the distance. Nay, observe the Sun, when from the summit of heaven, straight down, he strikes the Ethiopians with no point of his rays, when the vine-leaf shields the

tender fruit with its shade: if the ruler of light then drove his chariot nearer the eastern lands, the part of daylight still to be travelled would be greater than the part travelled, and in the morning the Sun would climb the heights of heaven up the opposing slope in a few hours, and late, over a greater span, would hide his team in the western ocean. Conversely, if the earth, near the western goal, stood far from the eastern, the Titan, long climbing in the morning the lofty summit of the aether, would quickly plunge into the western waves; nor would he, midway in the high aether, divide the times of daylight from his throne into equal spans, as he now does. Moreover, if the Sun showed himself nearer to the Indians than he sets to the western peoples, he would cast shorter shadows in equal hours than when, declining, shaking his reins, he makes for night along the shores of Calpe. For if an opaque body is set before a light, it stretches its dark shadows out the longer the farther you remove the light from the dense body. Now, since the Sun casts equal shadows in equal spans, he faces the earth with equal spans on every side. Equally near the western gate and the eastern, the orb of the earth neither leans down, inclined towards the hot South, nor rises towards the Maenalian Bear; but, hanging at the midpoint between the two Poles, it marks off the surrounding heaven with an equal bound. Do you not see when the swallow, messenger of the gentle spring, gives warning that the darkness is equal to the daylight? Or when Libra tempers days and nights in a just balance and a milder heat warms the mellow grapes, when Phoebus, rising in the early morning from the rosy east, pours the darts of his rays upon the moist lands, towered houses, walls armed with battlements, and the tree of the field — the boundary that shuts out quarrels between neighbours — cast the points of their Shadows straight towards the late couch of Phoebus; again, when in the evening, departing late, the panting Phoebus stables his horses in the waves, the point of the shadows is stretched towards the rosy rising; and when the Sun, declining towards the rainy South, holds Capricorn [Aegocerota], or when on high towards the Bears he flashes out and kindles the arms of the watery Crab, the shadow, slanting, makes now for the South wind, now for the North. But if the earth, leaving its station in the middle of the world, inclined itself more towards the Parrhasian Bear, every shadow would stretch towards the freezing Bear; if it leaned more towards the moist South, every shadow would stretch towards the moist South, and the evening shadow, flowing crosswise, would then cut the shadow stretched out far from the eastern mountains. Nor, if the earth were not at the middle of the axis between the two poles, would Delia, her brother's light withdrawn, grow pale from

the sudden shadow of the earth as often as, with heaven divided by an equal bound, it sets its orb against the rays of the Sun.

Most of the arguments already mentioned, however, which the other Authors indicated above also bring forward, avail only to show that the Earth cannot be outside the plane of the celestial Ecliptic, or, running off towards the South or the North, outside the centre of the Equator — which not even the Copernicans say. Therefore, passing over them, we shall select the remaining arguments.

I. Argumentum Generale ex Phaenomenis congruentibus situi Terrae in Mundi medio.

Argument 1, the general one, from the Phenomena that agree with the Earth's position in the middle of the World.

[Margin: Form of Argument 1.]

II. If the Earth is supposed to be at the centre of the World, all the Phenomena of the heavens are saved, and this supposition corresponds to the observations made by Astronomers. Therefore the Earth is at the centre of the World. This is, namely, the argument of Aristotle, *De caelo* 2, text 103, where he says: "The things said by the Mathematicians about Astrology also bear witness. For the appearances come about as the figures by which the order of the stars is determined change, just as if the Earth were placed in the middle."

[Margin: Aristotle's argument for the Earth's position.]

[Margin: Reply to Argument 1.]

The Copernicans reply by conceding the Antecedent, denying the Consequence, and retorting the argument: For the same Phenomena are saved if the Earth is supposed to turn about its own axis with the motion of rotation [motu vertiginis], and around the Sun with the annual motion of translation; therefore the Earth moves in this way. Since, then, the said Phenomena are saved in either way, the consequence is necessary for neither hypothesis; and the argument, reduced to form, rests on two particular affirmatives, from which nothing follows necessarily.

II. Argumentum à Duobus motibus apparentibus in Planetis.

Argument 2, from the two motions that appear in the Planets.

[Margin: Argument 2.]

III. If the Earth moved circularly, it would have to be moved by more than one motion. But it cannot be moved by more than one motion. Therefore the Earth does not move circularly. The MAJOR is plain by induction over all the spheres that move circularly; so if the Earth were placed among the Planets, it too would have to be moved by more than one motion. The MINOR is proved because great changes would then appear in the fixed stars and in their risings and settings, and these do not appear. This is Aristotle's argument, *De caelo* Book 2, text 97, which it is worth giving in his own words:

[Margin: Aristotle's other argument.]

"Moreover," he says, "all the things that are carried in a circular course seem to lag behind and to be moved by more than one course, except the first sphere; so that the Earth too, whether it is carried about the middle or placed in the middle, must be moved by two courses. But if this were to happen, there would necessarily come about chan- ges and turnings of the fixed stars. But this is not seen to happen; rather, the same stars always rise and set at the same places on it." The Philosopher, however, excepts the first sphere, that is, the primum mobile, to which he assigns a single motion, namely the diurnal one.

[Margin: Reply to the argument[49].]

The reply is by conceding the Major of real motions and denying it of apparent ones; and conversely, by denying the Minor of real motions and conceding it of apparent ones, of which alone the proof holds. For since, in this hypothesis, the eyes of the observers are moved together with the Earth by both motions, the Earth's own motions cannot appear to us; yet from its real motions it follows that the stars appear to us of the same size, according to what will be said shortly.

III. Argumentum ab Hemisphaerio ac medietate Caeli semper apparente.

Argument 3, from the hemisphere, or half, of the heavens that always appears.

[Margin: Form of Argument 3.]

IV. If the Earth were not in the middle of the World, the whole hemisphere of the heavens — that is, half of any heaven — could not appear to us wherever on earth we are placed, nor would six signs of the Zodiac always stand above the horizon. But the observation of all places on earth and of all ages teaches the contrary. Therefore, etc.

[Margin: Reply.]

The reply is by distinguishing the Major. It is conceded if the Earth were neither moved by the diurnal motion of 24 hours, nor the semidiameter of the annual orb of insensible proportion to the semidiameter of the sphere of the fixed stars, nor, finally, the semidiameter of the terrestrial globe small, to sense, with respect to the semidiameter of the heavens; otherwise the Major is denied. For the diurnal motion of 24 hours brings it about that things stand with the rising and setting of the stars just as if the stars themselves turned around the Earth as the centre of their revolution. The immense distance of the Fixed stars and of the visible signs of the Zodiac, in comparison with the distance of the Earth from the centre of the World and of the Fixed stars — which to sense is nothing — brings it about that six signs always appear, and the whole hemisphere of the sphere of the Fixed stars. Finally, the smallness of the Earth's semidiameter, compared with the semidiameter of the other spheres belonging to the Planets, brings it about that only a very small and barely sensible portion of the planetary heaven is hidden from us; and that the Earth's semidiameter, when we face one quadrant of the heavens, does not take from us an arc greater than the horizontal parallax of each Planet. That parallax is indeed a little more

[49]printed *argam.*, for *argum.*

than one degree in the Moon, but less than one degree in the other Planets; how great it is appears from what was said in Book 3, chapter 8, on the parallaxes of the Sun; in Book 4, chapter 14, on those of the Moon; and in Book 7, section 6, chapter 7, on those of the other Planets. When the horizontal parallax is taken from the quadrant, that is, from 90 degrees, there therefore remain 89 degrees and more — if you except the Moon — which we see when turned towards the East, and as many which we see when turned towards the West. So it is no wonder that we see almost the whole half of the Planetary heaven as well. And hence it also comes about that the Earth seems a point with respect to the heavens, especially the highest, as Ptolemy (*Almagest* Book 1, chapter 6), Alfraganus (difference 4), Proclus in the *Sphere*, Clavius in the *Sphere* (page 143) and others contend.

IV. Argumentum à Magnitudine apparenti Stellarum.

Argument 4, from the apparent size of the Stars.

[Margin: Form of Argument 4.]

V. If the Earth were not in the middle of the visible World, the same Stars would not be seen equal to themselves at rising, at midnight and at setting. But they are seen equal to themselves. Therefore, etc. The MAJOR is proved because they would be seen larger from the part of the Earth that was nearer to the heavens. But if you say that the vapours of the horizon hinder this view, take stars seen near the Meridian in different horizons, says Clavius on page 136 of the *Sphere*: for then everyone sees Arcturus of the same size, and so with the others — even at different times of the year.

[Margin: Reply.]

The reply is by conceding the Major if the distance of the Earth from the centre of the World were sensible, or of notable proportion, relative to the distance of the Stars, or if the Earth were not in the middle of the World Physically and to sense; but by denying it if the proportion between the said distances is insensible, or if the Earth is in the middle Physically, though not Mathematically.

V. Argumentum ab Vmbris Gnomonum.

Argument 5, from the shadows of gnomons.

[Margin: Form of Argument 5.]

VI. If the Earth were not in the middle of the World, the eastern shadows of gnomons would not be equal to the western ones at an equal altitude of the Sun, nor would they describe a straight line on a horizontal plane on the Equinoctial days. The consequent is false and against observations; therefore so is the antecedent from which it follows. The MAJOR is proved by Cleomedes, Book 1 of the *Cyclical Theory*, chapter 9. For if the Earth came nearer to the East, the shadows of gnomons would be shorter with the Sun rising than with it setting, since the nearer the luminous body is, other things being equal, the more the shadows contract; conversely, if the Earth came nearer to the West,

the shadows of the setting Sun would be shorter than those of the rising Sun. And if the Earth came nearer to one of the poles, the equinoctial shadows would describe a curved line, as they do on days away from the Equinoxes.

[Margin: Reply.]

The reply is by conceding the Major if, because of its position on the annual orb, the Earth came notably nearer to the rising Sun than to the setting Sun; otherwise, by denying it. Now the Earth is no farther from the Sun, whether rising or setting, than the Sun is from the Earth in the other hypothesis, since the Sun is supposed to be at the centre of the Earth's Great Orb, or very close to that centre. And the argument taken from the antemeridian semidiurnal arc, which, it seems, would not be equal to the postmeridian one, is answered in the same way.

VI. Argumentum à Vicissitudine dierum & noctium.

Argument 6, from the alternation of days and nights.

[Margin: Form of Argument 6, and reply.]

VII. If the Earth were outside the centre of the world, there would not occur each year two Equinoxes and two Solstices, nor the other alternations of days that appear in the threefold sphere — namely the Right, the Parallel and the Oblique. The consequent is false. Therefore, etc.

The reply is by conceding the Major if the Earth were not carried round yearly in the Plane of the Ecliptic about the Sun, which stands motionless at or near the centre of the world; or not in such a way that the terrestrial Equator is inclined to the Ecliptic by 23½° and always parallel to itself. Otherwise the Major is denied.

VII. Argumentum ab Eclipsibus Lunae.

Argument 7, from the Eclipses of the Moon.

[Margin: Form of Argument 7.]

VIII. If the Earth were not in the middle of the World, Eclipses of the Moon would not always occur with the Moon standing under the place of the Zodiac opposite to the one under which the Sun is. But Eclipses of the Moon always occur with the Moon and the Sun standing under opposite places of the Zodiac. Therefore the Earth is in the middle of the World. The MINOR is admitted among the Astronomers of every age. The MAJOR seems to be shown by Ptolemy, *Almagest* Book 1, chapter 5, in these words: "And, to touch on it briefly, the whole order that appears in the increase and decrease of days and nights would be thrown into utter confusion unless the earth held the middle position. Moreover, eclipses of the Moon too would happen in any parts of the heavens whatever, and could not take place at the place opposite the Sun, since the Earth would often set itself against it not at opposition but at intervals smaller than a semicircle." This argument is pressed by Averroes, *De caelo* Book 2, on text 103; Regiomontanus, *Epitome of the Almagest* Book 1; Maurolycus, dialogue 1 of the *Cosmographia*, page 9; and our Clavius on the *Sphere*, page

142. But Maurolycus and Clavius apply themselves to this proof more earnestly: each of them thinks the matter can be settled from only two Eclipses, using this figure, in which two Lunar Eclipses made at different places of the Zodiac are represented, but in such a way that the place of the Sun under the Zodiac is opposite to the Moon's place under the Zodiac — that is, when the centres of the Luminaries are opposed along a diameter. From these, they say, it follows that the Earth, whose shadow C eclipses the Moon, is on both diameters, and so at their common intersection. Therefore, since all the diameters of the World intersect one another at the centre of the World, it is neces-

Diagram. A small woodcut set into the right column beside the description of the two lunar eclipses: a circle (the Zodiac) carrying, at its upper left and upper right, two rayed discs (the Sun) and, at its lower left and lower right, two dark round sorts shaded on their lower half (the eclipsed Moon). Two diameters cross at the centre, each joining one Sun to the Moon diagonally opposite it. One letter stands on the figure.

- C (just above the crossing of the two diameters): the Earth's shadow, "whose shadow C eclipses the Moon".

sary, they think, that the Earth is at the centre of the World; and Maurolycus thinks this so manifest that he concludes that *nothing ambiguous remains*.

[Margin: Reply to Argument 7.]

The reply, however, is by distinguishing the Major. It is conceded if the Earth were outside the centre of the World in such a way that not the Earth itself, but the Sun as well as the Moon revolved around that centre — the Sun yearly, the Moon monthly. But the same Major is denied if the Earth's centre, carrying the lunar heaven with it, revolves yearly around the Sun, which is very close to the centre of the world, while the Moon completes its monthly revolutions around the Earth. For then the Sun can be seen from the Earth under any place of the Zodiac and the Moon under the opposite place, and so any lunar eclipse whatever can occur with the Luminaries in diametral opposition. The argument of the astronomers already mentioned therefore does not strike at the Copernicans, but at those who might perhaps imagine that the Sun moves yearly around the centre of the World and that the Earth, having no annual revolution, is outside the centre of the World. For the Copernicans, however, look at the Scheme set out in chapter 4, number 17.

VIII. Argumentum ab Eclipſibus Lunæ Horizontalibus.

Argument 8, from horizontal Eclipses of the Moon.

[Margin: Form of Argument 8.]

IX. *If the Earth were outside the centre of the World, Eclipses of the Moon could never occur with the luminaries appearing on the Horizon on either side. But such Eclipses do sometimes occur. Therefore the Earth is not outside the centre of the World.* This, indeed, is the argument in which Andrea Argoli, out of inexperience, sang a triumph over Copernicus in his Ephemeris for the year 1668, on the occasion of the lunar eclipse due on May 25. With respect to the Roman Horizon that

eclipse will fall so that in the morning, as the Sun rises, the Moon, diametrically opposite it and already about to set below the Horizon, will appear eclipsed. This author's words are:

[Margin: Argoli's argument, but an empty one, against the Copernicans.]

"The second Eclipse of the Moon, May 25 at 16^h 26^m. We have deliberately set out its calculation and figure, since it occurs almost at the rising of the Sun, and for this reason: that people may see whether, at the opposition of the Luminaries, both are seen from the Horizon — a sign that the earth is set in the middle of the Firmament, against the Copernicans. Yet this can be seen constantly from the rising or setting of Palilicium [Aldebaran] or Antares, stars diametrically opposite to each other: when one of them is placed in the East, the other offers itself to be seen in the West, and conversely."

The Major of the proposed argument is therefore proved as follows. If a lunar Eclipse must occur in such a way that the Moon is not only diametrically opposed to the Sun but both Luminaries also appear on the Horizon at the same time, then a whole hemisphere, that is, a semicircle of the Zodiac, must be seen, since the Luminaries are then a whole semicircle apart from each other. But a whole semicircle of the Zodiac cannot be seen by us unless we and our Earth are at the centre of the celestial Zodiac, and so at the centre of the Firmament. The MINOR is proved by examples of horizontal Eclipses, and by the witness of Pliny the Elder (Book 2, chapter 13) and of Mästlin in his work on Eclipses; we say more about these in Book 5, chapter 5, proposition 5. Indeed, there is no Eclipse of the Moon that is not of this kind with respect to some Horizon, since there is no moment at which the Sun is not rising for some Horizon.

[Margin: Reply to Argument 8.]

The reply, however, is by distinguishing the Major. It is conceded if the Earth were outside the centre of the World but motionless, and the Sun turned in the annual orb around the centre of the World, as Argoli still imagines. But the Major is denied if the Earth's centre revolves with an annual period around the Sun, which is set near the centre of the World, and the Moon revolves around the Earth in a monthly circuit. Nor is it necessary, for the phenomenon of such Eclipses, that we see a semicircle of the celestial Zodiac. It is enough that the Earth be in the Ecliptic which it describes with its centre, placed so that it sees the Sun under one point of this Ecliptic and the Moon under the opposite point, as far as the Moon's Latitude allows, and so that the Earth is on a straight line set between the Luminaries; everything else is joined to these Eclipses only accidentally. For Aldebaran in the East and Antares in the West to be visible at the same time, however — and indeed by every one of the Earth's inhabitants — the Earth must be in the middle of the World Physically, and in such a way that its distance from the centre of the World bears no sensible ratio to the distance of the Fixed stars, as has been said more than once.

IX. Argumentum ab Euidentia motus Solis.

Argument 9, from the Evidence of the Sun's motion.

[Margin: Form of Argument 9.]

X. *If it is Physically evident that the Sun moves yearly around the centre of the World, it is evident that the Earth does not so move but is at the centre of the World. But it is Physically evident that the Sun moves yearly around the centre of the World. Therefore it is evident that the Earth does not so move but is at the centre of the World.* The MAJOR is certain, at least on the Copernican hypothesis, in which the Earth is led round in the annual orb about the motionless Sun solely so that it may perform what the Sun is supposed by others to perform in the annual orb about the resting earth — granted that, in Astronomical rigour, it is not inconsistent for both globes to be carried round yearly at an equal pace under the Zodiac. The MINOR is proved because it is no less, indeed more, Physically evident that the Sun moves with a proper motion than that the other Planets likewise move with a proper motion towards the East. For the motions of the others too are adjusted to the Sun's motion; and the daily elongation of the Planets from some one of the Fixed stars towards the East, which is the evidence of their proper motion, appears no less, indeed more, in the Sun. Now it is so Physically evident that the other Planets move with a proper motion that their motion cannot be converted into a motion of the Earth; therefore not even the apparent motion of the Sun can be converted into a motion of the Earth without injury to Physical evidence.

[Margin: Reply to Argument 9, but an invalid one.]

They reply: let the Major pass; and they deny the Minor. For it is evident only as a disjunction that either the Sun moves yearly around the Earth or the Earth around the Sun; since it is certain that, if we were on the Sun, the Earth would seem to us to move under the Zodiac exactly as the Sun now seems to move to us who are placed on the Earth. And the reason why we cannot perceive the Earth's annual motion, if there is one, is that the motion is common to us and to our eyes, which are carried along if the Earth is carried. For the same reason, if we were placed on the Sun, we would not perceive the Sun's motion either, even if the Sun really moved and the Earth stood still. This being so, they say, those who philosophize circumspectly ought not to deduce from this appearance the real motion of the one rather than of the other, but only the apparent motion of the Sun. To the proof of the Minor the reply is by denying the parity. The Phenomena of all the Planets cannot be saved if the Earth is posited to move around them while they rest, and itself to perform their periods; but the phenomena both of the Planets and of the Sun can stand if the Earth is posited to move yearly around the Sun, resting near the centre of the World, in such a way that its motion lies between the orb of Mars and that of Venus, etc., according to the system set out in chapter 4, number 15, and chapter 8, number 22. Nevertheless, that disjunctive proposition is evident not merely Physically but Mathematically; but Physical evidence alone, taken absolutely, stands for the motion of the Sun, and it suffices so long as the opposite is not demonstrated.

CAPVT XXVIII. Proponuntur ac Diſſoluuntur Tria Argumenta Contra motum Annuum Terræ; ſumpta ex Parallaxi Orbis Annui.

Chapter 28. Three Arguments against the annual motion of the Earth, taken from the Parallax of the annual orb, are proposed and resolved.

[Margin: Definition of the Parallax of the annual orb.]

I. The PARALLAX of the annual orb is a variation of view arising from the different position of the observer, who is carried with the Earth through the annual orb. This variation can be either in the apparent size of the Stars, or in their altitude or distance from the vertex, or in their distance from some visible and motionless point or object — such as the Sun is in the Copernican hypothesis. Accordingly the asserters of the Earth's immobility contend: if the Earth were carried through the annual orb, now to one place and now to another, the variations already mentioned would appear in some stars; since they do not appear, the argu-

ment is that the Earth does not move through the annual orb.

[Margin: Explanation of the scheme for the Parallax of the annual orb.]

Now, so that the force of the Arguments and their Solutions may be grasped, let there be, in the following scheme, at A the centre of the Sun and of the World, around which the semicircle of the Ecliptic, or of the annual orb, is BDC, so that the diameter of the annual orb is BAC and its semidiameter AB. Let the centre of the Earth be at one time at B, where the night hemisphere of the earth is BK and the day hemisphere — the one lit by the Sun — is BS; and at another time, 6 months later, at C, where the night hemisphere is CN and the day hemisphere CR. This happens, for example, when the Earth is carried from one Solstitial point to the other, or from one Equinoctial point to the other. From the same centre A let a great semicircle EFG be described in the sphere of the Fixed stars, whose diameter EAG coincides with the diameter of the annual orb. Let this semicircle be understood as erected at right angles to the plane of the Ecliptic; let it be, for example, the Solstitial Colure, and at the same time serve as the Meridian; and in it let F be the Pole of the Ecliptic, where some star is imagined to be, to which the straight lines BF and CF are drawn from the centres B and C. Let the eye on the surface of the earth be once at I and once at O, and through these points let the straight lines AIM and AOP be drawn, touching the earth at I and at O and serving as the Physical Horizon. Through it the eye at I sees the Sun A setting for it (since the diurnal motion goes from S to I, towards K, etc.), but at O sees the Sun rising for it. Again, let there be another star L, outside the Ecliptic and the poles of the Ecliptic, to which the straight lines BL and CL are drawn from the Earth's centres B and C. Neglecting now the parallax of the terrestrial globe, let the eye at B be imagined to see L along the straight line BL: it will see it raised by the angle GBL, much greater than when, carried to C, it sees it along CL raised by the angle GCL. In this case, therefore, the parallax of the annual orb will be the

angle BLC, arising from the diameter BAC, just as in the former case it would be the angle BFC. We shall call this Parallax parallax in itself, whether it is then observable or, accidentally, not observable, because the star L or F, once seen when the earth is at B, cannot be seen six months later, when the earth is at C, the day or the brightness of the Sun preventing it. For we shall later separate these aspects, and teach what can be observed when the Earth has been carried along.

Diagram. A woodcut in the left column illustrating the parallax of the annual orb. A vertical diameter G–K–B–S–A–R–C–N–E runs down the left side; a large arc (part of the great semicircle EFG in the sphere of the fixed stars) sweeps from G at the top through L, F and V to E at the bottom. Two small circles, the Earth at its two positions, are centred at B and C, each with one half hatched dark (the night hemisphere). A horizontal line runs from H through K and M to L at the top. Straight lines from B and C run to L, F and V, and lines from A pass through I and O towards M and P; a dotted line runs from B towards L.

- G (top of the vertical diameter): end of the diameter EAG of the great semicircle
- H (top left, on the horizontal line): end of the tangent HKL
- K (top of the upper Earth): the eye in the tangent HKL; end of the night hemisphere BK
- M (on the horizontal line, between K and L): end of the line AIM
- L (top right, on the arc): the star L outside the Ecliptic and its poles
- B (centre of the upper Earth): the Earth's centre at one time
- I (on the upper Earth's edge): the eye at I, where AIM touches the Earth
- S (below B): the end of the day hemisphere BS; the Antipode of K
- A (on the diameter, at the level of F): the centre of the Sun and of the World
- D (right of A): a point on the semicircle of the Ecliptic BDC
- F (right, on the arc, level with A): the Pole of the Ecliptic, where a star is imagined
- R (between A and C): end of the day hemisphere CR
- O (on the lower Earth's edge): the eye at O, where AOP touches the Earth
- V (right, on the arc below F): no referent in the text on this page
- C (centre of the lower Earth): the Earth's centre six months later
- P (below O, right): end of the line AOP
- N (below C): end of the night hemisphere CN
- E (bottom of the vertical diameter): end of the diameter EAG

[Margin: Galileo's [?] first proposition.]

II. With these premises established, Galileo, in Dialogue 3 of the *System of the World* (page 376 of the Italian, 385 of the Latin), demonstrates that *the greatest parallax of the annual orb that stars can undergo in altitude, or in distance from the vertex, is that of the stars at the Poles of the Ecliptic; there is none for those in the*

Ecliptic; and it is the smaller, the nearer they are to the Ecliptic and the farther from the poles of the Ecliptic. Thus in the preceding figure the greatest parallax is that of star F, and there is none for star G or E; and that of star L is smaller than that of star F, because the parallactic angle BFC is greater than the parallactic angle BLC — indeed it is the greatest of all the angles contained on the same base BAC within the same periphery EFG — as he shows in the same place. It can also be gathered from the fact that the angle diminishes from F towards G, so that at G it finally vanishes. Hence Fixed stars placed in the Ecliptic are never raised or depressed more or less because of the motion of the earth, granted that they become now nearer to the eye, now farther from it.

[Margin: Galileo's [?] second proposition.]

And for that reason, on page 373 of the Italian (382 of the Latin) of the same dialogue, he demonstrated this other proposition, which for him comes first: *the greatest Parallax of the annual orb that stars can undergo in apparent size is that of the stars in the Ecliptic; there is none for those at the poles of the Ecliptic; and it is the smaller, the nearer they are to the poles of the Ecliptic and the farther from the Ecliptic.* The first proposition, however, holds in the case supposed in the description of the figure, with the distance of the Fixed stars G and E taken as immense; otherwise a case can be given in which even the stars G and E acquire some parallax from the annual orb, according to what was said in chapter 11, number 14.

III. It is now worth inquiring how great the greatest parallax of the annual orb would be, supposing both the moderate distance of the Sun and the Fixed stars from the Earth that some asserters of the Earth's immobility posit, and the distance that the more eminent Copernicans posit. We shall obtain this easily in the triangle ABF, right-angled at A. In it, from the hypotheses of the authors already mentioned, the side AB is given — the semidiameter of the annual orb, that is, the mean distance of the Sun from the Earth — and the side AF, which is the distance of the Fixed stars from the centre of the World. Therefore, by the Fifth [proposition] of Plane Right-angled Triangles, treated in Book 10, section 1, chapter 2, the angle AFB will become known; and by doubling it we shall have the whole parallactic angle BFC, standing on the diameter BC.

[Margin: The slip of the Copernicans over the Parallax of the annual orb.]

Granted, all the Copernicans until now have pressed the angle AFB on us, absolutely, as the parallax of the annual orb, as we showed in Book 6, chapter 7, numbers 10 to 15 — whether they used dissimulation in order to diminish this parallax, or rather through an inadvertence that arose from their habit with the parallax of the terrestrial globe, which the Earth's semidiameter produces. For just as in the preceding figure — with the star placed at L, rising for the eye at K and seen along the tangent HKL, and with the straight line BL drawn from the centre B — the horizontal parallax of the star is the angle BLK, standing on the Earth's semidiameter BK, so they reckoned the parallax of the annual orb from the semidiameter AB of the annual orb alone, and no greater than the angle AFB. But just as, if someone, with the earth standing still, were carried from K

to S, the place of his Antipode, and could see the star L from both places, the whole parallax would be the angle SLK, arising from the diameter KS; so, with the Earth carried from B to C, the Parallax of the annual orb, taken adequately, turns out to be BFC, because of the whole diameter BC. To show the difference between the two views, however, we shall set out in the following Table both the angle AFB and the angle CFB, with its quantity derived from the given sides AB and AF that follow. We took the first of these from Book 3, chapter 7, and the second from Book 6, chapter 7, where we also cited the authors of the distances and the places where they give them.

TABVLA PARALLAXIS MAXIMÆ ORBIS ANNVI.

Table of the Greatest Parallax of the Annual Orb.

Authors of the distances	Distance in Earth semidiameters: of the Sun from the Earth, or side AB	Distance of the Fixed stars from the centre of the World, or side AF	Semiparallax, or angle AFB	Parallax, or angle CFB
Ptolemy	1126	20 220	3° 11′ 34″	6° 23′ 8″
al-Battānī	1068	19 000	3° 13′ 20″	6° 26′ 40″
Tycho	1120	14 000	4° 35′ 30″	9° 11′ 0″
We	7300	100 000	4° 10′ 30″	8° 21′ 0″
Kepler	3469	60 000 000	0° 0′ 12″	0° 0′ 24″
Lansbergen	1498½	41 958 000	0° 0′ 7⅓″	0° 0′ 15″
Galileo	1208	13 046 400	0° 0′ 20″	0° 0′ 40″
Hortensius	1498½	10 312 227	0° 0′ 30″	0° 1′ 0″
Hérigone	1200	1 440 000	0° 3′ 0″	0° 6′ 0″

[Margin: Copernicans.]

It should be noted, however, that Lansbergen, together with Hortensius, once admitted a Parallax of the annual orb in the Fixed stars of 30″ (in fact a semiparallax), as though it could not be detected by any observations; but that later, in the *Uranometria*, Book 3, element 7, he reduced it to 7″ 22‴. Doubling it, therefore, as is proper, the whole parallax comes to 14″ 44‴, or nearly 15″.

[Margin: The distance of the Fixed stars that must be asserted if the Parallax of the annual orb is not to be greater than 10 Seconds.]

IV. Besides knowing the parallax already mentioned, since we judge that with our Instruments properly applied a difference in the altitude of the stars can be detected that is not less than ten Seconds, it is worth investigating what distance of the Fixed stars from the centre of the World the Authors must establish if they want the parallax of the annual orb, at its greatest possible, not to exceed 10″ — that is, if the angle CFB already mentioned is to be 10″ and AFB 5″ — with the side AB, the distance between the Sun and the Earth, taken as great as each of the Authors listed below supposes. We shall settle this easily by analysing the triangle ABF already mentioned, right-angled at A, in which AB is given and the opposite angle AFB is assumed to be 5″. Then by the 7th [proposition] of Plane Right-angled Triangles we shall find how great the distance AF of the Fixed stars must be. Here, then, is the small table below.

With the angle AFB 5″ and CFB 10″, and AB in Earth semidiameters		AF, in Earth semidiameters, is
Copernicus	1150	47 439 800
Kepler	3469	142 746 428
Galileo	1208	49 832 416
Lansbergen	1498½	61 616 122
Hortensius	1498½	61 616 122
Boulliau	1460	60 227 920
Hérigone	1200	49 502 400
Wendelen	14656	604 589 312
Us	7300	301 146 419

[Margin: There is no sensible variation in the apparent size of the Fixed stars because of the Parallax of the annual orb.]

V. It remains to examine how much larger a Fixed star of the first magnitude, such as Sirius, would appear if the Earth approached it by the whole diameter of the annual orb, and if such a star were imagined to be in the Ecliptic, taking the least distance of the Fixed stars from the centre of the World that some Copernicans posit — namely 1 440 000 terrestrial semidiameters, the figure Hérigone posits. Now the apparent diameter of Sirius is only 18 Seconds, as we showed in Book 7, section 6, chapter 11, in the first table. In the following figure, then, let AC be the distance of Sirius from the centre of the world C, and let the apparent semidiameter of Sirius stand under the angle ACB, of 9″. For when the tangent CB and the semidiameter AB are drawn, there are given in the triangle ABC, right-angled at the point of contact B, the Base AC, 1 440 000, and the adjacent angle ACB, 9″. From these, by the first [proposition] of these Triangles, the true semidiameter of Sirius is found to be 62 and 784/1000 terrestrial semidiameters. Now suppose the eye has approached the star, so that Sirius is distant from the eye at C by the interval CP, namely 1 437 600 semidiameters — subtracting, that is, from the semidiameter of 1 440 000 the 2400 that Hérigone gives to the diameter of the annual orb (although in the Copernican hypothesis only the semidiameter would have to be subtracted, unless distances from the centre of the earth are taken instead of distances from the centre of the World) — and let DP be 62 and 784/1000. Then in the triangle PDC, right-angled at D, the angle PCD will be found, by the Second [proposition] of plane right-angled triangles, to be 9″ 2‴. The whole apparent diameter of Sirius will therefore be 18″ 4‴, and so, because of the approach already mentioned, no greater by more than 4‴ — a difference that is entirely unobservable. How much less observable, then, will it be in other, smaller stars, outside the Ecliptic and more distant from the centre of the world? With these preparations made, let us come to the Arguments.

Diagram. A small woodcut set into the left column beside the computation for Sirius: two circles, one above the other, representing the star seen from two distances. In the upper circle a short radius runs from the centre A to the point B on its left edge; in the lower circle a radius runs from the centre P to

the point D on its left edge. From C at the foot two long lines run upward, touching the circles at B and D, and a line runs from C up through P to A.

- A (centre of the upper circle): Sirius, at the distance AC from the centre of the world C
- B (left edge of the upper circle): point of contact of the tangent CB
- D (left edge of the lower circle): point of contact, right angle of the triangle PDC
- P (centre of the lower circle): Sirius at the nearer distance CP
- C (foot of the figure): the centre of the world, and the eye

I. Argumentum à Parallaxi Orbis Annui in Altitudine Fixarum.

Argument 1, from the Parallax of the annual orb in the Altitude of the Fixed stars.

VI. *If the Earth moved in the Annual Orb, some sensible parallax would be observed in the meridian altitude of the Fixed stars, taken after three or six months at the same Horizon with large instruments, exactly made and applied. But no such parallax has appeared so far. Therefore the Earth does not move in the Annual Orb.*

[Margin: Proof of the Major.]

The MAJOR appears to be proved by the Trigonometric calculation and the table at the end of number 3, at least for stars placed at the pole of the Ecliptic or not far from it, such as the star in the bend of Draco and, in the other hemisphere, the star in the breast of the fish Dorado. It can also be proved from Sirius, which we have observed on the Meridian more than once: shortly after the autumnal Equinox in the morning, with the Sun rising, and shortly after the vernal Equinox in the evening, with the Sun setting. For the brightness of this star is so great that, with a clear horizon, it can be seen even for about a quarter of an hour before sunset or after sunrise, and both its distance from the Sun as seen and its meridian altitude can be taken. Now let Sirius be at L in the figure set out in number 1, and let its Southern latitude GL, that is, the angle GAL, be 39° 32′ 58″, from what was said in Book 6, chapter 24. Let AB, following Hérigone, be 1200 terrestrial semidiameters, and AL 1 440 000. From these and the included angle BAL, of 39° 32′ 58″, the angle ALB comes out, by the 3rd [proposition] of Plane Oblique-angled Triangles, as 1′ 50″; therefore the whole parallactic angle CLB is very nearly 3′ 40″. Now let the Polar star be at V, whose latitude EV, that is, the angle EAV, is 66° 2′; and in the triangle CAV, besides the angle already mentioned, let there be given, as above, AC, 1200, and AV, 1 440 000 semidiameters of the earth. The angle AVC will be found to be 2′ 38″, and BVC nearly 5′ 16″. So great, then, would the parallax in the altitude of these stars appear if they could be viewed on the Meridian from the earth carried from B to C through the whole diameter BAC. But if Kepler's distances are taken, AB 3469 and AL or AV 60 000 000, ALB comes out as 8″ and CLB nearly 16″; but AVC as 12″ and CVB nearly 24″.

[Margin: Proof of the Minor.]

The MINOR is proved because neither have we detected so great a parallax in the altitude of Sirius, nor have either we or Tycho detected it in the altitude

of the Polar star. Indeed, in the Year 1586 Tycho observed the greatest meridian altitude of that star at midnight after the autumnal Equinox; and in the Years 1577, 1581, 1586 and 1589, after the winter Solstice, he observed its least altitude towards morning and its greatest after evening; and from all these observations he found its distance from the pole of the world always the same. In particular, in the Year 1586 he found it, from the Equinoctial and the winter observation, to be 2° 56′ 10″, when he ought to have found a different one because of the Earth's translation over the space of three months; and he detected no parallax at all, not even of ten Seconds, as Longomontanus also relates in Book 1 of the *Theorics*, chapter 1, page 159. Kepler too confirms this in Book 4 of the *Epitome of Copernican Astronomy*, page 493, saying of Tycho: *"He observed the greatest altitude of the polar star, which at this time is in 7° of Aries, in the year 1586, at midnight after the autumnal equinox, and it was 58° 51′. He observed the same also about the winter Solstice, on December 26, at about hour 6 in the evening, and again found 58° 51′; so there was no difference at all. Yet in the month of September the horizon cut the sphere of the Fixed stars lower, by almost the whole semidiameter of the orb in which the earth is carried round, than on December 26, since then the Sun appeared in Libra, now in Capricorn. The same happened also when the least altitude was observed at midnight after the vernal Equinox, and after the winter Solstice in the morning at hour 6: on both occasions 52° 59′ 30″ was found, although in the month of March the Horizon cut the Fixed stars higher, by almost the whole semidiameter of the orb in which the Earth is carried, than in December. Therefore this diameter of the orb in which the earth is carried round is not sensible with the Brahean instruments."*

[Margin: Reply 1, Kepler's, a faulty one.]

VII. 1. Kepler would reply, on the same page 493, by denying the Major, because from his distances there does not follow a parallax of the annual orb greater than 12 Seconds, which he denies can be perceived by any diligence of craftsmen, especially *since the diameter of the polar star appears to equal at least one minute, and the diligence of craftsmen is not to be trusted about a fifth part of one minute.* But this reply suffers from four faults. *First*, it estimates the parallax at 12″ from the semidiameter of the annual orb alone, whereas the whole parallax, which must be estimated from the diameter, is 24″, as is clear from the table set out in number 3. *Second*, the apparent diameter of the Polar star is

only 7″ 54‴, or at most 8″, according to our corrected observations given in Book 7, section 6, chapter 11, in the first table. *Third*, even if this diameter were one minute, threads so fine can nevertheless be stretched at the centre of an astronomical quadrant that one can sight along them at the very centre of the star, and its disc is cut in two by them. *Fourth*, he does an injustice to his own Tycho, who often asserts in his *Mechanica* that he observed the altitudes of the Sun and of the Fixed stars down to a distinction of ten Seconds, that is, of the sixth part of one minute.

[Margin: Reply 2, Hortensius's, a faulty one.]

VIII. 2. Hortensius, in the dissertation with Gassendi on Mercury seen under the ☉ [Sun], replies by denying the Minor: for he admits a parallax of 30″, but

denies that it can be clearly perceived with any instruments. But his reply too errs in two ways. *First*, that parallax was derived by him from the semidiameter of the annual orb alone; from the whole diameter it comes to 60″, that is, a whole minute. *Second*, he too does an injustice to Tycho and to other more diligent Astronomers of this century, who in observing the altitude of the stars descend at least to tens of Seconds.

[Margin: Reply 3, Mästlin's and Hérigone's, insufficient.]

IX. 3. Mästlin, in his addition to the *Narratio prima* of Rheticus, page 114, and Pierre Hérigone, in volume 5 of his *Cursus Mathematicus*, page 615, reply by denying the Major. For although the parallax arising from the annual orb is in itself so great that, if the same star could be seen on the Meridian or on the same vertical by the same observer, remaining at the same Horizon, in two observations taken six months apart, it would be 3′ near the pole of the Ecliptic, as Hérigone grants — or 2′ or 3′ in stars rising or setting about midnight, as Mästlin admits — yet it is unobservable per accidens. This is either because of the horizontal refractions of stars rising or setting, or because, if a star appears on the Meridian once by night, it cannot appear on it six months later, the daylight of the Sun preventing it; and after three months that parallax would be much less than 2′ or 3′, and so, because of its smallness, not clearly sensible. But this reply too, unless something else is added, is insufficient, at least as regards stars observable on the Meridian. *First*, Sirius, the Sun notwithstanding, can be observed six months later on the same Meridian on which it was observed before, as I said in the proof of the Major. *Second*, the very parallax that Hérigone admits will occur after 6 months is, from his own distances, nearly three Minutes, since it is estimated from the semidiameter; for the parallax from the whole diameter would be 6 minutes, as is clear from the table of number 3. And who would deny that a parallax of 3 Minutes can be perceived, on account of its smallness, unless he were utterly unskilled in astronomical observations?

[Margin: Reply 4, ours.]

X. 4. The reply, therefore, is to deny the Major. *First*, because Copernicus wants so great a distance of the Fixed stars to be assumed that all parallax of the annual orb vanishes, even if this interval had to be increased finitely to infinity. And although the Major tells against Hérigone, and almost against Mästlin and Hortensius — especially in Sirius, which some of them thought could not be observed on the Meridian once and again six months later — it does not tell in the same way against the other Copernicans in the table of number 3, and much less against Kepler. For that parallax, as great as it comes out when derived from the whole diameter of the annual orb according to their distances, can be fitted only to stars placed at the pole of the Ecliptic, and none of these can be seen on the Meridian once and again six months later, since the brilliance of the Sun prevents one of the two observations. Sirius, on the other hand, which can be seen twice, at the two ends of roughly six months, is so far from the pole of the Ecliptic that the parallax of the annual orb on Kepler's distances does not come out greater than 16″. The parallax that would reach

24″ in the polar star is not observable, since the light of the Sun prevents one of the observations. And the distance of these and of all the Fixed stars from the pole of the Ecliptic, like their latitude, is invariable. *Second*, because the Parallax which in itself would be observable after an interval of three months in other Fixed stars visible on the Meridian by night, if the centre of the Earth ran from N to A along the very diameter of the annual orb, cannot in fact be observed, since the centre of the Earth is carried along the circumference of the annual orb from C to D. In that position neither the diameter nor the semidiameter of the annual orb can fall in the plane of the Meridian, and so no triangle can be formed in which a parallactic angle arises. It is no wonder, then, if after three months no parallax of the orb, or of the semi-orb, can be observed, in this hypothesis of the Earth's motion as well. *Third*, because not even the Parallax of Sirius already mentioned is observable, for another reason: namely, when Sirius appears on the Meridian at sunrise or sunset, the Sun appears to the Earth under the Equinoctial points, or near them, and not under the Solstitial points; and in the Copernican hypothesis the Earth is at or near the Equinoctial points, in which position the diameter of the annual orb through the centre of the earth lies in a plane entirely different from the plane of the Meridian — for it lies in the plane of the Horizon, and cuts the plane of the Meridian nearly at right angles. Hence no triangle can be formed on it in which the meridian altitude and its parallax arise.

II. Argumentum à Parallaxi Orbis Annui in Distantia Sirij à Sole.

Argument 2, from the Parallax of the annual orb in the Distance of Sirius from the Sun.

XI. *If the Earth moved through the annual Orb, some Parallax of the annual Orb would appear in the distance of Sirius, taken from the Sun once when it is rising and again, 6 months later, when it is setting. But none appears. Therefore, etc.*

The MAJOR is proved by taking up again the figure set out in number 1, in which, however, let EFG be a great circle drawn through the Equinoctial points (which are here to be imagined as G and E) and through the centre L of Sirius. For since Sirius is seen not only when the Sun rises or sets at or near the equinoctial points, but also somewhat after sunrise and before sunset, its distance from the Sun can be taken. Let AF, then, be the solstitial colure, and Sirius at L. When the Sun A rises to the eye at O, near the autumnal Equinox, Sirius will appear distant from the Sun by the acute angle AOL; but when, near the vernal Equinox, the Sun sets to the eye at I, Sirius L will appear distant from the Sun by the obtuse angle AIL (supply what is missing in the figure). Therefore the difference between the angles already mentioned will be the parallax arising from the annual orb.

The MINOR is proved by experience, because no such parallax in fact appears in the distance of Sirius from the Sun.

Father Francesco Maria Grimaldi proves the same Major in another way. If the earth is at A, the distance of Sirius from the Sun at B, the point of the

Autumnal Equinox, when it is rising, observed through the angle BAL, together with the same distance of Sirius from the Sun when it is setting at C, the point of the Vernal Equinox, observed through the angle CAL, will make up two right angles, or 180°, by [proposition] 13 of the first book of Euclid. But if, with the Sun motionless at A, the earth, placed now at B, observes the distance of Sirius from the Sun through the angle LBA, and now at C observes the same through the angle LCA, these two distances will not make up 180°; the quantity of the parallactic angle BLC will be lacking.

[Margin: Reply to Argument 2.]

XII. I reply by denying both the Minor and the consequence of the Major. For that difference between the obtuse and the acute angle does not arise from the motion of the Earth through the annual orb, but from the distance of Sirius from the solstitial colure, since Sirius in this century is nearer to the autumnal Equinox than to the vernal. So it comes about that, whether the Earth moves through its annual orb or the Sun through its annual one, Sirius must appear distant from the rising Sun at the autumnal Equinox by an acute angle, and from the setting Sun at the vernal Equinox by an obtuse angle. But if Sirius were at F, the point of the solstitial colure, it would appear, in the hypothesis of the Earth moving as much as in that of the Earth at rest, distant from the Sun at either Equinox by a right angle, AIF and AOF, formed by one line running straight from the eye to the centre of Sirius and by another which would be tangent to the earth at the point of the eye; and that same line would be the physical Horizon, in which the centre of the Sun would rise or set for the eye at O and at I. I say nothing, meanwhile, of the variation of the Solar refractions at the horizon, which could disturb the clarity of this parallax even if it were otherwise sensible in itself — although Copernicus would avoid this sensibility by increasing the distance of the Fixed stars to infinity. And from this, likewise, the reply is given to the other proof of the Major: namely, that because of the immense and unconstrained distance of the Fixed stars the lines AL, BL, CL would all turn out parallel, and therefore the angles at A, B, C would appear equal; besides which, that observation is too slippery, and it can scarcely happen that the Equinox falls at the rising or setting of the Sun.

III. Argumentum à Parallaxi in Magnitudine apparenti Fixarum.

Argument 3, from the Parallax in the apparent Size of the Fixed stars.

XIII. *If the Earth moved through the annual orb, a great variation would appear in the apparent diameter of the Fixed stars. But none appears. Therefore, etc.*

[Margin: Reply to Argument 3.]

The reply is to deny the Major, because not even in Sirius would the variation be greater than 4‴, even if Sirius were supposed to be in the Ecliptic, as was shown in number 5, and if the stars were no less distant from the centre of the World than 1,440,000 terrestrial semidiameters, as Hérigone posits; and so slight a difference as 4‴ cannot be clearly observed with any instruments. How much less, if the star were far from the Ecliptic, or if Kepler's distance

of the Fixed stars were assumed, or as great a distance as Copernicus allows, who allows so great a one in his hypothesis that every difference of this kind becomes entirely insensible. As for the fact that in the Planets, especially in Mars and Venus, a notable variation of apparent size is seen, this is no more an argument for these Planets approaching an immobile Earth than for a moving Earth approaching them.

CAPVT XXIX. Proponuntur Tria Argumenta Contra motum Telluris Annuum, sumpta ex nimia Distantia Fixarum, & magnitudine Octauæ sphæræ. Vbi opiniones de illarum Distantia ex Copernicanorum varijs hypothesibus recensentur cum fundamentis earum.

Chapter 29. Three Arguments against the annual motion of the Earth are proposed, taken from the excessive Distance of the Fixed stars and the size of the eighth sphere. Here the opinions on their Distance drawn from the various hypotheses of the Copernicans are reviewed, together with their grounds.

I. From number 4 of the preceding chapter it is established that, if the parallax of the Fixed stars arising from the annual Orb of the Earth must be unobservable, or at least not exceed 10″, the distance of the Fixed stars must be greater than 47,000,000 terrestrial semidiameters, as is gathered from the table placed there. But from so great a distance it follows that between Saturn and the Fixed stars there is an incredible space, and that the sphere of the Fixed stars is of an immense bulk, surpassing almost all belief. But since different authors suppose different values in computing each of these magnitudes, I think it right to rehearse the principal opinions here — those of the Copernicans themselves, those of others, and our own.

Opiniones Copernicanorum.

Opinions of the Copernicans.

[Margin: Opinion 1, that of Aristarchus of Samos.]

II. The *first* and most ancient Opinion was that of Aristarchus of Samos. Although he said that the annual orb, through which he held the Earth to be carried round, is to the sphere of the Fixed stars as a point or centre, he must be understood in the sense in which Cosmographers usually say that the Earth is like a point with respect to the heavens, namely to the senses. And this is how Archimedes kindly interpreted him at the beginning of the *Sand-Reckoner*: having said that it is impossible for the Earth's annual orb to be to the sphere of the Fixed stars as a centre, because a centre is nothing, or has no ratio at all to a sphere, he added: *"But it must be granted that Aristarchus meant this: since we suppose the Earth to be placed about the centre of the world, he thought it must be laid down (taking his demonstrations from the Phenomena) that the ratio which the Earth has to the World as we have described it is the same ratio that the sphere of the circle carrying the Earth round has to the sphere of the Fixed stars."* Now the

World which Archimedes had described a little before is the annual orb of the Sun itself, for he had said: *"You are not unaware that most astronomers call the World the sphere whose centre is the centre of the Earth, and whose Radius is equal to the straight line lying between the centre of the Sun and the centre of the Earth."* So, on Archimedes' interpretation, Aristarchus thought that the ratio between the annual orb and the orb of the Fixed stars is the same as that between the Earth and the annual orb. We must therefore find this ratio according to the view of Aristarchus.

[Margin: Aristarchus's view on the distance of the Sun.]

Now Aristarchus, in the book *On the Sizes and Distances of the Sun and Moon*, proposition 7, demonstrated this Theorem: *"The distance by which the Sun is distant from the Earth is greater than eighteen times the Moon's distance from the Earth, but less than twenty times."* That is to say, it is to the Moon's distance as 19, approximately, to 1. Plutarch alludes to this in Book 2 of *De placitis Philosophorum*, chapter 31, and Pliny the Elder in Book 2, chapter 21, saying: *"Many have also tried to investigate the distances of the stars from the Earth, and they have reported that the Sun is nineteen parts as far from the Moon as the Moon itself is from the Earth."* Now according to the Ancients the Moon is distant from the earth by 64 terrestrial semidiameters, which multiplied by 19 make the Sun's distance, that is, the semidiameter of the Annual Orb, 1216 semidiameters of the earth; and there are as many diameters of the earth in the diameter of the annual orb. This number 1216 multiplied by itself gives the Square number 1478 656, which multiplied again by 1216 makes the Cubic number 1788 045 696; while the cube of one diameter of the Earth is unity, or 1. Aristarchus therefore holds that the sphere of the Fixed stars contains the annual orb nearly 1800 000 000 times, and that the semidiameter of the annual orb is to the semidiameter of the sphere of the Fixed stars as the semidiameter of the Earth is to the semidiameter of the annual orb. Let it be, then, as 1 to 1216, so 1216 to a fourth term, and the semidiameter of the orb of the Fixed stars will come out as 1478 656 terrestrial semidiameters. Mästlin too, among others, admits this proportion, as we shall see shortly.

[Margin: Opinion 2, Mästlin's.]

III. The *second* Opinion is that of Michael Mästlin, in his additions to the *Narratio prima* of Georg Joachim Rheticus, page 114. There he does not hesitate to admit, in Fixed stars rising or setting about midnight, a horizontal parallax of two or three Minutes, which he nevertheless denies can be observed in that position, because of the horizontal refractions that absorb it. He adds that the Copernican hypothesis does not require the distance of the Fixed stars to vanish entirely when compared with the distance of the Sun from the Earth, but only that it vanish to the senses and the judgement of the eyes, that is, that the parallax cannot be observed; and that it neither contradicts Copernicus nor leads to any absurdity if the distance of the Fixed stars from the centre of the universe contains the greatest distance of Saturn from the same centre seven hundred times and more. Taking Saturn's distance from Tycho as 12 900 terrestrial

semidiameters, the distance of the Fixed stars then contains 9 030 000 terrestrial semidiameters, 12,900 being multiplied, that is, by 700. But a little later he says: *"He therefore cannot be convicted of any absurdity who does not hesitate to assert that the ratio of the distance of the fixed stars from the centre of the World is at the least equal to the ratio of the distance of the Sun from the Earth, that is, to the semidiameter of the Great Orb, and that on this account the Orb of the Fixed stars can also, in this way, be called like the infinite."* This is exactly what we showed in number 2 that Aristarchus held. Now the mean distance of the Sun from the Earth, from what was said in Book 3, chapter 7, is for Mästlin 1160 semidiameters of the earth. If, then, it is made as 1 to 1160, so 1160 to a fourth term, the distance of the Fixed stars will come out as 1 345 600 terrestrial semidiameters. Lower down on the same page he writes as follows: *"It is therefore beyond doubt that Copernicus had regard to the judgement of the eyes, not to the universal exclusion of all parallax; for this remoteness of the starry orb is sufficient for the demonstrations of the motions, a remoteness because of which, and in comparison with which, the size of the Great Orb cannot be discerned by the eyes. And that this remoteness, indicated in the way described and weighed according to all the circumstances, should, even if it does not exceed the greatest altitude of Saturn seven hundred times, yet equal it a hundred or two hundred times, is altogether most probable."* Since, then, he says in the same place that the greatest distance of Saturn from the centre of the world rises to 12 900 semidiameters of the earth, and that a distance that great, or no less, is established by Astronomical demonstrations, it follows that the most probable distance of the Fixed stars from the centre of the World, in his opinion, is either 1,290,000 or even 2 580 000 semidiameters of the Earth. Finally, elsewhere he sets almost the same distance as Galileo, namely 13 046 400 terrestrial semidiameters. So inconsistent was he on this matter, as the figures below show; among these, however, he seems to have settled on the middle one,

which contains Saturn's distance two hundred times, that is, the one that has 2 580 000 terrestrial semidiameters.

Distance of the Fixed stars from the centre of the World admitted by Mästlin, in semidiameters of the Earth
1 290 000
1 345 600
2 580 000
9030 000
13 046 400

[Margin: Opinion 3, Kepler's.]

IV. The *third* Opinion was Kepler's, in his book on the New Star in Serpentarius (*De stella nova*), chapter 16. There he gives the Sun a semidiameter of 6 semidiameters of the earth, the Earth's distance from the Sun 1432 terrestrial semidiameters, and Saturn's distance ten times this, namely 14 320; and he says it is probable that Saturn's distance is the mean proportional between the two

immobile bodies, that is, between the Sun, the mover of the Planets, and the sphere of the Fixed stars. He therefore makes it: as 6 to 14 320, so 14,320 to 34 077 066⅔ terrestrial semidiameters; and that is the distance of the Fixed stars he sets there. But in the *Epitome of Copernican Astronomy*, Book 4, pages 479, 485 and 492, he chooses a semidiameter of the Sun of 15 terrestrial semidiameters, a distance of the Sun from the Earth of 3469 semidiameters of the earth, and a distance of Saturn of 30 000 semidiameters of the earth. Keeping, then, the same proportion mentioned above, he makes it: as 15 to 30 000, so 30 000 to 60 000 000 semidiameters of the earth; and he rests content with this distance of the Fixed stars.

[Margin: Opinion 4, Lansbergen's and Hortensius's.]

V. The *fourth* Opinion was that of Lansbergen, formerly, in his commentary on the motion of the Earth, and of Martinus Hortensius, in the dissertation with Gassendi on Mercury seen in the Sun and Venus unseen. They judged that the parallax of the Fixed stars produced by the annual orb can reach 30″ without evident inconvenience to observation; and from this, and from a semidiameter of the annual orb of 1498½ terrestrial semidiameters, they gathered by the rules of right-angled triangles a distance of the Fixed stars of 10 312 227 terrestrial semidiameters. But later that parallax seemed too great to Lansbergen. In Book 3 of the *Uranometria*, element 7, he therefore makes it: as the periodic time of one revolution of the Earth through the annual orb, that is, one year, is to the radius of its orb, 10000, so the periodic time of the revolution of the Fixed stars, which he sets at 28 000 years, is to the radius of the sphere of the Fixed stars, 280 000 000. Since, then, the radius of the annual orb is for Lansbergen 1498½ terrestrial semidiameters, if it is made as 10 000 to 1498½, so 280 000 000 to a fourth term, the distance of the Fixed stars comes out as 41 958 000 terrestrial semidiameters. From this he concludes that the ancient and the more recent Astronomers were utterly mistaken in making one heaven out of two, since between the heaven of the Planets and the heaven of the Fixed stars there is a vast gap; and that, as the Sun is the centre of the Planetary sphere, so the whole sphere of the Planets is, as it were, the centre of the sphere of the Fixed stars.

[Margin: Opinion 5, Galileo's.]

VI. The *fifth* Opinion was Galileo's, in the third dialogue on the System of the World. There, on page 244 of the Latin and 323 of the Italian, he does not disapprove of Simplicio saying that it is more probable that not all the Fixed stars are equally distant from the centre of the World, but some higher than others, and that their innumerable multitude is contained between two surfaces, one convex and the other concave, separated from each other by a great interval; and he confirms this on page 284 of the Latin. On page 270 of the Latin and 357 of the Italian he determines the distance of the Fixed stars from the ratio of the periodic revolution of the Fixed stars, which he takes from Ptolemy as 36 000 years. Since, then, the revolution of the Sun, or of the Earth, is completed in one year and that of Saturn in 30 years, while Saturn's distance, as he thinks, is nine times higher than the Earth's, he argues thus: *"If the orb of*

Saturn, being nine times greater than the orb of the Sun, revolves in a time thirty times greater, then by the ratio reversed [per rationem euersam] the orb, or distance, of the Fixed stars, since it revolves 36 000 times more slowly, must be 10 800 semidiameters of the Great Orb." In this way this distance comes out five times greater than the one he had computed a little before from the hypothesis that a Fixed star of the sixth magnitude equals the Sun, namely on page 266 of the Latin and 351 of the Italian, where from that supposition he had deduced a distance of the Fixed stars of not more than 2160 semidiameters of the Great Orb; and in the same place he had said that the distance of the Sun from the earth is, by the agreement of all, 1208 terrestrial semidiameters. Multiplying, then, 10,800 by 1208 gives 13 046 400 for the distance of the Fixed stars from the centre of the World.

[Margin: Opinion 6, Hérigone's.]

VII. The *sixth* Opinion is that of Pierre Hérigone, who in volume 5 of the *Cursus Mathematicus*, page 618, assumes a distance of the Sun from the Earth of 1200 terrestrial semidiameters, and on page 615 supposes that the ratio of the semidiameter of the Earth to the semidiameter of the annual orb is the same as that of the semidiameter of the annual orb to the semidiameter of the Firmament. Hence, if it is made as 1 to 1200, so 1200 to a fourth term, the distance of the Fixed stars comes out as 1 440 000, from which he gathers a parallax of 2′ or 3′.

[Margin: Opinion 7, Gassendi's.]

VIII. The *seventh* Opinion is that of Pierre Gassendi, in the second letter *De motu impresso a motore translato*. He asserts that in the Copernican hypothesis the size of the World must be conceived as so great that the whole sphere of the heaven of the Planets, seen from the Fixed stars, would appear like a single star — in the way that the cluster of Jupiter and the Jovian stars appears to us as a single Planet — or at least so that the whole annual orb, seen from the Fixed stars, would be [?] as it were a point, or as it were the least of the tiny stars. Taking, then, a semidiameter of the annual orb of 1150 semidiameters of the earth, which he does not reject in Tycho in Book 2 of the *Institutio Astronomica*, and an apparent semidiameter of the smallest Fixed stars visible to the naked eye which we established, in Book 6, chapter 11, is not two Seconds, since the little star Alcor has an apparent diameter of only 4″ 24‴ — from this angle, I say, and from the side opposite it, of 1150 semidiameters, by the problem given in the preceding chapter, number 5, it follows that the distance of the Fixed stars is 118 602 274 terrestrial semidiameters.

[Margin: Gassendi, once a Copernican but not afterwards.]

I have counted Gassendi among the supporters of the Copernican sect because he did in fact favour it for a long time, before he had seen the decrees of the sacred Congregation; once he had seen them, or heard of them, he acquiesced piously and prudently, as is clear from the end of the same letter.

Opiniones non Copernicanorum, sed ex Hypothesi Copernicæa disserentium.

Opinions of those who are not Copernicans, but who reason from the Copernican Hypothesis.

[Margin: Opinion 8, Magini's.]

IX. The *eighth* Opinion was that of Giovanni Antonio Magini, who in Book II of the *Primum Mobile*, Problem 29, has these words: *"To leave aside the opinion of Copernicus, who asserts that between the sphere of Saturn and the Eighth there is so immense a vastness that the eighth sphere is removed from the Earth by at least 7 850 000 semidiameters."* This number, however, is nowhere found in Copernicus. But whether Tycho took the number from here, or Magini took this number from Tycho, I do not know.

[Margin: And Tycho's.]

Certainly Tycho, in the letter to Rothmann dated 1589 November 24, old style, page 167, has these words: *"As for the other motion of the Earth, the Annual, which would remove the eighth sphere so far that the Orb this motion would describe vanishes with respect to it: tell me, does it seem probable to you that the space from the Sun, then the centre of the universe, to Saturn should be contained more than 700 times between Saturn and the sphere of the fixed stars, and that all of it should be filled with no stars at all? Yet this must be so, if the Annual Orb of the Earth is to appear even as large as one Minute. Indeed, then the Fixed stars of the third magnitude too, which have one minute in diameter, will necessarily be equal to this whole Annual Orb, that is, they will comprise in their diameter 2284 semidiameters of the Earth; for they will be distant 7 850 000 of the same semidiameters, approximately."* So too, in volume I of the *Progymnasmata*, page 481, he affirms that it follows from the Copernican hypothesis that, if the semidiameter of the annual orb must vanish against the distance of the Fixed stars, this distance is 700 times greater than the distance of Saturn from the centre of the World.

[Margin: Opinion 9, Longomontanus's.]

X. The *ninth* Opinion, the one closest to the Tychonic, is that of Longomontanus, in the *Astronomia Danica*, Book I of the *Theorics*, chapter I, folio 159 in my copy. He takes from Tycho a semidiameter of the Annual Orb of 1150 terrestrial semidiameters, and holds that the annual Orb, in order to vanish against the sphere of the Fixed stars, must be of one minute, and so the semidiameter of the annual Orb must subtend an angle of 30″. Let the figure set out in the preceding chapter, number 5, now be repeated here, and in it let DP be the semidiameter of the annual orb, subtending the angle DCP of 30″; and so let the other acute angle, CPD, in the triangle CDP, right-angled at D, be 89° 59′ 30″; and let the distance of the Fixed stars, CD, be sought by his Method, which is this. As 1 454 441, the right Sine of the angle DCP of 30″, is to the side DP, of 1150 semidia-

meters of the earth, so 9 999 999 894, the right Sine of the angle CPD, of 89° 59′ 30″, is to CD, 7 906 818 semidiameters of the earth, that is, to the distance of the Fixed stars; and this is somewhat greater than the one Tycho deduced.

[Margin: Opinion 10, Scheiner's.]

XI. The *tenth* Opinion is that of our Christoph Scheiner, in the *Disquisitiones Mathematicae*, pages 25, 26 and 27. To remove the Fixed stars from all suspicion of parallax, in keeping with Copernicus's mind, he uses this proportion: as the Earth's Semidiameter, 1, is to Saturn's greatest distance, 10 872 terrestrial semidiameters, so the semidiameter of the annual Orb, 1208 terrestrial semidiameters, is to the distance of the Fixed stars, 13 133 376 terrestrial semidiameters. He confirms that this is not excessive from Tycho, Book 1 of the *Progymnasmata*, pages 480 and 481, who says that the Copernican distance of Saturn from the Earth is 12 900 terrestrial semidiameters, and that this must be multiplied more than seven hundred times to obtain the Copernican distance of the Fixed stars. And so, if it is multiplied by 800, Scheiner obtains 10 320 000 terrestrial semidiameters, that is, not much less than the preceding.

[Margin: Opinion 11, Chiaramonti's.]

XII. The *eleventh* Opinion is that of Scipione Chiaramonti, in the Italian defence of his *Antitycho*, part 4, chapter 13. There he assumes from Copernicus that the semidiameter of the Annual Orb is like a point compared with the semidiameter of the Firmament, so that the same Fixed star can be seen through a sight [dioptra] parallel to the horizon whether the eye is at the centre of the annual orb, or on its circumference, or on the surface of the Earth; and that the chord subtending the diameter of a Fixed star is at least 1105 terrestrial semidiameters, which is the least distance of the Sun from the earth according to Copernicus. Cubing 1105, then, he obtains 1 349 232 625, namely the ratio of the solid area, or solidity, of such a star to the solidity of the terrestrial globe (though he ought to have said: to the eighth part of the Earth's solidity). "But," he says, "the Sun contains the Earth only 166 or 167 times; therefore such a star would contain the Sun 8 079 237 times." And since Galileo, in the dialogues, page 265 of the Italian, had said that the Fixed stars are no less bright than the Sun, he concludes that if a single Fixed star is greater than the Sun 8 079 237 times, and yet should give no more light than the Sun, then, for the distance to be proportional to the size, the distance of the Sun, which is 1105 semidiameters of the earth, must be multiplied by 8 079 237; that is, the distance is 8 927 556 885 terrestrial semidiameters.

[Margin: Opinion 12, ours.]

XIII. The *twelfth* Opinion is ours: namely, that the distance of the Fixed stars must be so great that, when the Earth is carried through the annual Orb from one point of the annual circumference to the opposite point, no sensible parallax at all — that is, one of 10″ — can be observed in any Fixed stars, not even in those placed at the poles of the Ecliptic. On this supposition, from the various semidiameters of the annual orb set by the Copernicans, or by quasi-Copernicans, we derived a different distance of the Fixed stars by the Problem given in the preceding chapter, number 4, where we also displayed a table for these distances. We shall nevertheless repeat it here, so that it can be

compared alongside the distances collected from others up to this point. Here, then, in the following Synopsis, are the opinions already mentioned.

Table I. Distance of the Fixed stars deduced from the Copernican Hypothesis by various authors, with respect to the centre of the Earth or of the Universe

Order of the opinions	**Authors**	**Semidiameters of the Earth**
1	Aristarchus	1 478 656
		1 290 000
		1 345 600
2	Mästlin	2 580 000
		9 030 000
		13 046 400
3	Kepler, in the New Star	34 077 066⅔
	But in the *Epitome of Astronomy*	60 000 000
4	Lansbergen formerly, and Hortensius	10 312 227
	Lansbergen afterwards	41 958 000

Remainder of the Preceding Table

Order of the opinions	**Authors**	**Semidiameters of the Earth**
5	Galileo	13 046 400
6	Hérigone	1 440 000
7	Gassendi	118 602 274
8	Magini and Tycho	7 850 000
9	Longomontanus	7 906 818
10	Scheiner	13 133 376
11	Chiaramonti	8 927 556 885
12	We, taking the Semidiameter of the Annual Orb from: Copernicus	47 439 800
	Hérigone	49 502 400

	Ourselves	301 146 419

Table I. Distance of the Fixed stars deduced from the Copernican Hypothesis by various authors, with respect to the centre of the Earth or of the Universe

	Wendelen	604 589 312

De Mole & Distantia Sphæræ Fixarum comparata ad molem Terræ, Orbis annui, & Orbis Saturni, & ad Distantiam Solis ac Saturni.

On the Bulk and the Distance of the Sphere of the Fixed stars, compared with the bulk of the Earth, of the annual Orb and of the Orb of Saturn, and with the Distance of the Sun and of Saturn.

XIV. An argument against the Copernican hypothesis can be taken not only from the distance but also from the bulk of the sphere of the Fixed stars, and that bulk seems comparable above all with three bodies: with the globe of the Earth; with the Great, or annual, Orb, which the Ptolemaic hypothesis would call the sphere of the Solar heaven; and with the Orb of Saturn, that is, with the whole sphere enclosing the whole system of the elements and of the Planets. Since this is so, we must derive the bulk from the distance of the Fixed stars, that is, from the semidiameter of the sphere of the Fixed stars, by proposition 18 of book 12 of Euclid's *Elements*, where it is shown that spheres are to one another in the triplicate ratio of their diameters, or by proposition 12 of book 8 of the same *Elements*, by which it is shown that spheres are to one another as the cubes of their diameters; on these we have said more in Book 7, section 6, chapter 8, problem 8. It is not worth the trouble, however, to bring in all the distances of the Fixed stars reviewed a little earlier, or their exact numbers. It suffices to use some selected ones, the more notable — partly the extremes, partly the middle ones — and their numbers rounded in Millions of terrestrial semidiameters. Further, we shall always make the semidiameter of the orb of Saturn ten times the semidiameter of the annual orb; how great the semidiameter of the annual orb is, we have already said in the preceding chapter, in the table of number 4, and in Book 3, at the end of chapter 7. On these premises, let us display in the following table the diameters of the three spheres — namely of the annual orb, of the sphere of Saturn, or the Planetary sphere, and of the sphere of the Fixed stars — in parts of which the diameter of the terrestrial globe is one, so that from this we may afterwards derive the proportion of the spheres.

Table II. Diameters of the Three Notable spheres, expressed in diameters of the Earth

From the Authors	**Annual Orb: Diam. of the Earth**	**Sphere of Saturn (♄): Diam. of the Earth**	**Sphere of the Fixed stars: Diam. of the Earth**
Aristarchus	1216	12160	1 500 000
Copernicus	1142	11420	47 000000

Table II. Diameters of the Three Notable spheres, expressed in diameters of the Earth

Mästlin	1160	11600	2600 000
Hérigone	1200	12000	1400 000
Galileo	1208	12080	13 000 000
Scheiner	1208	12080	13 000 000
Tycho	1150	11500	8 000 000
Longomontanus	1288	12880	8 000 000
Boulliau	1460	14600	60 000 000
Lansbergen	1498½	14985	61 000 000
Kepler	3469	34690	60 000 000
Ourselves	7300	73000	300 000 000
Wendelen	14656	146560	600 000 000
Gassendi	1150	11500	120 000 000

[Margin: Notice for the following table.]

XV. Next, the cubic numbers of the numbers already mentioned must be found. This is done by multiplying them by themselves and multiplying the product again by the first number. Thus 1142 multiplied by 1142 makes this square number, 1 304 164, which, multiplied again by 1142, makes the cube, or cubic number, 1 489 355 288. In its place, however, we shall put in the following table the first two initial figures, namely 15, with 8 zeros [cyphrae], so that from these round numbers a sufficient judgement can be formed more quickly about the bulk of the Sphere of the Fixed stars compared with the bulk of the spheres of the annual Orb and of Saturn. Further, we shall not attach the zeros themselves, written out, to the initial figures, but the number of zeros to be added to the initial figures, so as not to give the Printers occasion to err. For the rest, when you see, for example, that 8 zeros are to be added to the initial figure 15, know that it is the same as if you read 1 500 000 000; and so for the others.

Table III. Cubes of the Numbers of the preceding Table, in round figures

Deduced from the Authors	**Cube of the Diameter of the Annual Orb, in cubic diameters of the Earth: Figures**	**with ze-ros**	**Cube of the Diameter of the sphere of Saturn, in cubic diameters of the Earth: Figures**	**with ze-ros**	**Cube of the Diameter of the sphere of the Fixed stars, in cubic diameters of the Earth: Figures**	**with ze-ros**
Aristarchus	18	with 8	18	with 11	23	with 16
Copernicus	15	8	15	11	10	22
Mästlin	17	8	17	11	18	18
Hérigone	17	8	17	11	27	17

Table III. Cubes of the Numbers of the preceding Table, in round figures						
Galileo	17	8	17	11	22	20
Scheiner	17	8	17	11	22	20
Tycho	16	8	16	11	51	18
Longomontanus	22	8	22	11	51	18
Boulliau	34	8	34	11	22	21
Lansbergen	34	8	34	11	23	22
Kepler	42	9	42	12	22	21
Ourselves	39	10	39	13	27	24
Wendelen	34	11	34	14	22	25
Gassendi	16	8	16	11	17	23

XVI. Dividing, then, the cube of the diameter of the sphere of the Fixed stars, set in the last column of the preceding table, by the cube of the diameter of the sphere of Saturn in the penultimate column, or by the cube of the diameter of the annual orb set in the 2nd column, you will find how many times, according to the hypotheses of the authors already mentioned, the sphere of the Fixed stars contains either the sphere of Saturn or that of the annual Orb. The cubic number set in the last column, moreover, shows by itself, without any further division, how many times the sphere of the Fixed stars contains the globe of the Earth. For example, according to Copernicus's hypotheses, the sphere of the Fixed stars contains the Earth 100 000 000 000 000 000 000 000 times, that is, the number 10 taken with 22 zeros; and so for the others. But dividing the same number by 15 with 11 zeros, the sphere of the Fixed stars contains the sphere of Saturn 66 666 666 666⅓ times. Finally, dividing the same number by 15 with eight zeros, the sphere of the Fixed stars contains the annual orb 66 666 666 666 666⅓ times; and so for the others. Let this, then, be Table IV, in which we have likewise chosen round numbers and their two initial figures, with zeros substituted in place of the remaining figures.

Table IV. The Sphere of the Fixed stars Contains the Planetary Sphere and the Annual Orb the Number of Times written below

Deduced from the Authors	**The Planetary Sphere**	**The Annual Orb**
Aristarchus	130 000	130 000 000
Copernicus	67 000 000 000	67 000 000 000 000
Mästlin	11 000 000	11 000 000 000
Hérigone	1600 000	1600 000 000

Remainder of Table IV

Table IV. The Sphere of the Fixed stars Contains the Planetary Sphere and the Annual Orb the Number of Times written below

Deduced from the Authors	**The Planetary Sphere**	**The Annual Orb**
Galileo	1900 000 000	1900 000 000 000
Scheiner	1900 000 000	1900 000 000 000
Tycho	32 000 000	32 000 000 000
Longomontanus	23 000 000	23 000 000 000
Boulliau	6500 000 000	6500 000 000 000
Lansbergen	65 000 000 000	65 000 000 000 000
Kepler	520 000 000	520 000 000 000
Ourselves	69 000 000 000	69 000 000 000 000
Wendelen	61 000 000 000	61 000 000 000 000
Gassendi	1100 000 000 000	1100 000 000 000 000

Let no one be surprised, however, if according to some Authors, who disagree greatly among themselves about the semidiameter of the Annual Orb, the total of the sphere of the Fixed stars compared with the annual orb, or with the Planetary sphere, nonetheless does not differ so much. For when the semidiameter of the annual orb is increased, the semidiameter of the orb of Saturn is also increased proportionally, and so are their orbs; and the result is that these orbs are contained fewer times in the sphere of the Fixed stars, since this sphere too must grow proportionally with the increase of the semidiameter of the annual orb, in order to avoid a sensible parallax — a parallax that would be the greater, the greater the semidiameter of the annual orb. It is no wonder, therefore, if among the measures of Copernicus, Lansbergen, Wendelen and our own, set in Table 4, there is so close an affinity, namely of the numbers 67, 65, 69, 61, with 9 zeros in the first column and 12 in the second. These matters having been prepared sufficiently, indeed abundantly, for the proof of the following Arguments, the arguments themselves must now be set out.

I. Argumentum ab Immensitate sphæræ Fixarum.

Argument 1, from the Immensity of the sphere of the Fixed stars.

[Margin: The Form of Argument 1.]

XVII. *If the Earth moved through the Annual Orb, the sphere of the Fixed stars would turn out Immense, and of an altogether incredible, or improbable, bulk. Therefore the Earth does not move through the Annual Orb.*

[Margin: Scheiner's argument from the vastness of the sphere of the Fixed stars.]

This is the substance of the Argument that Scheiner urges with such weight of words in the *Disquisitiones Mathematicae*, page 27, where he says: *"This so great immensity of the Firmament and vastness of the stars Copernicus himself noticed well enough, in Book 1 of the Revolutions, chapter 6; nor do his followers dare to hide it — so Rheticus, in the Narratio prima, page 118 — but from it they go on to magnify the majesty of the creator. Ridiculously, since they, that is, the stars, appear so tiny, and even the most learned man can scarcely grasp this enormity. But the wiser Astronomers, both of old and now, would rightly have taken this superfluous bulk ill."*

[Margin: And Archimedes's.]

At this point he also brings in Archimedes himself, as one who counts this bulk among impossibilities. The words of Archimedes, from the *Sand-Reckoner* [Arenarius], that is, from the book on the number of the sand, faithfully translated from the Greek, are these: *"Aristarchus of Samos, then, refuting and altering these things which are found written among the Astrologers, put out certain writings filled with certain hypotheses, from which it is evident that the World is much greater than the World described up to now. For he supposes that the fixed stars and the Sun remain motionless; that the Earth is carried around the Sun on the circumference of a circle which is situated in the middle of the course of the Planets; and that the Sphere of the Fixed stars is situated about the same centre as the Sun, and is of such a size that the circle about which the Earth is supposed to be carried has the same ratio to the distance of the Fixed stars as the centre of any sphere has to its surface. But this is manifestly impossible: since the centre of a sphere has no magnitude, it must not be supposed to have any ratio at all to the surface of the sphere. Yet it must be granted that Aristarchus understood this: namely, since we think the Earth placed about the centre of the world, he held that it must be established, by demonstrations drawn from the phenomena, that whatever ratio the Earth has to the World as described by us, that same*

proportion is had by the sphere of the circle that carries the Earth around, relative to the sphere of the fixed stars." Further, the World that Archimedes had spoken of before extends as far as the annual Orb of the Sun; for he had said at the beginning of the *Sand-Reckoner*: *"You are not unaware, however, that the World is called by many Astrologers the sphere whose centre is the centre of the Earth, and whose Radius is equal to the straight line that lies between the centre of the Sun and the centre of the Earth."* Although Archimedes, then, thought it absurd that the annual Orb should be like a point compared with the sphere of the Fixed stars, he nevertheless interprets Aristarchus more kindly, and gathers from his hypothesis that the proportion of the annual orb to the orb of the Fixed stars is that of the Earth to the annual Orb, or to the World as commonly understood. So, just as we are accustomed to say that the Earth is like a point compared

with the whole heaven, the annual orb would be like a point compared with the orb of the Fixed stars in Aristarchus's hypothesis — that is, not absolutely a point and nothing, but comparatively, or to sense. Whatever may be true of Aristarchus's mind, however, the Antecedent is now proved from Table 4, set out in number 16. For in it, if you take the smallest measure, the one dug out of Aristarchus, the sphere of the Fixed stars contains the annual Orb 130 000 000 times; but if you take the Copernican measure, 67 000 000 000 000 times; if Lansbergen's, 65 000 000 000 000 times; if ours, 69 000 000 000 000 times. Nor are the other measures, deduced from the hypotheses of others, so small that they do not contain an incredible vastness of the orb of the Fixed stars, as will be clear to anyone who surveys that Table.

[Margin: Reply to argument 1.]

XVIII. The Copernicans, however, *reply* by denying the Antecedent, namely that from the motion of the Earth through the annual orb there follows a Bulk of the sphere of the Fixed stars so great that it is incredible. The Reasons for which they deny that it is incredible or improbable are four.

[Margin: The 1st Reason of the Reply.]

The *first* is Mästlin's, who denies that, in Copernicus's mind, a distance of the Fixed stars, or a bulk of the sphere of the Fixed stars, is required so great that against it the distance of the Earth from the Sun, or the annual orb, vanishes entirely; it is enough, he holds, if it vanishes to sense. See his own words, already reported in number 3, in the 2nd opinion; and the 1st opinion, that of Aristarchus, which does not require so great a distance of the Fixed stars in the hypothesis of the moving Earth, supports him.

[Margin: The 2nd Reason of the Reply.]

The *second* reason, which Kepler and Galileo suggest, is the comparison of this distance and Magnitude of the sphere of the Fixed stars in the Copernican hypothesis with the speed of the same sphere in the Ptolemaic hypothesis. For they say that that Copernican Magnitude, though motionless, is far more probable than the Ptolemaic smallness moving with so rapid a speed. But this very comparison must be dealt with more calmly below, in chapter 30.

[Margin: The 3rd Reason of the Reply.]

The *third* reason is the comparison of the other spheres with one another, whose size must be admitted, and is admitted, in the hypothesis of the motionless Earth. Is not the heaven of the Fixed stars, says Gassendi in the second letter *De motu impresso*, page 124, by common opinion so vast that our Earth, however great, compared with it is nevertheless only like a point? Just as this, then, which is commonly reckoned a Paradox, is nevertheless most true in Astronomical rigour, why should it seem incredible that the whole annual Orb is like a point with respect to the sphere of the Fixed stars? Who would believe that the Sun, which is commonly reckoned a foot across, is greater than the Earth 38,600 times, as we showed in Book 3, chapter 11? Moreover, if you follow the opinion of many Copernicans, the excess of the Planetary sphere over the sphere of the terraqueous globe is greater than the excess of the sphere of the Fixed stars

over the Planetary sphere, or over the sphere of the annual orb. For, as above in Table 3, the Planetary sphere on Kepler's hypothesis contains the Earth approximately 42 000 000 000 000 times; but in Table 4 the sphere of the Fixed stars, on the same Kepler's hypothesis, contains the Planetary sphere only 520 000 000 times, and the annual Orb 520 000 000 000 times; and so for not a few others. Just as so great a vastness of the sphere of Saturn, and its excess with respect to our Earth, is not incredible to the wise, why then should a smaller excess of the sphere of the Fixed stars over the sphere of Saturn, or over that of the annual orb, seem incredible? For on this reasoning, says Galileo in the third dialogue, elephants will seem incredible to ants, and whales to little fish.

[Margin: The 4th Reason of the Reply.]

The *fourth* and chief reason is the commendation of the Divine Omnipotence and Magnificence, for which so great a bulk of the work wins esteem. And so *Copernicus*, having said in Book 1, chapter 10, that from the highest of the wandering stars, Saturn, to the sphere of the Fixed stars there is a very great distance, and that between the moved bodies, that is, the Planets, and the unmoved, that is, the Fixed stars, there lies the greatest interval, replaced incredulity with wonder, exclaiming: *"So great, indeed, is this divine Fabric of the Best and Greatest!"*

[Margin: Rothmann's opinion for the immensity of the heaven, in commendation of the Divine Majesty.]

So Christoph Rothmann, in the Letter to Tycho dated 1590 April 18, which is among Tycho's letters, page 186, replies to Tycho thus: *"Why should it not seem probable to me that the space from the Sun to Saturn is contained so many times within the remoteness between Saturn and the fixed stars? Or what absurdity follows if a star of the third magnitude equals the whole annual orb? Does this conflict with the divine will, or is it impossible to the divine Nature, or does it not befit an infinite Nature? You must demonstrate these things without fail, if you mean to gather some absurdity from this [?]. Things that commonly seem absurd at first sight cannot so easily be convicted of absurdity. But the Divine Wisdom and Majesty is far greater; and however great a vastness and size of the World you grant, it will still have no proportion to the infinite Creator. The greater the King, the greater and more ample the palace he thinks befits his Majesty. What will you think of GOD?"* And indeed Tycho himself, in the same Letters, page 191, conceded that the World is of almost infinite bulk, when he said: *"And although the heaven, the Universe, is indeed finite in place and in time, yet it is like the infinite in its incredible magnitude and perpetuity."* Why then, in the same place and on page 167, does he call incredible that Magnitude which the Copernicans ascribe to the sphere of the Fixed stars?

[Margin: The opinion of Rheticus and of Pliny, for the same.]

Rheticus, certainly, in the *Narratio prima*, commending this Copernican magnificence, more rightly confirmed it with that well-known sentence of Pliny's, Book 2, chapter 1: *"Of the world, or heaven, by whose curve all things are covered, etc., it is no concern of men to search out what lies outside, nor can the*

conjecture of the human mind grasp it. It is sacred, etc., immense, etc., finite and like the infinite."

[Margin: Mästlin's opinion, for the same.]

But Mästlin, in the additions to Rheticus's *Narratio prima*, page 114, judges it harsh, and almost injurious to the Divine Omnipotence and Wisdom, to call the sphere of the Fixed stars that Tycho gathered from the Copernican hypothesis too vast and useless.

[Margin: Lansbergen's opinion, for the same.]

So too *Lansbergen*, in Book 3 of the *Uranometria*, element 7, concludes: *"This is our opinion on the distance of the fixed stars from the Earth; and as it is not foreign to Geometry, so too it detracts nothing from the Majesty and the infinite Power of GOD, Best and Greatest, but rather magnifies and illustrates it much more. For it teaches that, since the sphere of the fixed stars is so vast, we must be astonished at the infinite Power of GOD the Architect, and worship and venerate it submissively."* So, finally, Gassendi, in the second letter *De motu impresso*, turning the argument back, says that just as the Ptolemaics argue that there is no reason to think God willed to make the World so vast and august, so the Copernicans argue that there is no reason to think God willed to make the World so narrow; and since neither side can demonstrate what pleased God, the latter opinion, which amplifies the majesty of things, seems the more to commend the Magnificence of the supreme Maker.

Finally, what if God willed to sketch, in so vast a bulk, some trace of infinity and immensity? What if, in proportion to the innumerable number of the Fixed stars, he granted them a region so much ampler than he granted the seven Planets? What if, for the sake of the Saints, he also willed to construct so great a proof of his works, so that they might see how much he has wrought for them and for the throne of Christ the Lord, and how much greater things are to be expected from him above the Empyrean?

[Margin: Baruch 3.]

Let the holy Prophet Baruch, indeed, close this reply with that Epiphonema: *"O Israel, how great is the house of God, and how vast the place of his possession? It is great and has no end; high and immeasurable."*

II. Argumentum ab Immenso Interuallo inter Saturnum & Fixas, eoq. Stellis vacuo & otioso.

Argument 2, from the Immense Interval between Saturn and the Fixed stars, an interval empty of Stars and idle.

[Margin: The Form of Argument 2.]

XIX. *If the Earth moved through the Annual Orb, there would be between Saturn and the Fixed stars an immense space, empty of stars and altogether idle. But this is absurd. Therefore, etc.* This argument, more than the preceding one, is made much of above all by *Tycho*, in the letters, page 167, whose words I have already reported in number 9, but chiefly on page 192, where

against Rothmann, who attributes so great a vastness to the divine Omnipotence, he says that God is indeed omnipotent, but does nothing in a disordered way; on the contrary, he disposes all things in weight, number and measure, and contrives nothing empty or useless, nothing that does not answer to itself in a fixed harmony; and that accordingly an interval of more than 7 000 000 semidiameters of the Earth, empty of stars and destined for no use of the Earth's inhabitants, ought not to be admitted between Saturn and the Fixed stars, since the Fixed stars themselves, which lie above it, were established for their use.

[Margin: Tycho's argument against [?] Copernicus.]

[Margin: Rothmann sings a palinode [?].]

And he adds: *"Away with this ageometry and asymmetry, this disordered way of philosophizing, utterly foreign to the divine Wisdom and Providence — which even ROTHMANN himself, when he was with me, no longer dared to defend; rather, in the course of our discussions, he at last admitted, not unwillingly, that a great absurdity, joined with an equal incredibility, lay beneath these things."* And a little later he confesses that the world is indeed finite and has no proportion to the infinite Creator, but that as regards its parts it is proportioned to the whole in the highest degree, just as one may see in the parts of animals, and above all in the Microcosm, that is, in the human body — the singular symmetry of which Microcosm *Durerus* [Albrecht Dürer] demonstrated. He presses the same absurdity in volume 1 of the *Progymnasmata*, page 481.

[Margin: Scheiner's argument against [?] Copernicus.]

No less sharply does *Scheiner* press it, on page 28 of the *Disquisitiones Mathematicae*, saying against the Copernicans: *"What good are such great machines — were they produced for the sake of so tiny a speck, the Earth? Why, then, are they so remote that they appear so small, and have almost no power over the Earth? What is that insane abyss between them and Saturn for? All things, it seems, are in vain."* Accordingly, at the end of the same page, he concludes thus: *"The Copernican motion of the Earth puts between Saturn and the Firmament an immense vastness of distance, the use of which they themselves do not know; therefore it does not seem admissible."* Finally *Longomontanus*, Book 1 of the *Theorics*, chapter 1: *"To what purpose is the empty gap between Saturn and the fixed stars, which is drawn from the premisses as* 7 894 818 *semidiameters of the earth?"*

[Margin: Proof of the Major.]

The MAJOR of our argument, moreover, is proved from Table II, set out in number 14: namely, if you subtract the numbers of the second column from the numbers of the third, or last, column. For example, if from Kepler's distance of the Fixed stars, which is 60 000 000, you subtract the distance of Saturn, which is about 35 000, there will remain between Saturn and the Fixed stars a gap of 59 965 000 terrestrial semidiameters; and so with the hypotheses of the others, from all of which that interval is always gathered to be huge.

[Margin: Proof of the Minor.]

The MINOR is proved from an axiom often employed by the Copernicans when they busy themselves with banishing the Ptolemaic Epicycles and the

like. For nothing is more often on their lips than that GOD and Nature do nothing in vain, and do not attempt through more means what can be done through fewer. Therefore they act absurdly when they put so vast a space, in vain and without any use, between the sphere of the Planets and that of the Fixed stars.

[Margin: The 1st Reply, Copernicus's, insufficient.]

XX. *Copernicus* would reply, 1st, by denying the Minor, in Book 1 of the *Revolutions*, chapter 10: because *"between the moved and the unmoved there had to be the greatest difference"*, that is, between the Planets, which are moved, and the Fixed stars, which he held to be motionless. But since for him the Sun too is motionless, and yet is not distant from Mercury — which is moved, and is innermost and nearest to it — by more than 561 terrestrial semidiameters, as we showed from Copernicus in Book 7, section 6, chapter 2, in Table 4, a few more semidiameters of the Earth would have sufficed between Saturn, the outermost of the moving bodies, and the Fixed stars.

[Margin: The 2nd Reply, the Copernicans', insufficient.]

Rheticus, Mästlin, Galileo, Lansbergen and *Gassendi* would reply, 2nd, by having recourse to the Divine Omnipotence and Magnificence, in accordance with what we reviewed in number 18, in the 4th reason of the reply; and so by denying the Minor. But granted that the divine Omnipotence and Majesty is commended by the huge bulk of the sphere of the Fixed stars, insofar as it is the sphere of the Fixed stars, or by that part of its bulk which the innumerable population of the Fixed stars inhabits, it is nevertheless not commended by that insane and useless space between the Fixed stars and Saturn — whether it is supposed empty of every other body, or filled only with ethereal air — unless its use is apparent. *Galileo*, however, persists, in the third dialogue, page 272, and says *that it is rash to call vain and superfluous everything in the Universe that does not serve our uses.*

[Margin: The 3rd Reply, that of René Descartes.]

Renatus de Cartes [René Descartes], then, would reply, 3rd, in the *Principles of Philosophy*, part 3, by denying rather the Major; for in number 20 he says: *"We are not yet certain how far the Fixed stars are distant from us, nor can we imagine them so remote that this conflicts with the Phenomena. Let us not be content to suppose them above Saturn, as all commonly admit, but let us take the liberty of judging them as much higher as we please. For if we wished to compare their height with the distances known to us here above the earth, the height already granted to them by everyone would be no less incredible than any greater one. But if we look to the Omnipotence of God the Creator, none can be conceived so great that it is for that reason less credible than any smaller one. And I shall show below that, to explain conveniently the Phenomena not only of the Planets but also of the Comets, a very great space must be set between them and the sphere of Saturn."* Yet from number 119, where he begins to treat of Comets, he nowhere shows this; rather, he supposes from his own principles immense vortices, through which the Fixed stars are moved and are changed sometimes into Comets, sometimes into new

Planets. Seneca nevertheless supports him, in Book 7 of the *Natural Questions*, chapter 24, where he judges that innumerable stars unknown to us run through the immense space of the heavens, and so that what seems empty to us is not empty of stars. But we have already shown in Book 8 that it has not yet been demonstrated by anyone that Comets or new stars were above Saturn; nor is it fitting, for the sake of one or another such phenomenon, to set so great a vastness between Saturn and the Fixed stars, since for these Phenomena there amply suffice, in part the region of air or of fire itself, in part the fluid heaven of the Planets, in part the heaven of the Fixed stars, especially if that too is admitted to be liquid; or at least some moderate space between the Fixed stars and Saturn would suffice — say, as much as there is from the centre of the World to Saturn.

[Margin: The 4th Reply, the Copernicans'.]

Not a few Copernicans reply, 4th, by implicitly denying the Major, when they indicate that the space above Saturn is not wholly empty of stars, granted that the stars which can be observed by us with the naked eye, and of which there can be no sensible parallax, are removed from the sphere of Saturn by a vast interval. They could therefore say that there are innumerable stars which can be distinguished only with the Telescope, and which cannot be observed in such a way that their parallax, if they have any a little smaller than Saturn's parallax, could be observed; and that very many stars of this kind are scattered within the interval already mentioned, and that it is not idle and empty, as Tycho, Scheiner and others thought. I had devised this reply for myself when I came upon another akin to it in *Galileo*, in the third dialogue *On the System of the World*, page 284 of the Latin edition, where he says that some of the fixed stars are two or three times more remote than others, and that it may happen that one day, by means of the Telescope, some variation like the variation of the Planets is observed in some of them. So too *Mästlin*, in the additions to Rheticus's *Narratio prima*, page 113, denies that the gap must be so vast, since not all the Fixed stars are equally distant from the centre — Tycho himself conceding this in volume 1 of the *Progymnasmata*, 470 and 481. For the rest, although this reply cannot be convicted of falsity by anyone, it is nevertheless apparent that it was devised arbitrarily to protect the hypothesis of Copernicus. For who would believe that God removed all the stars that appear larger to us, and whose parallax, if there were any, we could observe, so far from us that we could not observe that parallax; and that he made the others, which as regards their distance are otherwise subject to parallax, so small that they could not be observed by us with the naked eye? It would surely follow — if one may speak so — that God, in distributing the Fixed stars right from the beginning of the World, was a Copernican, that is, a supporter of this sect, which he nevertheless foresaw would one day be condemned by sacred decrees.

III. Argumentum à Solis exilitate non valentis Fixas illustrare ob ingentem distantiam.

Argument 3, from the smallness of the Sun, which is unable to illuminate the Fixed stars on account of their huge distance.

[Margin: The Form of Argument 3.]

XXI. *If the Earth moved through the Annual orb around the Sun, the Fixed stars would have to be removed so far from the Sun that the Sun, seen from them, would be like a point, and so could not illuminate the stars with its light. The consequent is false. Therefore so is that from which it follows.*

Gassendi replies, in the second letter *De motu impresso*, page 126, first by denying the Major: for it could spread its rays all the way there, even if it were like a point; secondly by denying the Minor: for the Fixed stars have their own light from themselves, not from the Sun — which we too taught in Book 6, chapter 2.

CAPVT XXX. Proponitur Argumentum ab Ingenti Mole Fixarum, Contra motum Terræ Annuum. Qua occasione disputatur An hæc sit incredibilior in Fixis immotis, quàm Celeritas illarum motui diurno in hypothesi Terræ quiescentis conueniens?

Chapter 30. The Argument from the Huge Bulk of the Fixed stars is put forward against the annual motion of the Earth. On this occasion it is disputed whether this bulk is more incredible in motionless Fixed stars than the Speed that befits them for the diurnal motion in the hypothesis of the resting Earth.

I. To most people the huge Magnitude of the Fixed stars that follows from their distance in the Copernican hypothesis has seemed much more absurd than the bulk of the whole sphere of the Fixed stars — whether the Fixed stars themselves are compared with the globe of the Earth, or with the Sun, or with the whole Annual Orb. The Copernicans believe, however, that this magnitude came out greater than it should for Tycho, Longomontanus, Scheiner, Chiaramonti and some others, because they assumed too large an apparent diameter for the Fixed stars.

[Margin: Tycho's opinion on the magnitude of the Fixed stars in the Copernican hypothesis.]

For Tycho, in the letter of the year 1589, November 24, written to Rothmann, page 167, says: *"Indeed, even then the fixed stars of the third magnitude, which have one Minute in diameter, will necessarily be equal to this whole Annual Orb, that is, they will comprise 2284 semidiameters of the Earth in diameter; for they will be distant about 7 850 000 of the same semidiameters. What shall we say of the stars of the first magnitude, some of which occupy two, and some three, Minutes in visible diameter?"* He repeats this on page 191. He takes from Copernicus, moreover,

a semidiameter of the annual orb of 1142 terrestrial semidiameters, and so a diameter of 2284.

II. *Longomontanus* likewise, in Book 1 of the *Theorics*, chapter 1, page 1, investigates the magnitude of the fixed stars with a diagram added, in the way that we too did in Book 6, chapter 9, number 9.

[Margin: The method of investigating the true magnitude of a Star.]

Diagram. A woodcut set in the left column. A circle, the star, with centre B; a vertical line runs from H at the top of the circle through B and F down to the apex G; from G two straight lines touch the circle at D on the left and at E on the right; a flatter arc, the portion of the circumference of the highest heaven, runs from A on the left across the circle near the level of B to C on the right; straight lines join B to D and B to E.

- H (top of the circle): a point of the star's circumference
- B (centre of the circle): the centre of the star
- A (left end of the arc): one end of the arc ABC of the highest heaven
- D (left, where the tangent meets the circle): point of tangency
- E (right, where the tangent meets the circle): point of tangency
- C (right end of the arc): the other end of the arc ABC
- F (on the vertical below B): a point of the star's circumference
- G (foot of the figure): the centre of the World, from which the arc is described

For let ABC be a portion of the circumference of the highest heaven, described from the centre G, and let DHEF be some Fixed star, whose centre is B; and from G let the straight lines GD and GE be drawn, touching the globe of the star at D and E. By the 18th of the third book of Euclid, they will make the angles at D and E right angles with the star's semidiameters BD on the one side and BE on the other; and the angle DGE will subtend and measure the apparent diameter of the star. When the angle G is bisected by the straight line BG, a double triangle arises, right-angled at D and at E. Therefore, if in either triangle, say DBG, the base BG is given — that is, the distance of the Fixed star from G, the centre of the World — and the angle DGB, which measures the apparent semidiameter of the star, then by the rules of right-angled rectilinear triangles the true size of the semidiameter DB will at once be found, in parts of which GB is known. When BD is doubled, the diameter will be known; multiplied by itself, it will give the square number, and this, multiplied again by the number of the diameter, will give the cubic number, which indicates how many times the solidity of the earth is contained in the Solidity of the star — provided that the true diameter of the star is known in diameters of the earth. Accordingly *Longomontanus*, having found from the Copernican hypothesis the distance of the Fixed stars, BG, to be 7 906 818 semidiameters of the earth, and having assumed the apparent semidiameter of a Fixed star of the first magnitude, that is, the angle BGD, to be 1 Minute, sets up the proportion: as the Radius BG, of 10 000 000 parts, is to the distance BG of 7 906 818 semidiameters of the earth,

[Margin: Longomontanus's opinion on the magnitude of the Fixed stars in the Copernican hypothesis.]

so is the Tangent of the angle BGD of 1 Minute, 2909, to BD, 2300 terrestrial semidiameters; and so he gathers the diameter of such a star to be 2300 terrestrial diameters. The square of this number multiplied into itself is 5 290 000; and this, multiplied again by 2300, makes the Cube 12 167 000 000. *"So many times, then,"* he says, *"does a star of the first magnitude contain the Earth in the Copernican hypothesis,"* since, when the terrestrial diameter is taken as 1, its cube is 1. And since the Sun contains the Earth 140 times, as Longomontanus thinks, if 12 167 000 000 is divided by 140, the same star will be found to be greater than the Sun 86 907 143 times. Finally, since the diameter of the annual Orb is 1142 diameters of the earth for Copernicus, while the diameter of the Fixed star already mentioned is 2300 diameters of the earth — that is, about twice as great — and stands to it as 2 to 1, and since the cube of the number 2 is 8 and the cube of unity is 1, it follows that a Fixed star of the first rank comes out eight times greater than the whole annual orb. *Longomontanus* therefore concludes in the same place: *"Since, then, both from the immense remoteness of the fixed stars from the earth, and from the gap between the last of the Planets and the orb of those same Fixed stars, and from the incredible magnitude of a fixed star of the first rank that follows from this, relative to the annual orb of the earth, likewise to the Sun, and much more to the earth, all the well-ordered symmetry of the parts of the world is easily taken away, besides the absurd, etc., I therefore think that the Copernican hypothesis — of the annual motion of the earth above all, and of its libration upon its poles — is rightly to be removed."*

[Margin: Scheiner's opinion on the magnitude of the Fixed stars in the Copernican hypothesis.]

III. But *Christoph Scheiner*, in the *Disquisitiones Mathematicae*, page 26, having derived from the Copernican hypothesis a distance of the Fixed stars of 13 133 376 semidiameters of the earth, assumes a distance of the Sun of 1208 semidiameters of the earth, and its true diameter of 11 terrestrial semidiameters. Multiplying 13 133 376 by these, he gathers the sum 144 467 136; dividing this by 1208, he finds 119 592 semidiameters of the earth, which the diameter of the Sun would contain if it were in the Firmament. Then, putting the visual diameter of the Sun at apogee at 30′, and the visual diameter of a fixed star of the first magnitude at 2′, he sets up the proportion: as 30 is to 119 592, so is 2 to 7972 semidiameters of the earth, comprised in the diameter of the fixed star; and by the same reasoning, for a star of 1 apparent minute, or of the third magnitude, he gathers 3986 semidiameters. From this he deduces that the diameter of the annual orb, which is 2416 semidiameters of the earth, is contained in the diameter of a star of the first rank 3 181/604 times, in the diameter of a star of the third rank 1 785/1208 times, and in a star of the sixth order about once. Finally, since the cube of the diameter of the annual orb, taken as 1, is 1, and the cube of the diameter of a Fixed star of the first rank, taken as 3 18/60, is about 32, he gathers that a star such as the Dog-star contains the annual orb within itself 32

times. Accordingly, on page 28, he concludes thus: *"The Copernican motion of the Earth makes any star of the first magnitude thirty times, and more, larger than the entire heaven of the Sun, and any little star seen in the starry sphere larger than that same heaven. Therefore it does not seem admissible."*

[Margin: Chiaramonti's opinion on the magnitude of the Fixed stars in the Copernican hypothesis.]

IV. By what method, further, *Chiaramonti*, in the defence of the *Antitycho*, part 3, chapter 13, gathers that a fixed star of the first magnitude in the Copernican hypothesis contains the globe of the earth 1 349 232 625 times, and the Sun 8 079 237 times, has already been stated in the preceding chapter, number 12.

[Margin: And Lansbergen's.]

Among the Copernicans, *Lansbergen*, in the *Uranometria*, Book 3, from element 20 on, attributing to a Fixed star of the first magnitude a diameter of 1 minute, and to the distance of the Fixed stars 41 958 000 terrestrial semidiameters, gathers by the method described in number 2 the true diameter of a Fixed star, and sets it at 40 712 terrestrial diameters; and he gathers that the Great Orb is contained in its solidity 20 053 times. For the diameter of the annual orb is, for him, 1498½ diameters of the earth, whose cube is 3 364 884 747; and the cube of the number 40 712 is 67 478 794 224 128, which contains the former cube 20 053 times. For a star of the sixth rank, however, he makes the apparent semidiameter 2½″ and the true one 3388 terrestrial semidiameters; from which he deduces that its diameter is to the diameter of the Annual Orb as 3388 to 1498½, and that its solidity, or cube, is greater than the solidity of the annual Orb 11½ times. For the remaining stars, further, see what I reported in Book 6, chapter 9, at the end of Scholium 4.

[Margin: Hortensius's opinion on the same.]

V. *Hortensius*, however, himself an Astronomer of the Copernican sect, in the dissertation with Gassendi on Mercury seen in the

Sun and Venus unseen, gives the stars of the first magnitude only 8″ for their apparent diameter, and those of the sixth magnitude 2″. From this, and from the distance of the Fixed stars, which for him is 10 312 227 semidiameters of the earth, and from the semidiameter of the Annual Orb, 1498½ semidiameters of the earth, he gathers that a star of the first magnitude is smaller than the Great Orb 422 times, and a star of the third magnitude 27 826 times — so far is it from being equal to it or greater.

[Margin: Galileo's opinion on the same magnitude of the Fixed stars.]

But *Galileo* makes them smaller still. For in the third dialogue *On the System of the World*, page 265 of the Latin and 351 of the Italian, he rebukes those who gather from the system of Copernicus that some Fixed star is greater than the whole Great Orb; and on page 267 he teaches a method of measuring the apparent diameter of the Fixed stars, from which he asserts, on page 268, that the apparent diameter of a star of the first magnitude does not exceed 5″ — from which there follows a bulk far smaller than that of the annual Orb. But I have reported his method in Book 6, chapter 9, number 3.

[Margin: Our opinion on the Magnitude of the Fixed stars.]

VI. What I, for my part, accomplished together with Father Francesco Maria Grimaldi in investigating the apparent diameters of the Fixed stars by a far more certain method, I have already related in Book 6, chapter 9, from number 6, and in Book 7, section 6, chapter 9; and I illustrated it with examples and demonstrations in Book 7, section 6, chapters 10 and 11, and showed that a star of the first magnitude, such as Sirius, has an apparent diameter of 18″, while the smallest of the stars visible to the naked eye, such as the little star in the tail of Ursa Major called Alcor, has a diameter of 4″ 24‴. From these, according to the various opinions on the distance of the Fixed stars, I deduced the various true Magnitudes of these stars and arranged them in three tables, set out in that chapter 11, of which the last two rest on Copernican distances; and I think the Reader should be referred to them for fuller instruction. Here, however, I shall repeat what is more necessary for setting out the force of this argument, which I have in hand. In the 1st and 3rd tables I shall give the cubic diameters of the earth contained in the bodies of the Fixed stars Sirius and Alcor, so that from these two, the greatest and the smallest of the Fixed stars visible to the naked eye, a judgement may be made about the rest; and in the 2nd and 4th tables I shall give how many times stars of this kind contain the Annual Orb, or are contained in it — dividing, that is, the number of cubic terrestrial diameters contained in the body of the star by the number of cubic diameters contained in the annual orb, taken from the preceding chapter, number 15, in the 1st column of table 3.

Table I. The True Magnitude of the Greatest of the Fixed stars, namely SIRIUS, and of the Smallest visible to the naked eye, namely ALCOR; the apparent diameter of Sirius being put at 18″ and of Alcor at 4″ 24‴, and the Distance of the Fixed stars being that asserted by the four Copernicans written below.

From the authors	Distance of the Fixed stars, in semidiameters of the Earth	Semidiameter of the Annual Orb, Earth semidiameters	Sirius therefore contains: diameter, Earth diameters	Sirius: body, the Earth so many times	Alcor contains: diameter, Earth diameters	Alcor: body, the Earth so many times
Hortensius	10 312 227	1498½	899	726 572 600	442	86 355 888
Galileo	13 046 400	1208	1138	1 473 760 072	558	173 741 112
Lansbergen	41 958 000	1498½	3658	48 947 466 312	1796	5 793 206 336
Kepler	60 000 000	3469	5232	143 219 897 228	2568	16 933 994 432

Table II.	Sirius, therefore	Times	And Alcor	Times
Hortensius	is contained in the Annual Orb	about 5	is contained in the Annual Orb	39½
Galileo	is contained in the Annual Orb	about 1 2/15	is contained in the Annual Orb	10
Lansbergen	contains the Annual Orb	about 145	contains the Annual Orb	1 12/17
Kepler	contains the Annual Orb	about 3⅓	is contained in the Annual Orb	2 9/17

Table III. The True Magnitude of SIRIUS and ALCOR, their Apparent Semidiameter being supposed 18″ for Sirius and 4″ 24‴ for Alcor, the Distance of the Fixed stars being so great that the Parallax of the Annual Orb does not exceed 10″, and the Semidiameter of the Annual Orb being supposed from the Authors written below.

From the authors	Distance of the Fixed stars, in terrestrial semidiameters	Semidiameter of the Annual Orb, Earth semidiameters	Sirius therefore contains: diameter, Earth diameters	Sirius: body, the Earth so many times	Alcor contains: diameter, Earth diameters	Alcor: body, the Earth so many times
Copernicus	47 439 800	1142	4170	71 677 713 000	1992	4 378 454 048
Hérigone	49 502 400	1200	4350	82 312 875 000	2068	8 844 058 432
Galileo	49 832 416	1208	4380	88 427 672 000	2092	9 155 562 688
Boulliau	60 227 920	1460	5300	148 877 000 000	2530	15 941 277 000
Lansbergen	61 616 122	1498½	5424	159 371 956 024	2588	17 333 761 472
Kepler	142 746 428	3469	12550	1 976 656 375 000	6000	216 000 000 000

Table IV.	The Annual Orb is therefore contained by Sirius, times	by Alcor, times
Copernicus	48	4
Hérigone	48	4⅕
Galileo	52	5⅓
Boulliau	44	4⅔
Lansbergen	47	5
Kepler	46	5

[Margin: The Argument in Form.]

VII. With these premisses, the Argument is Formed thus. *If the Earth moved through the Annual orb, the Fixed stars not only of the first but also of the lowest magnitude would have too great a bulk, that is, one greater than the Sun and the Annual Orb itself, or than the solar heaven. But this is absurd and incredible. Therefore, etc.* The MAJOR is proved from the tables set out a little before. The MINOR is proved from the comparison of the Fixed stars with the Sun and the other

Planets, which are much smaller; from the symmetry of the Universe; and from Rothmann himself, Copernican though he was, who at last yielded to Tycho on this point, as Tycho himself relates in the letters, page 192, saying of Rothmann:

[Margin: Rothmann's confession of the absurdity of the Copernican hypothesis.]

"For I remember that he once said to me, among other things, that if the Copernican assumption held in the truth of the matter, it would be necessary that most of the fixed stars should exceed the whole annual Orb, or the sphere of the Sun, in their true size, before so inexhaustible a distance as Copernicus's reasoning necessarily attributes to them would grant them the visible size that we discern from the Earth: just as

had been objected to him by me. Yet he did not deny that this surpassed all belief and seemed utterly absurd; nor did he try any longer to excuse it by the divine Omnipotence; and he admitted, not unwillingly, that a great asymmetry too was introduced by these things."

[Margin: 1. Reply, insufficient.]

First, *Galileo and Hortensius* reply, as we saw in number 5, by denying the Major: Tycho and others, they say, deduced from too large an apparent diameter of the Fixed stars a magnitude for them larger than is right. But granted that Tycho, Longomontanus, Scheiner and some others assumed too large a diameter for them, Galileo and Hortensius themselves nevertheless assumed too small a one. If, however, we assume the diameter that is to be chosen from our more certain observations, together with the Annual Orb asserted by the Copernicans, and with the distance of the Fixed stars either as asserted by the same men, as we did in the 1st table, or as it must be asserted if they wish to avoid a parallax of 10″ arising from the whole diameter of the Annual Orb, as we did in the 3rd Table — taking these things together, I say, Sirius, which is a Fixed star of the first magnitude, and Alcor, which is a star of the sixth and lowest magnitude (of those visible, that is, without the Telescope), turn out too large with respect to the annual Orb, as is plain from the 2nd Table; indeed both turn out larger than the annual Orb, Sirius at least 44 times, and Alcor 4 times. Therefore, if the matter is handled honestly, the Copernicans cannot evade the Major.

[Margin: 2. Reply, and its threefold reason, but insufficient.]

Secondly, the Copernicans reply by denying the Minor: first, in view of the Divine Magnificence, which grows the greater from the vastness of these stars; next, by comparing other bodies of the World with one another, which all Cosmographers must nevertheless admit. For it must be admitted that the Sun, to say nothing of the rest, although it looks a foot across, is nevertheless greater than the terrestrial globe not only 140 or 160 times but 38 600 times, if the distance of it that we elicited from the lunar dichotomies is true — indeed 262 144 times, if the distance of the Sun asserted by Wendelen were true, as I showed in Book 3, chapter 11, problem 1. Finally, by comparing the Copernican

bulk of the Fixed stars with their Ptolemaic speed: for the former, they say, is much more credible than the latter.

But none of these reasons satisfies. Not the *first*: for if God had wished His Magnificence to be recognized by mortals in this life from the vastness of the Fixed stars, there was no reason for Him to remove them from our eyes by so great an interval that they should appear so tiny to us, and should scarcely equal with their apparent diameter a hundredth part of the Sun's apparent diameter; or at least He would have allowed us to come, by some other sensible sign, to certain knowledge of this distance and magnitude. That He has by no means done so is plain from what has been said so far, since all the Astronomical phenomena are saved without the Copernican hypothesis, while physical experiments with heavy bodies and the impacts of projectiles plainly convict that hypothesis of falsity. Nor is the *second* reason valid. That the Sun should be of so great a bulk is not incredible, if its functions in the Universe are considered: for the Sun is the source of the Light of all the Planets, and the universal secondary cause of all natural sublunary effects. It is no wonder, then, if it is so much greater than the Earth. But it seems wonderful and hardly credible that any little fixed star whatever should be greater not only than the Earth and the Sun — and that far more so than the Sun is — but greater by so many times even than the whole heaven of the Sun itself, when no reason appears for so great a bulk. For if the reason had been that it should act on these lower things more abundantly and powerfully than the Sun, there was no reason why it should be removed so far from the Planetary system. And it is established from Sacred Scripture, namely from Deuteronomy, that all the stars were created for the service of men, and that on this ground too their worship is forbidden, since they serve us and do not rule us. Finally, how weak the *third* reason is — about the greater likelihood of a huge bulk of the Fixed stars without motion than of a moderate magnitude with remarkable speed — will become plain from what is about to be said.

Diſcutitur An credibilior ſit Moles Fixarum in Copernicæa hypotheſi, quàm earumdem Celeritas in Ptolemaica hypotheſi.

It is discussed whether the Bulk of the Fixed stars in the Copernican hypothesis is more credible than their Speed in the Ptolemaic hypothesis.

VIII. That the speed of the Fixed stars is not incredible in the Ptolemaic hypothesis, nor indeed in our own, we showed in chapter 6. There, from number 1 to 7, we enumerated the opinions and calculations of the Copernicans against this speed, and in numbers 7 and 8 we refuted their twofold argument, full of equivocation and sophistical fallacy. We therefore refer the Reader there, certain that, if he is willing to judge without prejudice, he will pronounce against the Copernicans on this point. And to gather in summary the chief reasons adduced there: I said, and I say, that the speed of the Fixed stars does

not increase beyond the measure of its subject, as Galileo, following Kepler, pretends; for it increases only as much as their distance does. For it is certain that in any wheel or movable sphere the parts of the circumference move the faster with the common motion (for it is in this that the comparison must be made) the farther they are from the centre. Next, the speed of the Fixed stars seems excessive because we express it in miles of our own paces, just as a Giant's speed would seem excessive if someone expressed a single one of his paces cut up into thousands of an ant's paces.

[Margin: 1. Reason against the Copernicans.]

Comparing, moreover, the Ptolemaic speed of the Fixed stars with their Copernican Magnitude: *first*, I say that this comparison does not tell against those semi-Copernicans who attribute only the diurnal motion to the Earth, and not to the Fixed stars, as Longomontanus, Origanus [David Origanus], Argoli, etc. do; for to them the Copernican magnitude of the Fixed stars seemed absurd. Nor can its absurdity be removed by turning the diurnal rapidity of the Fixed stars back upon them, since they transfer it from the Fixed stars to the Earth.

[Margin: 2. Reason against the Copernicans.]

Secondly, I said, and I say, that the speed of the Fixed stars arises from the magnitude of the circumference of the eighth sphere, as they call it — compared by the Copernicans with the circumference of the terrestrial globe — and from its having to turn round in the time of 24 hours; whereas the immensity of the Fixed stars arises from the solidity or corpulence of the Fixed stars, which, if the comparison is to be on equal terms, must certainly be compared with the globe of the Earth. But the excess of the corpulence of a single Fixed star over the globe of the Earth, in the Copernican hypothesis, is far greater than the excess of the circumference of the eighth sphere, turning round in 24 hours in the Ptolemaic and in our own hypothesis, over the circumference of the terrestrial globe. For since circumferences are to one another as their diameters, by Theorem 5 of Book 11 of the *Mathematical Collections* of Pappus of Alexandria, the diameter of the eighth sphere contains the diameter of the Earth only 20 220 times if you follow Ptolemy, or 40 440 times if Alfraganus, or 100 000 or 210 000 times if one of our own opinions, according to what was said in Book 6, chapter 7, number 6, and in the 1st Table. But not only Sirius, the greatest of the stars, but even Alcor, the smallest, turns out in the Copernican hypothesis to be greater than the Earth by far more times, as will at once be plain to anyone who runs through tables 1 and 3 shown in this chapter, in the columns that give how many times these stars contain the Earth. If the Copernicans wish to draw us back to the comparison of a Fixed star with the annual orb, so that its excess may appear smaller, we shall not refuse, provided that they too (as is fair and just) compare the circumference of the Fixed stars, taken from the Ptolemaic hypothesis or from ours, with the circumference of the annual orb, Ptolemaic or ours, and from both estimate the speed of the diurnal motion. Now Sirius must contain the annual orb at least 44 times, as is

plain from the 4th table of this chapter and its most solid foundations; whereas the Ptolemaic circumference of the Fixed stars is to the circumference of the annual orb as the diameter 20 220 to the diameter 1210, that is, as 16 86/121 to 1. And our circumference of the Fixed stars is to the annual orb as the diameter 100 000 to 7300, that is, as 13 51/73 to 1; or as 210 000 to 7300, that is, as 28 56/73 to 1. The excess of Sirius over the Earth — and indeed over the Copernican Annual Orb itself — is therefore much greater than the excess of the diurnal speed and of the circumference of the sphere of the Fixed stars, Ptolemaic or ours, over the diurnal speed and the circumference of the terrestrial globe or of the Annual Orb.

[Margin: 3. Reason against the Copernicans.]

Thirdly, as I said in the same place, other things being equal, a moderate magnitude of a body in the World, commensurate with its other parts, together with some swift motion, is more credible than an immoderate one that is inert and without motion. And God Himself, in the sacred writings, commends Himself by the speed of the Sun — which, He revealed to us through the Psalmist, exulted like a giant to run the way of its diurnal motion — rather than by the magnitude of the bulk of the fixed stars, of which He nowhere made mention, but rather of their innumerable multitude; and

among the stars He commended the Sun alone for its magnitude, calling it a *Giant* in Psalm 18, and *"an admirable vessel, the work of the most High"* in Ecclesiasticus — the Sun which, if the Copernicans were listened to, would turn out a pygmy, a contemptible little vessel beside the Fixed stars. Let the Conclusion, therefore, stand.

CONCLVSIO.

Conclusion.

The Diurnal Speed of the Fixed stars in the Hypothesis of the resting Earth is more credible than their insane Bulk in the Hypothesis of the Earth going round through the Annual Orb.

CAPVT XXXI.

Chapter 31.

Proponuntur Argumenta 6. Contra motum Terræ Annuum, ex Refractione Fixarum.

Six Arguments are proposed against the Annual motion of the Earth, from the Refraction of the Fixed stars.

I. From Parallax we pass conveniently to the Refraction of the Fixed stars, from which, it seems, the following arguments can be drawn against the excessive distance of the Fixed stars that follows from the annual motion of the Earth.

I. Argumentum à Deſtructione ſenſibilis Refractionis Fixarum in Aere noſtro.

Argument I, from the Destruction of the sensible Refraction of the Fixed stars in our Air.

If the Earth revolved in the annual orb, there would be no sensible Refractions of the Fixed stars in the air that surrounds the earth more closely. But the Consequent is false; therefore so is that from which it follows.

[Margin: Proof of the Major.]

The MAJOR is proved. If all sensible inclination of the ray above the surface of our air were taken away, all sensible refraction would be taken away, since refraction, by the common opinion of the writers on Dioptrics (to be reported in Book 10, section 6, chapter 2), is always less than the inclination of the ray in the same transparent medium. But if the Earth revolved in the annual orb, it would be necessary, in order to avoid a sensible parallax of the Fixed stars, to remove them so far from us that the whole diameter of the annual orb — let alone the orb of the Earth clothed with its air — would be insensible with respect to the distance of the Fixed stars; that is, it would be like a point escaping every visual angle, or incapable of grounding a sensible angle of inclination.

[Margin: Proof of the Minor.]

[Margin: Sign of the Refraction of the Fixed stars.]

The MINOR is plain from the observations of Tycho and of others, and from our own. In them, when the true altitude of the Fixed stars, known beforehand by calculation, is compared with the altitude seen or observed, especially near the horizon, the latter is found greater than the true — which can come about from no other source than Refraction, whose property it is to raise the stars in appearance. And *Kepler* himself, a most zealous follower of the Copernicans, in the *Epitome of Copernican Astronomy*, Book 1, page 61, adduces this from a frequent observation of Tycho's to confirm the Refractions of the Fixed stars: the star of the Lion's Tail and Spica, when they are near the Meridian, were found by instruments to be 35° and nearly 2′ apart; but when, in the eastern quarter, the Lion's Tail has reached an altitude of 34° 30′, Spica, in very nearly the same vertical, is already beginning to appear on the physical horizon — which could not happen unless a refraction of about 30′ diminished Spica's distance from the Lion's Tail and raised it above both horizons.

[Margin: Reply.]

The reply, however, is to deny the Major; and as to its proof, the rest being granted, it is denied that from the smallness of the orb of the earth, taken together with the refractive air and compared with the orb and the distance of the Fixed stars, it follows that there is no angle of inclination of the rays, or that the angle is insensible with respect to an eye on the surface of the Earth, or to an angle standing at the surface of the air — granted that the whole sphere of the elements would appear from the Fixed stars as a point, indeed would not even appear at all. For we measure this angle and its size from the given

refraction, the height of the refractive air and the semidiameter of the earth, as we shall teach in Book 10, section 6, problem 45. But see here the reply to the 3rd argument.

II. Argumentum ab Exceſſu Refractionis ſupra Inclinationem.

Argument II, from the Excess of Refraction over Inclination.

[Margin: Form of the 2nd Argument.]

II. *If the Earth moved in the Annual Orb, the Refraction of the ray of the Fixed stars would turn out greater than its Inclination above the surface of the refractive air. But this is inadmissible; therefore, etc.*

[Margin: Proof of the Major and of the Minor.]

The MAJOR is urged thus: because of the huge distance of the Fixed stars, the inclination would turn out insensible, or much less than 30′; and yet the horizontal Refraction of the Fixed stars, according to Tycho, volume 1 of the *Progymnasmata*, page 280, is 30′. The MINOR is proved from the laws of the Opticians in Dioptrics: refraction is always less than inclination, since the Inclination itself, or the angle equal to the inclination, is composed of the angle of Refraction and the refracted angle, as we shall say in Book 10, section 6, chapter 2, axiom 8.

The reply is to deny the Major, and as to its proof, the consequence is denied. For the horizontal refraction of the Fixed stars would still be much less than the inclination of the ray, as will presently be established from the reply to the 3rd argument, however great a distance of the Fixed stars the Copernicans might imagine.

III. Argumentum ab Exceſſu Refractionis Fixarum ſupra dimidium Inclinationis.

Argument III, from the Excess of the Refraction of the Fixed stars over half the Inclination.

III. *If the Earth moved in the Annual Orb, the Refraction of the Fixed stars would be greater than half the angle of Inclination of their ray. But this is inadmissible; therefore, etc.* The MAJOR is proved by the same reasoning by which the Major of the 1st and 2nd Argument was proved. The Minor is proved from the laws of the Opticians: for the refractions in glass themselves, which are greater than refractions in air, are very nearly a third part of the inclination up to the thirtieth degree of Inclination, as we shall teach in Book 10, section 6, chapter 3, proposition 3. But the sensible refractions of the Fixed stars cease before the thirtieth degree of inclination is reached; therefore, before that degree, they must always be less than half the inclination.

[Margin: Reply.]

I reply by denying the Major, since the horizontal refractions of the Fixed stars themselves, which are the greatest, can never equal half the angle of inclination, however great a distance of the Fixed stars the Copernicans may

posit. It will be worth the trouble to demonstrate this here; for I learned from a letter he sent me that a man otherwise most expert in Optics, and a very close friend of mine, had counted on a great argument against the Copernicans in this matter — but in vain.

[Margin: Explanation of the figure.]

From the centre of the Earth, A, let three arcs of vertical circles, each more than a quadrant, be described: one, BCD, in the Heaven of the Fixed stars; another, EFG, of the refractive air; and the third, HIK, of the terrestrial surface. Let the true horizon be AL and the physical horizon HC, the vertical line AB, and the eye at H. Now let a Fixed star be at

Diagram. A woodcut set within the right column. From A, at the lower left, a vertical line rises through H, E and B to a letter at the top. Three concentric arcs are drawn about A: the outermost, the heaven of the fixed stars, through B, P and C down to D at the foot; a middle arc, the refractive air, through E and F down to G; and an innermost arc, the Earth's surface, through H and I down to K. A horizontal line runs from H through F and C to O; a line from A runs to N, with L on it near the outer arc; a line runs from A to D. From F one line rises to P and another runs up to R; further lines run down to the right from F toward D and the lower-right corner.

- Z (top of the vertical): unexplained on this page
- B (vertical, on the outer arc)
- P (outer arc, upper right): unexplained on this page
- R (upper left, end of the line from F)
- [?] (left edge, above E; a small letter, Y or V): unexplained on this page
- E (vertical, on the middle arc)
- H (vertical, on the inner arc; the eye)
- F (middle arc; point of incidence)
- C (outer arc, on the horizontal from H)
- O (right, end of the horizontal through C): unexplained on this page
- I (inner arc)
- L (on the line from A to N)
- N (right, end of the line from A): unexplained on this page
- A (lower left; centre of the Earth)
- K, G (foot of the inner and middle arcs)
- D (foot of the outer arc; the star)
- [?] (lower right corner; a round letter with a tail, Q or O): unexplained on this page

D, distant from the centre A by the straight line AD, and sending its ray DF to the point F of the air, so that it enters the air and does not go straight on to R, but, from the point of incidence F, is refracted to the eye H along the horizontal line HF, and so appears to the eye H as if it were at C. And let there be drawn from A,

through F, the perpendicular AP. Then the angle of refraction will be HFR; the refracted angle HFA, equal to the angle PFC by the 15th of the first book of

the *Elements*; and the angle of inclination PFD, by which, namely, the incident ray DF declines from the perpendicular PF. By the definitions of the Opticians this angle is equal to the refracted angle PFC, that is AFH, and the angle of refraction CFD, that is HFR, taken together; and it is always, at least in air, more than double the angle of refraction.

[Margin: 1st step: for the Inclination.]

IV. With these things laid down, the inclination PFD is to be sought. This will easily be done, given, from Book 2, chapter 7, the semidiameter of the earth AH, 4139 Bolognese miles, and AF, made up of AI, which equals AH itself, and of the height of the refractive air IF, which I shall show in Book 10, section 6, problem 51, to be 20 miles in some places; so the whole AF is at times 4159 miles. Therefore in the triangle AHF, right-angled at H (for the horizon HC makes right angles with the vertical AB), the angle AFH is found by the rules of triangles to be 84° 22′, and PFC is just as great. If you add to it the horizontal refraction of the Fixed stars according to Tycho, RFH, that is CFD, 30′, the angle of Inclination PFD will come out 84° 52′.

[Margin: 2nd step: for the Parallax.]

Let us now suppose, first, that the distance of the Fixed stars AD is as great as Tycho assumed, namely 14,000 terrestrial semidiameters, that is, 5 794 600 Bolognese miles — the 4139 of AH, that is, being multiplied by 14,000. For in the triangle AFD, given AD, 5 794 600 of the parts of which AF is 4159, and the angle AFD, which is the complement of the inclination PFD already found and is therefore 95° 8′, it follows that the parallactic angle FDA is 15″ — a parallax not of the orb of the earth taken bare, but of that orb increased by the thickness of the refractive air.

[Margin: 3rd step: for the decrease of the Inclination.]

V. Now let the Heaven of the Fixed stars be not the Tychonic BCD but the Copernican ZOQ, which because of its huge distance is just as if it had been described from the centre of the annual orb. The star that was supposed at D is then at Q, and the one that appeared at C appears at O, through the refracted horizontal ray HF; the incident ray at F is QF, and the inclination is PFQ. The task now is to find how much smaller the inclination PFQ can become than PFD when the distance AD is increased and carried out as far as Q, as far as the Copernicans wish — that is, how great the angle DFQ is, which is the difference of the inclinations already mentioned. But I say briefly that even if AD is increased to infinity, the star Q remaining at the same true distance from the vertex Z, that is, the angle ZAQ remaining the same, the angle DFQ can never become greater than, nor even equal to, the parallactic angle ADF set down before. For by the 16th and 32nd of the first book of Euclid's *Elements*, the exterior angle ADF is greater than either of the interior angles DFQ and DQF, being equal to both of them taken together. Therefore the inclination PFD, found in number 4 to be 84° 52′, cannot become less than 84° 51′ 45″ even if you increase the distance AQ to infinity, since no more than 15″ can be taken from it. And I say the same of any other parallax ADF, which, it is

certain, cannot be imagined in the Fixed stars to be of one degree, nor even of 4′, for it would exceed the parallax of the Sun — just as it is not permitted to imagine the height of the refractive air greater than 100 Italian miles, as we shall teach in Book 10, section 6, problem 51. Thus, everything computed, the Inclination of the ray of the Fixed stars above the refractive air is greater than 84°, and it can never decrease so far as not always to be greater than double the horizontal refraction of the Fixed stars, if this is put one degree less. Nor, conversely, can the Refraction of the Fixed stars ever reach half this inclination, that is, 42°: for even if the air became as dense as water, the refraction from air to water corresponding to an inclination of 84° would not exceed 35°, as is plain from *Vitellio* [Witelo], Book 10, proposition 8, and from the anaclastic tables to be placed at the end of Book 10.

But someone will say that, as the distance of the Fixed stars increases, the angle OFQ would diminish, so that at last it would perish entirely, together with the refraction. This argument will indeed seem more plausible, since it is easier, when the star's distance is freely increased, for the inclination of the ray to decrease until it coincides with the horizontal line OF than for it to reach the perpendicular PF itself. The reply, however, is to deny the consequence, because, from what has been said, that angle could not decrease beyond 15 Seconds.

IV. Argumentum à Diſtantia Fixarum, ex Refractione Horizontali earumdem deducta.

Argument IV, from the Distance of the Fixed stars, deduced from their Horizontal Refraction.

[Margin: Form of the 4th Argument.]

VI. *If the horizontal Refraction of the Fixed stars is not less than 30′, it follows that their distance is much smaller than the hypothesis of the Copernicans, who revolve the Earth in the annual orb, requires. But it is not less than 30′; therefore the Earth is not revolved in the annual orb.* The MINOR is certain from the observations of Tycho, volume 1 of the *Progymnasmata*, page 280; indeed, from Kepler himself, who, although a Copernican, nevertheless admits a horizontal refraction of the Fixed stars of 30′ in the *Rudolphine Tables*, in the last precept and in the table of refractions that he places there on the last page of the tables; and so do most of the more recent Astronomers.

[Margin: 1st proof of the Major.]

The MAJOR is proved, first, geometrically, in the figure set out in number 3, by considering the triangles AHF and AFD. For AH, the semidiameter of the Earth, is 4139 Bolognese miles, from Book 2, chapter 7; and AF cannot be greater than 4239 miles nor less than 4141 miles, because the height of the refractive air IF cannot be imagined greater than 100 miles or less than 2 — indeed, from what is to be said in Book 10, section 6, problem 51, it is about 20, so that the whole AF is 4159 miles. From the side AH and the base AF, by

the laws of triangles, the angle AFH becomes manifest; and equal to it are both the vertically opposite angle PFC, by the 15th of the first book of *Euclid*, and the alternate angle FAL between the two parallel horizons, by the 29th of the same book. Now if you add the refraction of 30′, that is, the angle HFR, to which CFD is equal by the 15th of the first book of *Euclid*, to the angle PFC, the inclination PFD will be known; and by the 13th of the first book of *Euclid* the angle AFD will be manifest, as its supplement to two right angles. Finally, the angle of depression of the Fixed star that has undergone the horizontal refraction, that is LAD, is known: it is as great as the horizontal refraction, if Tycho, in gathering that refraction, neglected the parallax of the Fixed stars, deeming it nil; or, if he did compute it, LAD is a little less than 30′, yet greater than 29′. But if it is greater than 29′ and less than 30′, and is added to the angle FAL, already known as I said, the angle FAD will be known in the triangle AFD, in which the angle AFD and the side AF are manifest. Therefore, by the laws of triangles, the side AD will be known, that is, the distance of the Fixed stars from the Earth; and if LAD is greater than 29′ and less than 30′, or even exactly 30′, this distance will be much smaller than the Copernican hypothesis requires.

[Margin: 2nd proof.]

VII. It is proved, secondly, as follows. As the difference of the horizontal refractions of the Sun and the Moon is to the difference of their distances from the earth, so is the difference of the horizontal refractions of the Fixed stars and of either Luminary to the difference between the distance of the Fixed stars and the distance of either the Moon or the Sun. Now the horizontal refraction, according to *Tycho*, volume 1 of the *Progymnasmata*, pages 79, 124 and 280, and to *Kepler* at the end of the *Rudolphine Tables*, is 33′ for the Moon, 34′ for the Sun and 30′ for the Fixed stars. But because of the excessive parallax of the Sun, as *Kepler* notes in the last precept of the *Rudolphine Tables*, the solar refraction came out greater than the lunar, whereas, because of the smaller Inclination that follows from the greater distance, it ought to have been smaller, and at most 32′. The distance of the Sun to that of the Moon, moreover, is for Copernicus as 1 140 to about 60, or twentyfold, for Kepler sixtyfold, and for us as 140 to 1, from what was said in Book 3, chapter 7, and Book 4, chapter 14. Therefore, if the difference of two minutes between the refractions of the Sun and the Moon does not presuppose an excess of the solar distance over the lunar greater than twentyfold, or sixtyfold, or a hundred-and-fortyfold, then the difference of two minutes between the refraction of the Fixed stars and that of the Sun does not presuppose a greater excess of the distance of the Fixed stars from the earth over the solar distance than either twentyfold, or sixtyfold, or a hundred-and-fortyfold. But the distance of the Sun, from what was said in Book 3, chapter 7, is not greater than 1180 terrestrial semidiameters for *Copernicus*, 3469 for *Kepler*, and 7600 for us. Therefore the distance of the Fixed stars cannot be greater than 23 600 terrestrial semidiameters for Copernicus, 208 140 for Kepler, and 1 064 000 for us, as is plain to anyone who multiplies 1180 by 20, or 3469 by

60, or 7600 by 140. But these distances are much smaller than the Copernican hypothesis requires, since, from what was said in Book 6, chapter 7, number 17, no one among the Copernicans requires a distance of the Fixed stars smaller than 47 000 000 semidiameters of the earth.

[Margin: [?] Reply to the [?] proof of the Major.]

VIII. The reply, however, is to deny the Major. As to its first proof, the rest being granted, it is denied that from the angles already mentioned and the side AF it follows that the distance of the Fixed stars is smaller than the Copernican one. For if the angle LAD were precisely 30′, as great as the refraction CFD, then FD and AD would be parallel, by the 28th of the first book of Euclid, and so the triangle AFD would perish, and the distance AD could be infinite; or at any rate, if this triangle were retained, there would be more than two right angles in it, contrary to the 32nd of the first book of Euclid. This is easily shown. For let the angle PFC, and therefore FAL, be 84° 22′, from the calculation of number 4. When the refraction of 30′ is added to each, both PFD and FAD will come out 84° 52′; and by the 13th of the first book of Euclid, AFD will be 95° 8′, as the supplement to two right angles. Therefore AFD, 95° 8′, and FAD, 84° 52′, taken together, will make 180°, that is, two right angles; so the angle ADF, however small it is imagined, will together with them make more than two right angles. But if LAD is put less than 30′ and greater than 29′, the parallactic angle ADF will indeed not be greater than one minute; yet, with everything else laid down in the proof of the Major left intact, it can be of so few Seconds that the distance AD comes out infinitely greater than the Copernicans require, as is plain from what was said in Book 6, chapter 7, number 17. Therefore, unless a Parallax of the Fixed stars is posited distinct from the simple Refraction — the one raising the star from D to L — the integral Refraction cannot be known, which raises it from D to C, overcoming the horizontal parallax, which is as great as the arc CL. But the parallax of the Fixed stars itself cannot be known unless their distance is first supposed. Besides, the parallactic angle ADF is not taken from the semidiameter of the earth AH or AI, but from the semidiameter AF; and the horizontal Refraction makes the star standing at D appear higher by as much as the angle CFD, which is somewhat greater than the arc CD, since that arc is described not from F but from A. So the Refraction, strictly taken, is greater than the arc CD. But let this be said for good measure.

[Margin: [?] Reply to the 2nd proof of the Major.]

IX. To the 2nd Proof of the Major, the Major is denied — that is, that proportion of distances and refractions, which is framed in too topical a manner and cannot be proved either from the common principles of Optics or Dioptrics or from the proper principles of Anaclastics. Rather, the decrease of the Refraction follows the decrease of the Inclination, which is unknown as long as the integral Refraction, including the correction for parallax, is not known; and the parallax of the Fixed stars is unknown as long as their distance is unknown.

V. Argumentum à Deſtructione Refractionum Fixarum in lentibus Teleſcopij.

Argument V, from the Destruction of the Refractions of the Fixed stars in the lenses of the Telescope.

[Margin: Form of the 5th Argument.]

X. *If the Earth were moved in the Annual Orb, the Fixed stars would not be represented larger, by the force of refraction, through the lenses of the Telescope than without them; but they are so represented; therefore etc.* The Minor is plain. The MAJOR is proved, because that representation requires a sensible refraction in the glass lenses, made towards the perpendicular, as is known from Dioptrics. But if the Earth revolved in the annual orb, there would, because of the huge distance of the Fixed stars, be no sensible inclination of the ray of the Fixed stars upon the glass lenses, and therefore no sensible refraction either.

[Margin: Proof of the Major.]

[Margin: Reply to Argument 5.]

I reply by denying the Major, for the reason stated once already in the reply to the proof brought for the major of argument 1.

VI. Argumentum à Multiplicatione, vel incertitudine diſtantiæ Veræ à vertice, & Parallaxium.

Argument VI, from the Multiplication, or the uncertainty, of the True distance from the vertex, and of the Parallaxes.

[Margin: Form of the 6th Argument.]

XI. *If the Earth moves in the Annual Orb, either we are uncertain what the true distance of a star from the vertex is, or at any rate a twofold distance and a twofold parallax are multiplied without necessity. But this is absurd; therefore etc.* The Minor is plain. The MAJOR is proved, because if we are not certain whether the earth moves or not, we do not know from where we ought to estimate and measure the true distance of a Fixed star from the vertex — whether from the centre of the Earth or from the centre of the Annual Orb. And if from the centre of the annual orb, then both this distance and the parallax of the annual orb, over and above the parallax of the orb of the earth, are multiplied without necessity, since without them all the Phenomena are saved in the hypothesis of the moved earth.

[Margin: Reply to Argument 5.]

The reply is to deny both the first part of the Major, concerning uncertainty, and the second, concerning a multiplication made without necessity. For by the very fact that the Earth is supposed to move in the annual orb, it is certain that the true distance of a Fixed star from the vertex is to be estimated principally from the centre of the Annual Orb, and the apparent distance from the surface of the Earth — granted that, secondarily, a true distance can be estimated from the centre of the orb of the earth, provided that the one is not confused with

the other but they are kept distinct. As for the necessity: although it is not a posteriori, from the phenomena, the Copernicans will nevertheless say that it is a priori, from the most fitting reasons, so that other entities are not multiplied without necessity; and so they will evade the argument.

CAPVT XXXII.

Chapter XXXII.

Proponitur Argumentum contra Hypotheſim Copernicanam, à nimia licentia fingendi diuerſa ſyſtemata.

An Argument is proposed against the Copernican Hypothesis, from the excessive licence of devising different systems.

[Margin: Form of the Argument.]

I. *If, abandoning sense and following certain fitting reasons, one may devise a system such as Aristarchus and Copernicus devised, there will be no certain System in Astronomy; rather, anyone ingenious and imbued with Astronomical learning will be free to devise several different systems. But this seems inadmissible. Therefore etc.* The MAJOR is proved. For someone could place the Moon at the centre of the universe, as Signor Baliani once thought, from what was said in chapter 15; or any one of the Planets, if not all of them together; or he could move the Sun up and down in a librating circle around the Earth — the Earth set at the centre of the World but turned round by the diurnal motion alone — as Father Francesco Maria Grimaldi once thought, for the sake of exercise, but not with any intention of asserting it; and so on with similar things.

[Margin: Reply.]

The reply is to deny the Major's consequence. For it does not follow, from one system determined by Aristarchus or Copernicus, that others equally good can be devised and so render Astronomy uncertain; it follows only that one must either stand by the Copernican system or devise another of equal perfection — which the Copernicans [?] will deny can be done.

CAPVT XXXIII.

Chapter XXXIII.

Rediguntur in Epitomen Argumenta & Solutiones Argumentorum, hactenus facta pro Motu Diurno & Annuo Terræ.

The Arguments, and the Solutions of the Arguments, made so far for the Diurnal and Annual Motion of the Earth, are reduced to an Epitome.

I would not wish anyone, whether from weariness of the labour or through inexperience in Geometrical demonstrations, to fly to the summary in this chapter in such a way as to think that he can draw from it a knowledge

sufficient for passing a certain judgement on these hypotheses among those versed in these matters, without the danger of discoursing on them with little consistency and firmness, or at least with little learning, in ignorance of the Authors who supplied these Arguments. For no one will avoid a danger of this kind except one who has read through the preceding chapters of this section. For a knowledge of things neither small nor few, and indeed often remote from the senses of the common people, must first be possessed by anyone who, on a controversy that is the most celebrated among Astronomical controversies in this age and has been debated among the most learned men on both sides,

wishes to pass a decisive — indeed, as they call it, a peremptory — sentence, and to uphold it once passed. Nevertheless I could not but gather the chief heads of the arguments and replies into a single view, so that I might pluck [?] the conclusions to be set down below from nearer branches, whose long roots, driven higher and deeper, can be seen in what has gone before. Meanwhile let no one be surprised if, for the sake of brevity, we do not bring the Arguments in syllogistic form, and indeed sometimes vary the order of the propositions.

Argumenta 20. Pro Motu Diurno Terræ ac Solutiones eorum; quæ tradita ſunt à Capite 5. ad 7. incluſiuè

The 20 Arguments for the Diurnal Motion of the Earth, and their Solutions, which were given from Chapter 5 to 7 inclusive.

[Margin: See chapter 5, from number 1 to 8.]

I. *The First Argument.* The diurnal motion should be attributed to the Earth, which is certainly spherical and therefore suited to rotation about its own centre, rather than to the heaven of the Fixed stars, of whose roundness, and therefore of whose aptitude for this rotation, we are not certain.

[Margin: Threefold reply.]

The reply was to grant the argument, *first*, if the appearance of the diurnal motion must necessarily be saved by a rotation about a centre, really distinct from the other motions that appear in the heaven; *secondly*, if all else is equal; *thirdly*, if a figure suited to this rotation is required, or if the roundness of the earth is ordained of itself for this rotation. Otherwise, however, it was to deny it: for the appearances of all the celestial motions can be represented by a single real motion of the Fixed stars and a single one in each of the Planets; there are many other reasons against the diurnal motion of the Earth which outweigh this slight little reason taken from sphericity, so that all else is not equal; and the roundness of the Earth is ordained of itself for other ends than for motion.

[Margin: See chapter 5, from number 8 to 11.]

II. *The Second Argument.* If the whole heaven is moved westward by a diurnal rotation, all the elements must be moved by it in the same direction with the rapt motion [motus raptus], and so must the earth, since it hangs in the middle of the air and is not at all hindered from this carrying-along either by any resistance of the air, which is none, or by the force of its own heaviness, since

this does not hinder circular motion but straight motion upward. But if the Earth is moved by a diurnal rotation, the heaven need not be moved by it, and so the multiplication of motions is spared. Therefore the diurnal motion should be ascribed to the Earth rather than to the heaven.

[Margin: The threefold reason of the reply.]

The reply was to deny the consequence of the Major: first, because if the Earth were moved with the heaven by the rapt motion and the rotation of 24 hours, very many celestial Phenomena, which are discussed there, would be lost to us; second, because that rapt motion supposes the heaven solid as far as the Moon, whereas the fluidity of the Planetary heaven is more probable; and finally, because not even the wiser Peripatetics grant that the rapt motion reaches as far as the middle region of the Air, let alone the lowest; and even if it did reach it, it would still be powerless, because of its fluidity and rarity, to impress motion through the whole depth of the Earth, a body most gross and most dense. It was further denied to Galileo that the Earth is of itself as indifferent to motion as to stability.

[Margin: See chapter 5, from number 11 to 16.]

III. *The Third Argument.* Circular motion is more natural to the elements than straight motion, since it is uniform and finite, and belongs to them when they are already ordered and set in their own place; whereas straight motion — uniformly difform in the ascent of light bodies and the descent of heavy ones, and infinite — belongs only to things disordered and, as it were, sick, or faring ill outside their own place. Therefore, if Aristotle attributed circular motion to Fire and to the uppermost region of the air — from without, and violent or preternatural — much more ought he to have granted circular motion to them and to the other elements, and so to the Earth.

[Margin: 1st reply.]

The reply was, 1st, to deny the Major. For no circular motion belongs to the elements from within, but at most a rapt motion from without, which therefore ought not to be called absolutely natural. Indeed, no motion at all belongs absolutely to them when they are well ordered and set in their own place; to disordered ones, however, belongs the motion that takes place along the shortest line and as swiftly as their nature allows — such as is the motion of heavy and light bodies along a straight perpendicular line, uniformly difformly, always accelerated towards the end, and as finite as their removal from their proper place is finite. Therefore this motion, on the supposition of their removal from their place, befits them rather than any other. For these and other reasons we taught that the Peripatetic doctrine on this point is much more solid than the Copernican or the Galilean, and indeed that the latter is hardly consistent with itself: as when they say that circular motion is likened rather to the finite, and straight motion to the infinite, whereas straight motion has ends on both sides and circular motion has none, but always begins again where it seemed about to end. Or when they say that circular motion is more perfect and more congruent with the elements because it is more like rest, as being made wholly

within itself: rather, then, rest itself, being more perfect than circular motion, should be attributed to the elements; for, as in God immobility supposes less need than motion does, it is therefore to be attributed to God as a perfection simply simple. Besides, once the annual motion of translation is added to the Earth, that perfection really perishes, and the diurnal motion is no longer made wholly within itself. See many other points in their place.

[Margin: 2nd reply.]

The reply was, 2nd, to deny the Consequence regarding circular motion towards the West, such as Aristotle attributed to the element of Fire; for if he had attributed this motion to the earth too, rather than motion towards the East, as the Copernicans do, the celestial Phenomena would not be saved.

[Margin: See chapter 5, from number 16 to 18.]

IV. *The Fourth Argument.* It is absurd that the whole heaven and the sphere of the Fixed stars, which has the character of the whole and is incomparably greater than the Earth, should be moved for the sake of the Earth, which is so tiny a particle of the Universe, rather than the Earth itself. Therefore the Earth rather than the heaven is moved with the diurnal motion.

[Margin: Threefold reply.]

The reply was to deny the Antecedent: first, because the heaven, though greater in bulk, is nevertheless less in power and in perfection of substance than the Earth taken together with men and the other animals, for the moving Intelligences are not an intrinsic part of the heaven; second, because neither the heaven nor the moving Intelligences are moved for the sake of the Earth and its inhabitants as for their ultimate end, but so that they may tell the glory of God and serve the Creator — for which end it was not even absurd that Angels, and the very Son of God, should be destined to the salvation of men. Otherwise it would also be absurd for the Planets to be moved around the Earth, or for the Earth to be moved, for the sake of men, who are smaller than the Earth itself; and so the argument was turned back.

[Margin: See chapter 5, from number 18.]

V. *The Fifth Argument.* It is easier, and of less expense, to move the tiny globe of the Earth than the immense machine of the heaven; therefore God and Nature, which does what is easier, move the Earth rather than the heaven with the diurnal motion.

[Margin: Threefold reply.]

The reply was to deny both the Antecedent — because greatness of bulk, taken precisely, does not make its motion more difficult unless some other quality is added, resistive or obstructive in comparison with the motive force, and there is none such with respect to God, or to the Intelligences, in the heaven any more than on the Earth — and the Consequence, because all else is not equal, and there are other, stronger reasons for which God and Nature would not do this, which at first sight seems easier; just as in many other things too Nature has not pursued what seemed easier or of less expense.

[Margin: See chapter 5, from number 18 to 24.]

VI. *The Sixth Argument.* The diurnal motion should be attributed to the body that is certainly established to be movable in this way rather than to one of whose mobility we are not certain. But of the mobility of the Earth we are certain, because we are certain of its finiteness; whereas of the mobility of the highest heaven we are as uncertain as it is uncertain whether it is finite or infinite. For if it were infinite, it would not be movable by a diurnal revolution, or at least it is disputed among the Physicists whether it would be movable.

[Margin: Threefold reply.]

The reply was to grant the Major if all else is equal and deny it if unequal (as in truth they are unequal), and to deny the Minor. For it is physically evident to us that the Fixed stars move: the possession of this evidence lies with the senses, and the proof to the contrary is incumbent on the one who denies it; and from this we gather their mobility more immediately than from finiteness. The evidence of this disjunctive proposition, however — Either the Fixed stars move, or we with the Earth — is not Physical only, but Mathematical, or Metaphysical, which is not necessarily required in Physics; otherwise not even the finiteness of the Earth would be evident, since its measure depends on experiments that are only physically evident. Many things bearing on learning about the infinity of the World were said on that occasion.

[Margin: See chapter 5, number 24.]

VII. *The Seventh Argument.* Local motion should be attributed to the thing located rather than to the place, since a place of itself requires immobility. But the highest heaven is the place with respect to the Earth, and the Earth is the thing located; therefore motion should be attributed to the Earth rather than to the heaven.

[Margin: Twofold or threefold reply.]

The reply was to grant the Major concerning that local motion by which a place loses the character of a place, because it is carried elsewhere together with the thing located and so takes on the character of a vessel, or else deserts the thing located; but to deny the Major concerning motion that is not repugnant to the essence of a physical place — although the Minor is not true either, concerning the immediate place. The argument was moreover turned back: for neither ought the Earth to be moved together with the neighbouring air, since the Earth, together with that air, is the place of animals and plants; and much less ought it to be moved with a motion of translation, which destroys the immobility of the place — such as is the annual motion that the Copernicans add to the diurnal.

[Margin: See chapter 5, number 25.]

VIII. *The Eighth Argument.* Immobility is nobler than motion and more akin to incorruptibility, since local motion is instituted either to preserve from corruption what would otherwise wither in torpor, or else it tends towards corruption. Therefore immobility should be granted to the heaven, and motion to the Earth, as being more subject to corruption than the heaven.

[Margin: Reply.]

The reply was to deny that part of the Antecedent concerning the end of local motion. For local motion is not of itself instituted to preserve from corruption, and much less is the circular diurnal motion; nor, again, does it tend of itself towards corruption, but towards place as place. Further, neither is the heaven, as is supposed, incorruptible by its own nature and from within; nor is the diurnal revolution of the Earth together with the neighbouring air useful for preserving the Earth's surface from corruption, but rather the agitation of the air and the water by the winds, the rivers, the ebb and flow of the sea, etc.

[Margin: See chapter 5, from number 26 to 30.]

IX. *The Ninth Argument.* All the Fixed stars, from the observations of all ages compared with one another, keep perpetually among themselves the same distance that they once had. But if they were moved by a diurnal rotation, they would not keep it: for either they would be moved with the motion of a solid Firmament, and its parts would be scattered by excessive speed; or they would move of themselves in a fluid heaven, and would be scattered much more and drift with a wandering motion, both because of the rapidity of the rotation and because of the fluidity.

[Margin: Reply.]

The reply was to grant the Major and deny the Minor. For if the Firmament is solid, as is gathered from the authority of several Fathers, it is not for that reason worn away, or shaken by a reciprocal motion, nor does it strike against another hard body or grow hot; and therefore no scattering of its parts is to be feared for it. Indeed, from that very preservation of the distance of the Fixed stars among themselves, together with the supposition of their motion, its solidity and indissipable firmness is the more probably inferred. But if it is Fluid, the stars are nevertheless moved by Intelligences, so that they keep that equality of distance and are moved like *the vessel of the camps* [vas castrorum], as *Ecclesiasticus* chapter 43 speaks of these stars, and remain in their watches while they move, as *Baruch* 3 says. Finally, God commends himself in Job 38 on this ground: that the circuit of Arcturus and of the Pleiades, and the constellation, cannot be scattered. Nor indeed ought the wonder that shines forth in a host of stars advancing in so great and so perpetual an order to detract from belief in the divine works — and much less among the Copernicans, who, as will be said later, are accustomed to commend the divine Omnipotence and Magnificence from the immensity of the interval between Saturn and the Fixed stars, and from the vastness of the eighth sphere, and indeed of Fixed stars greater than the Annual Orb itself, in their own hypothesis.

[Margin: See chapter 5, numbers 31 and 32.]

X. *The Tenth Argument.* It seems absurd, indeed ridiculous, that the Fixed Stars and their sphere — so vast, needing nothing terrestrial, but wholly independent of the Earth — should be moved around so small an Earth, and for the favour and good of the Earth as the end of their motion, rather than the Earth itself, which depends on the heaven and needs its influences. Therefore the Earth rather than the heaven is moved with the diurnal motion.

[Margin: Reply.]

The reply was to deny the Antecedent. For the Earth, being full of animals, especially rational ones, is greater than the heaven as regards the magnitude of power and of nobler substance; and it does not need the heaven and the stars as masters but as servants, which, as is established from the sacred Scriptures, are moved for the good of men in such a way that the ultimate end is nevertheless the glory of God.

[Margin: See chapter 6, from number 1 to 7.]

XI. *The Eleventh Argument.* If the diurnal motion is ascribed to the Fixed stars rather than to the Earth, their speed becomes altogether incredible and far exceeds the measure of the subject. For from the Ptolemaic distance of the Fixed stars it follows that any one of the Fixed stars on the celestial Equator passes through 760 German miles in one beat of the human artery — indeed many more, if we follow the Keplerian distance. And if we follow Ours, then in each pulse of the artery each Fixed star passes through 152⅔ semidiameters of the Earth, that is, 629 128 Italian miles, or 157 282 German miles. Therefore the Earth rather than the Fixed stars is moved with the diurnal motion: for in one pulse of the human artery a point on the terrestrial Equator has to pass through no more than 376 geometric paces, from what was said in chapter 19, number 13.

[Margin: Reply.]

The reply was to deny both parts of the Antecedent. The first, because a speed does not become incredible merely because it is greater than the speed of something else, unless it exceeds the capacity or the motive power of the subject, or would offend the senses by its rapidity. None of these is found in the speed of the Fixed stars, because it is commensurate with their distance and with the magnitude of their circumference, and comes from the power of the Intelligences, and yet it is scarcely perceptible to the senses, since they scarcely seem to move within a short time. The second part, concerning the measure of the subject, is denied because, if any two circles differing in magnitude by however much are described about the same centre, and each is revolved whole in the same time, the motion of their parts, or of similar arcs, is as proportioned as those arcs are similar to each other; and the arcs of the circles already mentioned that are enclosed within the same lines drawn from the centre are similar to each other and of as many degrees. Therefore 629 128 Italian miles are as proportioned to one Second of the celestial Equator as 376 paces are to one Second of the terrestrial Equator, as the proportion of the distance from the same centre requires, with the straight lines drawn from it to each circumference serving as legs — of which the former would suit the heaven as a giant, the latter the Earth as an ant. Add that a speed which saves the evidence of the senses is more credible than one which destroys it; and the speed of the Fixed stars asserted by the Ptolemaics is much more credible than the bulk of the Fixed stars asserted by the Copernicans, as was shown in chapter 30, number 8.

[Margin: See chapter 6, from number 8 to 11.]

XII. *The Twelfth Argument.* The motion of the celestial bodies is the slower the farther they are from the centre of the universe: thus the motion of Jupiter is slower than the motion of Mars, and the motion of Saturn than the motion of Jupiter, etc. But if the diurnal motion were attributed to the Fixed stars, it would be far swifter than the motion of Saturn, although the Fixed stars are much farther from the centre of the Universe than Saturn is; and so it would exceed the measure of the subject and the proportion of the intervals. It is therefore to be attributed not to the Fixed stars but to the Earth.

[Margin: Reply.]

The reply was to grant the Major concerning the proper motion that appears towards the East, but to deny it concerning the common or diurnal motion towards the West — or, as they call it, the motion of the primum mobile. For if all the circles about the same centre are moved in the same direction in the same time, the arcs of the more remote circles must be greater, and therefore their motion swifter. But in the Minor the terms are changed, and the discussion concerns the diurnal and common motion, whereas in the Major it concerned the proper motion. And yet (who would believe it?) Galileo, Kepler and Lansbergen fell into this so shameful a fallacy and equivocation, as we showed in its place from their own words — as if they did not know what is known even to beginners in Astronomy: that the proper motion of the Fixed stars is so much slower than the motion of Saturn that, while Saturn requires barely 30 years for one revolution, the Fixed stars nevertheless require 26000 years, or indeed, according to Ptolemy, 36000. For the rest bearing on this learning, see chapter 6, from number 9 to 11.

[Margin: See chapter 6, from number 11.]

XIII. *The Thirteenth Argument.* If the Fixed stars and the other stars were moved towards the West by the diurnal motion, or the common motion of the primum mobile, while a proper motion towards the East cannot be denied them, the same movable body would be moved by two contrary motions at the same time — which is either impossible, or at least so hard to grasp that even the appearance and suspicion of it should be avoided. But it is avoided if the Earth alone, by a diurnal revolution towards the East,

is turned, while the stars individually perform their own simple motions towards the East. Therefore the diurnal motion should be ascribed to the Earth rather than to the Fixed stars and the other heavenly bodies.

[Margin: Twofold reply.]

The reply was, first, to deny the Major. For there is a single motion in the Fixed stars and a single one in Saturn (and so for the rest), towards the West, by spirals; but it is swifter in the Fixed stars than in Saturn, and swifter in Saturn than in Jupiter, etc., because each day the higher stars are revolved to the same meridian sooner than the lower ones. From this arose the illusion by which the lower stars, being left behind by the swifter ones moving towards the West, are commonly thought to recede towards the East — and so the occasion of

suspecting two contrary motions. But this contrariety is as false as it would be in any two bodies running round a circle in the same direction, one of which reaches the same goal more slowly than the other. Yet this very appearance of contrariety would not be avoided by the motion of the Earth, because, once that motion is supposed, everything would nonetheless appear just as it does now, as the Copernicans profess. Next, the argument was turned back against the contrariety of motions that would follow, on the Copernican hypothesis, in heavy bodies or in bodies projected towards the West.

[Margin: See chapter 6, numbers 14 and 15.]

XIV. *The Fourteenth Argument.* Fewer and simpler motions are posited if a single diurnal motion is attributed to the Earth, and to each planet its own motion towards the East, than if a diurnal motion is added to the Fixed stars and the Planets over and above their proper motion. Therefore etc.

[Margin: Twofold reply.]

The reply was to deny the Antecedent. For the diurnal motion of the Fixed stars and of the Planets is not in reality distinct from their proper motion, since the proper motion is not such except in appearance, on account of their falling behind and their later arrival at the meridian; and so no more than 8 motions are posited in the heaven, one in the Fixed stars and 7 in the Planets. (For there is no point here in counting the motions of the Satellites of Saturn and of Jupiter, because these too must be multiplied no less in the Copernican hypothesis than in the more common one.) But if a diurnal motion is given to the Earth, that motion is then really distinct from the proper motion of the Fixed stars (which, of course, Lansbergen, Longomontanus, Boulliau and many others among the Copernicans or Semi-Copernicans admit in the Fixed stars) and from the 7 motions of the Planets; and moreover, in the motion of heavy and light bodies — indeed in all terrestrial and aquatic mixed bodies — several motions mixed of straight and circular must be admitted. Therefore, when everything is reckoned as it really is, more motions are multiplied, and more compounded ones among terrestrial things; hence the argument was turned back against the Copernicans.

[Margin: See chapter 6, number 16.]

XV. *The Fifteenth Argument.* If the Fixed stars were moved by the diurnal motion rather than the Earth, then, not only in different times but in the same time as well, some would describe great circles — namely those on the Equator — and others the smallest circles — namely those near the poles; and so the former would be the swiftest, the latter the slowest. But this is absurd. Therefore the Earth rather than the Fixed stars is moved by the diurnal motion. I should be ashamed even to have put this argument forward, were not the whole shame to overflow onto Galileo, who urges it in earnest — and who would certainly be thrashed by mere beginners in Astronomy.

[Margin: Threefold reply.]

For the reply was, first, to deny the Minor, since this arises from geometrical necessity: namely, that of the parts of a spherical surface revolved by a single

motion of the sphere, those nearer the poles describe smaller circles and move more slowly than those farther from the poles of the sphere. Second, that comparative particle of the Major, *rather than the Earth*, was denied. For granting — without conceding — a diurnal motion of the Earth, neither would the appearance of slowness in the Fixed stars nearer the pole, and of speed in the Fixed stars near the Equator, be removed; and in the parts of the Earth itself there would really be that inequality of speed and of circles, according as they are nearer to or farther from the poles of the terrestrial revolution. Therefore, if this were absurd, the absurdity would be double, or in a double subject: one apparent, in the eighth sphere; the other real, in the Earth. Whereas it would be single, or real in a single subject, if the diurnal motion is attributed to the Fixed stars. So the argument already mentioned can accordingly be turned back *ad hominem*.

[Margin: See chapter 6, numbers 17 and 18.]

XVI. *The Sixteenth Argument.* If the Fixed stars were moved by the diurnal motion, they would perpetually vary their declination from the Equator, and therefore their speed as well, so that a star that had once been the swiftest, on the Equator, would in some age become the slowest because of its nearness to the Pole. But this is absurd. Therefore etc. So too Galileo, and in earnest — although this argument has no kernel at all.

[Margin: Threefold reply [?].]

The reply was, first, to deny the Major if the diurnal motion is considered precisely, and to concede it if an apparent proper motion is granted to the Fixed stars — that is, if that single motion towards the West is completed by spirals in latitude. *Secondly*, granting the Major, to deny the Minor: for this is no more absurd in the heaven than it would be on the Earth if it moved with the diurnal motion and besides with a motion of the axis and a libration accounting for the proper motion that appears in the Fixed stars. Indeed, it would follow more on the Earth, where animals, rivers, ships, clouds, etc. perpetually change their declination from the terrestrial Equator, more frequently and with greater variety. Accordingly the reply was, *Thirdly*, to turn the argument back. But what we indicated there about Fixed stars that will reach the pole, and about the retrogradation of some of them in right ascension, and set out in book 6, chapters 11 and 19, problems 5, 10, 11, cannot be explained in a few words in this place.

[Margin: See chapter 6, number 19.]

XVII. *The Seventeenth Argument.* The annual inequality of the natural days, which is manifest to Astronomers, has a more evident cause if the diurnal motion is attributed to the Earth together with the annual one, inasmuch as the Earth is quickened by its approach to the Sun and slowed by its recession. So *Kepler*.

[Margin: Reply.]

The reply to him was to deny the Antecedent. For if that inequality arises from the variation of the distance between the Sun and the Earth, then whether

the Earth really approaches the Sun or the Sun the Earth, we have an equal account of the inequality either way.

[Margin: See chapter 7, numbers 1, 2 and 3.]

XVIII. *The Eighteenth Argument.* It is more probable that the Comets do not have a diurnal motion in themselves, but only their own trajections, so that we do not increase the difficulties in so wandering and manifold a motion. Therefore the diurnal motion towards the West that appears in the Comets really comes from the turning of the Earth towards the East; for it cannot be attributed to a sweeping-along of the fire or the air, since the heavens of the Planets are not solid and do not sweep the fire along, etc.

[Margin: Reply.]

The reply was to deny the Antecedent. For just as the diurnal motion in the Planets is more evident than their proper motion, so it is in the Comets too; and therefore, just as we must not deny the diurnal motion to the Planets, so neither to the Comets. Otherwise we should rather be multiplying motions — namely a proper trajectory motion in the Comets and a common diurnal motion in the Earth — whereas the same Intelligence or force that moves the Comets with the diurnal motion can move them by spirals looser than in the Planets, so that by the looseness of the spirals a motion in latitude, and by the slowness of the revolution to the meridian or the horizon a motion in longitude towards the East, is represented, though by a single motion in reality.

[Margin: See chapter 7, from number 4 to 8.]

XIX. *The Nineteenth Argument.* The perpetual wind and breeze within the Tropics, which is at least a partial cause of the easier and shorter navigation towards the West than towards the East, more probably comes from the diurnal motion of the Earth towards the East, which leaves the air behind; for the air, because of its fluxibility, does not receive so great an impetus, and is not carried along by the Earth's rotation so as to follow it exactly. Therefore it is more probable that the Earth is moved by a diurnal motion than not. For the rest, to grasp the force of this argument better, see the place cited.

[Margin: Reply.]

The reply was to deny the Antecedent. For since the diurnal motion of the Sun and the other Planets towards the West is more evident to sense, the cause of that perpetual breeze should rather be attributed to the Sun, with the other Planets assisting it, carrying vapours and exhalations around or raising them successively towards the West — especially since the breeze is not so perpetual and continuous as it would have to be if it came from the Earth's rotation. On this variation consult the history of these Winds that we selected, in chapter 7, from number 4.

[Margin: See chapter 7, from number 9 to the end.]

XX. *The Twentieth Argument.* A small sphere made of the magnet-stone, which is called a terrella, if it is suspended on the poles of its own axis — the axis along which the magnetic virtue extends towards the Poles of the terrestrial Equator — revolves with a diurnal revolution towards the East. The

spagyrists also report this of the chymical or Hermetic Earth. Therefore the whole Earth too, which is a great Magnet, is turned towards the East with a diurnal revolution.

[Margin: Reply.]

The reply was to deny the Antecedent. For the experiment — which was not performed, but feigned in the imagination by Petrus Peregrinus from a conjecture that seemed probable to himself — has been neither found nor held to be true by Gilbert, nor by the Fathers of our Society Athanasius Kircher, Cabeo or Niccolò Zucchi, who have written best of all on this subject; indeed,

rather, they teach that a Magnetic virtue has been implanted in the Earth so that it keeps itself immovably in the position that GOD once established for it with respect to the Poles of the World. The terrella already mentioned is indeed moved towards the Poles under the meridian, if it is suspended from the poles of the meridian, until its axis coincides with the axis of the terrestrial Equator; but this motion is not the one we are disputing about. Yet the Earth is not a great magnet. For the rest of the learning needed here, see chapter 7, from number 9.

Argumenta 29. Pro ſitu Solis in centro Vniuerſi, & Motu Telluris Annuo circa Vniuerſi centrum; ſimul cum Diurno: ac Solutiones eorum, quæ traditæ ſunt à Capite 8. ad 18. incluſiuè.

29 Arguments for the position of the Sun at the centre of the Universe and for the annual motion of the Earth about the centre of the Universe, together with the diurnal motion; and their Solutions, as given from chapter 8 to 18 inclusive.

[Margin: See chapter 8, numbers 2 and 3.]

XXI. *The First Argument.* The centre of the World is the noblest place, and the Sun is nobler than the Earth; therefore that place is owed to the Sun rather than to the Earth.

[Margin: Reply.]

The reply was to concede the first part of the antecedent in the natural order — for in the supernatural order the nobler place is the Empyrean, and the lowest and worst is Hell, the place of the damned — but the latter part was denied. For the Earth, with its living things and animals, especially the rational ones, is nobler than the Sun.

[Margin: See chapter 8, numbers 4, 5, 6.]

XXII. *The Second Argument.* The Sun is the centre of the Planetary system, since it is now certain that Mercury and Venus move about it, from which a similar conjecture is made about the others. Therefore it must be the centre of the Universe.

[Margin: Twofold reply.]

The reply was, 1, to deny the Antecedent concerning the system of the Planets taken adequately: for the Sun is not the centre of the Moon's motion — indeed,

probably not even of Saturn's and Jupiter's, for the reasons given in their place. 2, to deny the consequence, because the centre of the Universe must be the centre of all the bodies of the World — that is, of the elements and of all the celestial bodies, and so also of the sphere of the Fixed stars and of the new Phenomena — and such a centre is the Earth, or the Earth's centre; and so the argument was turned back against the Copernicans.

[Margin: See chapter 8, numbers 7, 8, 9.]

XXIII. *The Third Argument.* The Sun is the source of the light and heat of the whole Universe. Therefore it must be placed in the middle of the Universe, so as to illuminate all things equally.

[Margin: Reply.]

The reply was to deny both the Antecedent, because the Sun is not the source of the light of the Fixed stars, and the Consequence, because it does not illuminate all the Planets equally, as is clear from the variety of their phases. It suffices, then, if it moves in such a heaven that it can illuminate the Earth and the Planets in the way it now illuminates them, according to the measure of divine Providence.

[Margin: See chapter 8, numbers 10, 11, 12.]

XXIV. *The Fourth Argument.* The Sun is the source of the motion of the Planets, since they are attuned to its motion. Therefore it must be at the centre of the World.

[Margin: Reply.]

The reply was to deny the Consequence, because the Sun is not the source of the motion of the Fixed stars, of the New Phenomena, of the Elements, etc. Indeed, it is not even the efficient cause of the motion of the Planets, as Kepler imagines, but an exemplary cause with respect to some aspect of the motion; whereas the Earth, with men, is the final and objective cause of the motion of the stars.

[Margin: See chapter 8, number 13.]

XXV. *The Fifth Argument.* It is more credible that the Planets and the Earth are moved about that which is greater than all of them, namely about the Sun, than that the Sun is moved about the Earth, which is smaller than many Planets.

[Margin: Twofold reply.]

The reply was to concede this likelihood if other things are equal, and if what is greater in bulk is also greater in power and in perfection of substance — in the way that the Earth, with men, is greater than all the Planets; but if magnitude of bulk alone is considered, the proposition is denied. Next, if the ground for rest is to be taken from bulk, then it is more credible that the Sun is moved about the elementary sphere than that this sphere, with the lunar heaven, is moved about the Sun — the Sun being, indeed, much smaller than that sphere.

[Margin: See chapter 8, number 14.]

XXVI. *The Sixth Argument.* It is the Earth that needs the Sun and the other Planets, and in it is the creature that measures out and contemplates the divine works — not in the Sun. Therefore the Earth rather ought, by an annual

translation of itself, to approach the various parts of the world in order to contemplate them, and to bring back from them the wares of their influences.

[Margin: Reply.]

The reply was that the Earth needs the stars not as masters but as servants, waiting on it by divine command and ordinance and serving man; and that for contemplating and measuring the intervals and magnitudes of the stars the motion of the Earth contributes nothing more than the motion of the Sun and the other stars about an immovable Earth, since the same things appear in either hypothesis; and that it suffices for man to go out into the open and, by observations duly made, to measure the motions, intervals and magnitudes of the stars.

[Margin: See chapter 8, number 15.]

XXVII. *The Seventh Argument.* In the Microcosm, that is, in man, the feet are moved with progressive motion, not the head. Therefore in the Macrocosm too, that is, in the World, the Earth must be moved, not the Sun.

[Margin: Reply.]

The reply was to deny the Consequence: both because the Earth is not the foot in the World — and much less so in the Copernican hypothesis, since in that hypothesis it is not the lowest — but is the immovable footstool of the feet of GOD, as the Royal psalmist says; and because, just as the head too is carried along with the motion of the feet, so with the motion of the Earth either the Sun or the sphere of the Fixed stars ought to be carried along, since one or the other would have to be called the head; but the Copernicans concede neither.

[Margin: See chapter 8, numbers 16 and 17.]

XXVIII. *The Eighth Argument.* Unless the Sun is at the centre of the World, and the Earth, with the Elements and the lunar heaven, moves between the convex of Venus and the concave of Mars, to the Sun, the greatest of the Planets, falls the least thick heaven of all, and to Venus and Mars by far the greatest; and too great a space would lie between the convex of the Sun and the concave of Mars.

[Margin: Twofold reply.]

The reply was that it is a greater absurdity that no heaven be given to the Sun, placed immovably at the centre, than that some heaven be given to it outside the centre; and to count the Earth, with the elements, among the celestial bodies. Next, if Mercury, Venus, or even Mars are supposed satellites of the Sun, all these belong to a single heaven; on this we said more in our new system, at the end of the third section.

[Margin: See chapter 8, numbers 18 and 19.]

XXIX. *The Ninth Argument.* Unless the Sun rests at the centre of the World, and the Earth moves through the Annual Orb, approaching Mars and receding from it, Mars at perigee must not infrequently be nearer to the Earth than the Sun is, and so must penetrate the heaven of the Sun, and thus the distinction of the heavens is removed. But this is unfitting. Therefore etc.

[Margin: Threefold reply.]

The reply was to deny the Minor. For if the Sun rests at the centre, it no longer has any need of a heaven; and if the Earth proceeds annually between Venus and Mars, it becomes, with its elements, one of the Planets. But it is a greater absurdity to cast the Sun out of every heaven and to raise the Earth with its elements into the heaven in its place than for the heaven of one Planet to be mingled with that of another. Next, if Mars, as we said in our system, is a satellite of the Sun together with Venus and Mercury, the same heaven serves the Sun and these three. Finally, since the heaven of the Planets is fluid, there is no greater necessity to assign the Planets a distinct heaven than to assign birds or fishes a distinct region of air or water.

[Margin: See chapter 8, from number 20 to 26.]

XXX. *The Tenth Argument.* If the Earth is moved by an annual motion about the Sun placed at the centre of the World, and the Earth's Annual Orb lies between the concave of Mars and the convex orb of Venus, an account is given of the number of the Planets, and of the intervals between the Planets, from most beautiful proportions worthy of God as their maker — namely from the commensurations of the five Regular bodies inscribed in or circumscribed about spheres. Therefore it is far more probable that the Earth is moved in this way than that it is not moved. The Antecedent is proved: for if you circumscribe a Dodecahedron about the annual orb of the Earth, the circle circumscribed about it will be the concave of the orb of Mars; if you circumscribe a Tetrahedron about the convex of the orb of Mars, the circle enclosing it will be the concave of the orb of Jupiter; and if you circumscribe a Cube, or Hexahedron, about the convex of the orb of Jupiter, the circle embracing it will be the concave of Saturn. Next, if you inscribe an Icosahedron in the concave of the Annual orb, the circle inscribed in this Icosahedron will be the convex of the orb of Venus; finally, if you inscribe an Octahedron in the concave of Venus, the circle inscribed in it will be the convex of the orb of Mercury. Kepler called this the *Mysterium Cosmographicum*, and fitted it, in imitation of the Pythagoreans and the Platonists, to the order and symmetry of the World. On this truly ingenious application see what was said in chapter 8, from number 20.

[Margin: Reply 1.]

The reply was fourfold. First, by denying the Antecedent: because that beauty in the distribution of the planetary intervals, apparent at first sight, contains many absurdities within it, and yet does not give an account of the number of the Planets. For it destroys the number of the primary Planets commonly received by the learned, since it turns the Sun from a Planet into a Fixed star; does not count the Moon, in this distribution of the bodies, among the primary Planets, but makes it the Earth's companion, while making the Earth, together with the elements, a primary Planet; and reckons Mercury and Venus among the Primary ones. Consequently, from that proportion no more than 6 Planets arise, namely Saturn, Jupiter, Mars, the Earth or sphere of the Elements, Venus and Mercury. But what is more absurd than to strike off the roll of the Planets the two great Luminaries, by whose motions, most evident to sense, the years

and months are distinguished, and to tear apart that Septenary number of the Planets — as it were the Heptachord of the World, far better known and more celebrated than the Pythagorean distribution of the bodies of the World?

[Margin: Reply 2.]

Secondly, the Antecedent was denied, because not even so is an account of the planetary intervals given adequately, since no account is given of the thickness of the heavens, especially of Saturn's and Mercury's, nor of the interval between Saturn and the Fixed stars. Indeed, of the remaining five intervals there are only two that correspond closely to the distances owed to the Copernican hypothesis and derived from observations — namely those of Mars and of Venus; the rest are far off, and cannot be brought into agreement with the proportions of the Regular bodies except by numbers violently begged, as I showed in chapter 8, number 25, reply 4.

[Margin: Reply 3.]

Thirdly, the Consequence is denied: since, if we wish to make the intervals of the Planets conform to the measures of the Regular bodies, the Phenomena are not saved, as I showed in the same place, in reply 2.

[Margin: Reply 4.]

Fourthly, the Consequence is likewise denied, because that proportion and beauty of the Regular bodies does not seem suited to the Physical effects that divine Providence willed to exist in the nature of things. For it consists in a determinate number of regular faces by which those five of the bodies are bounded; but the intervals of the Planets are not taken from bodies as bodies; nor in fluid heavens is there a real distinction of the heavens, much less of Regular bodies; nor do they exert influence on these lower things as such bodies, but by reason of light and of the influences flowing through light into the lower things. Besides, neither the Platonists nor the Pythagoreans distributed those bodies in this way; rather, they assigned the Cube to the Earth, the Tetrahedron to Fire, the Octahedron to Air, the Icosahedron to Water and the Dodecahedron to the globe of the Universe — and that not with regard to quantity and measure, as Kepler does, but speaking metaphorically and with regard to other properties: namely stability in the Cube, the mobility of Fire in the Tetrahedron or pyramid, etc., as may be seen in Plutarch, book 2 of *De placitis*, chapter 6. Moreover, Kepler himself confessed that harmonic proportions are found in the hypothesis of the immovable Earth as well, as I showed in chapter 8, number 26.

[Margin: See chapter 9, from number 1 to 5.]

XXXI. *The Eleventh Argument.* Motions, or the instruments of motions, are not to be multiplied without necessity. But if the Earth is at rest, the motions of the second Anomaly are multiplied in the five lesser Planets, and so are the instruments of these motions — namely three Epicycles in the three superior Planets and two Eccentrics in the two inferior Planets — and that without necessity, since all of them can be accomplished by the single Annual Orb of

the Earth. Therefore the Earth moves through the Annual orb rather than being at rest.

[Margin: Twofold reply.]

The reply was, 1, to deny the Minor, because the motions are not really multiplied if there is a single spiral motion in each Planet. Moreover, the multiplication of apparent motions comes from a twofold necessity. *The first* is that the motions evident to sense be saved — such as the motion of the Sun, and the harmony of the other Planets attuned to the motion of the Sun — and that in their place motions of the Earth and of the other elements not be introduced, from which the intellect recoils more than from a mere multiplicity of motions. *The other* necessity is that other motions, more manifold and differing in species, number and accidents, not be multiplied — namely an annual motion in the lunar heaven, in the Earth and all the Elements, and in the inhabitants of the elements. 2, *the reply was* by distinguishing the Major: denying it of mere arithmetical multiplication, and conceding it of a multiplication that is useless or superfluous for the end intended by God and by Nature — for the sake of which end, in many other things too, what could otherwise be done arithmetically by fewer means is accomplished by more, but not equally well, and without attaining the end.

[Margin: See chapter 8, from number 6 to 9.]

XXXII. *The Twelfth Argument.* In the apparent motion of the Planets there are many imperfections, if that motion were really such as it appears — chiefly the Stations and Retrogradations, and the excess of the Epicycle of Mars and of Jupiter over the Epicycles of the others, although their Eccentrics are the smallest; and the more frequent alternations of Stations and Retrogradations in the slower Planets; and the like. But if they are not real but merely apparent, they are not Physical imperfections but Optical ones, and more tolerable. Yet if the Earth does not move, they are real and Physical; if it moves, they are merely apparent and Optical, for they all occur because of the approach of the Earth, moving annually, to the Planets as they go towards the East on a mere and simple eccentric, or because of the Earth's recession from them. Therefore the Earth moves annually rather than not.

[Margin: Fourfold reply.]

The reply was: *First*, by denying that they are imperfections absolutely; for neither inequality in motion, nor pauses, nor an acceleration and retardation suited to the end of the motion, is an imperfection, but a perfection — just as in harmonic concords and rhythmic dances. *Secondly*, by denying that they are imperfections comparatively, that is, greater than those that must be admitted in the hypothesis of the Earth moved annually and daily. For every motion of the Sun must be extinguished, which is worse than a momentary station or retrogradation of some Planets; the Earth with its elements must be transferred into the heaven; innumerable motions must be attributed to all who inhabit the Earth, the Water and the Air near the Earth; and the lunar heaven must be inserted between Mars and Venus and moved with an annual motion together

with the Earth, etc. *Thirdly*, by denying that they are real imperfections in one hypothesis and apparent ones in the other; for in both they are apparent, because they come from the position of the eye: if the eye were at the centre of the Epicycle of the five Planets, they would be seen always to advance. *Fourthly*, the argument was turned back: because in the hypothesis of the Earth's annual motion mixed with the diurnal, one must admit a far more frequent appearance of Stations and Retrogradations, and an inequality of motion mixed of the diurnal and the annual — and that without any necessity, or foundation taken from the senses, which perceive no motion of the Earth, much less its inequality. But these things cannot be understood perfectly unless what was said in chapter 8, from number 6 to 9, and in chapter 14, from number 4, is read. Moreover, Kepler confessed that in the Tychonic hypothesis too, and in others equivalent to it, an account of the Stations and Retrogradations can be given, as I showed in the same place.

[Margin: See chapter 9, from number 10 to 12.]

XXXIII. *The Thirteenth Argument.* There are many other things in the heaven of which no sufficient account can be given by the hypotheses of others, but of which an account is given by the single annual motion of the Earth as it approaches the Planets and recedes from them: namely, why the Eccentrics of the Sun, Venus and Mercury have equal revolutions; why the Superior Planets appear now very large, now very small; and why at opposition with the Sun they are always low, and at conjunction high, etc. Therefore the Earth moves with an Annual motion.

[Margin: Twofold reply.]

The reply was, 1, to deny the Antecedent: for in the hypothesis of the others, too, a sufficient account is given. For whether the Earth itself approaches the Planets, which are moved by no other motion than a single one in longitude, or, with the Earth unmoved, the Planets themselves approach the Earth by an apparently twofold motion, the same Phenomena result; indeed, fewer motions arise if the individual Planets, as we suppose, are carried round by an Intelligence along a single spiral line representing several motions in length and breadth. 2, the Consequence was denied, because, granted that an account of the effects already mentioned were given by the annual motion of the Earth, many other more absurd things would nevertheless lie hidden in this motion, which we have indicated above more than once; and still others will be uncovered in the next chapter.

[Margin: See chapter 9, from number 13 to 15.]

XXXIV. *The Fourteenth Argument.* If the Earth moves with an annual motion, the inclination of the orbit of the five lesser Planets keeps a constant angle, and there is no need for a libration of the orbs or for a tortuousness of the Planet's path;

but it is otherwise if the Earth does not move in this way. Therefore the Earth does move in this way.

[Margin: Twofold reply [?].] *The reply was*: 1. By denying the Antecedent, since that constancy of the angle can be saved in other hypotheses of a resting Earth as well, as I showed in chapter 9. Next, the consequence is denied, because in the hypothesis of the moving Earth there lie hidden many other imperfections, far greater than an inconstant inclination of the orbit and a winding path of the Planets would be.

[Margin: See chapter 9, numbers 16 and 17.] XXXV. *The Fifteenth Argument.* The equant circle [Circulus Æquans] is out of keeping in astronomy, since the Planet is supposed to move uniformly with respect to it, even though it does not move on that circle but on another. But this imperfection is removed by the annual motion of the Earth, and not by its rest. Therefore etc.

[Margin: Reply.] *The reply was*: First, by denying the Major, if the equant seems absurd because it supposes a real inequality in the motion of the Planets; for we have shown sufficiently, in section 2, chapter 4, that this inequality must be admitted and is no imperfection. Second, we denied the Minor: for the imperfection of the equant, taken as the bisection of the eccentricity, is not removed in the hypothesis of Kepler and Boulliau, who nevertheless posit an annual motion of the Earth; and it is removed in the hypothesis of Tycho, of Longomontanus, and in our own.

[Margin: See chapter [?]0, number 1.] XXXVI. *The Sixteenth Argument.* The same Fixed stars appear swifter and larger than themselves (other things being equal as to the clearness of the air and the distance from the horizon) at one time of the year than at the opposite time, as Io. Stadius, Io. Pena and Rothmann have asserted. Therefore it is a sign that the Earth approaches them at one time and recedes from them at the other.

[Margin: Reply.] *The reply was*: by denying the Antecedent, which is contradicted both by our own experience and by the common experience of observers, and by the very hypothesis of Copernicus, in which it is supposed that the annual orb produces no sensible Parallax, or variation of view, in the Fixed stars.

[Margin: See chapter [?]0, number 2.] XXXVII. *The Seventeenth Argument.* The revolution of Jupiter's satellites around Jupiter is not regular if it is reckoned from lines drawn from the centre of the earth; but it is regular if reckoned from the centre of the Sun — so Simon Marius observed. Therefore the Earth, rather than the Sun, moves with the annual motion.

[Margin: Reply.] *The reply was*: granting the Antecedent, though it may be doubted, by denying the consequence. For from it there follows not the motion of the Earth, but at most that the Sun is the centre of the motions of the Planets, or that it serves Jupiter as a model for revolving its satellites in the same way as the Sun leads its own, Venus and Mercury, around itself.

[Margin: See chapter [?], number 3 [?] 5.] XXXVIII. *The Eighteenth Argument.* The variation of motion and the libration of the Moon's body are better explained by supposing an annual motion of the Earth. Therefore etc.

[Margin: Reply.] *The reply was*: by denying the Antecedent — both because they are explained equally well by a small librating circle [circellus libratorius]; and because that libration and variation are monthly, and therefore have no fitting account from the annual motion as such; and because many things concerning it have been falsely supposed by Hevelius and Boulliau, which we shall expose in the Appendix to book 4. Besides, there are many other absurdities in the Earth's motion which outweigh this very slight convenience, if convenience there were.

[Margin: See chapter [?], number 6.] XXXIX. *The Nineteenth Argument.* The new star which appeared in Cassiopeia in the year 1572 gave evidence, by its own increase, of the Earth's approach to it. [Margin: Reply.] *The reply was*: by denying the antecedent, since the star decreased continuously, even at the time when the Earth, had it moved annually, would have approached it; see what was said in chapter 10, number 6.

[Margin: See chapter [?], number 7.] XL. *The Twentieth Argument.* The path of the Comets, as to their motion both in longitude and in latitude, is explained much more readily in the hypothesis of an Earth carried round annually. Therefore the Earth moves annually.

[Margin: Twofold reply [?].] *The reply was*: 1. By denying the Antecedent, since Tycho rather confirms the Earth's rest from it: for if the Earth moved with this motion, some Comets ought to have appeared Retrograde and slower, and yet they did not appear so. 2. By denying the Consequence — both because of the other absurdities of the Earth's annual motion, pointed out in chapter 9 from number 5, which extinguish this little spark of probability violently struck out of the Comets; and because Kepler supposes a rectilinear and regularly decreasing motion in the Comets, although he has demonstrated neither. But we have said more on this matter both in chapter 10, number 7, and in book 8, section 1, chapter 26.

[Margin: See chapter 11, from number 1 to 5.] XLI. *The Twenty-first Argument.* The Meridian line gradually, after some centuries, changes its position and declines from the original plane of the Meridian. Therefore this arises from the motion of the Earth.

[Margin: Reply.] *The reply was*: 1. By denying the Antecedent, which Iosephus Scaliger deduced *a priori* from most fallacious principles, and Caesar Marsilius [Cesare Marsili] from slippery little observations. 2. By denying the Consequence, because the Copernican hypothesis rather requires a stable appearance of the meridian line; but see what was said in chapter 11, from number 1 to 5.

[Margin: See chapter 11, from number 6 to 16.] XLII. *The Twenty-second Argument.* The altitudes of the Pole at one and the same place have been found to vary: either after many centuries, as Dominicus Maria [Domenico Maria Novara], Iosephus Scaliger, Io. Stadius and Io. Antonius Maginus noticed; or at least twice a year, as Rothmann observed; or finally every day, as Alexander Calignonus observed from the nutation of plumb-lines towards the sides of

the world, and as Gassendi did not deny. Therefore the Earth moves annually. Someone could confirm this if a pendulum 40 Paris feet long and weighing 5 pounds performed, on the day of the summer Solstice, 20 or 30 fewer vibrations in one hour in the evening than in the morning — for Mersenne thought that the truth of one or the other hypothesis could be decided from this, and wrote to the most illustrious Count of Alais, Governor of Provence; Father Paulus Casatus [Paolo Casati] showed me a copy of his letter.

[Margin: Twofold reply.] *The reply was*: 1. By denying the Antecedent, and by exposing the fallacies, and indeed the inconsistency, in the observations. 2. By denying the Consequence drawn from the first and third kinds of change: for from these there would follow a secular motion, or a diurnal motion towards the poles, but not an annual one; and yet that motion is opposed by the magnetism of the Earth, which many Copernicans have attributed to it precisely so that the Earth may keep itself in the same position with respect to the Poles. But see chapter 11, from number 6 to 16.

[Margin: The argument from the vibrations of the pendulum for deciding between the Ptolemaic and the Copernican Hypothesis.] As for the number of evening vibrations of the pendulum, etc.: I replied that an experiment of this kind is tried in vain, since it would be better tried with a shorter pendulum, as one that exhibits a greater number of vibrations. And yet neither in the morning, nor in the evening, nor about Midday or Midnight (which would be better, since the difference which the diurnal motion would add to the annual would then be more evident than in the morning or evening) has any certain and sensible difference appeared to us between the vibrations of one equal hour, marked by the transits of the stars, and those of another. Nor can such a difference arise of itself from the motion of the earth, since the pendulum itself must follow both motions of the earth, according to Copernicus; and all the phenomena of natural motions must be saved equally in either hypothesis — whatever may be the case with violent or preternatural motions.

[Margin: See the whole of chapter 12.] XLIII. *The Twenty-third Argument.* The apparent path of the Solar Spots, and their truly wonderful and most certain alternations, are explained by simpler and fewer motions if an annual motion of the Earth is asserted than if one of the Sun. Therefore the Earth, rather than the Sun, moves annually.

[Margin: Twofold reply.] *The reply was*: 1. By denying the Antecedent: for in either hypothesis only three real motions are necessary to save the Phenomena of the Solar Spots. Namely, in the hypothesis of the moving Earth: the annual motion of the Earth, the diurnal motion of the Earth, and the motion of rotation [motus Vertiginis] of the Sun about its own centre. In the hypothesis of the motionless Earth, on the other hand, there are required: the spiral motion of the Sun's centre, but slower than the motion of the Fixed stars and of the primum mobile, and therefore representing in itself, though single, both the diurnal and the annual motion; and the annual motion of the poles of the Sun's mobile Axis about its fixed axis, performed from West to East; and a third

motion, an as it were monthly rotation about another mobile axis, from East to West. Therefore in the number of real motions there is parity. But there is this disparity: Galileo distributes these motions to two really distinct subjects — namely the diurnal and the annual to the Earth, and the monthly rotation to the Sun — and so it is no wonder if the Sun's motion seems simpler; whereas Scheiner gives all three to the same subject, namely the Sun; and these motions are more evident to the senses. 2. The Consequence was denied, because of the many other inconveniences lurking in the motions of the Earth, but already pointed out often, and especially in chapter 9 from number 5.

[Margin: See chapter 13, number 1.] XLIV. *The Twenty-fourth Argument* is taken from the perpetual wind which is felt blowing towards the West, especially in the Torrid Zone; for from this some people beg a little breath of support for the annual motion too. [Margin: Reply.] But this argument would require continuous, and over the whole tract of the Torrid Zone, win- ds, if the cause were the motion of the Earth — which, however, is false according to the historical record. And another, more probable cause shows itself in the Sun, which raises one vapour and exhalation after another in succession as it moves towards the West. Indeed, a wind of this kind would have to run towards the East by day and towards the West by night, which is very much to be noted.

[Margin: See chapter 13, number 2.] XLV. *The Twenty-fifth Argument.* The fibres and veins of metal in mines are seen to face the East: therefore this comes from the annual motion of the Earth towards the East. [Margin: Reply.] But the Consequence was denied, because, if this is true, it arises from the illumination of the Sun, which rises and takes its increase from the eastern quarter. For why would rivers, which are more fluid, not bend their course towards the East because of the Earth's annual motion, overcoming very many obstacles? It is truer, however, that those veins face the Poles of the world, as appears in quarries and in the cut trunks of trees.

[Margin: See chapter 13, number 3.] XLVI. *The Twenty-sixth Argument.* An iron plate hung in equilibrium from a bronze thread in a small, closed room, so that it faces the East with one end and the West with the other, nevertheless turns itself at last towards the poles. From this some have suspected that the cause is the motion of the Earth compounded of the annual and the diurnal, [Margin: Reply.] whereas they ought rather to recognize the magnetic force of the iron, which directs itself towards the poles of the world.

[Margin: See chapter 13, number 4.] XLVII. Some take the *Twenty-seventh Argument* from the danger of putrefaction, unless the Earth is either perpetually agitated or preserved by a soul, as if by salt. [Margin: Reply.] But corruption at the surface of the earth is not in fact avoided altogether, since it occurs in very many parts; and in the depths it is feared in vain.

[Margin: See the whole of chapter 14.] XLVIII. *The Twenty-eighth Argument.* The alternating changes in the Tide of the Sea, which all the Schools have admired up to now — whether you consider the daily ones, which mostly return every six hours; or the monthly ones, which vary notably at New Moons

and Full Moons; or the annual ones, which show a remarkable difference at the Equinoxes and Solstices — are explained in no other more convenient way, and with no more evident, or at least more probable, cause adduced, than by an unequal motion of the Earth, arising from the varied mixture of the diurnal motion with the annual. Therefore, even from this one advantage, each of the two motions of the Earth comes out more probable than rest. As to how Galileo, and Gassendi subscribing to him, explain the flux and reflux of the Sea by both motions of the Earth, see chapter 14, from number 1 to 10.

[Margin: Reply.] *The reply was*: by denying the Antecedent. First, because that inequality which would arise from the diurnal and annual motion of the earth would be insensible and without any sudden change in itself, and therefore unfit to shake the Earth and, by the shaking, to cause the tide of the sea. Second, because even if it were sensible, it would not suffice to produce the very many variations of the tides that are manifest. Indeed, Galileo's doctrine would overturn the most certain Rules of the most experienced pilots [Naucleri], which depend on the phases and motions of the Moon; and the greatest part of the historical record of the Tide of the Sea would be false. On the other hand, although no opinion on the cause of the tide of the Sea has yet stood out that removes all difficulties and satisfies an intellect contemplating all the differences of the tides, there are nevertheless some that are far more probable than Galileo's opinion — which Chiaramonti, Cabeo and Fournier have therefore deservedly hissed off the stage. But to check Galileo's boasting in this argument, we resolved in chapter 14 to gather, by a most diligent inquiry, the historical record of the motions of the Sea, and above all of the tide, which we did from number 11 to 20; the choicest Rules of the pilots, which was done from number 20 to 22; and finally the opinions on the cause of the tide of the Sea, namely from number 23 to 43. Once these are read through, Galileo's whole argument will without doubt vanish, just like a bubble or the thinnest foam of the Sea. Whatever may be the case with the system of Signor Giovanni Battista Baliani, in which he asserts that the tide of the Sea is better explained with the Moon placed at the centre and the Earth around it — a system which he devised not absolutely, but in order to beat Galileo's hypothesis with a better one — out of reverence for the decrees of the Sacred Congregation he did not publish it, as we said in chapter 15.

[Margin: See the whole of chapters 16 and 17.] XLIX. *The Twenty-ninth Argument.* By the diurnal motion of the Earth together with the annual alone, the difficulty is removed of giving the reason why heavy and light bodies, in their natural descent or ascent, acquire a continuous increase of speed, that is, move faster and faster towards the end. For it is shown that their motion is in reality circular and uniform in the spaces of the World, granted that to us, carried along together with them, it appears rectilinear and non-uniform. Therefore, even for this one reason, the motion of the Earth is more probable than rest.

[Margin: Twofold reply.] *The reply was*: 1. By denying the Antecedent, because by the figure of motion that Boulliau, or above all Galileo, ascribed to this motion, the real difference in the impact of heavy bodies is not saved — a difference which is the greater, and evident from the most manifest effects, the higher the place from which a heavy body descends; and it presupposes a real increase of impetus, which Galileo acknowledged elsewhere, though forgetting himself. Next, by that same circular figure the motion of heavy bodies is not saved unless they are in the plane of the Equator, and of such slowness that they would require exactly 6 hours for their arrival at the centre of the earth, and unless the motion of the Earth is diurnal only; although not even with these conditions laid down will that line be circular from the beginning to the end of the motion. Outside the Equator, on the other hand, the line of this motion would be a spiral about a Cone or a Cylinder, but always unfit to save the real difference of impacts, because the motion of heavy and light bodies would in reality be uniform, or without sensible inequality. [Margin: See chapter 18.] *Secondly*, the Antecedent was denied as regards the particle "alone" [solum]. For the reason of the increase already mentioned is given in another way, more Physical and better; for which reason, having collected the opinions of others in chapter 18, we chose to add our own view on the cause of this increase as well.

CAPVT XXXIV.

Chapter XXXIV.

The arguments of very many authors, put forward up to now for the Immobility of the Earth, are reduced to an Epitome, with their Solutions. And first, the 38 Arguments against the Diurnal and the Annual motion together, from Chapter 19 to 24 inclusive.

[Margin: See chapter 19, from number 1 to 7.] I. THE FIRST *Argument.* Many heavy bodies let fall through the air in the plane of the Equator would descend to the Earth with a real, and not only an apparent, increase of speed. But if the Earth moved with the motion of diurnal rotation, they would descend not with a real increase, but only with an apparent increase of speed. Therefore the Earth does not move with the motion of diurnal rotation. The Major was demonstrated from our own most certain experiments and those of others — made, indeed, outside the Equator, but shown to hold at the Equator as well. The Minor, too, was demonstrated from the real Uniformity of motion which the bodies would necessarily keep by force of the diurnal rotation; and the Argument is in form. [Margin: No solid reply.] And so no solid reply could be found to this argument, by me at least; rather, on account of its Physico-mathematical evidence, it has wrung necessary assent from me and from others to whom I put it. Some frivolous and insufficient replies, however, were brought forward and rejected in number 5.

The same Argument was applied, in chapter 19, number 7, to heavy bodies placed outside the Equator.

[Margin: See chapter 19, from number 8 to 15.] II. *The Second Argument* is altogether the same as the preceding one, except that in the Minor the annual motion was also added, and in the Conclusion the same was excluded. This argument was demonstrated in chapter 19, from number 8 to 15 inclusive. Those demonstrations, being subordinate to Geometry rather than to Physics, cannot be reduced to a summary; but they tend to this: [Margin: No solid reply.] it is demonstrated that the motion of heavy bodies, if the Earth moved with the diurnal and annual motion together, would still be really uniform, or without sensible inequality, and therefore physically incompatible with a real increase of impetus, which we know for certain from the stronger impact. And so not even for this argument could a solution be found up to now that was not sophistical and full of empty evasion. Likewise the same argument was applied, in chapter 19, number 15, to heavy bodies placed outside the Equator.

[Margin: See chapter 19, numbers 16 and [?]7.] III. *The Third Argument.* If the Earth moved with the diurnal motion, the same heavy body — keeping the same heaviness, shape, bulk, density and all its other intrinsic conditions, and let fall from an equal height through air of the same temperature — would nevertheless not descend with equal speed when let fall over any part of the Earth whatever. For one let fall at the Equator would descend without real inequality along a curved line, granted that it would apparently descend non-uniformly along a straight line; but one let fall over the poles of the terrestrial Equator would descend not only apparently but also really along a straight line, covering unequal spaces in equal times, as was shown in chapter 19, number 16. But this is absurd in itself, and contrary to the nature of heavy bodies that are in the same condition; nor is the absurdity avoided in any other way than by supposing the hypothesis of the Earth's diurnal motion, with circumstances invented by the Copernicans. But the motion of the earth is in dispute, and must not be supposed as known, but proved or disproved from better-known things; and it is better known that the same thing, remaining the same, if it is a natural agent, always does the same thing, than that the Earth moves.

[Margin: Three replies rejected [?].] *Three replies* by which the argument could be evaded were rejected as empty in chapter 19, number 17: one, which is sought from the thicker air beneath the poles; another, from the magnetic power of the earth; and a third, from a twofold power of heavy bodies — one moving downwards for the good of the parts of heavy bodies, the other moving circularly for the common good of the parts that follow their whole. It is clear that this was invented on the presumption of this hypothesis; otherwise it serves no good purpose, since it is better for heavy bodies to reach their place and their whole by a straight and as short as possible a way, etc., as discussed there. Therefore the Argument already mentioned has Physical evidence.

[Margin: See chapter 19, number 18.] IV. *The Fourth Argument.* It is the same as the 3rd, but applied to excluding the Annual motion. For with that motion posited, there would still be no diurnal motion at the poles of the Earth; so heavy bodies would not have to traverse that portion of the line which outside

the poles they would have to traverse by force of the diurnal motion, but only the portion they traverse by force of the annual motion, which carries the poles along; and so the motion would in reality be non-uniform, precisely because of the descent over different parts of the Earth.

[Margin: See chapter 19, number 19.] V. *The Fifth Argument.* It is the same as the 1st, 2nd, 3rd and 4th, but applied to light bodies tending upwards. On account of the real increase of impetus which we have observed in light bodies too, by certain experiments — though these are not so readily available to everyone — it compels us to retain the immobility of the Earth.

[Margin: See chapter 20, from number 1 to 9.] VI. *The Sixth Argument.* It is physically evident that heavy bodies naturally descend along a straight line perpendicular to the Earth, and that, if they have been thrown upwards along it, they fall back along the same line to the same place; and this is so evident that its evidence cannot be convicted of falsity either by other, more certain sensations, or by any necessary *a priori* reasons, or from things revealed by God. And so the sense, and the intellect relying on sensations of this kind, is in possession of this evidence, and can never be ousted from it by mere congruences in favour of the opposite. Now if the Earth moved with the diurnal or even the annual motion, heavy bodies would really descend along a curved and longer line, as has already been demonstrated in chapter 17, from number 16, and as the Copernicans themselves admit.

[Margin: A reply, but invalid.] *All the replies* conspire in the end to this: to teach that sense is deceptive, and that therefore only one of two things, under a disjunction, is evident — namely, that heavy bodies descend either along such a line as they appear to descend along, that is, a straight one, or along one different from the line along which they appear to descend; but which of these it is must be determined from something other than sense, since the senses are deceptive and cannot discern it. But that disjunctive proposition is evident not only Physically but also Mathematically and Metaphysically; and for us in this place Physical evidence suffices — evidence which the sensation, not of one man or a few men or times, but of all, repeated almost infinitely, has produced, and which keeps its force as long as the contrary is not proved. But I have said more on the degrees of this and of the other species of evidence in chapter 20, number 6. Certainly, if it is not evident to sense that heavy bodies descend along a straight line, nothing will be evident to it, and the whole of Physical science will perish: for nothing presents itself to sense in such a way that it could not be otherwise by the absolute power of God.

[Margin: See chapter 20, number 10.] VII. *The Seventh Argument.* The nature of heavy and light bodies requires that they return to their place and be united to their whole by the shortest possible way. But if the Earth moved with the diurnal or even the annual motion, they would not return to their place by the shortest way: not along a straight line perpendicular to the earth, but along a much longer curved one, as we showed in chapter 20, number 10. Therefore the Earth moves neither with the diurnal nor with the annual motion.

[Margin: A reply not very firm.] *The reply was* that the shortness of this return is to be taken not absolutely, but relative to the motions necessary to heavy bodies, among which is the curvilinear motion, so that they fall onto the place over which they hung perpendicularly at the moment they were let go. But who does not see that this has been scraped together by begging, not from the nature of heavy bodies, but to defend the hypothesis of the earth's motion? For it was more connatural to heavy bodies to move downwards along a straight perpendicular line, and after their union with the Earth, to rest with it if it rests, or to move circularly with it if it moves; but in order that they fall onto the same place, this longer motion along a curvilinear path had to be feigned. A better reply seemed to be that of those who concede the Major, unless, with the Earth at rest, the diurnal motion had to be multiplied in the stars, and the motion of the second inequality in the five lesser Planets. But we have already said in the preceding chapter, in the replies to Argument 13, 14 and 11, number 31, that more motions are multiplied in the World if the Earth moves than if it rests, even counting the motions of the stars; and so each Reply seems not very firm.

[Margin: See chapter 20, numbers 12 and 13.] VIII. *The Eighth Argument.* If the Earth does not move, a most natural reason can be given why heavy bodies, in descending, tend to the place to which we see them tend: namely, so that as soon as possible, and by the shortest possible way, they may lie beneath less heavy bodies, and so occupy the place due to them in the system of the elements. If, on the contrary, the Earth moves, no such reason can be given except by recourse to the very motion of the Earth, which is in dispute. For why does water let fall onto dust or sand or live coals fall into the dust or onto the coals, by which it is to be consumed? Certainly not so as to be joined to the sand or the coals, etc. But see the whole discussion conducted in chapter 20, from number 12. Certainly, from what we know, no one of sound judgement would say that a stone placed near the centre of the Earth would ascend through the water surrounding it on every side to the rest of the earth, so as to be united to its whole; since we do not see a stone let fall down a well cling to the side of the well, so as to be united at once in this way to its whole, namely the earth.

[Margin: A reply not very firm.] Any *reply* presupposes what is in question, and has no foundation prior to the motion of the Earth.

[Margin: See chapter 20, number 11.] IX. *The Ninth Argument.* Species of motions, or different inequalities and different degrees of speed in the same mobile, are not to be multiplied without necessity. But they are multiplied if the Earth moves with the diurnal or even the annual motion, as was shown in chapter 20, number 11.

[Margin: A reply not very firm.] *The reply was* by denying that this happens without necessity; for it happens so that the diurnal motion is not multiplied in the Fixed stars and in the Planets, and, besides, the Epicyclic motion in the Planets. But the Reply collapses, because in fact more motions are posited in the system of the World if the Earth moves than if it rests — and without a

foundation taken from the senses, indeed contrary to sense. For the apparent motion in the Planets and in the Fixed stars, even with the earth at rest, is a single one in each, namely the diurnal motion towards the West, but slower in those nearer the Earth; and on account of this slowness a second motion, towards the East, is believed to exist.

[Margin: See chapter 20, number 14.] X. *The Tenth Argument.* If an Angel let down a metal sphere of great weight hung from a chain, holding the other end of the chain motionless, that chain would be stretched by the force of the sphere perpendicularly towards the Earth; but according to the Copernicans it ought to be bent obliquely towards the East. [Margin: Reply.] But from this neither hypothesis can be convicted of falsity, because each person must imagine this experiment according to the properties of his own hypothesis.

[Margin: See chapter 20, number 15.] XI. *The Eleventh Argument.* Granted the motion of the Earth, no straight lines that we mark out with a cord, a thread or ink would really be straight. But before God and the Angels they would be different figures, etc. [Margin: Reply.] But the Copernicans will deny that the reasons for which they assert the motion of the Earth are absurd to those who understand them; and since they have once dared to deny evidence that is Physi-

cal — the evidence of the natural motion of heavy bodies along a straight line — what wonder is it if in other, similar cases too they have denied the real straightness of the lines we draw, and conceded only an apparent one?

[Margin: See chapter 21, from number 1.] XII. *The Twelfth Argument.* If the Earth moved with the diurnal or even the annual motion, clouds and birds hanging in the air, or trying to fly towards the East, and things like them, would nevertheless appear to fly towards the West, since they would be left behind by the Earth, and by us, who are carried towards the East together with the Earth much faster. But this is contrary to the experiments. Therefore etc.

[Margin: Reply.] *The Copernicans reply* by denying the Major: all bodies akin to the Earth and the Water, besides their own private motion, if they have one, also have the motion common to the whole earth and water, by which they are carried towards the East with equal speed, that is, through similar arcs; granted that this motion is not seen by us, because it is common to us as well.

[Margin: See chapter 21, number 3.] XIII. *The Thirteenth Argument* is taken from the motion being more difficult westward than eastward, because of the resistance of the air coming to meet it. But the Copernicans say that bodies akin to the Earth, no differently from the air near the earth, share a common motion towards the East.

[Margin: See chapter 21, number 4.] XIV. *The Fourteenth Argument.* If the Earth moved daily or even yearly, the vanes of towers, hair, flames and smoke would be turned eastward, or rather westward. But the Copernicans deny this, on account of the common motion towards the East that the terrestrial air and the other bodies akin to the Earth have.

[Margin: See chapter 21, number 5.] XV. *The Fifteenth Argument* is drawn from the scattering of many things that would arise from the motion of the earth; which, however, the Copernicans deny, on account of the eastward common motion, so often mentioned, that all bodies akin to the earth have.

[Margin: See chapter 21, numbers 6 and 7.] XVI. *The Sixteenth Argument.* If the Earth turned with a diurnal rotation, or even with the annual motion, the same cannon-ball, fired in the same way and with the same force, would cover less space when sent towards the East than towards the West. For the Earth, carrying the cannon off towards the East, would follow the eastern ball but abandon the western one, that is, the one sent at a western target; because the force impressed on the ball by the kindled powder would resist, and break, the force intrinsic to the ball that imitates the diurnal motion — just as that same force overcomes the heaviness of the same ball, not allowing it to descend for some distance from the straight line along which the cannon-ball is carried; granted that it is overcome in this, that it carries the ball more slowly. But the consequent is contrary to the experiments of Tycho and of the Landgrave of Hesse, on which more in chapter 21, number 6.

[Margin: Reply.] *The reply was* by denying the Major. Indeed, the case would rather be the opposite: the ball sent towards the East would land farther from the cannon than one sent towards the West, because towards the East both moving powers would agree; whereas in a ball fired towards the West, the force of the fiery exhalation would resist the power moving it eastward in such a way that the latter would nonetheless resist the former more, and blunt it more, being stronger, perpetual, natural, etc.

[Margin: See chapter 21, number 8.] XVII. *The Seventeenth Argument.* If the Earth moved with the diurnal or even the annual motion, the same cannon-ball, fired in the same way, would cover a notably different distance if it were fired along parallels near the poles than if along parallels near the Equator, or in the plane of the Meridian towards the poles: because of the very slow motion of the earth near the poles, and the smaller resistance arising from it to the motion of a ball sent towards the poles. But this is contrary to the experiments of Tycho, etc. Therefore etc. [Margin: No solid reply.] No valid reply to this argument appears, unless perhaps someone were to deny that experiments of this kind have been made. But they certainly can be made; nor will the difference between the intervals already mentioned be insensible, since each motion is so violent.

[Margin: See chapter 21, number 9.] XVIII. *The Eighteenth Argument.* If the Earth moved with the diurnal or even the annual motion, a cannon-ball fired either towards the East or towards the West would fail to strike the target: for if it were aimed towards the East it would strike above the target, and if towards the West, below it, because by force of the earth's motion the eastern target would be lowered and the western one raised. But this is contrary to experiment.

[Margin: Reply.] *Galileo replied*, 1. by calling these experiments into doubt, as inadequate for discerning so fine a difference of excess or defect from the target; but better, by denying the Major, because the ball would not run along the same tangent to the Earth, as the inexpert imagine, but along one after another, and at the end of its motion would be found on the one that can be drawn from the target to the mouth of the cannon. But you should see more in chapter 21, number 9.

[Margin: See chapter 21, number 10.] XIX. *The Nineteenth Argument.* If the Earth moved with the diurnal or even the annual motion, the impact of a cannon-ball, or of one driven by a rammer or a ballista, sent towards either pole of the world would be much weaker than the impact of the same sent towards the East or the West, even if everything else were equal. But this is contrary to the experiments: therefore the Earth would move with neither of those motions. The Minor is not in dispute. The Major was demonstrated Physically by Father Francesco Maria Grimaldi, chapter 21, number 10. [Margin: No reply.] Nor has any reply been offered that weakens the stronger part of the Argument made there.

[Margin: See chapter 21, number 11.] XX. *The Twentieth Argument.* If the Earth moved with the diurnal or even the annual motion, the same ball — from cannon [bombardibus], or from a ballista, or driven by a rammer — sent in the same way once towards the East and again towards the West, would strike the eastern target with a greater impact than the western one at an equal distance. But the consequent is utterly false, and conflicts with our experiments and with those open to anyone; therefore the Earth moves with neither the diurnal nor the annual motion. [Margin: No reply that is solid.] For this argument no solid reply has been found.

[Margin: See chapter 21, number 12.] XXI. *The Twenty-first Argument.* If the Earth moved with the diurnal or also the annual motion, the same mobile could be moved at the same time with two contrary motions; for whatever we now see moving towards the West would nevertheless also be moving towards the East, with a motion equal to the Earth's. But this is impossible. Therefore etc.

[Margin: A twofold reply.] *The reply was*, 1. by denying the Major in the sense in which the Minor is to be conceded. For the mobile would not really be approaching the same terminus, fixed in the space of the world, from which it was meanwhile receding; in fact it would always be approaching the eastern terminus — though less swiftly than if, by its striving towards the West, it did not diminish the speed towards the East that it would otherwise have. 2. The argument was turned back upon the two contrary motions of the heavens: if these can be reconciled in the heavens, they can also be reconciled on the Earth by an equivalent reasoning. But see chapter 21, number 12.

[Margin: See chapter 21, number 13.] XXII. *The Twenty-second Argument.* If the Earth moved with the diurnal or also the annual motion, innumerable motions of the same species would be multiplied without necessity; for it would

be necessary to attribute to each individual animal, besides its own proper motion, the motion common to the Earth, so that the apparent experiences might be saved. But this multiplication is absurd. Therefore.

[Margin: Reply.] *The reply was* by denying the Major: there is a necessity, namely, that motions should not be multiplied in the heavens. But there is less foundation for multiplying these motions in the heavens than on the Earth, and fewer are in fact multiplied if they are attributed to the heavens than if to the Earth; and from this arises the following, very strong argument.

[Margin: See chapter 21, number 14.] XXIII. *The Twenty-third Argument.* There is a greater foundation for attributing the diurnal motion to the stars and the annual to the Sun than the diurnal and the annual to the Earth; and if the former is done, the multiplication of real motions is smaller than if they are attributed to the Earth. Therefore the diurnal motion is to be attributed to the stars, and the annual to the Sun, rather than to the Earth. See the force of the argument in chapter 21, number 14, and you will find no solid reply. [Margin: No solid reply.]

[Margin: See chapter 21, number 15.] XXIV. *The Twenty-fourth Argument.* If the Earth moves with the diurnal or even the annual motion, motions that manifestly appear to us must be done away with without any necessary reason, and in their place motions must be substituted that do not appear: which is surely absurd in itself. See chapter 21, number 15.

[Margin: See chapter 21, number 16.] XXV. *The Twenty-fifth Argument.* If the Earth moved with the diurnal and annual motion, a motion variable by innumerable inequality would have to be attributed to the same mobile, and far more so than if the motion is attributed to the stars. Therefore etc. See chapter 21, number 16, where we said that no firm reply to this argument appears. [Margin: No solid reply.]

[Margin: See chapter 22, numbers 1 and 2.] XXVI. *The Twenty-sixth Argument.* The Earth is extremely dense and extremely heavy; therefore it is inert towards every motion. [Margin: Reply.] *The reply was* by denying the Consequence as regards circular motion, to which heaviness offers no resistance. But as to whether the Earth as a whole, insofar as it is a whole, is heavy, see chapter 21, number 2.

[Margin: See chapter 22, number 3.] XXVII. *The Twenty-seventh Argument.* The speed of the diurnal motion would be so great that it would overcome the flight of birds, let alone the course of rivers or of ships towards the East; therefore no birds, ships etc. could reach their eastern terminus, which is contrary to the experiments.

[Margin: Reply.] *The reply was* by denying the Consequence, because in Copernicus's hypothesis birds, ships etc. move not by their own motion alone but also by the common motion, equally with the Earth. How great the speed of the Earth would be, I have taught accurately in chapter 21, number 1.

[Margin: See chapter 22, number 4.] XXVIII. *The Twenty-eighth Argument.* If the Earth moved with the diurnal and annual motion, we would feel a

perpetual wind towards the West, and a noise and whistling from the air dashed against trees, mountains, towers etc. But we feel these not at all.

[Margin: Reply.] *The reply was* by denying the Minor as regards the almost perpetual winds within the Tropics, and the Major as regards the other effects, because the air near the Earth too, being full of exhalations and vapours, would move with the common motion together with the Earth.

[Margin: See chapter 22, numbers 5 and 6.] XXIX. *The Twenty-ninth Argument* is from the shaking and collapse of buildings, or the flinging off of bodies weakly attached to the Earth, which would seem bound to follow from the Earth's rapid rotation.

[Margin: Reply.] *The reply was* that there is no such danger in the Copernican hypothesis, as is clear from what was said in chapter 22, number 6.

[Margin: See chapter 22, number 7.] XXX. *The Thirtieth Argument.* We ought to feel this motion in ourselves, if it were common to us with the earth. [Margin: Reply.] But we have shown in chapter 22, number 7, that there is in truth no necessity for this sensation.

[Margin: See chapter 23, number 1.] XXXI. *The Thirty-first Argument.* If the Earth turned towards the East, the eastern mountains would appear to us to descend and the western ones to ascend. [Margin: Reply.] But this consequence was denied by the Copernicans, because the plane on which we stand with the mountains, and the mountains themselves, move with us with an equal motion; and so we do not notice their motion, which is common to us.

[Margin: See chapter 23, from number 1 to 8.] XXXII. *The Thirty-second Argument.* If the Earth moved with at least the diurnal motion, we, looking up from the bottom of a well at some Fixed star standing over our zenith, would lose sight of it once a blink of the eye had passed, because in the blink of an eye the whole breadth of the well's mouth would pass by, by force of the diurnal rotation. But this is contrary to the experiments. Therefore.

[Margin: Reply.] *The reply was* by denying the consequence of the Major, because our wells neither reach the centre of the Earth nor are much wider than four or five feet; so the visual angle at the bottom of such wells takes in much more of the circumference of the heavens than the terrestrial arc that the Earth traverses in one blink of the eye. But this reply will become clearer from the Problems, very well worth knowing, which we gave on this occasion in chapter 23, from number 2 to 8.

[Margin: See chapter 23, number 8.] XXXIII. *The Thirty-third Argument.* If the Earth moved with at least the diurnal motion, Gnomons erected in the Tropics on the solstitial days would cast sensible shadows at the time nearest to Noon. But Strabo and Pliny the Elder relate that it turns out otherwise. [Margin: Reply.] Yet the consequence of the Major is denied, for the cause adduced in chapter 23, number 8.

[Margin: See chapter 23, number 9.] XXXIV. *The Thirty-fourth Argument.* The eclipse of the Sun at the death of CHRIST was total for three hours; but if

the Earth had been turned with the diurnal motion, it would not have lasted total for three hours, for the Earth's rotation would at once have withdrawn Palestine into another position, from which it could have seen the Sun. Therefore.

[Margin: Reply.] *The reply was* by denying the Minor, because the Moon could have been kept between the Sun and Palestine for three hours, carried forward towards the East as far as the motion of the Earth would require. For the rest, see chapter 23, number 9.

[Margin: See chapter 24, numbers 1 and 2.] XXXV. *The Thirty-fifth Argument.* Circular motion is violent or preternatural to the particles of the earth, and therefore to the whole Earth too; therefore it does not belong to the Earth perpetually. So Aristotle.

[Margin: A twofold reply.] *The reply was*, 1. by denying the Antecedent: for in the Copernican hypothesis a really circular motion belongs naturally to the parts of the Earth when they are united to their whole, and a motion mixed of straight and circular if they are separated — granted that it does not appear to us insofar as it is circular, because we too are turned with such a motion together with the Earth. 2. The argument was turned back against Aristotle, who admits in the elementary Fire a perpetual circular motion, although a preternatural one.

[Margin: See chapter 24, number 3.] XXXVI. *The Thirty-sixth Argument.* The Copernican motion of the Earth removes from the Universe the simple motion of things up and down; therefore it is not to be admitted. [Margin: Reply.] *The Copernicans reply* by denying the antecedent as regards apparent motion.

[Margin: See chapter 24, number 4.] XXXVII. *The Thirty-seventh Argument.* No principle of the earth's motion can be assigned without great inconveniences. Therefore. *The Copernicans reply* by denying the antecedent, and they say that the principle is intrinsic and natural: see chapter 24, number 4. [Margin: Reply.]

[Margin: See chapter 24, from number 5 and 6.] XXXVIII. *The Thirty-eighth Argument.* The Copernican motion of the Earth makes the motion of Heavy and Light bodies unnatural, and the circular motion natural — and that in things most diverse in nature — and it is entangled in insoluble questions. Therefore.

[Margin: Reply.] *The Copernicans reply* by denying the 1st and the 3rd part of the antecedent; and the eleven principal Questions put by Scheiner were answered in chapter 24, number 6.

Argumenta 39. Contra Situm & Motum Annuum Terræ, ſeorſim à Diurno conſideratum, & Solutiones eorum traditæ à cap.25. ad 31. Incluſiuè.

39 Arguments against the Position and the Annual Motion of the Earth, considered separately from the Diurnal, and their Solutions, given from chapter 25 to 31 inclusive.

[Margin: See chapter 25, from number 1 to 5.] XXXIX. THE FIRST *Argument.* The centre of the Earth is where the terminus is to which all Heavy bodies tend naturally and of themselves; but this terminus is the centre of the

Universe; therefore the centre of the Earth is at the centre of the Universe. Aristotle proves the Minor: 1. Because, even if the Earth were taken away, heavy bodies would still tend to the centre of the Universe; therefore heavy bodies are not carried to the centre of the Earth of themselves and as the Earth's centre, but insofar as it is the centre of the Universe. 2. Because the terminus to which heavy bodies tend of themselves is the one that is the terminus from which light bodies move of themselves; but light bodies recede of themselves from the centre of the Earth insofar as it is the centre of the universe, since they tend towards the circumference of the highest heaven, that is, of the Universe, along perpendicular lines.

[Margin: A manifold reply.] *Galileo replied* in three ways, and not badly from his own hypothesis, as is clear in chapter 25, number 6; and Kepler too, but in Kepler's solution we noted five faults, on which see chapter 25, number 7. *Our own reply was*, granting the Major, by denying the Minor and the Antecedent of the proof: for if the Earth were taken away, that is, moved elsewhere, heavy bodies would tend to the centre of the Earth; but if it were destroyed, with the remaining elements and mixed bodies left, they would tend to the centre of the Water, which would then take the place of the earth — that is, to the centre of the heaviest body. To the 2nd proof the Minor was denied: for light bodies tend to the highest circumference of the elementary sphere, which Aristotle supposed, but did not prove, to be concentric with the Universe. Whether in this he begged the question or reasoned fallaciously, see what was said in chapter 25, number 6.

[Margin: See chapter 25, number 9.] XL. *The Second Argument.* Light bodies ascend from any point of the earth's surface towards the highest heaven along a straight line perpendicular both to the convexity of the terrestrial globe and to the concavity of the highest heaven; therefore they ascend from the middle of the Universe; but they ascend by receding from the middle of the earth; therefore the middle of the Earth and the middle, or centre, of the Universe are the same.

[Margin: Reply.] *The reply was* by denying the Major: for they tend not to the highest heaven but towards the highest surface of the elementary sphere, which is concentric with the Earth; but whether it is concentric with the Universe is doubtful, unless that is shown from elsewhere; and the Copernicans contend that it is eccentric.

[Margin: See chapter 25, number 10.] XLI. *The Third Argument.* Heaviness and Lightness were given to bodies not so that they should be united to their whole and to what is like them, but so that they should keep or recover a determinate place in the universe; for place, insofar as it is place, is the formal terminus of locomotion. Therefore they have an immovable place at or around the centre of the Universe; but they would not have this if the Earth moved through the annual orb.

[Margin: Reply.] *The reply was* by denying the Major; for they were given so that bodies should acquire and keep a place in the elementary system, wherever that system may be, abstracting from its mobility and immobility.

[Margin: See chapter 25, number 11.] XLII. *The Fourth Argument.* Unless the Earth occupies the World's cen- tre, no sufficient reason can be given why it does not, as a whole, move downwards, or to the place to which its parts move. Therefore it occupies the centre of the World.

[Margin: A twofold reply.] *The reply was given by Kepler*, by denying the Antecedent: for the reason is that the whole Earth, insofar as it is a whole, is not heavy — granted that Chiaramonti said both that it is heavy and that its weight can be known approximately; on which see chapter 25, number 11. *Other Copernicans, however, would reply* that the cause is that the whole Earth is naturally determined to circular motion around the centre of the world.

[Margin: See chapter 25, number 12.] XLIII *The Fifth Argument.* If the Earth were transferred to the Moon, heavy bodies would nevertheless not tend there, but to the centre of the Universe etc. [Margin: Reply.] *The Copernicans reply* by denying the antecedent, which Aristotle has not yet shown.

[Margin: See chapter 25, number 13.] XLIV. *The Sixth Argument.* The lowest place is owed to the heaviest and lowest of bodies: the Earth is the heaviest, and the centre of the World is the lowest place. Therefore. [Margin: Reply.] *They reply* by conceding this of the lowest place in the elementary system, and denying it of the absolutely lowest.

[Margin: See chapter 25, number 14.] XLV. *The Seventh Argument.* Those bodies are called heavy without qualification which are carried towards the Middle, and light those carried away from the Middle; but these definitions would perish if this Middle were not the Middle of the Universe. [Margin: Reply.] *They reply* by denying the Minor; for it is enough if it is the middle of the elementary system.

[Margin: See chapter 25, number 15.] XLVI. *The Eighth Argument.* Unless the centre of the Earth and of the elementary system is the centre of the Universe, positive lightness is removed and reduced to a privation of greater heaviness. But this is contrary to reasons resting on our experiments. Therefore. The Major is proved from the lack of a determinate place for light bodies.

[Margin: Reply.] *The reply was* by denying the Major: for the Physical place of light bodies — of fire, for instance — would be the space between the Moon and the heavier elements, even if the whole elementary sphere were transferred to another Mathematical place in the space of the World.

[Margin: See chapter 25, number 16.] XLVII. *The Ninth Argument.* Heavy bodies, in descending to the centre of the Earth, would sometimes recede from the centre of the World, if the Earth were outside it; and light bodies would approach it by receding from the earth. Therefore the definitions of Heavy and Light would be confounded.

[Margin: Reply.] *The reply was* by conceding the consequence as regards the definitions as Aristotle understood them, and denying it as regards definitions

rightly understood, that is, given in relation to the middle of the elementary system.

[Margin: See chapter 25, number 17.] XLVIII. *The Tenth Argument.* Heaviness and Lightness are implanted in bodies so that they may rest in their own place, or tend towards it in such a way as to rest in it. But they would never rest if the Earth were revolved with the elements through the annual orb.

[Margin: Reply.] *The reply was* by conceding the Major as regards the place of Heavy and Light bodies as such — that is, that heavy bodies should stand beneath light ones, and light ones stand above heavy ones, in the elementary system; and in this sense the Minor was denied.

[Margin: See chapter 25, number 18.] XLIX. *The Eleventh Argument.* Centres, and positions of centres, would be multiplied without necessity: for the centre of the Universe would be one thing, and the centre of the Earth and of the elementary system another, and always a different one. Therefore etc.

[Margin: A twofold reply.] *The reply was*, 1. by denying the Antecedent: for the necessity, *a priori*, lies in all the arguments, or all the best of them, on account of which the Copernicans posit the annual motion of the Earth. 2. By turning the argument back: for otherwise the centre of the Universe and the centre of the Planetary system — which is now held to be the Sun — would be multiplied, unless the Sun were at the centre of the World and the Earth went around it.

[Margin: See chapter 26, number 1.] L. *The Twelfth Argument.* All who look at the sky from any part of the Earth judge that the sky is up and the Earth down; but this judgement would be false if the Earth were outside the centre of the World. Therefore.

[Margin: Reply.] *The reply was* by conceding the Minor as regards the centre taken also Physically and to sense, and denying it as regards the centre taken Mathematically.

[Margin: See chapter 26, number 2.] LI. *The Thirteenth Argument.* The Earth is the lowest not only of the elements but of all the Bodies of the World; therefore the lowest place is owed to it not only in the elementary System but also in the World, and that is the centre of the World.

[Margin: Reply.] *The reply was* by denying the Antecedent, if the Earth is taken together with men and the other animals. For other replies, see chapter 26, number 2.

[Margin: See chapter 26, number 3.] LII. *The Fourteenth Argument.* Too much licence would be given for placing the Earth wherever one pleased.

[Margin: Reply.] *The reply was* by denying the antecedent: for the Earth must stand in such a position that half of the heavens is visible to sense on every side, and the remaining phenomena of the heavens are saved.

[Margin: See chapter 26, number 4.] LIII. *The Fifteenth Argument.* With the Earth placed outside the centre of the World, Hell [Infernus], the place of the damned, would not be the nether place; indeed some who tend towards it would ascend. Therefore.

[Margin: Reply.] *The reply was* by denying the Antecedent: for that place is called Hell in comparison with the surface of the earth, on which men were wayfarers, and with the Empyrean, the place of the comprehensors; and these two relations would remain, notwithstanding the motion of the Earth. For the rest, see chapter 26, number 4.

[Margin: See chapter 26, number 5.] LIV. *The Sixteenth Argument.* If the Earth is in the Annual Orb with the elements, the order of the Planetary and elementary system is overturned: the elementary sphere becomes one great Planet and is placed in the heavens; and the number of the primary Planets, 7, is overthrown, since the Sun ceases to be a Planet, and the Moon a primary Planet — for it becomes the earth's attendant — while the Earth with the elements becomes a primary Planet, and only 6 primary Planets are retained. But this is most absurd.

[Margin: Reply.] *The Copernicans reply*, granting the Major, by distinguishing the Minor: conceding it with respect to those who, accustomed to the Peripatos, judge everything from the senses; denying it with respect to those who, contemplating the Platonic Ideas and initiated into the Pythagorean mysteries, judge the order of things from archetypal reasons.

[Margin: See chapter 27, numbers 1 and 2.] LV. *The Seventeenth Argument.* With the Earth placed at the centre of the World, all the Phenomena of the heavens are saved. Therefore. *The reply is* by denying the Consequence, because they are saved even if the Earth moves in the annual orb, with the diurnal motion.

[Margin: Chapter 27, number 3.] LVI. *The Eighteenth Argument.* More motions would have to be attributed to the Earth, with more changes in the stars, etc. *Reply*: by conceding the first and denying the second.

[Margin: Chapter 27, number 4.] LVII. *The Nineteenth Argument.* A whole hemisphere of the sky could not be seen by us from any part of the earth. *Reply*: by denying the consequence, because no more of the sky is hidden than the horizontal parallax of the heavenly bodies, which, the Moon excepted, is less than a whole degree.

[Margin: Chapter 27, number 5.] LVIII. *The Twentieth Argument.* The Fixed Stars that the Earth approached would appear larger than themselves. *Reply*: by denying it, if the diameter of the annual orb were of insensible proportion to the distance of the Fixed stars, as Copernicus supposes.

[Margin: Chapter 27, number 6.] LIX. *The Twenty-first Argument.* The eastern shadows of gnomons, at an equal altitude of the Sun above the horizon, would not be equal to the western ones. *Reply*: by denying the consequence, because in both cases the Earth would be equally distant from the Sun, to sense.

[Margin: Chapter 27, number 7.] LX. *The Twenty-second Argument.* The alternations of days and nights in the threefold sphere would not occur in the way they now do. *Reply*: by denying the consequence, which arises from ignorance of the Copernican hypothesis set out in chapter 4.

[Margin: See chapter 27, number 8.] LXI. *The Twenty-third Argument.* Eclipses of the Moon would not always occur with the Moon set under the place of the Zodiac opposite to the one under which the Sun is. [Margin: Reply.] *Reply*: by denying the consequence: for the Sun would not be revolving around an Earth moved annually, but the Earth around the Sun, carrying the lunar heaven with it, etc.; therefore in an eclipse of the Moon the Earth would always be interposed between the Moon and the Sun on some diameter of the heavens drawn through the centre of the heavens, that is, through the centre of the Sun or of the annual orb.

[Margin: See chapter 27, number 9.] LXII. *The Twenty-fourth Argument.* But at least eclipses of the Moon would not happen with both Luminaries appearing on the horizon. [Margin: Reply.] *Reply*: by denying the consequence, for the reason indicated in the reply to the 23rd Argument. On the ignorance of Argoli, who makes much of this argument, see chapter 27, number 9.

[Margin: See chapter 27, number 10.] LXIII. *The Twenty-fifth Argument.* It is Physically evident that the Sun moves with the annual motion, that is, that it is slower in the diurnal motion in such a way that after 365¼ days it very nearly overtakes the same Fixed star again. Therefore it is Physically evident that the Earth does not move in this way; for only one of the two is possible in Astronomy.

[Margin: Reply invalid.] *They reply* by denying the Antecedent: for only this disjunction is evident — either that the Sun moves annually around an Earth that is not carried round, or that the Earth moves annually around a Sun that is not carried round. But, as has been said above more than once, this disjunction is evident not only Physically but also Mathe- matically. But here physical evidence suffices to determine one of the two hypotheses, provided it is of that kind and nothing contradicts it. Therefore no valid reply is brought against this Argument.

[Margin: See chapter 28, from number 1 to 6.] LXIV. *The Twenty-sixth Argument.* If the Earth moved through the annual orb, then, when it had been carried from one point of the annual orb to the opposite point after 6 months, a sensible variation would appear in the altitude of the same Fixed stars, that is, a notable parallax — at least in the stars nearer the pole. But astronomers have never noted any parallax in the Fixed stars within the same year. Therefore.

[Margin: Reply.] *The reply is* by conceding the Major against certain Copernicans who set too small a distance for the Fixed stars; but by denying it on Copernicus's Hypothesis, which requires so great a distance of the Fixed stars that the diameter of the annual orb vanishes, that is, makes no sensible parallax in the Fixed stars. Much on this parallax has been set out in chapter 28, from number 1 to 7, and from there onwards the various replies of the Copernicans; read them.

[Margin: See chapter 28, number 11.] LXV. *The Twenty-seventh Argument.* If the Earth moved through the annual orb, then, with the earth approaching the Fixed stars after 6 months at the Equinoctial points, a great parallax would be

felt in the apparent distance of Sirius from the Sun rising or setting. But none is felt. Therefore.

[Margin: Reply.] *The reply was* by denying the Major, because that variation arises from the distance of Sirius from the solstitial colure, whether the Earth stands still or moves. And if any other variation is said to be in prospect, it is removed at once by the distance of the Fixed stars [Eixarum] [recte: Fixarum], increased finitely to infinity by the Copernicans.

[Margin: See chapter 28, number 13.] LXVI. *The Twenty-eighth Argument.* But surely a notable parallax would be felt in the apparent magnitude of the Fixed stars. [Margin: Reply.] *The reply is* by denying it of the Fixed stars: for even if they were in the Ecliptic, that variation would not be greater than 4‴; indeed it would be much smaller, if their distance were increased as much as Copernicus permits.

[Margin: See chapter 29, from number 1 to 18.] LXVII. *The Twenty-ninth Argument.* Granted the annual motion of the Earth, then, so that no sensible Parallax should follow, one must set the distance of the Fixed stars from the centre of the Earth and of the Universe so great that their sphere would turn out to be of mad and wholly incredible bulk; as is clear from what was said in chapter 29 on the distance of the Fixed stars in Copernicus's hypothesis, from number 1 to 13 inclusive, where you have a selection of opinions, and on the bulk of the sphere of the Fixed stars, from number 14 to 16 inclusive.

[Margin: Reply.] *The Copernicans nevertheless reply* by denying that this bulk or distance is incredible — granted that it is admirable, and commends the Divine Omnipotence and Magnificence all the more. But see what was said in chapter 29, number 18.

[Margin: See chapter 29, numbers 19 and 20.] LXVIII. *The Thirtieth Argument.* If the Earth moved through the annual orb, then, to avoid a sensible Parallax of the Fixed stars arising from the diameter of the annual orb, one would have to set between Saturn and the Fixed stars an immense space, empty of stars and idle. But this is absurd and exceeds all belief, especially since the Copernicans themselves so often insist that God and Nature do nothing idly or in vain. Therefore.

[Margin: Reply.] I showed in chapter 29, number 20, that *the Replies of the Copernicans* are invalid and lean on begged, forced or improbable subtleties — granted that the last of them, which is the 4th there, cannot be convicted of falsity: namely, if someone says that in that space there are many of those Fixed stars which cannot be discerned without a Telescope, and whose place nevertheless cannot be observed so exactly with Astronomical Instruments that, if they have any parallax, it could be felt.

[Margin: See chapter 29, number 21.] LXIX. *The Thirty-first Argument.* But the stars would be so distant from the Sun that the Sun, viewed from them, would be like a point, and so unfit to illuminate them. [Margin: Reply.] *Reply*: by conceding the whole; for the Fixed stars do not have their light from the Sun.

[Margin: See chapter 30, the whole.] LXX. *The Thirty-second Argument.* If the Earth moved through the annual orb, the distance of the Fixed stars would be so great that their Magnitude would turn out greater than the whole annual orb; but this is incredible. Therefore. Moreover, we demonstrated in chapter 30, from number 1 to 6, that this Magnitude would be so great; for Galileo and Hortensius tried in vain to diminish it, from what was said in the same place, number 7. Reply 1.

[Margin: Reply.] *But other Copernicans reply* by denying the incredibility of so great a magnitude, again extolling the Magnificence of God on this account, and turning the argument back against the excessive speed of the Fixed stars that would follow from the Ptolemaic hypothesis, which they think more incredible than this Magnitude. On that occasion we showed, in number 8, that that speed is more credible than this bulk of the Fixed stars; and in number 7 we said that, if God had wished to be commended by this bulk, He would have given us some indication of it a posteriori, and would not have shown them to us so small, etc. But see that discussion, so that you may learn that the Reply, although it cannot be refuted as false, cannot satisfy more prudent men.

[Margin: See chapter 31, number 1.] LXXI. *The Thirty-third Argument.* If the Earth revolved in the annual orb, the distance of the Fixed stars would be so great that no sensible Refractions of the Fixed stars would occur, because the Inclination of the incident ray into our Air, in which the refraction would have to take place, would become insensible, as would the whole orb of the earth and of the surrounding air; whereas that Inclination is always greater than the refraction. But a sensible Refraction has been observed in the Fixed stars, indeed one of 30′ at the horizon, which the more recent Copernicans admit. Therefore.

[Margin: Reply.] *The reply was*: by denying the Major. For although the earth with its air, seen from the Fixed stars, would be like a point, nevertheless the angle of Inclination of the ray of the Fixed stars to us, who are close to it, is and would be very large; and we measure it from data of sensible and known magnitude, namely from the horizontal Refraction, the semidiameter of the earth, and the semidiameter of the refracting air.

[Margin: See chapter 31, number 2.] LXXII. *The Thirty-fourth Argument.* But at least the Refraction would not be greater than the Inclination of the incident Ray. But we likewise denied this consequence, in chapter 31, number 2, as will be clear a fortiori from the reply to the following argument.

[Margin: See chapter 31, from number 3 to 6.] LXXIII. *The Thirty-fifth Argument.* Yet the distance of the Fixed stars would be so great that the Refractions could not be less than half the Inclination; but this is against the canons of Dioptrics. Therefore.

[Margin: Reply.] *The reply was* by denying the Major, the opposite of which was clearly shown in chapter 31, from number 3 to 6, by calculations made most subtly; and it was shown that not even through a distance of the Fixed stars increased finitely to infinity would the refraction come to half the

Inclination; indeed, that the stars cannot be raised by any distance whatever in such a way that, while they appear on the physical horizon, they are really on it, all refraction having vanished.

[Margin: See chapter 31, from number 6 to 9.] LXXIV. *The Thirty-sixth Argument.* From a certain semidiameter of the earth, the altitude of the refracting air, the horizontal refraction of the Fixed stars and their true distance from the zenith; or at least from the proportion between the refractions of the Fixed stars derived from these, compared with the proportion of the refractions of the Sun and Moon; and then from the proportion of the distance of the Sun and Moon from the earth, it follows that the distance of the Fixed stars from the earth must be far less than the Copernican hypothesis requires for an annual motion of the earth. [Margin: Reply.] *The reply, however, was* by denying that this follows from the first of the positions already mentioned; and it was shown by a most certain proof that the distance of the Fixed stars can increase finitely to infinity, without prejudice to what is stated in the first position. As for the proportion already mentioned, which is touched on in the second supposition, we denied that it should be relied on.

[Margin: See chapter 31, number 10.] LXXV. *The Thirty-seventh Argument.* In the lenses of the Telescope all refractions of Fixed stars so remote would cease; and therefore the Fixed stars could not appear larger to us by means of the Telescope, because the inclinations of the rays upon the lenses would cease; which is contrary to experiments. [Margin: Reply.] *The reply was* by denying the consequence, for the same reason that we indicated in the reply to argument 33.

[Margin: See chapter 31, number 11.] LXXVI. *The Thirty-eighth Argument.* With the centres of the earth and of the universe separated by the semidiameter of the annual orb, we would be uncertain from which we ought to estimate the true altitude of the stars. [Margin: Reply.] *The reply is* by denying the consequence: for this measure would have to be estimated from both, though in different ways.

[Margin: See chapter 32, the whole.] LXXVII. *The Thirty-ninth Argument.* If the Copernican hypothesis were admitted, too much licence would be given to minds to invent one system after another, and to place at the centre of the World now this Planet, now that one, etc.

[Margin: Reply.] *The reply is* that some systems would be unfit for saving all the celestial Phenomena; but of the suitable ones, none is more apt than the Copernican.

CAPVT XXXV. In Quo ex meris Rationibus, & circumscripta omni Auctoritate Concluditur, Vtra Hypothesium absolutè asserenda sit, Illane quæ Motum, an illa quæ Immobilitatem Terræ supponit?

Chapter 35. In which it is concluded, from reasons alone and with all authority set aside, which of the hypotheses is to be asserted absolutely: the one that supposes the motion of the Earth, or the one that supposes its immobility?

I. CONCLVSIO.

Conclusion I.

I. *If the celestial Phenomena alone are considered, they are saved with Astronomical and Mathematical rigour in either Hypothesis, that is, as much in the one that supposes the immobility of the Earth as in the one that supposes the Diurnal and Annual motion of the Earth. Nor have any arguments drawn from the appearances in the heavens been devised so far that demonstrate the truth of the one and the falsity of the other.*

This is clear to anyone who surveys the Arguments and their solutions indicated in chapters 33 and 34, and discussed more fully from chapter 5 to 32 of this section, if one picks out those that are derived from the celestial motions and from other things that appear in the heavens. For all those arguments on either side have been answered — more or less, indeed, but still in such a way that the solutions have their own probability, or at least cannot be refuted as false. On this occasion, moreover, it will be evident that there are many arguments which, at first sight and when unforeseen, could alarm the defender of one or other hypothesis; and yet, examined closely, they have no force or very little, and not as much as the followers of either school have so far boasted. Indeed, not a few of those brought against the Immobility of the Earth are sophistical and full of fallacy, and yet are seriously pressed by the Copernicans — such are those in chapter 33, numbers 3, 12, 15, 48, 49 — or they are founded on doubtful experiments or slippery suppositions, like those we indicated in the same chapter at numbers 20, 36, 37, 39, 41, 42, 45. Just so, conversely, many arguments thrown out against the motion of the Earth fall in vain, because they arose from ignorance of the Copernican hypothesis, which was not examined with as much depth as was needed, not even by Tycho, Clavius, Scheiner and other great men. And when the Copernicans boast that the motion of the Earth and the rest of the Sun have been demonstrated, that is either a solemn lie, or it must be understood on the mere hypothesis — that is, that if the motion of the Earth etc. is supposed, the Phenomena of the heavens can be saved, and indeed sometimes with greater elegance in some respect, and with a more probable rationale. Indeed, Copernicus himself and Galileo, and not a few of the Copernicans, grant that all the phenomena of the heavens are saved equally in either hypothesis.

II. CONCLVSIO.

Conclusion II.

II. *If the certain and manifest Physical experiments in elementary bodies are considered, all are saved in either of the hypotheses already mentioned, according to Physicomathematical rigour, except those that concern the impact of heavy and light bodies naturally descending or ascending, or the impact [?] or velocity of projectiles directed now towards the poles of the world, now towards the East, now towards the West. For these cannot be saved in Physicomathematical rigour except in the hypothesis of the resting Earth alone.*

The first part is likewise evident to anyone who runs through the Arguments drawn from the motions of elementary things, with their solutions, indicated in chapters 33 and 34. The latter part is evident from Father Grimaldi's demonstrations and our own, indicated in chapter 34 at numbers 1, 2, 19 and 20, but set out clearly in their own places. Just as these, in so celebrated a controversy, are certainly not to be lightly regarded by fair judges of things, so it is right to credit them to God, who in His munificence has favoured our labours. Therefore, although Ptolemy had scented other experiments — or perhaps these, but confusedly — he declared skilfully, in book 1, chapter 7 of the *Magna constructio* [the *Almagest*], that the hypothesis of the moving Earth could be shaken by these rather than by Astronomical ones, when he said: *"For it escapes them"* — namely, the movers of the Earth — *"that as far as the appearances in the stars are concerned, nothing perhaps prevents things being so, if one considers it rather simply. But from the accidents that occur around us and in the air, this will seem very ridiculous."* [Margin: Ptolemy's [?] prudent judgement on the force of the arguments against the motion of the Earth.]

III. CONCLVSIO.

Conclusion III.

III. *If, moreover, Physical Evidence alone is considered (which indeed alone carries weight in Physical matters), there are some physically evident arguments for the Immobility of the Earth, but none for its motion.*

The first part will be clear to anyone who reads through the arguments in chapter 34 indicated at numbers 3, 4, 5, 6, 17, 19, 20, 23, 63, to which those we touched on in the same place at numbers 8 and 9 are also reduced. I said, moreover, that it carries weight in Physical science — to which, namely, Astronomy is subalternate — so long as mathematics does not resist those arguments; nor is it necessary that they have Mathematical evidence, when that cannot be had.

The negative latter part is evident from all the arguments for the motion of the Earth drawn from sensible experiment: so far are they from containing Physical evidence that they rather tend against the evidence of the senses, that is, against Physical evidence. The rest proceed from mere congruities, in a hypothesis about a thing that is not impossible and that has certain attractions.

IV. CONCLVSIO.

Conclusion IV.

IV. *If, setting aside the demonstrative and evident Arguments, one considers those which in themselves contain mere probability, there are not a few of this kind for each hypothesis, and so many and of such a kind that, according to each person's cast of mind, they can incline the intellect to either hypothesis — were it not that sacred Authority, that of the Divine Scriptures, stood in the way; and with that standing in the way, all that probability ceases.*

This conclusion is likewise clear enough when one considers the weightier arguments made for the motion of the Earth in chapter 33 — for instance those at numbers 9, 11, 29, 30, 32, 43, and any others of this kind — and those against the motion of the Earth indicated in chapter 34, for example at numbers 32, 54, 68, 70. I said "in themselves", because in the understanding of those who have assented to the Arguments we spoke of in conclusions 2 and 3, as demonstrative and evident against the motion of the Earth, no arguments for the motion of the earth will meanwhile be able actually to generate probability; and much less if the authority of divine Scripture stands in the way.

V. CONCLVSIO.

Conclusion V.

[Margin: The principal conclusion.] V. *Considering Reason alone and Intrinsic Arguments, with all Authority set aside, the Hypothesis that supposes the Immobility or Rest of the Earth is to be asserted absolutely as true; and that Hypothesis which attributes to the Earth either the Diurnal motion alone, or the Diurnal and Annual motion, is false and in conflict with Physical, indeed also with Physicomathematical, demonstrations.*

This conclusion follows from Conclusions 2 and 3.

VI. CONCLVSIO.

Conclusion VI.

VI. *For anyone who wishes either to champion or to attack either of the hypotheses already mentioned, with all the arguments devised so far drawn up in battle array, no amount of expertise in Physical or Theological matters suffices, unless he is also most expert in Astronomy, and not lightly versed in Geometry and Arithmetic and in not a few subalternate Mathematical disciplines.*

For it is clear from what was indicated in chapters 33 and 34 that, again and again, principles or conclusions of the more recondite Astronomy are required in the Arguments and their solutions; and I say the same of Geometry and Arithmetic, etc. Otherwise, we know that not only have purely Physical men failed to understand, or are going to fail to understand, even the terms of the arguments, but also that some who greeted Mathematics from the threshold have fallen into manifest errors. Let these things be taken as said for the sake of

counsel and admonition, not of indi- rect self-display. For if in this argument we have achieved anything not unworthy of learned men, we credit it to God alone, the Giver of Life, Talent, Judgement, Industry and of all other opportunities, and ascribe nothing, or very little, to our own weakness.

VII. CONCLVSIO.

Conclusion VII.

VII. *It is fair that the followers of the Copernican hypothesis in future, if there are any, should acknowledge that Theologians and Churchmen have sufficient expertise to pass judgement on these hypotheses; and that the Copernican hypothesis is rejected not from excessive or mere reverence towards Ecclesiastical decrees or the Sacred Scriptures, but also from a deeper examination of both hypotheses, and from reasons drawn from it with the utmost circumspection.*

Those who dispute with the Copernicans here and there know what this is aimed at — those who feel that, in speech or in writing, they are again and again charged with an ill-advised piety and a kind of religious timidity: as if, bound solely by this, and not philosophising with a free mind, they had clung immovably to the hypothesis of the Motionless Earth like polyps to a rock. For so Kepler, above all in the introduction to the *Commentaries on Mars*: *"But there are many more of those who are moved by piety not to assent to Copernicus, fearing that a lie may be imputed to the Holy Spirit speaking in the Scriptures, if we should say that the Earth moves and the Sun stands still."* We shall read similar things from him below, in chapter 38, number 3.

CAPVT XXXVI. Sacræ Scripturæ Authoritates pro Solis Motu & Immobilitate Terræ afferuntur.

Chapter 36. The authorities of Sacred Scripture for the motion of the Sun and the immobility of the Earth are brought forward.

I. This business is of greater moment than some of the Copernicans have thought. For on the occasion of this controversy about the motion and rest of the Earth — which in itself is purely Physical and Astronomical — both the literal sense of Sacred Scripture and the right to judge and define its true sense are now being turned by them into a controversy, if we accept their interpretation. Accordingly, both for the plan of the work I have undertaken, and for the duty of the Religious life and of Theology, which I professed by teaching publicly and privately for almost a whole decade, I must inquire with all the diligence and sincerity I can whether, and how far, the statements of the divine scriptures avail to settle this question — especially as weighed by the unanimous consensus of the Fathers and of the expositors. All the more since every year, according to the most praiseworthy custom of our Society, all the Masters of Theology and of Arts, together with our Scholastics, at the opening of the schools, in the profession of Faith prescribed by the Most Holy Council of Trent, are accustomed, by a most sacred oath upon the holy Gospel

of God, among other things to promise, vow and swear thus: *"Likewise I admit Sacred Scripture according to the sense which Holy Mother Church has held and holds, to whom it belongs to judge of the true sense and interpretation of the Sacred Scriptures; nor will I ever take and interpret it otherwise than according to the unanimous consensus of the Fathers."* [Margin: From the bull of Pius IV on the form of the oath of the Profession of Faith.] Similar things are found in Session 4, in the decree on the edition and use of the sacred books. And always to be kept before one's eyes, even in matters hard to understand, is that excellent saying of Saint Augustine in book 2 of *De Genesi ad litteram*, chapter 5: *"In whatever way, and whatever kind of waters are there, let us not in the least doubt that they are there. For the authority of this Scripture is greater than all the capacity of human ingenuity"*; and in chapter 9: *"For what divine authority says is true, rather than what human weakness conjectures."* [Margin: Saint Augustine's saying on the authority of Sacred Scripture [?].]

II. On the other hand, however, we must beware lest, when Sacred Scripture is capable of several interpretations, we cling to one that can be convicted of falsity on other grounds, and summon a defence for our errors from the divine scriptures. For the same Saint Augustine says most prudently, in book 1 of *De Genesi ad litteram*, chapter 18: *"And in obscure matters, very remote from our eyes, if we read anything written about them, even in the divine writings, that can, without prejudice to the Faith with which we are imbued, give rise to one opinion and another, let us not throw ourselves into any one of them with headlong affirmation in such a way that, if perhaps the truth, discussed more carefully, rightly overturns it, we fall — fighting not for the meaning of the divine Scriptures but for our own, so that we want ours to be the meaning of the Scriptures, when we ought rather to want the Scriptures' meaning to be ours."* [Margin: A saying of the same Saint Augustine on the use of Sacred Scripture.] He gives a similar warning at the end of book 2 of *De Genesi ad litteram*.

Moreover, we must take care not to hand the sacred scriptures over to ridicule by those to whom the error is manifest that we would wish to defend by misusing them: as if someone wished to maintain that a clod of earth placed on water can float, because of a wrongly understood Psalm 135. And so the same holy Doctor says, in book 2 of *De Genesi ad litteram*, chapter 1: *"Here it occurs to me to warn of the error to be avoided which we warned of in book 1 — lest perhaps, because it is written in the psalms, 'He founded the earth upon the waters', one of us should think that this testimony of the scriptures must be relied on against those who discourse subtly about the weights of the elements. For they, not being held by the authority of our writings, and not knowing in what sense it was said, will sooner ridicule the holy books than repudiate what they have either grasped by certain reasons or proved by the most manifest experiments."* Explaining that passage of the Psalm literally, he says it is to be understood of islands and continents that have a higher position above the waters, and of the roofs of caves made firm with a hanging solidity above the waters; and so he concludes: *"Therefore no one can understand what was said, 'He founded the earth upon the waters', even*

literally, in such a way as to think that the weight of the waters has been set by the natural order as if beneath the earthy weight to support it." Further, in book 1 of *De Genesi ad litteram*, chapter 19, having taught that it can happen that the author or writer of Sacred Scripture wished to be understood in a double sense, he insists that we must take care not to seek out from the divine utterances a defence for a falsehood easily made manifest by the rules of Astronomy, to the great detriment of the Catholic reputation. I shall not hesitate to copy his words here, because they serve our business very well: *"That he meant both"* — namely, the Sacred Writer — *"is not unfittingly believed, if a definite circumstance supports each opinion. For it very often happens that even a non-Christian knows something about the earth, about the heavens, about the other elements of this world, about the motion and revolution, or also the magnitude and intervals, of the stars, about the definite eclipses of the Sun and Moon, about the cycles of years and seasons, about the natures of animals, shrubs, stones and other things of this kind, in such a way that he holds it by most certain reasoning or experience. But it is exceedingly shameful and pernicious, and to be guarded against above all, that any unbeliever should hear a Christian, speaking about these things as if according to the Christian writings, talking such nonsense that, seeing him err by the whole sky (as the saying goes), he can scarcely hold back his laughter. And it is not so much that a man in error is laughed at that is troublesome, but that our authors are believed by those outside to have held such views, and, to the great ruin of those whose salvation we labour for, are censured and rejected as unlearned. For when they have caught someone from the number of Christians erring in a matter which they know very well, and asserting his vain opinion on the basis of our books, how are they going to believe those books about the resurrection of the dead, and about the hope of eternal life and the kingdom of heaven, when they have thought them written falsely about things which they have already been able to experience or to grasp by indubitable numbers? For what trouble and sorrow rash and presumptuous men bring upon prudent brethren cannot be adequately expressed: since, whenever they begin to be rebuked and refuted over their wrong and false opinion by those who are not bound by the authority of our books, they try to bring forward those same holy books, from which to prove what they have said with the lightest rashness and the most open falsity, etc."* With these preliminary warnings, let us approach the sacred scriptures.

Solis Motus ex Sacra Scriptura.

The Motion of the Sun from Sacred Scripture.

[Margin: The rising and setting of the Sun are frequent in the Scriptures.] III. First, Scripture often states expressly that the Sun rises and sets, and goes forth over the earth. So Genesis 15: *"And when the Sun was setting, a deep sleep fell upon Abraham"*; and chapter 19: *"The Sun went forth over the earth, and Lot entered Segor"*; and chapter 32: *"And at once the Sun rose upon him"*; and Judges 19: *"And the Sun set on them near Gabaa"*; and 3 Kings, chapter 22: *"Before the Sun set"*; and 2 Paralipomenon, chapter 18: *"He died as the Sun was setting"*; and Judith 14: *"And it shall be, when the Sun has gone forth"*; and Esther 11: *"Light and*

the Sun rose"; and in very many other places in which the rising or setting of the Sun is mentioned — but above all Matthew 5: *"Who makes his Sun rise upon the good and the bad"*; and Ephesians 4: *"Let not the Sun go down upon your anger."* Besides these, I have counted 40 and more other places on this point.

IV. Second, it is ascribed to a Miracle of divine Omnipotence that it can check the course of the Sun, and, conversely, shake the Earth, which stands unmoved. Job 9: *"Who shakes the earth out of its place, and its pillars tremble; who commands the Sun, and it does not rise"* — that is, if he commands it, it will not rise — [Margin: Joshua stops the Sun and the Moon.] as will happen at the end of the world, of which Habakkuk 3 says: *"The Sun and the Moon stood still"*; and as happened at the command of Joshua, chapter 10: *"Then Joshua spoke to the Lord on the day on which he delivered the Amorrhite into the sight of the children of Israel, and he said before them: Sun, do not move against Gabaon, and Moon, against the valley of Aialon. And the Sun and the Moon stood still, until the nation avenged itself on its enemies."* So the Vulgate. Granted that the Hebrew reading has *Sile* ["be silent"] for *ne movearis* ["do not move"], and *Siluit* ["was silent"] for *stetit* ["stood"], the Septuagint has [Greek: στήτω ὁ ἥλιος (stētō ho hēlios, "let the Sun stand")], "Stand, Sun." The Canonical writer continues in the same place, saying: *"Is this not written in the book of the Just? So the Sun stood still in the midst of heaven, and did not hasten to set for the space of one day. There was not, before or after, so long a day, God obeying the voice of a man and fighting for Israel."* In this place the Septuagint translators have: *"And the Sun in the midst of heaven did not proceed to the West"*; so it seems to have been checked at the time when it was at midday. To this refers that passage of 1 Paralipomenon, chapter 4: *"Who made the Sun stand"*; and of Ecclesiasticus 46: *"Was not the Sun hindered in his anger, and one day made as two?"*

Almost a twin to this portent, by far the most celebrated, was that other one in which the Sun, at God's command, turned back towards the East, so that the shadow of the gnomon on the dial of Ahaz went back 10 lines. [Margin: The Sun's going back on the dial of Ahaz.] For although 4 Kings, chapter 20, says: *"So Isaiah the Prophet called upon the Lord, and he brought the shadow back by the lines by which it had already gone down on the dial of Ahaz, ten steps backward"*, that bringing-back was nevertheless made in the motion of the Sun itself as it went back, as Isaiah himself, the agent and witness of this miracle, explains in chapter 38, saying expressly: *"Behold, I will make the shadow of the lines, by which it had gone down on the dial of Ahaz in the Sun, go back ten lines. E [?] the Sun went back ten lines, by the steps by which it had gone down."* And Ecclesiasticus confirms it in chapter 48, speaking of Hezekiah: *"In his days the Sun went back, and he added life to the King."* So the same portent appeared not only on the dial of Ahaz but on others too. This was the reason why the Babylonians, the most attentive observers of the stars and of the celestial motions, having noticed it and having heard its cause from the report of the miracle already spread abroad, sent envoys to Hezekiah, so as to be better informed of its circumstances. Book 2 of Paralipomenon, chapter 32, testifies to this embassy in these words: *"Yet in*

the embassy of the princes of Babylon, who had been sent to him to inquire about the portent that had happened upon the earth," etc.

[Margin: The motion of the Sun described in detail in the Sacred Scriptures.] V. Third, the motion of the Sun — chiefly the diurnal — and its vicissitudes, effects and speed are described in detail in the sacred writings. For in Psalm 18 the glory of God, appearing particularly in the Sun, is sung thus: *"In the Sun he has set his tabernacle; and he, like a bridegroom coming forth from his bridal chamber, has rejoiced like a giant to run his course; his going forth is from the highest heaven, and his circuit even to its highest, and there is none who hides himself from his heat."* Here, in the Astronomical manner, the beginning and end of the day are taken from the summit and at the summit of heaven, that is, from the culmination of the Meridian and the greatest altitude of the Sun. And what is clearer than those words of Ecclesiastes, chapter 1: *"A generation passes and a generation comes, but the Earth stands for ever. The Sun rises and sets, and returns to its place; and, reborn there, it circles through the South and bends to the North; surveying all things round about, the spirit goes on, and returns to its circles."* But passing from Ecclesiastes to Ecclesiasticus, it is truly worth noting how often the motion of the Sun is suggested by the latter. Chapter 26 says: *"As the Sun rising,"* etc.; and chapter 33: *"Why does day surpass day, and light light, and year year, by the Sun? They were separated by the knowledge of the Lord, the Sun having been made and keeping his command; they are divided by the wisdom of God."* It belongs, then, to the Sun and not to the Earth to obey God and to distinguish the days. And chapter 43: *"The Sun, at its appearing, announcing at its going forth, an admirable vessel, the work of the Most High,"* etc. *"Great is the Lord who made it, and at his words it has hastened its course."* Thus God himself commends his own greatness by the speed of the Sun's course. That speed is indeed as much greater than the speed of the Earth would be if it were turned by a diurnal rotation, as the circumference of the Ecliptic, along which the centre of the Sun advances, is greater than the circumference of the terrestrial globe; and in our view it is greater by 7300 times. The perpetual obedience of the same Sun towards God in its motion is commended in Baruch 6: *"The Sun indeed, and the Moon and the stars, being bright and sent forth for useful purposes, are obedient."* The rest we pass over, because for anyone whom these do not satisfy, no other testimonies would be enough.

Terræ Quies & Immobilitas ex Sacris Literis.

The Rest and Immobility of the Earth from the Sacred Writings.

VI. In book 1 of Paralipomenon, chapter 16, in the Canticle of David after the bringing back of the ark, it is said: *"Let all the earth be moved before his face, for he has founded the orb immovable"* — namely, the orb of the earth. And in Job 9 the power of God is praised because he could, if he wished, move the Earth from its place: *"Who shakes the earth out of its place, and its pillars tremble"* — and these are Job's own words; and chapter 26: *"Who stretches out the North over the void, and hangs the earth upon nothing"* — again Job's own words; and in chapter

38 God himself says: *"Upon what are its bases made firm?"* For that suspension and balancing signifies immobility; as also in Proverbs 8: *"When he was hanging up the foundations of the earth"*; and in Isaiah, chapter 40: *"Who has measured the waters in his fist, and weighed the heavens with his palm? Who has hung the mass of the earth on three fingers, and weighed the mountains in a balance, and the hills in a scale?"* Then in Psalm 74: *"The earth is melted, and all who dwell in it: I have made firm its pillars"*; that is, although the animals and inhabitants of the earth are melted like wax or ice and have vanished, the Earth itself nevertheless remains immovable, resting as if on the firmest pillars, by my command and power. On this point God is again commended in Psalm 92: *"For he has made firm the orb of the earth, which shall not be moved"*; and in Psalm 95: *"For he has set right the orb of the earth, which shall not be moved"*; and in Psalm 103: *"You who founded the earth upon its own stability: it shall not be bowed down for ever and ever"*; and in Psalm 118, verse 90: *"Your truth is from generation to generation; you founded the earth, and it abides."* Isaiah too, chapter 44: *"I am the Lord, who makes all things, who alone stretches out the heavens, who establishes the earth, and there is none with me."*

As for that passage of Ecclesiastes 1: *"A generation passes, and a generation comes; but the earth stands for ever"* — in Hebrew it reads thus: *"The Earth is fixed and steadfast for ever."* So the first and simple sense is that it stands, in the way that standing is opposed to transport, or local motion — especially since it is set against the local motion of the Sun, when it is said: *"The Sun rises and sets."* The secondary literal sense is that it does not pass away like the generations of men, that is, that it does not perish as a whole. For Saint Augustine teaches by examples, or in practice — book 12 of the *Confessions*, chapters 8, 19, 20, 24 and 31, and book 1 of *De Genesi ad litteram*, chapter 19 — and Saint Thomas, part 1, question 1, article 10, that Sacred Scripture can have many literal senses. But the same Saint Augustine, in book 1 of *De Genesi ad litteram*, chapter 19, and in book 3 of *De doctrina Christiana*, chapter 23, likewise teaches that when Scripture admits several senses that are not in conflict with one another, all of them are to be accepted together.

De Situ Terræ ex Sacra Scriptura.

The Position of the Earth from Sacred Scripture.

VII. The divine writings not rarely teach that Heaven is simply up and the Earth down:

namely, Deuteronomy 4, verse 39: *"Know therefore and consider in your heart that the Lord himself is God in heaven above and on earth below."* Joshua 2, verse 11, agrees with this: *"For the Lord your God, he is God in heaven above and on earth below."* And 3 Kings, chapter 8: *"Lord God of Israel, there is no God like you in heaven above and on earth below."* In Proverbs 25 too it is said: *"Heaven above and earth below."* And Jeremiah 31: *"Thus says the Lord: If the heavens above can be measured, and the foundations of the earth below searched out."* And Joel, chapter 2, which is quoted in chapter 2 of the Acts of the Apostles: *"I will give*

wonders in heaven above, and signs on earth below." Add to these many other places in which heaven is set against the Earth: Genesis 1: *"God created heaven and Earth"*; and Psalm 113: *"The heaven of heaven is the Lord's, but the Earth he has given to the children of men"*; and Colossians 1: *"In the Heavens and on Earth."* The Copernican system seems to agree little with these passages, since it does not place the Earth simply down [?], but sets the Sun at the centre of the universe as in the lowest place; and since it does not distinguish the Earth from heaven, but places it in heaven among the Planets.

CAPVT XXXVII. Quomodo Patres & Sacri Interpretes prædicta Sacræ Scripturæ loca intellexerint.

Chapter 37. How the Fathers and the Sacred Interpreters understood the passages of Sacred Scripture already mentioned.

De Motu Solis, ac Miraculis in Solis Motu diuinitus factis.

On the Motion of the Sun, and on the Miracles Divinely Worked in the Motion of the Sun.

I. I state very briefly that all the Holy Fathers, and all the Interpreters of Sacred Scripture not condemned by the Church, who have explained the passages adduced on the motion of the Sun, understood them first in the literal sense, of a true and real motion of the Sun — granted that some, on this foundation, afterwards built some senses that are not literal. To this belong all those whom we reviewed in section 1, chapter 1, questions 7, 8 and 9, and chapter 4, questions 2, 5 and 6, on the creation of Light and on the distinction of days and nights made by that light and afterwards by the Sun; for all of them speak in such a way that they suppose that the Sun, by a local motion of transport, brings about the alternations of days and nights, and also of years. To these Saint Augustine must be added, in book 1 of *De Genesi ad litteram*, chapter 10. There, explaining how day was made from evening and morning, he put forward an opinion that would explain this without local motion of the light and of the Sun, saying: *"Or must it be said that, since this work of God was quickly accomplished, the light stood for as long, with no night following, as it took for the space of a day to be completed; and that the night following the light remained for as long as it took for the space of nocturnal time to pass and for the morning of the following day to come, one and the first day being over?"* But he rejects it at once, adding: *"But if I say this, I fear I may be laughed at, both by those who know with the greatest certainty and by those who can very easily observe, that at the time when it is night with us, the presence of light illuminates those parts of the World through which the Sun returns from its Setting to its Rising; and that therefore through all 24 hours, around the circuit of the whole round, there is never lacking day in one place and night in another,"* etc. And in book 2 of *De Genesi ad litteram*, chapter 15, he has this: *"But the fixed hours and days and years, which we know by common usage, would not come about except by the motions of the stars. So if we understand times, days and years in this way —*

times as certain divisions which we reckon by clocks, or which are very well known in the sky, when the Sun rises from the East up to its Meridian altitude and from there declines again into the West, so that next either the Moon or some star can be noticed emerging from the East immediately after the setting of the Sun, which likewise, when it has come to the middle altitude of the sky, indicates the middle of the night, and is then about to set when, with the Sun's return, it becomes morning; whole days as the circuit of the Sun from East to West; and years either as these customary rounds of the Sun — not when it returns to the East, which it does daily, but when it returns to the same places among the stars, which it does only after three hundred and sixty-five days and six hours, that is, a quarter of a whole day, have been completed; which part, taken four times, compels one day to be inserted, which the Romans call the bissextile, so that the same circuit may be returned to — or else greater and more hidden years, for when the courses of other stars are completed, greater years are said to come about: if, then, we understand times, days and years in this way, no one doubts that these come about by the stars and Luminaries" — that is, by the motion of the stars and Luminaries, as he had said at the beginning.

[Margin: What kind of miracle Joshua's was in the course of the Sun.] II. As regards the Miracle of the Sun worked by Joshua, all likewise agree on a true and real checking of the motion of the solar body itself, as may be seen in Serarius [Nicolas Serarius] on chapter 10 of Joshua, from question 17 to 27; in Iacobus Salianus [Jacques Salian], volume 2 of the *Annals of the Old Testament*, at the year of the World 2584, from number 168, or page 303; in Cornelius à Lapide on chapter 46 of Ecclesiasticus, verse 5; in Oliverius Bonartius [Olivier Bonaert] in the same place; and in Cosmus Magalianus [Cosme de Magalhães] on chapter 10 of Joshua, section 1, from annotation 4. Nor did the Fathers understand this prodigy in any other sense — especially Saint Jerome, who says on chapter 28 of Isaiah: *"Trusting in God, who dwelt in him, Jesus [Joshua] said: Let the Sun stand"*; and Saint Ambrose, book 1 of the *De officiis*, chapter 40: *"Jesus Nave, in greatness of mind and of faith, cried out: Let the Sun stand; and it stood, until this victory was completed"*; and Saint Bernard, as found in the author of his life, book 2, chapter 7: *"Joshua fights, and, so that the day, prolonged, may suffice for the completion of the victory, he does not so much pray the Sun to stand as command it: his faith merits the obedience of the Sun as much as victory over the enemy laid low."* The Saints speak in the same way: Dionysius in the letter to Polycarp; Chrysostom, homily 27 on the Epistle to the Hebrews; Saint Augustine, book 21 of the *City of God*, chapter 8, and book 11 of the *Confessions*, chapter 23; Saint Ephrem, volume 3, in the sermon on the sinful woman; Saint Maximus, in the letter to Thalassius; the Author of the *Wonders of Sacred Scripture*, book 2, chapter 4; Tertullian, *Against the Psychics*, chapter 10; and others, of whom below.

But it is disputed whether the Sun was at midday or near the horizon, and how many hours that day had. That it was midday is held by the Author of the *Wonders of Sacred Scripture*, book 2, chapter 4, among the works of Saint Augustine: *"Jesus son of Nun commanded the Sun at midday not to move"*; by

Theodoret, question 13 on Joshua, from these words: *"For just as, when the Prophet was fighting, the Sun stood still"*; by Serarius, questions 21 and 22 on Joshua; by Lyranus, Arias [Benito Arias Montano], Radak [R. David Kimchi] and Vatablus [François Vatable] on chapter 10 of Joshua; and by Salianus, above. And the 70 Interpreters strongly favour them, saying: *"The Sun in the midst of heaven did not proceed to the West."* So too Sedulius sang:

The Sun stood still at Gabaon, and on the summit of mid-heaven fixed its panting light, the evening put off, unused to reining in the day.

Yet that the Sun was near its setting was held by Severus Sulpitius [Sulpicius Severus] in the *Ecclesiastical History*; by Comestor in the *Historia scholastica*, on chapter 9 of Joshua; by Dionysius Carthusianus; by Abulensis [Alonso Tostado], question 12; and by Hugo and Caietanus [Tommaso de Vio] on chapter 10 of Joshua — because for *ne moveare* ["do not move"] the Hebrews read *Expecta* ["wait"]. And so Caietanus says: *"For had he not seen that the setting of the Sun was imminent, he would not have said: Sun, wait."* Granted that other Hebrews read *Sol tace* ["Sun, be silent"], Magalianus and Cornelius à Lapide, above, subscribe to this 2nd opinion: both because those words of Joshua 10, *"the Sun did not hasten to set"*, indicate clearly enough that it was about to rush headlong below the horizon at once, had it not been restrained by Joshua's command; and because a miracle is not to be multiplied, nor brought about except under pressing necessity, and the phrase *"in the midst of heaven"* can be taken for any part of the visible hemisphere, which, with respect to some horizon, is nevertheless always on the meridian.

III. It is further asked to how many hours that day was prolonged; and whether those words of Joshua 10, *"It did not hasten to set for the space of one day"*, and those of Ecclesiasticus 46, *"And one day was made as two"*, ought to be understood of a whole natural day of 24 hours, or of an artificial day of 12 temporal hours, or — since the interpreters judge from the circumstances of the story that it was about the summer Solstice, and at Jerusalem, which has a pole altitude of 32° 10′, the longest day is of 14^{h} 5^{m} — are to be understood of a day of 14 equal hours. [Margin: How long was Joshua's day?] For if the Sun stood still for 24 hours, these, added to the temporal hours of the artificial day that had gone before, make 36 hours; but added to the equal hours, 14^{h} 5^{m}, they make 38^{h} 5^{m}. If, however, the Sun stood still for only 14 hours, these, added to the 14 hours likewise elapsed, make 28 hours. Indeed, if that standing were reckoned from midday, according to the opinion of those who judge that Joshua's command was given to the Sun when it held the meridian, there would be only 21 hours. That day lasted 36 hours, in the opinion of the Paraphrast — the Chaldean — of Dionysius Carthusianus and of Emmanuel Sà [Manuel de Sá]. The view is also attributed to Saint Justin, in the dialogue against Trypho, and it seems to be confirmed by the fact that Joshua 10 says there was not so long a day before or after — whereas the day prolonged by Isaiah's prayers as a favour to King Hezekiah is judged by some to have been of 32 hours. But even if that were granted, the writer of the book of Joshua spoke

of the days before Joshua and after him, up to his own age in which he was writing — whether he was Joshua himself, or Samuel, or someone else older than Isaiah. Within those 36 hours, however, some count a whole natural day of 24 hours together with the 12 hours of the artificial day that was prolonged, as Serarius does. But that day was composed of two artificial days, that is, of 24 temporal or 28 unequal hours, in the opinion of Caietanus, Vatablus, Rabbi Eliezer, Rabbi Kimhi, Magalianus on chapter 10 of Joshua, Serarius in the same place, question 23, and Cornelius à Lapide and Salianus, above; for this was enough to complete the victory. But these speak of a day not including the night. I am therefore surprised that Toletus [Francisco de Toledo], in book 4 of the *Physics*, chapter 14, question 16, favoured a stay of only three hours. Nor indeed does Saint Augustine say this, in book 11 of the *Confessions*, chapter 23; rather, he says: *"So that Joshua might finish the battle as victor, the sun stood, but time went on."* Saint Dionysius, in the letter to Polycarp: *"The Sun and Moon stand for one day"*; and Saints Jerome and Ephrem affirm one day — and so, indeed, does Tertullian.

[Margin: Whether the Sun alone stood still.] IV. It is also commonly asked whether the Sun alone stood still, or all the stars together with their leader and Choragus. Saint Dionysius the Areopagite, in the letter to Polycarp, adduces both miracles as an outstanding argument of divine power, and *trum* [?] determines; but he says that it would be more admirable if, while the Sun stood still, the other stars had completed their courses. It is more probable, however, that the whole heaven stood still with all the stars, as is held by the Author of the *Wonders of Sacred Scripture*, book 2, chapter 4; Saint Maximus, to Thalassius; Abulensis on chapter 10 of Joshua; Masius [Andreas Masius] and Caietanus in the same place; the Conimbricenses, book 2 of the *De caelo*, chapter 6, question 2, article 3; Serarius on chapter 10 of Joshua, question 26; and Salianus, Cornelius à Lapide and Bonartius, above. This is so both that the order of the celestial motions should not be disturbed, and because Joshua's command to the Moon seems to indicate it — the Moon, whose light was not necessary for completing the victory while the Sun was present. Rather, he seems to have said implicitly, and by Divine prompting: "Sun, and all you other lights of the world, do not move" — in brief, comprehending the whole host of heaven under the name of the Luminaries, as the king and queen of the stars. But if it was the Earth that had to stop, as the Copernicans would have it, there was no reason why God, who wished to work this prodigy at Joshua's prayer, should urge him by an inner impulse to stop the Moon as well; or certainly Saint Dionysius and the other sacred writers would have raised this question in vain — unless the Copernicans pretend that the miracle of the diurnal revolution was worked in the Earth, but that of the proper motion in the other Planets.

V. Finally, it is asked whether this prodigy was performed on any other occasion. For in 1 Paralipomenon, chapter 4, verse 22, someone among the sons of Sela is named *"Who made the Sun stand"*. The Rabbis say that this was

Elimelem, the husband of Noemi; but he was not of the sons of Sela, but of the sons of Phares. And in Hebrew, in place of that periphrasis *"Who made the Sun stand"*, there stands the name *Iocim*, or *Ioakim*, whose etymology is *"he made stand"*. But whether it was a fable invented by the Rabbis, as Caietanus on that passage of Paralipomenon and Serarius, question 25 on chapter 10 of Joshua, think, and the noun *Solem* ["the Sun"] was inserted into the sacred Bible by certain people; or whether he was rather a *stator Salis* [?], because like Elijah he brought drought upon the lands, as Magalianus holds on chapter 10 of Joshua, verse 22, annotation 7; or whether those words are to be read merely materially, as Salianus thinks in scholium 3 at the year of the World 2801, or as the etymology of a proper name, abstracting from the truth of its signification, as Gaspar Sanctius [Gaspar Sánchez] would have it on 4 Kings, chapter 20, and Bonartius, above; or whether, finally, he really made the Sun stand, as Saint Jerome reports from the tradition of the Hebrews, without rejecting it, in the book *De traditionibus Hebraeorum* on that passage, together with Abulensis in the same place, question 18, Lyranus, Hugo, Rabanus, Dionysius Carthusianus and many others — all this seems uncertain. Nor does Cornelius à Lapide, above, define anything, just as I do not either, out of reverence for the Vulgate edition, which I prefer to accept as it lies.

On this occasion, moreover, Cornelius à Lapide and Bonartius, on chapter 46 of Ecclesiasticus, add other prodigies, if not as great, still similar. For Saint Mutius the Abbot, as Ruffinus [Rufinus of Aquileia] relates in book 2 of the *Lives of the Fathers*, [Margin: Saint Mutius the Abbot and Bessarion stop the Sun.] chapter 9, going at God's prompting to visit one of the brethren who was sick: *"When he saw the Sun already sinking, he said to it: In the name of our Lord JESUS Christ, stand a little while on your way and wait for me, until I reach the village. And though it had already begun to sink in some part, it stopped, and did not set before the man of God had reached the village. And all who stood and watched the Sun's stays in its setting marvelled; and he said to them: Do you not remember the word of the Lord: If you have faith like a grain of mustard seed, you will do greater signs than these?"* So Ruffinus, and from him Maiolus in Colloquy 1 of the *Dies Caniculares*. And for a similar reason the Abbot Bessarion and another old man are said to have stopped the Sun, in book 6 of the *Lives of the Fathers*, chapter 2. [Margin: The Sun stands still under Charlemagne.] Turpin, Archbishop of Reims, who was an intimate of Charlemagne, relates in chapter 26 of the *Life of Charles* that the Sun also stood still under Charlemagne, to avenge the Saracens' killing of Roland and other princes of Charles in the defeat at Roncevaux; but Baronius [Cesare Baronio], Bellarminus [Roberto Bellarmino] and Possevinus [Antonio Possevino], in *De scriptoribus ecclesiasticis*, mark this author as suspect and fabulous. [Margin: And under Charles V.] Again, that the Sun stood still under Charles V, when he overcame the Saxon in battle, is affirmed by Ludovicus Avila [Luis de Ávila y Zúñiga] in book 2 of the *German War*, by Consalvus de Illescas [Gonzalo de Illescas] in part 2 of the *History of the Pontiffs*, and by others, whom Christoph Scheiner follows in the book *De refractionibus*

caelestibus, chapter 32. [Margin: And under Godefroy de Bouillon.] Likewise, Eucherius relates in his history, chapter 21, and Genebrardus from him in the *Chronicle*, book 4, that on the day on which Godefridus Bullionius [Godefroy de Bouillon] stormed Jerusalem, in the Year 1099 — on the sixth weekday, Friday, and at the hour at which Christ had been crucified there — the Sun went back some degrees. [Margin: And under Francisco Ximénez.] In the preceding century too, at the time when the Spaniards took Oran and defeated the Moors, the Sun stood still for 4 hours, as Alvarus Gomez [Álvar Gómez de Castro] testifies in book 4 of the *Deeds of Cardinal Francisco Ximénez*. Finally, Bonartius, in the place cited, relates from letters written from Madrid, and on the oath of Fathers of our Society, that the Sun, on the very point of setting, stood still for five hours and more, until our men, with others, could escape from the shoals that lie between Goa and Malacca, into which the ship's master had carelessly run, with the greatest danger. The danger was increased by a wind that suddenly arose and drove the ship onto the shoals. He says that this miracle was worked through the intercession of Saint Francis Xavier, to whom they had commended themselves, adding a vow to bring a silver lamp to his tomb. Cornelius à Lapide, however, explains portents of this kind as occurring not in the globe of the Sun itself but in its image, refracted through clouds or vapours of the horizon: "otherwise," he says, "if the Sun itself had stood still, the Astronomers of the whole world would have noted it." But I come to the other miracle, worked under Hezekiah.

[Margin: The miracle on the dial of Ahaz.] VI. For the Holy Fathers and Interpreters likewise treat of the Sun's going back under King Hezekiah, at the prayer and entreaties of Isaiah — on 4 Kings, chapter 20, or on chapter 38 of Isaiah, or on chapter 48 of Ecclesiasticus, or on book 2 of Paralipomenon, chapter 32, where this miracle is mentioned. But the most diligent of all are Gaspar Sanctius on 4 Kings, chapter 20; Salianus, volume 4 of the *Annals*, at the Year of the World 3322, from number 86; Cornelius à Lapide on chapter 38 of Isaiah and on chapter 48 of Ecclesiasticus; and Oliverius Bonartius on chapter 48 of Ecclesiasticus — all of our Society. The principal question about this miracle, then, is whether only the shadow went back on the dial of Ahaz, or the Sun itself. [Margin: Whether the Sun itself, or only the shadow, went back.] That only the shadow went back is held by Burgensis [Paul of Burgos] on 4 Kings, Vatablus, Arias Montanus on Isaiah, and Emmanuel Sà. Their reasons are these: the going back of the Sun is a greater miracle than its checking, and ought not to have been passed over in silence by Isaiah and by the writer of the book of Kings, who nevertheless mention only the shadow; nor was the choice offered to the King about anything but the shadow, since he, lying sick in bed, could not see the Sun, but only the shadow through the window; and finally, the Babylonians would not have been in doubt about the portent, since it would have been observed at Babylon too, and not merely carried to them by report. On the other hand, that the Sun itself went back is affirmed by the Siracid in Ecclesiasticus 48. Having said there: *"Isaiah, the great Prophet, and faithful in the*

sight of God", he at once added: *"In his days the Sun went back, and he added life to the King."* In Greek it is [Greek: ἀνεπόδισεν ὅ ἥλιος (anepodisen ho hēlios, "the Sun went back")], "the Sun stepped back"; and there the words [Greek: τὸ (to, the article, here "the words")] *"he added life to the King"* are referred to Isaiah rather than to the Sun — unless you understand that the Sun added it, that is, signified by its going back that it was to be added. Indeed, Isaiah himself says in chapter 38: *"And the Sun went back ten lines."* And in 2 Paralipomenon, chapter 32, that portent is said to have happened not at Jerusalem only but *"upon the earth"*, which signifies universality. Rightly, therefore, the opinion that the Sun itself stepped back was held by Saint Dionysius in the letter to Polycarp; Saints Jerome and Cyril on Isaiah; Procopius, Lyranus, Haymo, Hugo and Adamus in the same place; the Author of the *Wonders of Sacred Scripture*, book 2, chapter 48; Theodoret on Psalm 29; Elias Cretensis on the 19th oration of Saint Nazianzen [Gregory of Nazianzus]; Abulensis; Sanctius; Cornelius à Lapide on chapter 38 of Isaiah and on 4 Kings, chapter 20 — where Sanctius says that this is the constant opinion of almost all the Fathers and Interpreters; and finally Serarius on Joshua, and Salianus and Bonartius, above. Granted, Isaiah expressed to the King nothing but the going back of the shadow; but he did so as the effect from which the King could more conveniently and more evidently recognise the greatness of the miracle worked in the Sun. Nor did the Babylonian envoys doubt the substance of the prodigy, but only its manner and circumstances. There is the further point that dials can be made, by natural means, on which the shadow alone goes back, as Clavius demonstrates in the *Fabrica instrumenti ad horologia*, chapter 21. There he wisely refutes Petrus Nonius [Pedro Nunes], who says that this portent was produced by the sciateric art, and therefore naturally, when in fact it was worked miraculously and supernaturally.

[Margin: The time of the miracle, and the kind of dial.] VII. It is disputed, moreover, at what time of day, and on what kind of sundial, this miracle was worked. Scripture, in 4 Kings, chapter 20, brings in Isaiah speaking thus: *"Do you wish the shadow to go up ten lines, or to return as many steps?"*; and soon after: *"And Hezekiah said: It is easy for the shadow to grow ten lines; nor do I wish this to happen, but that it return backward ten steps. So Isaiah the Prophet called upon the Lord, and he brought the shadow back by the lines by which it had already gone down on the dial of Ahaz, ten steps backward."* And Isaiah 38: *"And the Sun went back ten lines, by the steps by which it had gone down."* From these words Cornelius à Lapide, on chapter 38 of Isaiah, gathers that the dial stood on a plane vertical to the Horizon, erected so that its face was turned toward the South. For since it is probable that it stood in full view on the wall of the royal palace, for common use, those conditions — the ascent and descent of the shadow, or rather the ascent of a growing shadow, and 10 hours from Rising to Setting — cannot be verified except of such a dial, since on it an ascent through 10 steps or lines could be marked, and a descent through as many lines. Concave hemispheres would have been less apt and convenient for this, and less exposed to observers. The same author further gathers that the time was midday, or close to it. For

as the Sun rose to the meridian the shadow had already gone down through 10 lines, and it would have gone up through as many if the King had wished; so the shadow seems to have stood at the point that ended the descent already made and began the ascent to come. [Margin: The antiquity of the sundial.] On this occasion note, in passing, that the inventor of the sundial was not Anaximenes, as Pliny the Elder thinks (book 2, chapter 76), who flourished about the fiftieth Olympiad; for Ahaz lived about the first Olympiad, that is, about 200 years before Anaximenes, and many more years before L. Papyrius Cursor, who was the first to set up a sundial for the Romans, at the temple of Quirinus, about the time of the first Punic War, as Pliny relates in book 7, chapter 60. But see Clavius, book 1 of the *Gnomonice*, page 7.

[Margin: Were the 10 lines of hours, or of half-hours?] VIII. Third, it is asked whether those ten lines marked ten whole hours, or halves or quarters of hours; on this depends the solution of the question about the length of that day. Another question, however, is also involved here: whether the going back of the Sun and of the shadow was made suddenly and in a moment, or gradually and successively. That those lines were lines of hours, not of half-hours, was indicated by Saint Dionysius in the letter to Polycarp; by the Author of the *Wonders of Sacred Scripture*, book 2, chapter 28; by Eucherius on 4 Kings, chapter 20; and by the Chaldean Paraphrast, Bede and Angelomus in the same place. And from these premises Saint Dionysius indicated that the day was 32 hours long: namely 12 temporal hours, and 10 which the Sun added by going back, and as many others which it added by going forward; and so the artificial day would have been nearly tripled. Others, however, say that the day was doubled: so the Author of the *Wonders of Sacred Scripture*; Procopius on chapter 38 of Isaiah; Rabbi Kimhi, as cited by Vatablus; Tornielus at the year of the world 3322, number 6; Abulensis and Caietanus; and Sanctius on Isaiah. On their view, either those lines were lines of half-hours, or else the Sun went back to the East in a moment of time, or at least very swiftly, and afterwards, advancing in its ordinary succession, added another 10 hours to the 12 hours, or 12 hours to the 10 already elapsed, so that the day was 22 hours long. For if the lines had been lines of hours, and the Sun had kept its accustomed slowness both in going back and in going forward, the Sun's shadow could not have grown through another 10 lines, as Isaiah had offered the King; otherwise the artificial day at Jerusalem would naturally have been 20 hours long — hours, that is, as marked on the dial. Cornelius à Lapide on Isaiah, however, thinks that it was then midday, and that only 10 hours were marked on that dial — five before midday, through 10 half-hour lines, and as many after midday; and so he likewise judges that the day was 15 hours long, a number certainly well suited to signify the 15 years which God granted Hezekiah over and above. From this it will likewise follow that the day lengthened at Joshua's command was longer than this day prolonged at Isaiah's prayers — although this is by no means necessary, since those words of Joshua 10, *"there was not before and after so long a day"*, refer only to the time at which the author of that book was writing. [Margin: Whether

the other stars went back.] On this occasion too, however, not the Sun alone but the other stars as well went back proportionally, so that the arrangement of the heavens should not be disturbed: so teach Saint Dionysius to Polycarp; the Author of the *Wonders of Sacred Scripture*, book 2, chapter 28; Abulensis on 4 Kings, question 33; Baradius, volume 1, book 5, chapter 14; Cornelius on chapter 38 of Isaiah; Salianus, above; and Bonartius.

[Margin: Our opinion on this miracle.] IX. For my part, I explain the miracle already mentioned as follows, always saving a better judgement. *First*, I say that Isaiah, when he offered the King a choice either of the ascent of the shadow or of its going back, offered some miracle in either case, and therefore an ascent of the shadow to be completed not after 10 or 5 hours, by the ordinary descent of the Sun to its Setting, but at once and almost in a single instant. The King, however, chose the going back of the shadow: either he had not understood that miracle, since the Prophet had not expressed it, or, when the choice was now being given, he was choosing a greater and more evident miracle, open to no ambiguity. For whether that miracle was to be completed very swiftly and almost in an instant, or with the succession customary to the Sun's motion, some miracle at any rate was to come, namely in the going back of the shadow through the same lines along which it had already advanced since the Sun's rising; and if this very thing was to be done in a moment, there was to be a double miracle within the one miracle. *Second*, I say that the going back of the Sun and of the shadow was made in a moment, or with the greatest possible speed, which is what those words signify: *"And he brought the shadow back by the lines by which it had already gone down."* For there was no reason to defer the completion of the miracle, and to keep the King in suspense and the Prophet occupied in the palace to no purpose for 10 or 5 hours. Finally, reason demands that the ascent of the shadow in going back should have been such as it would have been in going forward, if the King had chosen the first part of the offer; and that was without doubt going to be miraculous, and so without the customary delay of the Sun's course. Nor was it in keeping with the divine liberality, when the King was choosing a greater and surer miracle, to restrict it to the going back alone. *Third*, I say that, although it is gathered from the sacred text and from the property of that dial that the time was not yet past midday — for the shadow had gone down through ten lines, owing to the ascent of the Sun, in such a way that it could still have gone up through ten other lines as the Sun descended to its Setting, and could have grown, or advanced, to as many remaining lines, if the King had wished it to advance so suddenly at God's command; and yet it had already gone down through all the lines through which it went back, and had not gone down through some of them and begun to go up through any — it does not follow, nevertheless, that it was the very moment of midday. It could have been a time before midday, and the Prophet could still have made the shadow (had the King chosen the bare ascent) pass the meridian line at once and hurry to the last of the eastern lines, the Sun rushing headlong to its setting in an almost momentary leap.

Fourth, I say that the ten lines through which the shadow had already gone down cannot have been lines marking or bounding whole hours. For the hours before midday at Jerusalem, even on the artificial solstitial day, could not have been 10, but only 7^{h} $2½^{m}$, since the longest artificial day there is only 14^{h} 5^{m}. It is more probable, therefore, that they were lines of half-hours, and that on that dial not only the hours but also the half-hours were marked, as is done by the more careful makers of dials, in either the same or different colours. The ten lines, therefore, took in five whole hours. *Fifth*, I say that it is not probable that the craftsman, who was so diligent that on the wall of the royal palace not only the hours but also the di- stinctions of the half-hours were marked by him, should have drawn a dial so maimed and imperfect that for the whole day it marked only 10 hours, namely five before midday and as many after midday. For if those hours were unequal, or temporal, the first hour after sunrise and the last before sunset would have been missing, since the artificial day is of 12 temporal hours. If, on the other hand, the hours had been equal, then on the days nearest the summer solstice two hours would have been missing after sunrise and two before sunset, since the artificial day was, as I said, of 14 equal hours; and at the time of the equinox one hour would have been missing at each end. Nor would the dial have served accurately except on the days of the winter solstice, on which the day there was of 10 equal hours. Let it be granted, then, that at least 12 unequal hours were marked on that dial, by 24 half-hour lines; for it is more probable that the Hebrews, like the Romans and the Greeks, used temporal hours, as we have shown in our Chronological work. Therefore, since Isaiah brought the shadow back through all the lines through which it had already gone down, and these were 10, it is very probable that it was then the 5th hour from sunrise, and that one hour still remained until midday; and so, since the Sun covered these hours twice that day by its motion, the whole day was 17 temporal hours long. If, however, anyone would have those hours be equal, and the day a winter one, then it would have been midday, and the 10 hours of the artificial day, with 5 added over and above, would make up 15 hours — suitable for signifying the 15 years granted to the King by God over and above, granted that this signification is not necessary.

There are some, however, who think that the dial consisted of steps, like those of a staircase, rather than of lines, as we shall see below from Saints Hilary, Cyril and Jerome, and from Elias Cretensis. [Margin: Whether the dial of Ahaz was a kind of staircase.] But a dial of this kind — one that would serve all year round, be open at once to everyone, could be seen by the King lying in bed, and show at once the bringing back or going back of the shadow through 10 lines — would have been extremely difficult. Nor does it follow, from Scripture's saying *Steps*, that they were the real steps of some staircase. Scripture called them so because the lines on vertical dials are arranged about the gnomon in such a way that they imitate the steps of spiral staircases, whose plan an architect may lay out on the remaining plane; and in the same way the lines of the parallels on globes or geographical maps imitate the steps of a

staircase — the origin of the name *Climates* — and yet they are not in reality steps by which one climbs.

X. So much, up to this point, for the substance and circumstances of each miracle, whose exposition was not to be interrupted by the opinions of the Fathers. Here, however, I wish to set those opinions out, beginning with Saint Dionysius the Areopagite. [Margin: The opinion of Saint Dionysius the Areopagite on the standing and the going back of the Sun under Joshua and Hezekiah.] In the Letter to Polycarp, speaking of Apollophanes the Sophist, who wickedly used divine testimonies against divine things, he says: *"Apollophanes, being a wise man, ought to have understood that nothing in the order and motion of the heavens could ever have been changed from what it is, unless that order had had him who both keeps it in being and brought it forth, by whose motion and nod it was led to that point — he who, as it is in the divine writings, makes and changes all things. Why, then, does he not worship him whom from this too we have come to know as truly the God of all, admiring his power, which is the cause of all things and cannot be expressed in words? For by him the Sun and the Moon, by a force and a standing above the nature of the universe of things, are fixed wholly immovable; and for a whole day all things stand at the same points. Or, what is greater: while all the higher bodies were moved in a circle, the bodies contained in their embrace were not carried round in a circle together with them. And when another day was made, by continuation, almost three times longer, by a full twenty hours, either the universe took up again a contrary course for so long a time, and turned back with contrary revolutions so admirable; or the Sun, its varied motion contracted in its course into ten hours, completed the same whole again, going back, in another ten hours. This indeed terrified the Babylonians, rightly and deservedly, and subdued them to Hezekiah without a battle, as though he were equal and like to God, and excelled men."*

[Margin: Saint Hilary's opinion on the dial of Ahaz.] As for the dial of Ahaz, Saint Hilary, in the preface to Psalm 119, seems to hold that it distinguished the hours by certain steps of a staircase. For he says: *"In the book of Isaiah, when Hezekiah prayed, the sign given him of his prolonged well-being lies in the steps. Now there were in his house ten steps, which the Sun, beyond the course of its time, climbed with its light advancing, and again, on the day of his death, descended with its light descending."* And on Psalm 135 he says: *"That too belonged to a great miracle, when, at the word of Jesus Nave, the Sun stood still over against Gabaon, and the Moon over against the valley of Haylon. I do not know what more wonderful than this could be done: when, at the word of a man, the Sun and the Moon were held back from the law of their course for the stay of one day."* In the same place he describes the immobility of the Earth, as we shall see below.

[Margin: The opinion of Saint Cyril of Alexandria on the same dial and miracle.] Saint Cyril of Alexandria also seems to have held the same view as Saint Hilary, when in book 3 on Isaiah, at chapter 38, he says: *"They say that Ahaz, the father of Hezekiah, had certain steps made in his house, as if by a kind of machine and art, which would number the hours, as it were, and would measure the course of the Sun by the passage of the shadow made on them. That Hezekiah was to*

return to life God made plain, by the going back of the Sun's shadow and by the day being prolonged to an unaccustomed measure of hours." And on chapter 39 of Isaiah he teaches that the miracle was worked in the Sun itself, so that this was one of the principal reasons for which Merodach, son of Ladan, King of Babylon, sent envoys to Hezekiah with gifts and letters: *"But it was not only this that struck the Babylonian with wonder — that Hezekiah, I say, had been sick and had returned to good health again — but that altogether great and truly immense sign. By an ineffable and divine nod the Sun was ordered to run back and go backward, so that the shadow too went back 10 steps. The Babylonians and the Chaldeans, called by name the Sophi, that is, the wise, since they boast of being subtly learned in knowing the course of the Sun and the rising and setting of the stars, were not, it seems, ignorant of this reversion and of the unaccustomed length of that day,"* etc.

[Margin: Saint Gregory Nazianzen's view.] Let Saint Gregory Nazianzen be added to these. In oration 18, which is in praise of Saint Cyprian the Martyr, he lists these among the ancient miracles: *"The sea is divided, bread is poured down like rain, the Sun's course is checked,"* etc.; and in oration 20: *"Who divided the sea, held back the course of the Sun, checked the river,"* etc. Indeed, earlier, in oration 3, he had said: *"The Sun standing, and the Moon held back, and the course of the Jordan cut off,"* etc. In these places he points to the miracle of Joshua. But in oration 19 he touches on the other miracle, saying of Hezekiah: *"Whom God presented with an increase of life, and showed it by the shadow of the steps driven back, honouring the king, that is, at once with a favour and with a sign, and confirming it by the increase of the day."* [Margin: The opinion of Elias Cretensis on the dial of Ahaz, etc.] Elias Cretensis expounds this passage as follows: *"In the commentaries of the ancients we find that that day was of thirty-two hours. For there were twelve steps of the house, by which Ahaz, his father, reckoning the hours and giving his attention to this art, perceived the course of the Sun exactly; and at that time the Sun had run its course and reached the tenth hour, and in the same way the shadow had gone down ten steps. The Sun went back again ten steps, and so there came to be twenty hours; after which, when the Sun had again traversed its course in its own order, it went off to its setting. Thus the length of that day came to thirty-two hours, and this miracle spread through the whole world; for all saw the Sun go back."*

Theodoret agrees with these on Psalm 20, which begins (*"Lord, in your strength the King shall rejoice"*), and which he thinks was composed by David, in a prophetic spirit, about Hezekiah. So, explaining the verse (*"He asked life of you, and you gave it to him"*) and the following one (*"his glory is great in your salvation; glory and great splendour,"* etc.), [Margin: Theodoret's testimony on the miracle of Hezekiah.] he adds: *"You not only granted him life, but made him illustrious and famous, both by the wonderful destruction of his enemies and also because the Sun ran in reversed order; and this became so well known by land and sea that the king of the Babylonians sent gifts to those who had formerly lavished gifts on the Assyrians."*

Saint Augustine also mentions both miracles, in book 21 of the *City of God*, chapter 8, where he first relates the following about the star of Venus, from

M. Varro: [Margin: Venus changes its course.] *"In the heavens there occurred a wonderful portent. For in the most noble star of Venus, which Plautus calls Vesperugo and Homer Hesperos, calling it most beautiful, Castor writes that so great a portent occurred that it changed its colour, size, shape and course — which neither before nor since has happened so. Adrastus of Cyzicus and Dion of Naples, noble Mathematicians, said that this happened in the reign of King Ogyges."* And, a few words later: *"It certainly disturbed then the Canons of the Astrologers, if there were any by then,"* etc. But, to our point: [Margin: Saint Augustine's view.] *"We, however, read in the divine books that the Sun itself also stood still, when the holy man Jesus Nave had asked this of the Lord God, until victory should end the battle he had begun; and that it went back, so that the fifteen years added to King Hezekiah's life might be signified by this prodigy too, joined to God's promise."* Let us now hear Saint Jerome on chapter 7 of Isaiah, where, explaining the words (*"Ask for himself [?] a sign from the Lord God of yours, whether in the depth of hell or in the height above"*), and teaching by many examples that some signs were given on earth and others in heaven, he adds: *"I think that Hezekiah too, when the Sun went back ten lines, received a sign from heaven, and so did Jesus son of Nave at Gabaon and Haialon, when the Sun and the Moon stood still."* [Margin: Saint Jerome's opinion on the dial of Ahaz.] And on chapter 38 of Isaiah he indicates two opinions on the form of the dial, in these words: *"The sign is given that the Sun should go back ten steps, which we, following Symmachus, have translated as lines and dial; he understood the steps as lines, so as to make the sense plainer to readers. Or else the steps had been built by mechanical art in such a way that the shadow, descending through each of them, marked off the spaces of the hours; and this sign was a figure both of the present time and of the future, how the Sun would return to its beginning,"* etc. And on chapter 39: *"And because among the Chaldeans, whose King was Nebuchadnezzar, there is observation of the heavenly bodies, and the courses of the stars are known by long use and practice — as is shown too at the Lord's nativity — they understood that the Sun had gone back, and the spaces of the day been doubled, in the service of him whom they held to be the only God. And when they inquired into the causes and the reason of this miracle, as the report flew through all nations, they learned that the course of the brightest sign too had been changed on account of the illness of the king of Judah."* Saint Gregory, most briefly, on 1 Kings, chapter 2: *"Joshua fixed the Sun by his prayers."*

XI. That verse of Psalm 18, *"In the Sun he has set his tabernacle,"* etc., is taken by Saint Augustine, Saint Bernard, Cassiodorus and others in a mystical sense, of CHRIST and the Church, or of CHRIST in the womb of the Virgin MARY, etc.; its literal sense, nevertheless, concerns the Sun, the most illustrious of all the Planets, and its very swift motion. The words *"His going forth is from the highest heaven, and his circuit even to its highest"* are interpreted by many, as our Lorinus says on this passage, of the diurnal motion of the Sun from Rising to Setting: [Margin: The opinion of Caesarius.] especially by Caesarius, dialogue 1, Saint Chrysostom, homily 6 on Genesis, and Theodoret on Psalm 18; and by Saint Thomas, of the point of midday and of midnight, or of the same point of

midday, from which the Sun would begin the day astronomically and, meeting itself again at the same point, would end it. [Margin: The opinion of Arias and Caietanus.] Arias Montanus, on the other hand, understands it of the annual motion from one Equinoctial or Solstitial point to the other; and Caietanus of both motions, so that the diurnal is indicated by the going forth from the highest heaven, and the annual by the circuit, or return. We need not linger here over that passage of Esdras, book 3, chapter 34, *"The swift course of the Sun turns the heaven round in a circle to its place in one day"*, for the book is apocryphal. [Margin: What does Saint Nazianzen say of the Sun?] Let us rather hear Saint Gregory Nazianzen in oration 20, in which he compares Saint Basil to the Sun, saying: *"In David, Psalm 18, the Sun is praised for its beauty and size, its course and speed, its force and power: for it resembles a bridegroom in splendour and a giant in size, and, advancing far and wide, it has such force that it lights the furthest regions equally from the furthest, nor is its heat diminished in any way by distances of place. For Basil, beauty was virtue; size, Theology; course, the perpetual activity of virtue, reaching toward God by daily ascents; power, the sowing and distribution of doctrine. So I shall not shrink from saying even this: that his sound went out into all the earth, and the force of his words to the ends of the world."* He thus understands David to the letter, just as Saint John Chrysostom does in homily 6 on chapter 1 of Genesis. [Margin: Saint Chrysostom.] For Chrysostom says: *"Declaring its beauty, blessed David himself also said, 'as a bridegroom coming forth,' etc. Do you see how he declared its beauty and its speed in working? For by saying 'its going forth is from the highest heaven, and its circuit even to the highest of heaven', he signified to us how in one moment of time it runs through the whole world and sends its rays from end to end,"* etc. [Margin: Theodoret.] Let Theodoret follow him, on Psalm 18, who reads thus with three interpreters: *"He set the tabernacle of the Sun in them"*; and he adds: *"namely, in the heavens"*; and a little later: *"He set a tabernacle for the Sun in the heavens, so that it should be carried by them; in beauty it was to imitate a bridegroom coming forth from his chamber with much splendour, and in speed a kind of giant running with great strength, with nothing to hinder it from advancing further. For so it rises from the East and, running across in the space of one day, reaches the West."* And since David had said first, *"The heavens tell the glory of God"*, the Holy Fathers teach from this that the beauty and speed of the Sun, and its most ordered course, constant since the beginning of the world, are a most splendid argument of divine power and providence. [Margin: Saints Athanasius, Cyril of Jerusalem, Basil, Ambrose, Nazianzen, Nyssen.] So, above all, Saint Athanasius, in the oration *Against the Idols*, page 9; Saint Cyril of Jerusalem, Catechesis 9; Saint Basil, homily 6 on the *Hexaemeron*; Saint Ambrose, book 4 of the *Hexaemeron*, chapter 6; and Saint Gregory Nazianzen, oration 34, last page — who, weaving together outstanding encomia of the Sun, extol above all its course and motion. Saint Gregory of Nyssa, in oration 10 on the Canticle, proclaims the motion of the Sun about the Earth thus: *"For who does not know the motion of the Sun — that from the East, through the southern region of the heaven, it inclines by its appointed course toward the Setting? And since*

the figure of the Earth is globular, as those skilled in these things say, from whichever part it has been lit by the Sun, darkness must be produced on the other, opposite part," etc.

XII. Finally there remains that most celebrated testimony for the motion of the Sun, Ecclesiastes 1: *"The Sun rises and sets,"* etc., *"and returns to its place, and, reborn there,"* etc. [Margin: Saint Jerome on the motion of the Sun.] Saint Jerome, on chapter 1 of Ecclesiastes, interprets this passage of both motions of the Sun, first the diurnal and afterwards the annual — granted that he begins thus, in a florid and almost poetic style: *"The Sun itself, which was given to mortals for light, shows daily, by its rising and its setting, the passing away of the world. After it has dipped its burning wheel in the Ocean, it returns by ways unknown to us to the place from which it had set out, and, the course of the night completed, it bursts forth again in haste from its chamber."* Read the rest in his work. With Saint Jerome, moreover, the whole of this passage is understood of both courses of the Sun, the diurnal and the annual, by Saints Bonaventure and Thaumaturgus; by Theophilus of Alexandria in the 3rd Paschal Letter; and likewise by Olympiodorus, Hugo Victorinus [Hugh of Saint Victor], Hugo Cardinalis [Hugh of Saint-Cher], Lyranus, Albinus, Carthusianus, Caietanus and Io. Arboreus. But it is understood either solely or chiefly of the diurnal course by Saint John Chrysostom, homily 12 to the people of Antioch; by Saint Thomas on chapter 37 of Job; and by Lorinus on chapter 1 of Ecclesiastes. Yet certainly, on the one and the same day on which it circles through the South, it is not bent toward the North. Nor, even if it were moved by the force of two orbs, namely the Eccentric and the Epicycle, would it for that reason return into its many circles; and much less on the same day from the aux to the opposite of the aux, as Lorinus seems to want. For the revolution of these orbs is not completed in full except by the annual motion; and it is properly of that motion that both the bending now to the South, now to the North, and the plurality of circuits into which it returns, are verified. It is better, therefore, with Saint Jerome and the many others above, that those earlier words, up to *"and reborn there"*, are understood of the one diurnal circuit, and the rest of the remaining diurnal circuits that make up the annual course.

Moreover, to signify the acceleration of the Sun's motion, and, as it were, its longing to return to begin the new day, the words *"returns to its place"* are rendered by Aquila [Greek: προσέπνευσε (prosepneuse, "breathed toward")], or [Greek: ειασπνεῖ (eiaspnei, glossed on the page with the following Latin)] — that is, *aspirat*, "breathes toward" — and by the Chaldean, *"pants toward its place"*. The following words, *"and, reborn there, it circles through the South and bends to the North"*, the Chaldean paraphrast translates thus: *"It walks through the way of the abyss along the whole side of the South, and returns to the side of the North."* Finally, the words *"Surveying all things round about, the spirit goes on"* are separated by punctuation by Hugo Victorinus, who begins a new period from *"The spirit goes on,"* etc., understanding by the name of spirit the air and wind, which is carried round in a circle by the rapt motion [motus raptus].

This view did not displease Thaumaturgus either, in his paraphrase, nor Saint Bonaventure and Caietanus in their commentaries. [Margin: Whether, and why, the Sun is called Spirit.] Saint Nyssenus, however, interprets it of man, who is named spirit from his better part. But Saint Jerome understands the Sun, because it animates, breathes, etc., and he uses the testimony of Virgil, who sang in book 1 of the *Georgics*:

> *In the beginning the heaven and the earth and the liquid plains, The shining globe of the Moon and the Titanian stars, A spirit within nourishes,*
> etc.

But there Virgil signifies, from a false opinion, that the world is animated, not merely the Sun. Nor did Saint Jerome think the Sun animated, at least not by an intellective soul, since in the letter to Avitus, 59, and on Deuteronomy, chapter 32, and on chapter 45 of Isaiah, he counts it among the errors of Origen that he attributed a rational soul to the heavens. For my part, as I have already said in section 2, chapter 1, number 4, I am very well pleased with the opinion of Saint Thomas in opusculum 10, at article 6, who understands by the name of spirit an Angel, who is said figuratively to go on in a circuit because he makes the Sun go on while he moves it — in the way in which, in 1. Romans 8 [?], it is said, *"The Spirit intercedes for us"*, that is, causes intercession. And this opinion, in the end, seems to be subscribed to by

Lorinus, on chapter 1 of Ecclesiastes, toward the end of verse 6. [Margin: The unanimous consensus of the Fathers on the motion of the Sun.] Besides so many Fathers and interpreters who taught that the Sun moves locally, as we have so far shown abundantly, there concur also Origen, homily 3 on Matthew; Isidore of Pelusium, letter 100; Isidore of Seville, book 3 of the *Origins*, chapter 49; Saint Chrysostom on Psalm 134; Saint Justin, question 59; Glycas, part 2 of the *Annals*, page 271; Claudius Mamertus, book 2 of *De statu animae*, chapter 13; and, in the end, who does not? With good reason, therefore, we conclude that there is a unanimous consensus of the Fathers that the heaven moves round in a circle with local motion, and that Sacred Scripture was so understood by them.

Sententia Patrum de Stabilitate Loco ac Libramento Terrae ex Sacra Scriptura.

The Opinion of the Fathers on the Stability, Place and Poise of the Earth, from Sacred Scripture.

[Margin: Saint Basil on the place and immobility of the Earth.] XIII. In the first place there presents itself Saint Basil, homily 1 of the *Hexaemeron*, where he approves Aristotle's opinion and says: *"Setting these things aside, then, I advise that we do not even ask on what subject the earth is founded and rests; for in this way the mind will be thrown into a kind of dizziness, while its reasoning finds no certain way out"*; and again: *"This answer is indeed the safest for us for acquiring an understanding of Scripture, and useful to the hearers."* Then: *"But our discourse has already shown that the middle of the universe is the lowest place. Do not wonder, then, if the earth falls away in no part of itself, since it occupies the very middle place of the*

universe, the place most suited to it by nature." [Margin: Saint Ambrose.] Saint Ambrose imitates him, as is his custom, in book 1 of the *Hexaemeron*, chapter 6: *"Let it suffice for knowledge, what the series of the divine Scriptures contains: that he hangs the earth upon nothing. What is it to us to discuss whether it hangs in the air or upon water, so that a controversy should arise from it as to how the thin and softer nature of air could sustain the earthly mass?"* Afterwards he concludes that it has its stability not from being suspended in the middle as if in an equal balance, *"but because the majesty of God binds it by law through his will, so that it remains stable above an unstable and empty nature."* And again: *"The earth, moreover, is the foundation on which we stand; although both the discourse from outside celebrates it as being in the very centre of the heaven, and Scripture seems to signify this, when Job says: He hangs the earth upon nothing."* [Margin: Job, chapter 26.] [Margin: Saint Chrysostom.] Saint Chrysostom concurs, homily 2 on Psalm 103, at the words (*"you who founded the earth upon your stability; it shall not be inclined,"* etc.): *"But what,"* he says, *"is this stability? The effecting power, of course; for in his hand are all the ends of the earth."* And in homily 12 to the people of Antioch: *"The earth is fixed, but the waters are always moving."* [Margin: Saint Nazianzen.] [Margin: Saint Hilary.] Saint Nazianzen, oration 34, and Saint Hilary on Psalm 135 have recourse to the same power of God, Hilary explaining the words (*"who made firm the earth above the waters"*): *"Let it suffice to have learned from the authority of the Prophet that the earth stands above the waters with a hanging firmness."* [Margin: Saint Justin.] So too Saint Justin Martyr, question 130, where it is concluded most elegantly: *"The waters, then, sustain the heaven; the Earth sustains the waters; and the divine nod sustains the Earth — the nod which,"* he says, *"hangs the Earth upon nothing."* [Margin: Saint Damascene.] And so too Saint John Damascene, book 2 of *On the Orthodox Faith*, chapter 10: *"The earth is one of the four elements, endowed with dryness, coldness and heaviness, and without motion,"* etc. *"But on what thing it sits, or on what foundation it rests, no mortal has been able to say."* [Margin: Saint Nazianzen again.] There is also extant, in the *Catena of the Fathers* on Job, a saying of Saint Gregory Nazianzen about the Earth: *"By what reason, then, does it remain stable and firm? What is it that sustains it, and what makes firm that very thing which sustains it? Reason indeed finds nothing on which it may rest, except the will of God, which hung it and made it firm; nor is there anything else by which the earth is propped up or held together."* [Margin: Saint Jerome.] Saint Jerome was plainly of the same mind on chapter 26 of Job, expounding the saying (*"who hangs the earth upon nothing"*): *"This is to be understood thus: either that the earth was made from nothing, or that there is nothing beneath the earth by which the earth is sustained, since it itself sustains all things, and is itself balanced immovably by the power of God; for in him are all things, and by him all things are held together; of whom the Apostle says: upholding all things by the word of his power."* On Psalm 12, moreover, he affirms that the Earth is the lowest of all things, *"because the Earth is the end of creatures"*; and on chapter 13 of Jeremiah: *"Just as the heaven cannot be higher than it is, so the earth cannot be lower than it is."* [Margin: Saint Prosper.] Add to these Saint Prosper on Psalm 103, who in this tossing takes refuge in the

divine power as in a sacred anchor: *"Of this Earth it is laboriously asserted that it is not to be inclined for ever and ever, although it has been said: heaven and earth shall pass away. For that it was founded upon its firmness we can understand thus: that the force by which it is sustained and held together is called its firmness; and although this is hidden from us, it is nevertheless rightly believed to lie in the wisdom and power of the Creator, who made all things firm in himself, in whom he also founded all things."* [Margin: Saint Athanasius.] Saint Athanasius, however, seems to have held that the immediate cause is heaviness, in the oration *Against the Idols*, when he says: *"that the Earth, remaining immovable, bears fruit, and, being by nature the heaviest of all things, does not sink, but stands stable and immovable."* [Margin: Procopius.] So too Procopius, on chapter 1 of Genesis and on chapter 13 of Isaiah, explaining the words (*"Upon this I will trouble the heaven, and I will move the earth from its place"*), adds: *"For, suspended in an equal balance, since it stands at an equal distance on every side, it must be unmoved."* Theodoret hints at the same intrinsic force on Psalm 103: *"When he had built it upon itself, he granted it never to be moved"*; and Clement of Alexandria, in the oration of exhortation to the Gentiles: *"This has adorned the Universe also for you, in measure and harmony, and has brought the discord of the elements into order, so that the whole world might become a harmony for it; and it made the Earth stable and solid."* As for the other interpreters, they may be seen on chapters 26 and 38 of Job, on Psalm 103, and on chapter 1 of Ecclesiastes.

[Margin: Twofold cause of the stability of the Earth.] XIV. From what has been said so far we gather two causes of the Earth's stability. [Margin: 1. Extrinsic.] One is, as it were, extrinsic, which most of the Fathers acknowledge: namely the divine will and omnipotence. Of these, the will decreed from eternity that the Earth should be placed and should stand in this virtual part of the divine immensity itself rather than another — or, as others put it, in this region of imaginary space rather than another; the omnipotence, carrying out the divine decree, created the Earth from the beginning of the world and now preserves it in the same place, so that there is no created power that could move it from its place. For most of the Scholastics, with Saint Thomas in opusculum 10, article 16, and on book 2 of *De caelo*, lecture 2, teach that not even the Angels can do this — not so much because they could not overcome the whole weight of the earth, as lest the order of the universe established by God be disturbed. And Saint Thomas adds: *"But if it is asked about circular motion, by which the said order is not varied, it seems that the earth rests naturally."* [Margin: 2. Intrinsic cause.] The other cause is some intrinsic virtue conferred on the Earth by God, by which it can hold itself in the place once assigned to it: whether that is magnetism, as our Fathers Cabeo, Athanasius Kircher and Nicolaus Zucchius hold; or the weight and heaviness of all its parts toward that centre which God willed to be at once the centre of the Earth and of the Universe, from which it comes about that the Earth recedes equally from the extremes. [Margin: Ancient profane authors for the stability of the Earth.] And this cause, besides Saint Athanasius, Procopius and Theodoret, is acknowledged by most of the

philosophers, with Aristotle, book 2 of *De caelo*, from text 77, and by many other profane writers: namely Cicero in the *Dream of Scipio*, and Macrobius on it, book 1, chapter 22; Vitruvius, book 9, chapter 4; Pliny the Elder, book 2, chapter 5; Cleomedes, book 1 of the *Cyclical Theory*, chapter 9; Martianus Capella, page 192; Manilius, book 1 of the *Astronomicon*, chapter 2; and Ovid, book 1 of the *Metamorphoses*, in this verse:

Nor did the earth hang in the encircling air, poised by its own weights.

To him belongs this also:

The earth stands by its own force; from standing by force it is called Vesta.

On account of this very force, too, the Pythagoreans and Platonists attributed the Cube to the Earth as the symbol of stability, on the testimony of Plutarch, book 2 of *De placitis*, chapter 6; and the Roman priests used to sacrifice seated to Ops at rest — who is the Earth, so named because she brings help [opem] to all — according to the same Plutarch in the *Roman Questions*. And finally Cleanthes brought a charge before the Areopagites against Aristarchus of Samos, who carried the Earth round through the annual orb, on the ground that he had moved the sacred things of Vesta from their place, as the same Plutarch relates in the little work *On the Face of the Moon*. It should seem the less surprising, then, if we too bring a charge before the Sacred Tribunal against the Aristarchuses of our own age, returning to life from the underworld, that they have striven to move from its place, as it were, not only the Earth but Sacred Scripture itself. For the literal sense is, so to speak, a kind of place and foundation, in which its other senses rest; and in the following chapter we shall teach that, so long as nothing stands in the way, it is to be retained immovably.

CAPVT XXXVIII. Responsiones Copernicanorum ad Auctoritates Sacras circa Solis Motum ac Terrae Quietem afferuntur ac refutantur, tanquam non solum parum solidae, sed etiam periculosae.

Chapter 38. The replies of the Copernicans to the sacred authorities concerning the motion of the Sun and the rest of the Earth are brought forward and refuted, as being not only of little solidity but also dangerous.

I. The form and beauty of the Copernican hypothesis so bewitched the innovators and its followers, by some allurement or other, that they did not hesitate both to twist the words of Sacred Scripture to an alien sense and to despise the judgement of the holy Fathers and of churchmen. Copernicus himself, of course, raised their spirits and led the way by his example, in the preface of his work to Paul III, as we shall soon see. [Margin: Authors of the replies to the sacred authorities.] In devising replies to the sacred authorities he was followed by Johannes Kepler, in the Introduction to the *Commentaries on Mars*, in the notes to chapter 1 of his *Mysterium Cosmographicum*, and in the *Epitome of Copernican Astronomy*, book 1, from page 138; by Christoph Rothmann, in Tycho's letters, page 130; and by Paulus Antonius Foscarinus, in

the letter to Sebastianus Fantonus, General of the Carmelite Order, published in Italian at Naples in the year 1615, and afterwards rendered into Latin by David Lotaeus and published at Lyon in the year 1641 together with Galileo's dialogues, at the expense of Io. Antonius Huguetan [Jean-Antoine Huguetan] — in which letter the Author professes a conciliation of the authorities of Sacred Scripture and of theological propositions with Copernicus's opinion on the mobility of the Earth and the stability of the Sun. From these, some things were taken for the same conventicle by Redemptus Baranzanus [Redento Baranzano], part 1 of the *Uranoscopia*, doubt 10, member 3; by Petrus Herigonius [Pierre Hérigone], volume 5 of the *Cursus Mathematicus*, in the *Theorics of the Planets*, at the end of book 2, or from page 626; and by Jacob van Lansbergen, physician, in the *Apologia* for the commentaries of Philips van Lansbergen on the diurnal and annual motion of the Earth, against Libertus Fromondus, theologian of Louvain, and Io. Baptista Morinus [Jean-Baptiste Morin], mathematician of Paris, published at Middelburg in the year 1633. [Margin: The 5 chief heads of the replies.] Their replies, moreover, are reduced to 5 heads. The *first* is the lack of skill in astronomy, or in the whole of mathematics, in some ecclesiastical persons, so that they call the judgement and censure of those persons on these matters into contempt or suspicion. The *second* is that a knowledge of physical and astronomical matters was neither handed down by the Holy Spirit in the divine writings, nor is to be cared for by churchmen. The *third* (which is next to the second) is that if any things are found said in passing in the Scriptures about the motion of the Sun or the stability of the Earth, they do not belong to the dogmas of the Faith, especially if they are said by someone who does not bear the person of God. The *fourth* is that the passages customarily gathered from Sacred Scripture against the motion of the Earth and the stability of the Sun ought to be taken not in the proper literal sense, nor in the rigour of truth, but in a popular sense, or as to appearance, or figuratively. The *fifth* is the confirmation of the fourth from many other passages of Scripture in which physical or astronomical matters are touched on, which, it is agreed, are nevertheless to be taken not according to the rigour of the letter but with a more benign interpretation. Let us begin with the first head, setting up questions for each one, to be resolved in this chapter and the following.

Quaestio 1. An Physicae & Astronomiae peritia necessaria sit Personis Ecclesiasticis, ad ferendam validam & obligatoriam censuram de rebus physicis & astronomicis; ex regulis Fidei ac sacrorum Canonum.

Question 1. Whether skill in physics and astronomy is necessary for ecclesiastical persons in order to pass a valid and binding censure on physical and astronomical matters, by the rules of the Faith and of the sacred Canons.

[Margin: Authors for the affirmative side.] II. There is no doubt that Copernicus would answer us in the affirmative. For since he recognised to how great a danger he was exposing the novelty of his hypothesis, he said in the preface to Paul III, Supreme Pontiff: *"Although I know that the thoughts of a philosopher are*

far removed from the judgement of the common crowd, because his pursuit is to search out the truth in all things, so far as that is permitted to human reason by God, yet I consider that opinions wholly foreign to rightness are to be shunned. And so, when I thought to myself how absurd an ἀκρόαμα [Greek: akroama, "a thing heard", a doctrine] *those would think it who know that this opinion — that the earth is placed immovable in the middle of the heaven, as its centre — has been confirmed by the judgements of many centuries, if I on the contrary were to assert that the earth moves, I hesitated long with myself whether I should bring to light my commentaries written for the demonstration of its motion,"* etc. Though he acknowledged these things, he nevertheless adds that he had dedicated his work *On the Revolutions* to that Supreme Pontiff for this reason: as to one most highly cultivated in these arts, and so that he should not seem to fear the judgement of anyone fit to judge of these matters. [Margin: Why Copernicus dedicated his work to Paul III.] His words are: *"But so that the learned and the unlearned alike might see that I shun the judgement of no one at all, I preferred to dedicate these night-labours of mine to Your Holiness rather than to anyone else; because even in this most remote corner of the earth in which I live, you are held most eminent both for the dignity of your rank and for your love of all letters, and of mathematics too, so that by your authority and judgement you can easily check the bites of slanderers, although it is a proverb that there is no remedy against the bite of a sycophant."* But what will you do, Copernicus, if some who are steeped in mathematics not at all, or only very slightly, have spoken against you because of the authority of Sacred Scripture, which resists your hypothesis? [Margin: The arrogant saying of Copernicus.] He answers without hesitation: *"If perhaps there will be* ματαιόλογοι [Greek: mataiologoi, "idle talkers"] *who, though ignorant of all mathematics, nevertheless take on themselves to judge of these matters, and on account of some passage of Scripture badly twisted to their purpose dare to censure and attack this undertaking of mine, I do not regard them at all, so much so that I even despise their judgement as rash."* Lest this arrogant saying should seem harsher than is just, he tries to soften it with an example, saying: *"For it is not unknown that Lactantius, otherwise a celebrated writer but little of a mathematician, speaks quite childishly about the shape of the earth when he mocks those who declared that the earth has the shape of a globe. So it ought not to seem surprising if such people laugh at us too. Mathematics is written for mathematicians."*

III. With this standard raised, as it were, and the cap of liberty once thrown up, nothing stood in the way of minds like his flocking to the same place. Accordingly Kepler, at the very beginning of chapter 1 of his *Mysterium Cosmographicum*, in an opening certainly praiseworthy, professes as follows: *"Although it is pious, right at the beginning of this disputation about Nature, to see whether anything is said contrary to the sacred writings, I nevertheless judge it untimely to raise that controversy here before I am challenged [prius atq. folliciter]. This I promise in general: that I will say nothing that is injurious to the Sacred Writings, and that if Copernicus is convicted of anything together with me, I will hold him for nothing. And this has always been my mind, ever since I began to know Copernicus's books of*

the Revolutions." [Margin: Kepler requires skill in astronomy in religious men who are to judge of this matter.] But in the notes on this chapter, expounding the little word *untimely*, he says: *"Copernicus meets this scruple in the preface to Paul the Third, Supreme Pontiff, but a little too rigidly; and for that address he paid the penalty in the end, more than 70 years having elapsed since the publication of the book and since his death. For he has been SUSPENDED, says the censure, UNTIL HE BE CORRECTED; but I think that this too is to be understood: UNTIL HE BE EXPLAINED. For how he is not contrary to Scripture — his purpose, of course, being very far different — I have tried to show by reasons and examples in the Introduction to the Commentaries on Mars. I have also explained the words of Copernicus himself more clearly at the end of book 1 of the Epitome of Astronomy; and I hope that in these places the religious will be satisfied, provided they bring to this judgement such a mind and such a knowledge of astronomy that the glory of the visible works of God can safely be entrusted to their patronage."* But how much he grieved over the censures passed on Copernicus he indicates not much later, saying of every most religious person: *"Let him consider with himself whether the causes of the conciliation sought between the tongue and the finger of God were just enough, weighty enough; and whether it is expedient, that conciliation being repudiated, to suppress by censures this fame of the divine works of immense beauty."* Afterwards he concludes that the censures are vain, and that their invalidity, once discovered, brings it about that they have no force even in matter in which they ought to have force; for that is what that allegorical clause of Kepler's means: *"The edge of the axe, however, once struck against iron, is afterwards of no use even against wood. Let whoever it concerns take this to heart."* In the Introduction to the *Commentaries on Mars*, however, he offers the unlearned this advice in a freer style: *"But whoever is too dull to be able to grasp the science of astronomy, or too weak to believe Copernicus without offence to his piety, I advise him to dismiss the school of astronomy, to condemn, if he pleases, any of the tenets of the philosophers whatever, to mind his own affairs and, giving up this wandering through the world, to go home to cultivate his own little field; and, raising to this visible heaven the eyes with which alone he sees, to pour himself out with his whole heart in thanksgiving and praise of God the Creator, certain that he renders God no less worship than the astronomer, to whom God has granted that he sees more keenly with the eye of the mind,"* etc. [Margin: Kepler taunts the Office of the Sacred Inquisition.] Not content with this, he shows a little later, when he adds the following, with how much obstinacy he prefers his own judgement to the judgement of the Fathers and of the Church: *"To the tenets of the Saints about these natural matters, however, I answer in one word: in theology the weight of authorities is to be weighed, but in philosophy the weight of reasons. Holy, then, is Lactantius, who denied that the Earth is round; holy is Augustine, who, granting its roundness, nevertheless denied the Antipodes; holy is the Office of the people of today, who, granting the smallness of the Earth, nevertheless deny its motion. But holier to me is the truth, I who demonstrate from philosophy — with due respect to the doctors — that the Earth is round, and inhabited round about by Antipodes, and of most contemptible smallness, and finally that it is carried*

through the stars." As if Lactantius were held in the Catholic Church to be a saint, or a Doctor of infallible authority — a man whom all we Catholics admit to have erred in many things! Or as if the smallness of the Earth necessarily drew its motion along with it — when Kepler himself, with Copernicus, moves through the annual orb not the Earth alone, but the elementary sphere together with the lunar heaven, a machine much larger than the Sun! And how is due respect to the Doctors of the Church kept, if, on the question of how the divine writings are to be understood, you obstinately set your own judgement before theirs? Or with what face do you dare to say that the motion of the Earth has been demonstrated by you, when you have brought forward only probable arguments, or arguments that are indeed necessary, but only on the hypothesis of the Earth's motion, showing that if it moved the celestial phenomena could conveniently be saved?

Not content with this either, Kepler, at the end of book 1 of the *Epitome of Astronomy*, page 140, does not hesitate to brand with the mark of superstition those who have not subscribed to Copernicus. For he says: *"In the present age all the most eminent of the philosophers and astronomers concur with Copernicus. This ice has been broken; we are winning by the votes of the better sort; for the rest, almost nothing stands in the way but superstition, or fear of the Cleantheses."* By Cleantheses he means either the accusers or the judges of the Sacred Inquisition; for on the same page he had said that Aristarchus of Samos was accused of sacrilege before the Areopagites by Cleanthes, because, in asserting that the Earth moves, he had moved the sacred things of Vesta. In the *Hyperaspistes*, page 195, the same author calls it a wicked servitude to serve ecclesiastical decrees — if, understand, they have been made badly; and he seems tacitly to censure the sacred censors as punishing themselves while they punish others, or as not daring to defend the marks set by the sacred censures. For what else does that quip mean: *"But let Perilus teach his own bull to bellow. And unless all conjecture deceives me, he dreads the brow of Silenus, which Aegle herself, foolish, painted with vermilion"*? Finally, in the preface to book 4 of the same *Epitome*, he recites this fragment from his letter of apology: *"How severely were all the astronomers rebuked by the first Christians! Did not Eusebius write of one that he preferred to desert Christianity (because excommunicated, I suppose) rather than his profession? Did not those who taught that there are Antipodes seem to Tertullian and Augustine to be too wise? And Virgil, Bishop of Salzburg, was indeed removed from office because he had dared to assert it."* Here, however, he either lies or is mistaken in his history; for Virgil was neither removed from office nor accused for the bare assertion of the Antipodes, as we shall see below. [Margin: The danger of erring in censures through lack of skill in astronomy.] Lastly, to strengthen the opinion of these men, one could adduce the danger of passing censures, through lack of skill, against some truth demonstrable by natural reason — in the way that the Athenian judges of old, through ignorance of the causes from which eclipses of the Moon arise, would not tolerate Anaxagoras, nor those who taught that the Moon is deprived of its light by the shadow of the earth, as we related from

Plutarch's *Nicias* in book 5, chapter 1, number 1. Accordingly, how anxious Saint Augustine was lest his brethren, through lack of skill, should seek from the divine writings a defence for manifest errors in philosophy is already clear from what was said in chapter 36, number 2; and it is a wonder that his words should have been unknown to the Copernicans, since at first sight they support them wonderfully.

[Margin: The negative answer, and the reasons for it.] IV. Notwithstanding these things, however, to the question proposed at the beginning of number 3 I answer in the negative. *First*: when some physical or mathematical question has devolved, directly or indirectly, into a question about the Catholic Faith — as has this one, in which it is debated whether the motion of the Earth and the stability of the Sun are against Sacred Scripture — then, for those who preside over the Holy Office of the Inquisition to be able to pass a sufficient judgement, that is, one not only licit and prudent but also valid and binding, it suffices that they should have come to know, either by themselves or through other learned men, that a proposition on the one hand is not evidently true by physical or mathematical evidence, and on the other hand is against the plain and literal sense of Sacred Scripture in that part in which it is Sacred Scripture, or against some proposition of a canonical writer. [Margin: 1. Reason for the Sacred Inquisitors.] For this by itself is enough for them reasonably to be able to pass censure against the said proposition, because of that universal necessity by which all we Catholics are bound: that so long as no evident and manifest inconvenience follows from Sacred Scripture understood to the letter, we should understand it to the letter, and not follow another sense repugnant to the literal one. How much more, then, does it suffice if some proposition not only is not evidently true, but is against physical evidence, and has been hissed off as absurd, commonly in the Academies and also by some professors of astronomy; and if, on the other hand, it is established that the holy Fathers, the interpreters of the divine writings and the Doctors of the Church taught the contrary from Sacred Scripture? And so indeed the matter stood, and stands, in our case. For the Sacred Congregation deputed by the Supreme Pontiff Paul V, and afterwards by Urban VIII, a man most knowledgeable in astronomical matters, included, besides many Cardinals themselves very skilled in philosophy, theology or canon law and imbued to no slight degree with knowledge of the sacred writings, many others also appointed for this inquiry; and a most diligent inquiry had already been made beforehand by the Qualifiers. It was already certain, too, that the Copernican hypothesis not only had been demonstrated by no one (since the Copernicans themselves admit that all the celestial appearances can be explained, saving the rigour of astronomical truth, by either hypothesis — that is, of the Earth either moved or at rest), but also was against the evidence of common sense, and against that plain, obvious and literal sense of Sacred Scripture which the unanimous consensus of the Fathers and of the sacred interpreters had followed for one thousand six hundred years. Nothing, therefore, could keep them from being able to pass censure against

the hypothesis of Copernicus. Nor was it required that the persons already mentioned should be professors and masters of astronomy, since it was already commonly known in the Schools that the Copernicans had not demonstrated that their hypothesis is so in fact, but only that it is possible, and that by it the celestial phenomena are explained quite neatly and readily; and on account of this neatness and usefulness in composing and using astronomical tables, that hypothesis was permitted as a mere hypothesis, that is, provided that no one asserts that it is so in fact.

[Margin: 2. Reason.] V. *Second*: just as Kepler, for judging of astronomical matters, requires no common skill in astronomy and appeals to the court of Urania, so in matters of Faith and Religion Catholics must require no common skill in the divine writings, and appeal to the ecclesiastical court. Now this controversy, although materially, as they say in the Schools, it is astronomical and physical, is nevertheless formally a controversy about a matter pertaining to Faith and Religion, as I shall teach below; and this is clear even from the fact that what is disputed now is not whether the hypothesis of Copernicus is possible, or fit for saving the celestial phenomena, but whether it is against Sacred Scripture according to the received unanimous interpretation of the Fathers. And this skill is had far more abundantly and clearly from the sacred books themselves and the holy Fathers, and from the rules of theology and of the sacred Canons, than from mathematicians and astronomers as such. [Margin: 3. Reason.] *Third*: even if the Sacred Inquisitors or any judge in a cause of the Faith holding authority from the Supreme Pontiff, were to pronounce some censure against some proposition in a doubtful matter — one so far demonstrated in neither direction, or demonstrated indeed but not held to be so — and yet were to do so on suspicion of novelty and of some danger in matters of the Faith, the presumption would have to be in their favour, and that censure would have to be observed at least in the external forum, at any rate if it could be observed without grave inconvenience and without a fear of the kind that befalls a steadfast man. It would nevertheless be permitted to work for the said judges, once they recognized the demonstration of the truth for themselves or through others, to remove the censure. I assume this doctrine here as most certain, partly from the common doctrine on laws and on presumptions, partly from the particular doctrine of canon law on ecclesiastical censures.

VI. [Margin: 4th reason.] *Fourth*: not only the Sacred Inquisitors, whom Kepler seems to brand with inexperience in astronomical matters, but many men highly expert in astronomy have judged the Copernican hypothesis both absurd in itself and contrary to the authority of the Divine Scriptures. [Margin: Tycho's judgement on the sense of Sacred Scripture in this matter.] Thus Tycho, in a letter to Rothmann of the year 1589 February 21, admonishes him as follows: "There is no reason for you to persuade yourself that the physical absurdities which accompany the Copernican hypothesis have been sufficiently refuted by him. Much less will the pleas you put forward in excusing those things to which Sacred Scripture asserts the contrary be able to earn a place.

For the authority and reverence of the Divine Scriptures both is and ought to be greater than that it should be fitting to draw them on in this way, like a buskin." [Margin: And of Clavius.] Our own Clavius too, certainly no ordinary astronomer, in chapter 1 of the *Sphere*, where he taught by reasons that the Earth is immobile, added on page 196: "This opinion is also favoured by the sacred Scriptures, which in very many places affirm that the Earth is immobile and testify that the Sun and the other stars move; for we read in Psalm 103, etc." [Margin: And of Nicolaus Mulerus.] Nicolaus Mulerus [Nicolaus Mulerius] conducted himself with equal reverence in the *Isagoge* to the *Frisian Tables*, page 318. There, having mentioned the opinion of the Pythagoreans on the Sun's place at the centre of the world and on the Earth's motion, he added: "But since this question does not belong to this place, we do not wish to examine it here, testifying only this: that the authority of Sacred Scripture is so great with us, and our mind is moved by so great a reverence for it, that we do not dare to go over to the opinion of the Pythagoreans against its plain sense."

[Margin: The prudence and piety of Pierre Gassendi.] We also have a remarkable example of prudence and moderation in Pierre Gassendi. In his second letter *De motu impresso a motore translato* he had set out many arguments for the motion of the Earth and had solved not a few of the arguments usually raised against it; yet he first kept himself within the limits of a mere hypothesis, and then, in a doubtful matter, subscribed to the decrees of the Sacred Congregation. For he concludes that letter, written in the year 1640 on the Ides of December to Petrus Puteanus [Pierre Dupuy], thus: "You do not require me to repeat that I did this not to assert motion for the Earth, but, out of love of the truth, to hint that its rest must be established by a firmer reason." And a little after: "Accordingly I am of a mind to revere that decree by which some cardinals are said to have approved the rest of the Earth. For although the Copernicans might defend the passages of sacred Scripture which attribute standing or rest to the Earth and motion to the Sun, or hold that they are to be explained of the appearance itself, as they put it, etc., nevertheless, because those passages are explained otherwise by men whose authority in the Church is, as is well known, so great, for that reason I myself stand with them, and on this occasion I do not blush to make my understanding captive. Not that I therefore think it to be an article of faith; for (so far as I know, at least) this has not been asserted by them, nor promulgated and received throughout the universal Church; but because their judgement must be held a prejudgement, which could not be of the greatest weight among the faithful [?]." [Margin: The author's vote.] Nor can our own testimony, such as it is, be rejected on the ground that we have by no means weighed or understood the arguments of the Copernicans, if what we have taught in this whole Section is read through. Therefore let no one count us among those whom Copernicus and Kepler despise as unfit to judge of these matters.

VII. [Margin: 5th reason.] *Fifth*: as regards the Antipodes denied by Lactantius, he is not to be counted among the holy Fathers, and he denied the

Antipodes for no other reason than that he thought the heaven to be semispherical, and the Earth not round but itself hemispherical too, as is clear to anyone who reads him in book 3 of the *Divine Institutes*, chapter 24. [Margin: Why Lactantius denied the Antipodes.] Nor must it be denied that some other Fathers thought the heaven to be like a vault, and hemispherical. [Margin: Fathers for whom the heaven was hemispherical.] Among these, Ascanius Martinengus, in the *Glossa magna* on chapter 1 of Genesis, numbers Saint Chrysostom, *On the Incomprehensible Nature of God*, chapter 2; Procopius, Acacius and Severianus on book 1 of Genesis; Theophylact on the Epistle to the Hebrews; Theodoret, *On Matter and the World*; and Euthymius on Psalm 103. But this is no obstacle to us at all, because the Fathers who acknowledged the roundness of the heaven and of the Earth are far more numerous; and so there was no unanimous consensus of the Fathers about this figure, whereas about the stability of the Earth there was.

[Margin: Why Saint Augustine denied the Antipodes.] As for Saint Augustine, he did indeed deny the Antipodes in book 16 of the *City of God*, chapter 9, although he granted the roundness of the Earth. Because in the preceding chapters he had taught that all the human beings who inhabit the Earth are descended from Adam, he thought that the lower hemisphere of the Earth, which lies opposite the Holy Land, was either covered with water, or that men could not have migrated to those lands across so vast an expanse of seas as he supposed to lie between, since no history existed of such a migration. In this he followed not so much Lactantius, as Ludovicus Vives [Juan Luis Vives] says in that place, as Cicero in book 6 of the *Republic*, who held that an immense Ocean is poured between us and those antipodal lands — lest he should admit that there are some men not descended from Adam, and therefore neither redeemed by Christ nor belonging to the City of God. I do not transcribe all the holy Doctor's words, since they are readily available. But neither does this support our adversaries, because this was not the unanimous opinion of the Fathers, nor was it deduced from any positive passage of Scripture taken literally. What moved Saint Augustine was only a negative authority: Scripture, while it describes the propagation of the sons of Noah over the earth by families and heads, makes no mention of a land of the Antipodes to which they migrated. For he says: "Therefore, among those peoples of men of that time, who are gathered to have been divided into seventy nations and as many languages, let us seek, if we can, to find that City of God on pilgrimage on earth, etc." So, as Vives says, Saint Augustine had no slight reason for denying the Antipodes.

VIII. [Margin: Whether, and why, Bishop Virgil was deposed for asserting the Antipodes.] Finally, as regards Virgil, Bishop of Salzburg: as Baronius relates in volume 9, at the year of Christ 744, he was a very religious man from Ireland who, out of zeal for spreading the Faith, came with Sidonius into Baioaria, or Bavaria, and was known to Boniface, who presided over that Church as its prelate. A certain minister of his had baptized someone in debased Latin with this formula: *Baptizo te in nomine Patria et Filia et Spiritua Sancta*.

When Boniface, Bishop of Mainz, judged that the person should be baptized again, Virgil and Sidonius, out of modesty, thought that he should not be reproved before others, but that recourse should be had by letter to the Roman Pontiff Zachary; and Zachary wrote back to Boniface that the man was not to be rebaptized, and Boniface acquiesced in the judgement of the Supreme Pontiff, as Baronius reports in the same place. But at the year 748 Baronius relates a threefold calumny brought against Virgil before Boniface: namely, that he was sowing hatred between Boniface and Odilo, Duke of Bavaria; that he boasted that he had obtained the vacant bishopric from the Apostolic See; and finally that he asserted "that a new world is found, which is lit by another Sun and another Moon." Baronius shows that these were calumnies: when Boniface had written to the Pontiff about them, and the Pontiff had given him power to convene a provincial council and, if Virgil were proved guilty, to expel him from the Church and deprive him of the priesthood, not only was Virgil not deprived, but he was even raised to the episcopate, persevered in apostolic work with Boniface, spread the Gospel far and wide among the neighbouring peoples, and was afterwards enrolled among the saints by Gregory IX with solemn rite.

[Margin: Pope Zachary's rescript to Boniface concerning Virgil.] And lest anyone should think that Pope Zachary erred on a question of law — indeed, so that it may be clear that he did not err even on a question of fact, since he ordered Virgil to be punished not absolutely but only on a supposition — here is part of Zachary's letter to Boniface, which Baronius quotes in full at the year 748 [ab Annum] [recte: ad Annum]: "It has also been intimated by Your Holiness that that Virgil (we do not know whether he is called a priest), malignantly opposed to you because he was being charged by you with erring from the Catholic doctrine, was sowing hatred between you and Otilo, Duke of the Bavarians, saying that he had received licence from us that he should obtain the diocese of one of those four bishops, now deceased, whom your fraternity ordained there. This is by no means true, for iniquity has lied to itself. As for the perverse doctrine which he has spoken against the Lord and against his own soul — namely, that there is another world and other men beneath the earth, and another Sun and Moon — if he is convicted of so confessing, convene a council, expel him from the Church and deprive him of the honour of the priesthood, etc." Yet he was not expelled from the Church by Boniface; and so far was he from being deprived of the priesthood that he was rather made Bishop of Salzburg. He had therefore been accused of the said crimes by calumny; for because he was acceptable to God, it was necessary that temptation should prove him. Ignorantly, then, did Kepler above, and Jacob van Lansbergen in the *Apologia*, tract 3, assert that he was cast out of his bishopric; and far more imprudently do they say that this was done because he asserted the Antipodes. For, as Baronius adds in the margin to Zachary's letter: "To have doubted about the Antipodes is not heresy; but to have held that there are several worlds is repugnant to divine Scripture, and is therefore

shown to be heresy." On this story see also M. Velserus [Markus Welser], book 5 of the *Res Boicae*, Aventinus in the *Annales Boiorum*, and Mazzonus [Jacopo Mazzoni] in the *Defence of Dante*, book 3, chapter 33.

Quaestio 2. Vtrum Scriptura Doceat res Physicas aut Astronomicas.

Question 2. Whether Scripture teaches physical or astronomical matters.

IX. [Margin: What Sacred Scripture teaches.] It is not the purpose of sacred Scripture, the Copernicans say, nor of the Holy Spirit, to instruct men in physical or mathematical matters, but in those which pertain to morals and to eternal salvation. In their favour seems to be the Apostle's saying in Romans 15: "For whatever things were written were written for our instruction, that through patience and the comfort of the Scriptures we might have hope"; and 2 Timothy 2: "All scripture divinely inspired is profitable for teaching, for reproving, for instructing in history, that the man of God may be perfect, furnished for every good work." Finally there is the pronouncement of Christ the Lord himself on the love of God and of neighbour: "On these two commandments hangs the whole law and the Prophets"; and the saying of Isaiah 48: "I am the Lord God, teaching useful things," where the gloss adds: "not subtle ones." Accordingly Saint Augustine, in book 2 of *De Genesi ad litteram*, chapter 8, said: "It is also commonly asked what form and figure of the heaven is to be believed according to our Scriptures. For many dispute much about those things which our forebears, with greater prudence, passed over, since they would be of no profit to learners for the blessed life and — what is worse — take up much precious time that ought to be spent on wholesome things. For what does it matter to me whether the heaven, like a sphere, encloses the earth on every side, balanced in the middle of the mass of the world, or covers it from above on one side like a disc? But since the faith of the Scriptures is at stake, etc." And not much later: "Briefly, it must be said that our authors knew about the figure of the heaven what the truth holds, but that the Spirit of God, who spoke through them, did not wish to teach men these things, which would profit no one's salvation."

X. [Margin: Reply to Question 2.] To the question proposed, however, one must answer with a distinction. It must be granted that the per se and primary end of Sacred Scripture is not to instruct men in matters pertaining to mere physics or mathematics, or to natural or civil history and the other natural arts and faculties, stopping there. [Margin: For what end Sacred Scripture teaches natural things.] Yet it must be denied that it does not, from time to time, teach in passing some things pertaining to these sciences and natural faculties, so as to use them as means either to ground some doctrine on morals or on things conducive to eternal salvation, or to show the divine omnipotence, wisdom, providence, etc. "For the invisible things of him, from the creation of the world, are clearly seen, being understood by the things that are made; his eternal power also, and divinity," as the Apostle declares, Romans, chapter 1. Therefore, if it is established from the Sacred Scriptures who created heaven

and Earth with the remaining elements and mixed bodies, and in what order, and how great a wisdom and power shines forth in the founding, preservation and governance of these things, in their motions and other effects, and how far all creatures depend on his nod, the exposition of these things is referred to that end at which all divinely inspired Scripture aims. That is why the Apostle wisely added: "for instructing in history, that the man of God may be perfect, furnished for every good work." In these words he embraces not only civil history mixed with ecclesiastical, such as is found in the books of Judges, Kings, Paralipomenon, Tobit, Esther, etc., but also natural history, which is handed down at the beginning of sacred Genesis, in some chapters of Job and Ecclesiasticus, and also in some Psalms — toward the end I have mentioned. And so, to our purpose: when the speed and most constant course of the Sun, or the stability of the Earth hanging in the middle of the air, is asserted in the Scriptures, the Fathers and every pious reader of the divine codices [?] rise from this to the admiration and praise of God no less than when he learns from the same Sacred Letters that the Earth was uncovered from the waters and in places made higher than they, and prepared with so many plants and animals for the service of men; that the surges of the seething and raging sea are confined within fixed bounds of shore; that the rivers not only enter the sea in such a way that it does not overflow, but return to the place from which they come forth, to flow again; that the winds and snows are brought out of the treasuries of God; that the waters are bound up in the clouds; and many other things like these, which belong to natural history and physical science. And if these things are subtle, they are not so subtle that they are not also useful.

[Margin: Sacred Scripture does not teach falsehood.] *Second*: even if Sacred Scripture did not ordain the knowledge of such things to the end I have mentioned, far be it, nevertheless, that we should grant that in propositions of this kind it is deceived or deceives, or says what is false. And it would say what is false if, while the Sun stands still and the Earth goes round, it nevertheless said absolutely, as it does say, that the Sun moves and that the Earth is stable and in no way inclines. [Margin: Tycho's view on the truth of Sacred Scripture in physical matters.] Hence Tycho aptly added, in the letter already named above, page 147: "For although they — that is, the divine Letters — in physical matters and in certain others for the most part accommodate themselves to the capacity of the common people, far be it nevertheless that on that account we should hold that they speak in so vulgar a way that we do not believe they also set forth true things. Thus Moses, although in the first chapter of Genesis, treating of the creation of the world, he does not relate the inner secrets of astronomy, since he was writing for an unlearned people, nevertheless puts forward nothing that could not be granted by the astronomers themselves as well." How much knowledge of natural things sacred Scripture has handed down to us, and from how many errors and false opinions of the philosophers it has freed us, is clear from Saints Basil and Ambrose in their books *Hexaemeron*; from Junilius, Bede, Molina, Suárez and others who wrote on the work of the

six days; from Philo's *De opificio mundi*; and also from the books of Franciscus Valesius [Francisco Vallés] *De sacra philosophia*.

Quaestio 3. An Assertiones de Solis Motu & Stabilitate Terrae, quae habentur in Sacris Scripturis, ad Fidei & Religionis quaestiones pertineant.

Question 3. Whether the assertions about the motion of the Sun and the stability of the Earth that are found in the Sacred Scriptures pertain to questions of Faith and Religion.

XI. The Copernicans indeed deny it; but they ought to have used the distinction of Saint Thomas, *Prima Secundae*, question 1, article 6, and of the other theologians. Some things are of the Faith per se and directly, and of this kind are those commonly called Articles of Faith: for example, that God is one in nature and three in Persons; that CHRIST is God and man; the future resurrection of the dead, etc. [Margin: What things are of the Faith per se and directly, and what by accident and indirectly.] Others are of the Faith indirectly and by accident, insofar as they are ordained, as means or dispositions, to the things that are of the Faith per se. Of these Saint Thomas gives the example of Abraham, of whom we are bound to believe that he had two sons, one by the bondwoman and the other by the free woman. It is in this second way, then, that the propositions of Sacred Scripture on the Earth's standing still and the Sun's motion pertain to the Faith. [Margin: Reply to Question 3.] Moreover, those assertions pertain to a question of Faith not only insofar as they are ordained to the knowledge and praise of God, but also because, if they were not true, the truth of the whole of Sacred Scripture could be called into doubt and suspicion of falsehood; and so not even the remaining propositions, which per se concern the Faith and the morals necessary to eternal salvation, could be solidly proved and confirmed by the testimony of the divine Letters. Hence it is that Saint Augustine, in that very book 2 of *De Genesi ad litteram*, chapter 8 — in which he had raised the question "What form and figure of the heaven is to be believed according to our Scriptures", and had said that knowledge of this matter does not of itself pertain to salvation and the blessed life — nevertheless added: "But since the faith of the Scriptures is at stake, because of th- at reason which I have mentioned more than once — lest anyone who does not understand the divine utterances, when he has either found something of this kind about these matters in our books or heard it from them, which seems to oppose reasons he himself has grasped, should in no way believe them when they advise, narrate or pronounce other useful things — it must be said briefly about the figure of the heaven, etc." It therefore pertains to a question of Faith that we know in what way what Sacred Scripture says about these matters is true — whether in the plain and obvious, or literal, sense, or in some figurative sense — and that we defend its truth and authority. That authority is so great that it is even of faith that Tobias's dog, wagging its tail for joy at the return of the younger Tobias, ran ahead like a messenger,

because Sacred Scripture narrates this in Tobit 11; and yet the motion of that tail concerns the Faith far less than the motion of the Sun and the standing still of the Earth.

XII. [Margin: The decree of Trent on the true interpretation of Sacred Scripture.] From what has been said it is now clear how the decree of the holy Council of Trent, session 4, on the edition and use of the sacred books, is to be understood, where it is said: "Furthermore, in order to restrain petulant spirits, it decrees that no one, relying on his own prudence, in matters of faith and of morals pertaining to the edification of Christian doctrine, shall, wresting the sacred Scripture to his own senses, dare to interpret the sacred Scripture itself contrary to that sense which holy Mother Church has held and holds — whose it is to judge of the true sense and interpretation of the holy Scriptures — or even contrary to the unanimous consensus of the Fathers, even though such interpretations were never at any time to be published." For the holy Council must be judged to have included under these words everything that is referred to the Faith, both per se and directly and by accident and indirectly, according to the doctrine of Saint Augustine and Saint Thomas set out above. This is all the more so since a similar decree was confirmed, in a more universal formula and without restriction, by Pius IV in the Bull found at the end of the Council of Trent, where the formula of the profession of Faith is given, by which we are bound not to interpret Sacred Scripture except according to the unanimous consensus of the Fathers, as I have already said in chapter 36, number 1.

Saint Augustine is to be understood in the same way when, in book 2 of *De Genesi ad litteram*, chapter 10, he denies that churchmen ought to be occupied with these questions. For he is speaking of those on whom other ministries, more necessary to the salvation of souls, have been enjoined; not of the Doctors of the Church in the case where the authority of the divine Letters must be defended even down to one iota or one tittle, nor of those who have been appointed by their prelates to unravel these questions for the common benefit of the Church, so as to help others by the shortcut of their own labours. The holy Doctor's words, moreover, are these: "Some brethren also raise the question about the motion of the heaven, whether it stands still or moves. For if it moves, they say, how is it a firmament? But if it stands still, how do the stars, which are believed to be fixed in it, go round from the East to the West, the northern stars completing shorter circuits near the poles? etc. To them I answer that these things are investigated by very subtle and laborious reasonings, in order to perceive truly whether it is so or not so; and for taking up and treating these I have no time now, nor ought those to have it whom we desire to see instructed for their own salvation and for the necessary benefit of holy Church." Yet to defend the truth of sacred Scripture he adds that the name "firmament" does not necessarily signify immobility, since it can signify firmness and the impassable boundary of the upper and lower waters; and he adds: "Nor, if the truth should persuade us that the heaven stands still, are we prevented by the circuit of the stars from being able to understand this; for it has been found by those very

men who have investigated this most curiously and with the greatest leisure that, even with the heaven not moving, if the stars alone turned, everything that has been observed and comprehended in the revolutions of the stars could have come about."

As for Saint Thomas's saying in Opusculum 10, that "it seems safer that the things which the philosophers have commonly held, and which are not repugnant to our faith, should neither be asserted as dogmas of faith nor denied as contrary to it, lest occasion be given to the wise of this world to despise the doctrine of the faith": this does not favour the Copernicans. They do not teach what the philosophers have commonly held, but things so contrary to the common philosophy that they seem to be repugnant to the faith as well, by the very fact that they are repugnant to the divine Letters. I therefore wonder that Jacob van Lansbergen, in his *Apologia*, tract 3, used — or rather abused — this authority of Saint Thomas on behalf of Copernicus.

CAPVT XXXIX.

Chapter 39.

Quaestio 4. An Assertiones Sacrae Scripturae de Solis Motu & Stabilitate Terrae accipiendae sint secundum sensum literalem, An Figurate vel ad sensum vulgi, seu quoad apparentiam. Vbi de sensus literalis vsu Regulae Ecclesiasticae traduntur.

Question 4. Whether the assertions of Sacred Scripture about the motion of the Sun and the stability of the Earth are to be taken according to the literal sense, or figuratively, or according to the sense of the common people, that is, as regards appearance. Here the ecclesiastical rules on the use of the literal sense are set out.

I. This is the chief controversy between us and the Copernicans. For they contend that the Sacred Letters, in these physical and mathematical matters, accommodate themselves to the common sense of the people; and since to the people the Sun seems to move and the Earth to stand still — because the Sun seems much smaller than the Earth — Sacred Scripture had to adapt itself to them, leaving it meanwhile to more learned men to reconcile the tongue of God with the finger of God from the harmony and beauty of the divine works, judged by reason rather than by sense: that is, to reconcile the sacred expressions with effects worthy of the omnipotence of God. So Kepler, in the notes to chapter 1 of the *Mysterium Cosmographicum*: "There is indeed a tongue of God; but there is also a finger of God. And who would deny that the tongue of God is adapted both to its purpose and, on that account, to the popular tongue of men? In the most evident matters, therefore, to twist the tongue of God so that it refutes the finger of God in nature — this every most religious man will most carefully avoid. Let him to whom the praises of our Creator and Lord are a concern read — let him read, I say, my fifth book of the *Harmonics*; and, having grasped the most exquisitely harmonic polity of the motions, let him consider with himself whether the causes of the reconciliation sought between

the tongue and the finger of God were just enough and weighty enough, or whether it is expedient to reject the reconciliation and suppress with censures this report of the immense beauty of the divine works." The same author too, in the *Epitome of Copernican Astronomy*, at the end of book 1, having observed that astronomers also speak according to the sense of the eyes when they say that the planets stand still and retrogress, that the Sun keeps its solstices, etc., goes on to infer: "How much less will it be required of the divinely inspired Scriptures that, setting aside the common usage of speech, they should weigh their words by the rule of natural science, and by abstruse and ill-timed expressions about matters beyond the grasp of those to be instructed disturb the simple people of God, and thereby block for themselves the way to their genuine and far more sublime goal." And so, everywhere, do the other supporters of the Copernican sect whenever something from the sacrosanct books is objected to them.

II. [Margin: Reply to Question 4.] But I say that in these and all other propositions and expressions of Sacred Scripture the proper literal sense is to be followed, and their plain and obvious meaning, whenever this is not manifestly repugnant to some truth known from a more certain revelation or divine tradition, or from a definition of the Supreme Pontiff, or by the natural light. For if it is so repugnant, they are to be taken figuratively and interpreted in another sense. [Margin: Sacred Scripture is to be taken in its proper literal sense when that sense is not manifestly false.] When I say that the sense of the letter is to be followed, however, I do not exclude the other, mystical senses — allegorical, tropological and anagogical; but they may be used only in such a way that the literal sense is nevertheless not denied, but is either expressly set first as a foundation or implicitly and tacitly presupposed. When I have proved this proposition, it will then remain to show that, if the assertions of Sacred Scripture on the motion of the Sun and the immobility of the Earth are taken as uttered only with respect to appearance and the sense of the common people, and not with respect to truth, they are not only not taken literally but are taken in a plainly false sense — and that without any necessity, since their literal sense is repugnant to no truth evidently or certainly known from elsewhere. [Margin: Of how many kinds is the sense of Scripture?] Here, however, I presuppose the very celebrated division of the sense of Sacred Scripture into the literal or historical, of which one is called simple or proper and the other figurative; and into the spiritual or mystical, which is subdivided in three ways: namely into the allegorical, concerning something future in the Church of God militant; the anagogical, concerning what is to come in the other life; and the tropological or moral sense — although some confuse this last with the literal but figurative sense, and St Jerome, in question 12 to Hedibia, and St Augustine, in the book *On the Usefulness of Believing*, chapter 3, distribute these senses somewhat differently. On the common division of these senses, however, see above all St Thomas, Part 1, question 1; Sixtus Senensis, book 3 of the *Bibliotheca Sancta*; Possevinus, book 2 of the *Bibliotheca selecta*, chapter

18; Bellarmine, Controversy 1, book 3, chapter 3; and Salmeron, volume 1, Prolegomena 7 and 8.

[Margin: The reply is proved.] With these things presupposed, our reply is proved, first, because the literal sense is principally intended by God, who is the author of the divine letters, according to that saying of St Thomas, Part 1, question 1, article 10: "Since the literal sense is the one the author intends, and the author of Sacred Scripture is God, who comprehends all things at once in his intellect, it is not unfitting, as Augustine says in *Confessions* 12, if even according to the literal sense there are several senses in one letter of Scripture." [Margin: The authority of St Thomas.] The literal sense, simply speaking, is the one taken according to the proper and obvious meaning; it stands to the improper or figurative sense as any literal sense stands to the mystical, because the figurative is more hidden than the proper. The reason is that, as Sixtus Senensis says in book 3 of the *Bibliotheca Sancta*, under the title "On the use of historical exposition": "The historical kind of exposition is above all supremely necessary for instruction in those things which we are to believe, etc. For no exposition brought forward to prove dogmas has force and strength except one that explains the meaning of the letter truly, purely and genuinely." [Margin: Sixtus Senensis.] Our own Salmeron also inculcates the same most earnestly in volume 1, Prolegomenon 9, canon 33. [Margin: Salmeron.] There, having said that "one must by no means depart from the words of Sacred Scripture according to the rule of grammar, nor from the proper meaning of the words, unless some valid reason occurs that compels a figurative expression", he adds: "Otherwise the whole of Sacred Scripture would perish, and its literal sense with it, and it would hold only empty allegories and ill-timed interpretations, which each person would attach to it at his own will and pleasure; and so Scripture would always say what we wish, not what the Holy Spirit wished us to understand." He confirms this from the jurisconsults, under the title *De verborum significatione*, and from Marcellus the jurisconsult on the law *Non aliter*, L. 3 *de legatis*: these lay down that one must not depart from the proper sense of words unless it is gathered from the most manifest indications, and from the absurdity of the things themselves, that the speaker's mind was otherwise.

So too Bellarmine, Controversy 1, book 3, chapter 3: [Margin: Bellarmine.] "It is agreed between us and our adversaries that effective arguments must be sought from the literal sense alone; for it is certain that the sense which is gathered immediately from the words is the sense of the Holy Spirit." Antonio Possevino too, in book 2 of the *Bibliotheca selecta*, chapter 18, praises and lists those "who, either in ancient times or in this age, have interpreted the Divine Scripture according to the literal sense, which is the solid foundation of all the senses." [Margin: Possevinus.] But lest we seem to beg testimony only from our own household or from more recent writers, let us see the mind of the more ancient Fathers on this literal sense.

III. [Margin: St Basil.] St Basil, in Homily 9 on the *Hexaemeron*, calls those who drag Scripture into mere allegories, or in any way take away the truth of

the letter, "interpreters of their own dreams", and adds: "But I, when I hear 'grass', understand grass; and plant, and fish, and wild beast, and cattle — all these I take just as they have been said." Before him, however, Tertullian, in the book *On the Flesh of Christ*: [Margin: Tertullian.] "Certainly it is most perverse that, when we name the flesh, we should understand the soul, and, when they signify the soul, we should interpret them as the flesh. All things will be in danger of being taken otherwise than they are, and of losing what they are while they are taken otherwise, if they are named otherwise than they are." And further down he says: "The good faith of names is the safeguard of their properties." Above all, St Augustine teaches that the foundation of the literal notion must be laid beneath the other senses, in the sermon on Abraham and the sacrifice of Isaac, saying: [Margin: St Augustine.] "We admonish as much as we can, and we enjoin, that when you hear the mystery of Scripture expounded as it records the things that were done, you first believe that the deed was done just as it is read, lest, with the foundation of the deed withdrawn, you seek as it were to build in the air." For with this laid down, as the same author teaches in the book of *Eighty-three Questions*, "when deeds are allegorized, the things done do not lose their credibility." And in book 1 of *De Genesi ad litteram*, chapter 1, speaking of the manner of interpreting sacred Genesis, he says: "In the narration of things done, then, it is asked whether all of them are to be taken according to the figurative understanding only, or are also to be asserted according to the faith of things done"; and he solves the question, saying: "If, then, that Scripture is to be examined in both ways, let us ask how what is said is meant, apart from the allegorical signification, etc." And in chapter 21: "When we read the divine books, amid so great a multitude of true understandings which are drawn out of a few words and fortified by the soundness of the Catholic faith, let us choose above all that which it is clear the author we are reading meant, etc." The same holy Doctor, in book 3 of *On Christian Doctrine*, chapter 9: "As to follow the letter, and to take signs for the things signified by them, is a mark of servile weakness, so to interpret signs uselessly is a mark of error wandering astray." And in chapter 10: "To this observance, by which we beware of following a figurative — that is, a transferred — expression as if it were proper, must be added this one too: that we do not wish to take a proper expression as if it were figurative." And in chapter 39: "When the sense, if taken according to the proper meaning of the words, is absurd, one must certainly inquire whether perhaps what we do not understand has been said by this or that trope." Therefore, if it is not absurd, it is to be taken according to the proper meaning of the words.

[Margin: Argument from the waters above the heavens.] Moreover, Sacred Scripture tells us that there are waters above the heavens no more often, and in no clearer words, than it tells us that the Sun moves and the Earth is stable; and for that reason some of the Fathers — but rather few — understood those passages about the waters and the heavens not according to the proper sense of the letter but figuratively. St Augustine, however, took those waters according

to the proper sense of the letter to such a degree that in book 2 of *De Genesi ad litteram*, chapter 5, he pronounced that golden saying: "In whatever manner and of whatever kind the waters there may be, let us by no means doubt that they are there. For the authority of this Scripture is greater than all the capacity of human ingenuity." Further, the Apostle, in Galatians 2, relates that he withstood Cephas to his face because he was to be blamed: fearing to eat with the Gentiles in the presence of the Jews, he was in a way compelling the Gentiles by his example to judaize, that is, to abstain from the foods which the Mosaic law forbade. St Jerome, interpreting this passage, had said that Saints Peter and Paul did this by prior agreement; that St Paul did not truly think St Peter had done wrong, but that Peter wished to be rebuked in this way by St Paul so as to lift the ill will of the Jews from himself, etc.; and thus that St Paul had rebuked him as to appearance and outward sound. St Augustine withstood St Jerome, and contended in several letters to him that this way of interpreting sacred Scripture must not be admitted. These letters are found also among the Letters of St Jerome, volume 2, from letter 86 to 96; and letter 96 reads as follows: "For once an officious lie is admitted into the summit of so great an authority, no particle of those books will remain which, as it seems to anyone either difficult for morals or incredible for faith, will not be referred, by that same most pernicious rule, to the purpose and design of a lying author." He presses this reason in the remaining letters. And what he says of the officious lie he would certainly say of our case: for just as Peter not only seemed blameworthy but was truly blameworthy, and was not only apparently rebuked by St Paul but truly rebuked, as Augustine proved in letter 86 among Jerome's, so the Sun truly moves, and does not only seem to move, because Scripture says both; and there is nothing absurd in interpreting Scripture according to the proper sense of the letter.

[Margin: St Gregory the Great.] St Gregory the Great was plainly of the same mind in interpreting the divine letters. In book 1 of the *Moralia*, chapter 21, he likens the literal sense to drink, and the figurative or mystical to food, saying: "For Sacred Scripture is sometimes food for us, sometimes drink. It is food in the more obscure passages, because it is as it were broken by being expounded and swallowed by being chewed; it is drink in the more open passages, because it is drunk down just as it is found." And in book 31, chapter 23, explaining that saying of Job ("if my land cries out against me, and with it its furrows weep"), he says: "In this matter, because the order of the history fails, the mystical understanding shows itself to us as though the doors were now open, as if it plainly cried out: since you recognize that the sense of the letter has failed, it certainly remains for you to return to me without hesitation" — that is, to the mystical sense. But if the literal and historical sense can be retained, it must certainly be retained. Day would fail me if I wished to heap up here the testimonies of the other Fathers for our cause. It is enough for me to have pointed out that Ori- gen, because he shrank from the literal sense in explaining the divine letters, fell into intolerable errors, and clung so stubbornly

to his allegories that St Jerome, in the preface to the tenth vision of Isaiah, addressed to Bishop Amabilis, wrote of him: "Origen roams at large through the free spaces of allegory, and makes his own ingenuity the sacraments of the Church." The same must likewise befall those who, devoted to Platonic Ideas or to Pythagorean mysteries and philosophemes, have contrived the workmanship of the world not as Sacred Scripture sets it before us, but as they themselves fashioned it, contemplating archetypal reasons that were most beautiful to their own minds, however ill-fitting and absurd to others. Now we must clear away certain things that seem to stand in the way of our reply.

IV. [Margin: The 1st objection is cleared away.] *First*: against the literal sense and its followers stand those two passages of the Apostle, 1 Corinthians 7, "Now all these things happened to them in figure", and 2 Corinthians, chapter 10, "For the letter kills, but the spirit gives life." But the first passage does not mean that the precepts and ceremonies of the law are to be taken in a figurative sense only, with the proper meaning of the literal sense excluded; it means that they can be taken in an allegorical sense concerning Christ and the Church, while the literal notion is nevertheless retained, or kept safe. The second passage means that the old law, understood and observed according to the bare letter, with the spiritual sense of grace foreshadowed through Christ neglected, kills, that is, does not avail for salvation; but that the Spirit of grace, which is had from the New Testament, gives life — as Salmeron, among others, rightly expounds in volume 1, Prolegomenon 22. [Margin: The 2nd objection is cleared away.] *Second*: the literal sense is manifold, as St Augustine teaches in *Confessions* 12, chapters 26, 30 and 31; in book 1 of *De Genesi ad litteram*, chapters 19 and 21; in book 11 of the *City of God*, chapter 19; and in book 3 of *On Christian Doctrine*, chapter 27; so too St Thomas, Part 1, question 1, article 10, and many others cited by Salmeron, volume 1, Prolegomenon 8. But this does not prevent the proper literal sense from being taken in preference, if nothing absurd follows from it, even if nothing unfitting follows from the figurative sense. This rule, however, must always be kept: if no absurdity is demonstrated in the proper meaning of the literal sense, that sense holds first place; but if its absurdity has been proved from elsewhere, let us look for another sense, by which the truth of the sacred utterance may be kept safe. The same St Augustine taught this clearly in book 1 of *De Genesi ad litteram*, chapter 21, expounding the verse of Psalm 103, "stretching out the heaven like a skin": [Margin: A notable judgement of St Augustine for the use of the literal sense.] "But someone says: how is what is written in our letters, 'Who stretches out the heaven like a skin?', not contrary to those who attribute the figure of a sphere to the heaven? Let it indeed be contrary, if what they say is false; for that is true which the divine authority says, rather than what human weakness conjectures. But if perhaps they are able to prove it by such evidence that one ought not to doubt it thereafter, it must be demonstrated that what is said with us about the skin is not contrary to those true reasons." This is the rule we have so often inculcated above.

V. [Margin: The 3rd objection is cleared away.] *Third*: the sacred interpreters not seldom grant that Moses, in speaking of God's workmanship, accommodated himself to an uneducated people; and among others St Thomas Aquinas, in the First Part of the *Summa*, question 70, article 1, reply to 3, said: "It must be said that according to Ptolemy the luminaries are not fixed in the spheres, but have a motion separate from the motion of the spheres, etc. But according to the opinion of Aristotle the fixed stars are in their orbs and are not moved except by the motion of the orbs, according to the truth of the matter; yet the motion of the luminaries is perceived by sense, not the motion of the spheres. Moses, however, condescending to an uneducated people, followed what appears to the senses." Therefore no derogation is done to Sacred Scripture if it is said to have asserted the motion of the Sun and the rest of the Earth because they appear so to the common people, so as to accommodate itself to the common capacity of men. But it is one thing, of two things both of which are true, to pass over one in silence as hard to understand or not obvious to the senses — such as St Thomas thinks the motion of the celestial spheres to be — and to express the other, which is plain to the senses, such as the motion of the Sun; it is quite another thing to affirm what is false because what is true is not obvious to sense, and therefore not easy for the common people to understand. But if the Sun were immobile and the Earth moved, and Scripture nevertheless affirmed that the Sun moves and that the Earth does not move, it would not only be silent about the truth but would in addition assert a falsehood, which is unfitting. Here the saying of St Augustine in the book *On Lying* applies: "There can be no just cause for a lie to be told; but there can be a just cause for the truth sometimes to be kept silent." Let St Thomas be consulted, Part 1, question 67, article 4; question 68, article 3; question 69, article 2, reply to 3; and question 70, article 1, reply to 4, on how he explains the expressions of Moses without falsity, keeping some literal sense intact.

VI. [Margin: The 4th objection is cleared away.] *Fourth*, you will press: if the Sun stood still and the Earth really moved, Scripture would nevertheless have spoken in the same way as now, or at least could have spoken so, in order to adapt itself to the capacity of men. For who would have believed David, or Job, or Solomon, or the Son of Sirach, saying, "The Earth moves and returns in its circles", and conversely, "You who founded the Sun upon its stability; it shall not be inclined for ever and ever", or such παράδοξα [Greek: παράδοξα (paradoxa, "paradoxes" — things contrary to received opinion)], wholly foreign to the senses of men? But I deny that in that case Scripture would have spoken so, or could have spoken as it does now, with no indication anywhere from God, in another Scripture or in some natural effects manifest to sense mediately or immediately, of the rest of the Sun and the motion of the Earth — indications from which we would be compelled to take the other expressions about the motion of the Sun and the rest of the Earth figuratively. Besides, is it not most difficult to grasp, and not obvious to the senses, that there are waters above the heavens, and that the light of the Sun existed before the Sun? And yet

Scripture did not keep silent about these things; and much less did it keep silent about the mystery of the Most Holy Trinity, of the Incarnation, of the Eucharist, of the resurrection of the dead. On what ground, then, is it said so confidently that Scripture would have kept silent about that motion of the Earth, precisely because it is above or against the sense of men? Finally, you deny that anyone would believe Scripture asserting the motion of the Earth, because of the absurdity and παραδοξίαν [Greek: παραδοξίαν (paradoxian, "paradoxicality" — strangeness against received opinion)] of this motion; and yet you want Aristarchus or Copernicus to be believed when they assert so great an absurdity? Is not this itself a horrible monster of intolerable absurdity — not to grant to God speaking what you would grant to a little man speaking? Either, then, be silent about what you claim God ought to be silent about, or rather speak what God affirms by speaking.

VII. [Margin: The 5th objection is cleared away.] *Fifth*: the Copernicans bring forward many propositions of Sacred Scripture pertaining to cosmographical, physical or mathematical matters, in which it is nevertheless established that Scripture accommodates itself to the capacity and sense of the common people, and that the literal sense, according to the proper meaning of the language, cannot be taken. To all of these we reply in general that nothing is ever affirmed in them that is not so, or denied that is so. Next, if it is established that they are to be taken in a sense other than the literal and proper one, this must certainly be established either from other, clearer passages of Scripture, or from a definition of the Church, or from some evident proposition known by the natural light. But in none of these ways is it established that the passages adduced in chapter 36 for the motion of the Sun and the rest of the Earth are to be taken otherwise. We shall nevertheless run through these other passages, so that the difference in interpreting may appear more clearly.

Loca Sacrae Scripturae ad Physicam aut Mathesim pertinentia, quae Copernicani Figurate aut ad sensum Popularem accipienda esse contendunt, Examinantur.

The passages of Sacred Scripture pertaining to physics or mathematics which the Copernicans contend are to be taken figuratively, or according to the popular sense, are examined.

VIII. [Margin: Firmament.] Genesis 1 says: "And God called the firmament heaven." But if the heaven filled with fixed stars moves, how is it called a firmament? I answer: from its firmness, which does not necessarily signify local immobility. But see what I said in Section 1, chapter 2, question 1. [Margin: The great luminaries.] In the same chapter 1 of Genesis it is said: "And God made two great luminaries: the greater luminary to rule the day, and the lesser luminary to rule the night, and the stars." Here Moses seems to have spoken according to the sense of the people; otherwise the Moon is not a great luminary, since Saturn and Jupiter, etc., are planets much larger than the Moon; nor should the Sun or the Moon have been distinguished from the stars, as

though they themselves were not stars. But I have already expounded this passage at length, with the Fathers, in Section 1, chapter 4, question 5, which is found on page 231. There we taught that the Moon, considered as a luminary, is greater than all the other stars except the Sun, because it is like the Sun in illuminating, at least when it is full, and lights up the whole hemisphere at once far more than all the rest taken together. Therefore, even according to the proper sense of the letter the Moon is a great luminary, though smaller than the Sun — granted that in respect of its body, or as a planet, it is not great, or greater than all the others; and Tycho says almost the same in the *Epistolae Astronomicae*, page 148. Next, as I said in the same place, it is astronomically evident, from the Moon's apparent diameter and distance, that it is smaller than some of the planets; and therefore, if Moses had called the Moon a great planet (which, however, he did not do), we would be compelled to have recourse to its apparent magnitude. But no evidence compels us to say that the motion of the Sun and the stability of the Earth are asserted in the Scriptures with respect to appearance alone. Nor, when "the stars" is added, is it denied that the Moon and the Sun are stars with this name taken as generic, but only with it taken as specific; or else "and the rest" is to be understood.

[Margin: The geometrical measurement of the Brazen Sea.] 3 Kings, chapter 7, says: "He made also a molten sea of ten cubits from brim to brim, round in compass; its height was five cubits, and a line of thirty cubits encircled it round about." Jacob van Lansbergen, in tract 3 of the *Apologia*, tries to drag this passage to the sense of the common people, on the ground that if the diameter of this round vessel was 10 cubits, its circumference could not have been only 30 cubits but must have been greater, since — from what we said in book 1, chapter 4 — the diameter of a circle is to its circumference as 100 to 314. To this objection I reply in three ways. *First*: it is not established from Scripture whether that line — in Italian *il cordoncello* — lay in the same plane as the brim and the ten-cubit diameter; for it could have been somewhat lower than the brim, and so have been exactly 30 cubits, and somewhat less than the circumference. *Second*: even if the line is taken for the circumference of the brim, a round number is nevertheless set down truly and according to the proper sense of the letter, as often happens elsewhere; for this does not deny the more exact number, which had to be 31 2/5 if the diameter was 10; or, if the circumference was 30, the diameter had to be 9 174/314. *Third*: one would have to have recourse to this sense of a round signification, accommodated to the people, for this reason: that the ratio of the diameter to the circumference has been demonstrated by Archimedes and others; whereas none of the Copernicans has so far demonstrated that the Sun does not really move and that the Earth does move.

[Margin: The Sun coming forth from its chamber.] In Psalm 18 the Sun is said to come forth like a bridegroom from his chamber — not because it has slept the whole night, since it is said that there is no one who hides himself from its heat, and so it illuminates the other hemisphere by night as well, but in view

of the analogy between the splendour of its rising and the new adornments of a bridegroom. And in Psalm 23 the Earth is founded upon the seas and prepared upon the rivers [Margin: The Earth upon the waters.] — not because it can float upon the waters, but because, as St Augustine says in book 2 of *De Genesi ad litteram*, chapter 1, most riverbanks, and places receding from the shore, occupy a higher place than the water because of swellings of the ground and hills.

[Margin: The heaven stretched out like a skin.] In Psalm 103, moreover, God is said to have stretched out the heaven like a skin: that is, with the ease with which tents made of skins are stretched out; or because he clothed the world with the heaven as with a skin; or because a skin, too, in bellows and inflated wineskins, is so stretched that it tends to roundness. Therefore this is not repugnant to the roundness of the heaven. This is the exposition of St Augustine in book 2 of *De Genesi ad litteram*, chapter 8.

[Margin: The Earth stands for ever.] Ecclesiastes 1 says: "A generation passes away, and a generation comes; but the Earth stands for ever." This passage, as I said in chapter 36, has a twofold literal sense. One concerns the standing of the Earth as opposed to generation and corruption, signifying that the Earth is subject to generation and corruption neither as a whole nor in the greatest part of its depth; this is the only sense the Copernicans embrace. The other sense concerns standing as opposed to local motion. For the Earth is like a stage, on whose surface men succeed one another; but at length, having presented their brief spectacle, they pass away by local motion too, while the body passes into the bowels of the earth, and the soul formerly passed into the bowels of the same earth, but now passes either into its bowels or into heaven. But the Earth, exempt from all motion, stands for ever; and this sense is the principal one and conforms to the Hebrew root, as our own Pineda shows at length and learnedly on chapter 1 of Ecclesiastes.

[Margin: Put out into the deep.] Lastly, Christ the Lord says to Peter, in Luke 5, "Put out into the deep" — literally "into the high", because the sea seems higher than the shore through a deception whose cause the opticians explain, although because of the swelling of the waves it can sometimes really be higher than the shore. But if in this case we are compelled to take refuge in an optical expression and the popular sense, this happens because it is presupposed, as evidently known from elsewhere, that the sea is not really higher than the shores. Now, it is not evidently established that the Earth moves and the Sun stands still, so that we should be bound on that account to draw the propositions about the motion of the Sun and the standing of the Earth to a figurative sense or to appearance. *Altum* could also be taken for "deep". Let there now be:

VNICA CONCLVSIO.

The Single Conclusion.

PROPOSITIONES SACRAE SCRIPTURAE, IN QUIBUS SOLIS MOTUS, & TERRAE IMMOBILITAS ASSERITUR, ACCIPIENDAE SUNT AD LITERAM, SECUNDUM PROPRIUM SENSUM.

The propositions of Sacred Scripture in which the motion of the Sun and the immobility of the Earth are asserted are to be taken according to the letter, in their proper sense.

IX. The conclusion is proved by this single syllogism. *Every proposition that is found uttered by a canonical writer in Sacred Scripture is to be taken in the literal and proper sense whenever, in that sense, there is no repugnance with other propositions of the same Sacred Scripture that are equally or more certain, or with a definition of the Supreme Pontiff of the Catholic Roman Church, or with some proposition certain and evident by the natural light. But the propositions of Sacred Scripture in which the motion of the Sun and the stability of the Earth are asserted were uttered by a canonical writer, and are repugnant to none of the things enumerated in the major. Therefore they are to be taken in the literal and proper sense.*

[Margin: Proof of the major.] The MAJOR has been sufficiently proved from number 2 to 7. And as regards the definition of the Church made through the Roman Pontiff, it has already been most learnedly proved by Bellarmine, Controversy 1, book 3, from chapter 3 to 10. There, from the whole antiquity of the Fathers and the custom of the Church, and from the authority conferred by Christ on St Peter and his successors, he establishes that in a doubt whether a Sacred Scripture is to be received among the canonical books or not, or concerning the sense and interpretation of some proposition found in it, recourse must be had to a single, certain, visible rule, which is the Supreme Pontiff of the Catholic Roman Church; and this is confirmed from the decree of the Council of Trent, session 4, on the edition and use of the sacred books.

[Margin: Proof of the minor as to its three parts.] The MINOR is proved as regards the canonical writer. For the propositions asserting the motion of the Sun and the stability of the Earth were uttered by the author of the Book of Judges and of Paralipomenon, by David, by Ecclesiastes, by Ecclesiasticus, by Isaiah, and by Job himself, or by God speaking to Job — not, however, by the friends of Job — as is clear from what was said in chapter 36. All these authors and books are listed among the canonical books by the Council of Trent, and are defined as to be held for such, session 4. That they are not repugnant to another Scripture or to a definition of the Church is proved, both because no such proposition can be brought forward to which they are repugnant, and because, although it has not yet been defined by the Supreme Pontiff, it has nevertheless been defined by those deputed by him that it is rather the assertions of the motion of the Earth and the stability of the Sun that are repugnant to Sacred Scripture, as will be clear from what is to be said in the following chapter. Finally, that those propositions are not repugnant to any proposition certain and evident by the natural light is proved, *first*, because it is rather the propositions opposed to them that are repugnant to physico-mathematical demonstrations, as was said in chapter 35, conclusions 2 and 3; *second*, because if the celestial phenomena alone are considered, all of them can be saved in astronomical

rigour, whether the Earth is supposed to rest and the Sun to move, or the Earth to move and the Sun to rest, as was said in chapter 35, conclusion 1. For no one has so far demonstrated the motion of the Earth or the rest of the Sun; at most it has been demonstrated that, if the Earth moves through the annual orb with the diurnal motion and the libration of the axis, and the Sun at the centre of the world moves with no motion other than that of rotation about its own centre, all the celestial phenomena can occur, as to appearance, in the same way as if the Sun moved about the Earth resting at the centre of the world; and that for some of them a more probable account of such phenomena is given by the hypothesis of Copernicus, granted that in other respects it contains a greater absurdity, inwardly and outwardly. Finally, the Copernicans themselves admit that in astronomical rigour the same things would appear in the heaven whether the Earth stands and the Sun moves, or the Earth is carried round while the Sun stands still: Copernicus, book 1, chapter 5, says: "For between things moved equally in the same direction no motion is perceived — between the thing seen, I mean, and the one seeing. Now it is the Earth from which that celestial circuit is viewed and reproduced to our sight. If, then, some motion is assigned to the Earth, that same motion will appear in all things that are outside it, but in the opposite direction, as if they were passing by; and such, in the first place, is the daily revolution." And in chapter 8: "Why then should we not admit that the appearance of this daily revolution belongs to the heaven, and the reality to the Earth?" etc. Therefore, if the Earth is supposed to be at rest, the same motion will nevertheless appear in the celestial bodies. [Margin: Kepler's testimonies for the equipollence of the hypotheses of the Earth at rest and in motion.] And Kepler, in the introduction to the *Commentaries on Mars*: "The opinion of Brahe on the form of the world ought surely to be commended not a little to the learned. For, taking as it were a middle way, on the one hand it frees the astronomers, as far as can be done, from the useless apparatus of so many epicycles, and embraces with Copernicus the causes of the motions that were unknown to Ptolemy, giving some place to physical speculations by receiving the Sun into the centre of the planetary system; on the other hand it serves the common run of the learned, and eliminates the motion of the Earth, so hard to believe — although through it the theories of the planets are entangled in many difficulties in astronomical speculations and demonstrations, and celestial physics is not a little disturbed." That physics, namely, which Kepler feigns for himself in his mysteries — not the physics which God and the Intelligences understand, for whom those are no tangles which seem tangles to the weakness of our imagination. Meanwhile, however, Kepler admits that in the Tychonic hypothesis, which frees the Earth from all motion, the phenomena are saved.

But, you will say, if you listen to Kepler in his notes on chapter 1 of the *Mysterium Cosmographicum*, the harmonic laws in the motions of the planets do not seem able to hold together with the rest of the Earth and the motion of the Sun. I reply that this is utterly false, as Kepler himself at length admits and attests in book 5 of the *Harmonice*, chapter 3, where he speaks thus: "Although I cannot

do otherwise than put in its place the opinion of Copernicus on the world as the only one, and, if it were possible, persuade everyone of it; yet because the matter is still new among the common run of students, and the doctrine that the Earth is one of the planets and is carried among the stars around an immobile Sun is most absurd to the hearing of most people: let those, then, who are offended by this opinion know that these harmonic speculations hold their place in the hypotheses of Tycho Brahe as well, because that author holds in common with Copernicus all the rest that pertains to the disposition of the bodies and the tempering of the motions," etc. — see this in his own text if you want more. Meanwhile it also appears that that beauty of the Copernican hypothesis contends with the foulness of its absurdity, so that it is most difficult to believe. Again, in the *Hyperaspistes*, book 3, chapter 22, where he speaks of Chiaramonti and fears that Chiaramonti may turn the decrees of the Holy Inquisition against him, he says: "If he should seize the weapon of Jove and hurl his thunderbolt at the hypotheses which I follow; if he should bring an action against me, as Cleanthes once did against Aristarchus, for violated religion, because the sacred things of Vesta were moved from their place: the equipollence demonstrated in the *Commentaries on Mars* and inculcated in the *Harmonice* will amply satisfy the astronomers." Therefore, Kepler, you admit that the hypothesis of Brahe, demonstrated by you, which halts the Earth and moves the Sun, is equipollent to the Copernican hypothesis, which moves the Earth.

[Margin: Galileo's testimonies for the same equipollence.] Further, Galileo, in Dialogue 2, *On the Cosmic System*, Italian page 107, Latin page 81, speaking of the diurnal motion, says: "And this motion, as far as this first appearance goes, in no way prevents it from being able to belong to the Earth alone just as well as to the whole rest of the world, the Earth excepted. For the same appearances would be seen in the one position as in the other." And at Italian page 267, Latin 201, when Simplicio had said: "Whatever has been brought forward in confirmation of the Earth's motion concludes, in sum, nothing else than that the reasons asserting the stability of the Earth are not necessary; but meanwhile, from the contrary side, no demonstration has been produced that necessarily proves and concludes the mobility of the Earth," Salviati, who sustains the person of Galileo in those dialogues, replied: "I have never taken it upon myself to lead you away from your opinion, Simplicio; much less would I dare to pronounce a definitive sentence on so great a dispute." So much for the celestial phenomena. As for his saying, at the end of dialogue 4, that the flux and reflux of the sea give a most evident testimony for the motion of the Earth, with what vanity and falsity this was said is clear from what was said in chapter 14. Finally, that the motion of the Earth is not proved by Galileo from the circular motion of heavy bodies, etc., we have sufficiently demonstrated in chapter 17.

CAPVT XL.

Chapter 40.

Quam Censuram mereantur & retulerint a Doctis viris, sed praecipue a Sacra Congregatione Cardinalium Officio Inquisitionis a Summo Pontifice deputatorum, Assertores Motus Telluris & Immobilitatis Solis.

What censure the assertors of the motion of the Earth and of the immobility of the Sun deserve, and have received, from learned men, but above all from the Sacred Congregation of Cardinals deputed by the Supreme Pontiff to the Office of the Inquisition.

I. I shall first review some astronomers, philosophers and theologians who have condemned the hypothesis of Copernicus in more explicit formulae. [Margin: Tycho.] Tycho, in the *Epistolae Astronomicae*, page 147, judges it "absurd and contrary to Sacred Scripture". [Margin: Tassonus.] Alexander Tassonus, in book 4 of the *Diverse Thoughts* [diversarum Contemplationum], question 25, asserts that it is "against nature, against sense and physical reasons, against astronomy and mathematics, and against religion". [Margin: Mersennius.] Marinus Mersennius, however, in his *Questions on Genesis*, chapter 1, verse 10, article 7, rejects it in such a way as nevertheless to deny that it has so far been condemned as a heresy by the Catholic Church. [Margin: Gassendus.] Petrus Gassendus, at the end of the second letter *De motu impresso a motore translato*, does indeed condemn and repudiate that opinion, but he adds: "Not that I therefore consider it to be an article of faith," etc. [Margin: Scheinerus.] Our own Scheinerus, in the *Disquisitiones Mathematicae*, pages 28 and 35: the Copernican motion is "beyond all belief, and cannot be defended without innumerable absurdities; and it follows from it that many passages of Sacred Scripture, and the common forms of speech of the astronomers, must be twisted into a perverse sense without any necessity, when everything can be defended most conveniently in the plain sense". [Margin: Delphinus.] From the Franciscan family, Io. Antonius Delphinus, in his book *On the Celestial Globes and Motions*, chapter 18, calls the opinion of the Earth's motion "foolish, insipid, and long since hissed out of the schools". But others brand it with graver censures. [Margin: Kircher.] For Athanasius Kircher, in his *Magnes*, page 539, affirms that it is "dangerous in faith". [Margin: Lipsius.] Indeed Iustus Lipsius [Justus Lipsius], book 2 of the *Physiologia*, disputation 19 — which Georgius Polaccus too reports in his *Anticopernicus Catholicus*, assertions 1 and 45 — and, with Lipsius, [Margin: Tellez.] our own Balthassar Tellez, in his *Summa of Philosophy*, part 2, disputation 46, section 2, call the opinion of the Earth's motion a heresy. [Margin: Serarius.] Nicolaus Serarius of our Society does the same on chapter 10 of Joshua, question 14, where, speaking of Copernicus, he says: "Although he dedicated these revolutions of his to the Supreme Pontiff Paul III, so that they might escape all reprehension, nevertheless, if these hypotheses were seriously asserted as true, I do not see how they could be immune from

heresy. For Scripture always attributes rest to the Earth and motion to the Sun and Moon; or, if ever those stars stand still, it signifies that this happens by a great miracle." [Margin: Tannerus.] Moreover, Adamus Tannerus, a most learned theologian of our Society, in his dissertation *On the Heaven*, question 9, says that it is a certain and true assertion that the stars, not the Earth, are moved from east to west; and that the opposite, condemned as heresy or error by Philastrius and by Diodorus of Tarsus, can no longer be safely defended after the decree of the Cardinals. [Margin: Fromondus.] Likewise Fromondus in his *Vesta*, [Margin: Acarisius.] and Acarisius in his, subscribe to the same censures, which we shall shortly bring out from the decree of the Cardinals. [Margin: Inchofer.] Melchior Inchofer of our Society, in his *Tractatus Syllepticus*, from chapter 8 to 12, holds: 1. that the consensus of the Fathers is unanimous that the Sun moves; 2. that it is of faith that the Sun moves circularly; 3. that it is more probable that it is of faith that the Earth is at the centre of the world and does not move — of faith, I say, at least indirectly, inasmuch as from its opposite there follows something contrary to faith, namely that the passages of Scripture asserting the motion of the Sun and the stability of the Earth are false. [Margin: Polaccus.] Georgius Polaccus agrees with him in every respect in his *Anticopernicus Catholicus*, assertions 126, 127, 128, 129 and 130. [Margin: Pineda.] Our own Pineda, on chapter 1 of Ecclesiastes, page 114, calls the opinion of the Earth's motion "an absurd falsity"; [Margin: Lorinus.] and Lorinus of our Society asserts that this same falsity has been demonstrated by him from the divine letters, on the same chapter 1 of Ecclesiastes. [Margin: The author's opinion.] For my part, I do not dare to add anything to, or take anything from, the censure passed against this opinion by the Sacred Congregation of Cardinals, which I shall report a little below; rather, I subscribe to it entirely, as having been pronounced most prudently and for the most just reasons.

II. There now follows a copy of the decree issued under Paul V against the books of Copernicus, of Didacus Astunica [Diego de Zúñiga] and of Paulus Antonius Foscarinus, extracted from the Chancery of the Holy Office of the Inquisition at Rome; Tannerus too reports a great part of it, in his dissertation *On the Heaven*, question 9. To it we shall subjoin the emendation of the books of Copernicus promulgated at Rome in the year 1620, and the abjuration which Galileo was compelled to make in the year 1633 under Urban VIII. A copy of the abjuration was shown to us by the Most Reverend Father Pallavicinus, Inquisitor of Mantua, and Georgius Polaccus also recites it, in his *Anticopernicus Catholicus*, after assertion 123, from a letter of the Most Eminent Cardinal of St Onuphrius sent in the same year to the Most Reverend Inquisitor of Venice.

Extractus Decreti Sacrae Congregationis Eminentissimorum S.R.E. Cardinalium sub Paulo V. Editi V. Martij Anni M DC XVI.

Extract of the decree of the Sacred Congregation of the Most Eminent Cardinals of the Holy Roman Church, issued under Paul V on 1616 March 5.

And since it has also come to the notice of the Congregation named above that the false Pythagorean doctrine, altogether opposed to Divine Scripture, of the mobility of the Earth and the immobility of the Sun — which Nicolaus Copernicus in *De revolutionibus orbium caelestium*, and Didacus Astunica on Job, also teach — is now being spread abroad and accepted by many, as may be seen from a certain printed letter of a certain Carmelite Father, entitled *Lettera del R. P. Maestro Paolo Antonio Foscarini Carmelitano, sopra l'opinione de i Pittagorici, & del Copernico della mobilità della Terra, e stabilità del Sole, & il nuovo Pittagorico Sistema del Mondo* (Letter of the Reverend Father Master Paolo Antonio Foscarini, Carmelite, on the opinion of the Pythagoreans and of Copernicus concerning the mobility of the Earth and the stability of the Sun, and the new Pythagorean System of the World), Naples, Lazzaro Scorriggio, 1615, in which the said Father tries to show that the doctrine mentioned above, of the immobility of the Sun at the centre of the world and the mobility of the Earth, is consonant with the truth and not opposed to Sacred Scripture: therefore, lest an opinion of this kind creep any further to the ruin of Catholic truth, the Congregation has decided that the said Nicolaus Copernicus, *De revolutionibus orbium*, and Didacus Astunica on Job are to be suspended until they are corrected; that the book of Father Paulus Antonius Foscarinus, Carmelite, is to be altogether prohibited and condemned; and that all other books teaching the same thing are likewise to be prohibited — as by the present decree it prohibits, condemns and suspends them all, each in its respective way. In witness of which the present decree was signed and sealed by the hand and seal of the Most Illustrious and Most Reverend Lord Cardinal of St Cecilia, Bishop of Albano, on 1616 March 5. Rome, from the press of the Apostolic Camera, in the year 1616.

P., Bishop of Albano, Cardinal of St Cecilia.

Place of the seal.

Register, folio 90.

Fr. Franciscus Magdalenus Capiferreus [Francesco Maddaleni Capiferro], Secretary, of the Order of Preachers.

Monitum Sacrae Congregationis Ad Nicolai Copernici Lectorem eiusque Emendatio, Permissio, & Correctio.

Admonition of the Sacred Congregation to the reader of Nicolaus Copernicus, with its emendation, permission and correction.

The Fathers of the Sacred Congregation of the Index judged that the writings of Nicolaus Copernicus, the noble astrologer, *On the Revolutions of the World*, were to be altogether prohibited, for this reason: that he does not hesitate to treat principles about the position and motion of the terrestrial globe that are repugnant to Sacred Scripture and to its true and Catholic interpretation (something by no means to be tolerated in a Christian man), not by way of hypothesis, but to assert them as most true. Nevertheless, because there are in those writings many things most useful to the commonwealth, they came

with unanimous consent to the opinion that the works of Copernicus printed up to this day were to be permitted, as they have permitted them — but with those passages corrected, according to the emendation subjoined, in which he argues about the position and motion of the Earth not by way of hypothesis but by asserting it. Those copies, however, that are to be printed hereafter are permitted only with the passages already mentioned emended as follows, and with a correction of this kind prefixed to Copernicus's preface.

LOCORUM, QUAE IN COPERNICI LIBRIS VISA SUNT CORRECTIONE DIGNA, EMENDATIO.

Emendation of the passages in the books of Copernicus that have been judged worthy of correction.

In Praefatione circa finem.

In the Preface, near the end.

There, at *si fortasse* ("if perhaps"), delete everything up to the words *hi nostri labores* ("these labours of ours"), and adjust it thus: *Caeterum hi nostri labores* ("But these labours of ours").

In Cap. 6. lib. 1. pag. 6.

In chapter 6 of book 1, page 6.

There, at *Si tamen attentius*, correct: *Si tamen attentius rem consideremus; nihil refert, an Terram in medio Mundi, an extra medium existere, quoad solvendas caelestium motuum apparentias existimemus: omnis enim* etc. ("If, however, we consider the matter more attentively, it makes no difference whether we suppose the Earth to exist in the middle of the world or outside the middle, as regards resolving the appearances of the celestial motions; for all," etc.)

In Cap. 8. eiusdem Libri.

In chapter 8 of the same book.

This whole chapter could be struck out, because it treats professedly of the truth of the Earth's motion, while it refutes the reasons of the ancients proving the Earth's rest. Since, however, it seems to speak problematically, let it be emended as below, so that students may be satisfied and the sequence and order of the book may remain intact.

First, on page 6, delete the short passage from *Cur ergo* up to the word *provehimur*, and let the passage be corrected thus: *Cur ergo non possum mobilitatem illi formae suae concedere, magisque quod totus labatur mundus, cuius finis ignoratur scirique nequit, et quae apparent in caelo, perinde se habere, ac si diceret Virgilianus Aeneas,* ("Why then can I not grant to the Earth a mobility belonging to its form, and the more so since the whole world is slipping by, whose limit is unknown and cannot be known; and that the things which appear in the heaven behave just as if Virgil's Aeneas were saying,")

Second, on page 7, at the passage *Addo*, let it be corrected in this way: *Addo etiam difficilius non esse contento et locato, quod est Terra, motum adscribere, quam continenti* ("I add, too, that it is no more difficult to ascribe motion to what is contained and located, which is the Earth, than to what contains it").

Third, on the same page, at the end of the chapter, the passage *Vides* is to be deleted up to the end of the chapter.

In Cap. 9. pag. 7.

In chapter 9, page 7.

The beginning of this chapter, up to the passage *Quod enim*: correct it thus: *Cum igitur Terram moveri assumpserim: videndum nunc arbitror, an etiam illi plures possint convenire motus, quod enim* etc. ("Since, then, I have assumed that the Earth moves, I think we must now see whether several motions too can belong to it; for," etc.)

In Cap. 10. pag. 9.

In chapter 10, page 9.

The passage *Proinde*: correct it thus: *Proinde non pudet nos assumere* ("Hence we are not ashamed to assume"). And a little below, there, *Hoc potius in mobilitate Terrae verificari* ("that this is rather verified in the mobility of the Earth"): correct it to *Hoc consequenter in mobilitate Terrae verificari* ("that this is consequently verified in the mobility of the Earth"). On page 10, at the end of the chapter, delete those last words: *Tanta nimirum est divina haec D. O. M. fabrica* ("So great, indeed, is this divine workmanship of God, Best and Greatest").

In Cap. 11.

In chapter 11.

Let the title of the chapter be adapted in this way: *De Hypothesi triplicis motus Terrae, eiusque demonstratione* ("On the hypothesis of the threefold motion of the Earth, and its demonstration").

In lib. 4. cap. 10. pag. 122.

In book 4, chapter 10, page 122.

In the title of the chapter delete the words *horum trium siderum* ("of these three stars"), because the Earth is not a star, as Copernicus makes it.

Fr. Franciscus Magdalenus Capiferreus, of the Order of Preachers, Secretary of the Sacred Congregation.

Rome, from the press of the Reverend Apostolic Camera, 1620.

Literae Eminentiss. Cardinalis S. Onufrij Ad Reu. P. Inquisitorem Venetum.

Letter of the Most Eminent Cardinal of St Onuphrius to the Reverend Father Inquisitor of Venice.

VERY REVEREND FATHER.

CAPVT XL.

The treatise of Nicolaus Copernicus *De revolutionibus orbium caelestium* has been suspended by the Congregation of the Index, because it maintains that the Earth moves and not the Sun, but that the Sun stands at the centre of the world (an opinion which is contrary to Sacred Scripture); and Galileo Galilei, a Florentine, was prohibited many years ago by this Sacred Congregation of the Holy Office from holding, defending or teaching the said opinion in any manner, by word or in writing. Nevertheless the same Galileo dared to compose a book entitled *Galilaeus Galilaei Lynceus*; and, without disclosing the said prohibition, he extorted a licence to print it (as in fact he did print it). And while supposing, at its beginning, middle and end, that he wished to treat the already-mentioned opinion of Copernicus hypothetically, he nevertheless (although he could not treat of it in any manner) treated of it in such a way that he rendered himself vehemently suspect of adhering to such an opinion. For this reason, having been examined and shut up in the prison of the Holy Office, he was condemned by the sentence of these Most Eminent Lords of mine to abjure the said opinion, to remain in formal prison at the discretion of their Eminences, and to perform other salutary penances — as Your Reverence will see in the copy of the sentence and of the abjuration written below. It is sent to you so that you may notify it to your vicars, and so that knowledge of it may reach them and all professors of philosophy and mathematics; in order that, knowing how the said Galileo was dealt with, they may grasp the gravity of the error he committed, so as to avoid it, and also the penalties which they would suffer by falling into it. In closing, may the Lord God preserve Your Reverence. Rome, 1633 July 2.

Your Reverence's,
as a brother,
the Cardinal of St Onuphrius.

Sententia in Galilaeum & Abiuratio eiusdem.

The sentence against Galileo, and his abjuration.

[Margin: Names of the cardinals of the Sacred Congregation.] We, Gaspar, of the title of the Holy Cross of Jerusalem, Borgia [Gaspar de Borja];

Brother Felix Centinus [Felice Centini], of the title of St Anastasia, called of Ascoli;

Guidus, of the title of St Mary of the People, Bentivolus [Guido Bentivoglio];

Brother Desiderius Scaglia [Desiderio Scaglia], of the title of St Charles, called of Cremona;

Brother Antonius Barberinus [Antonio Barberini], called of St Onuphrius;

Laudivius Zacchia [Laudivio Zacchia], of the title of St Peter in Chains, called of St Sixtus;

Berlingerius, of the title of St Augustine, Gypsius [Berlinghiero Gessi];

Fabricius, of St Lawrence in Panisperna, Verospius [Fabrizio Verospi], called the Priest;

Franciscus, of St Lawrence in Damaso, Barberinus [Francesco Barberini], and

Martius, of St Mary the New, Ginettus [Marzio Ginetti], Deacons; by the mercy of God Cardinals of the Holy Roman Church, Inquisitors General throughout the whole Christian Commonwealth against heretical depravity, specially deputed by the Holy Apostolic See.

[Margin: The form of the sentence against Galileo.] Whereas you, Galileo, son of the late Vincenzio Galilei of Florence, aged seventy years, were denounced to this Holy Office in the year 1615 for holding as true the false doctrine taught by many, namely that the Sun is at the centre of the world and immobile, and that the Earth moves, even with a diurnal motion; also, that you had certain disciples whom you were teaching the same doctrine; also, that you kept up a correspondence about it with certain mathematicians of Germany; also, that you had published certain letters entitled *On the Sunspots*, in which you set out the same doctrine as true; and that you answered the objections drawn from Sacred Scripture, which were raised against you from time to time, by glossing the said Scripture according to your own sense; and whereas there was afterwards produced a copy of a writing in the form of a letter, said to have been written by you to a certain former disciple of yours, in which, following the hypotheses of Copernicus, you include several propositions contrary to the true sense and authority of Sacred Scripture:

This Holy Tribunal, therefore, wishing to provide against the disadvantages and damages that arose from this and were spreading to the ruin of the holy Faith, by order of Our Lord and of the Most Eminent Lords Cardinals of this supreme and universal Inquisition, had the two propositions on the stability of the Sun and the motion of the Earth qualified by the theological Qualifiers, as follows:

That the Sun is at the centre of the world and immobile with respect to local motion is a proposition absurd and false in philosophy, and formally heretical, because it is expressly contrary to Sacred Scripture.

That the Earth is not the centre of the world, nor immobile, but moves even with a diurnal motion, is likewise a proposition absurd and false in philosophy, and, considered theologically, at the least erroneous in faith.

But since it then pleased us, for the time being, to proceed gently with you, it was decreed in the Holy Congregation held before Our Lord on 1616 February 25 that the Most Eminent Lord Cardinal Bellarmine should enjoin you to abandon altogether the said false doctrine; and that, if you refused, you should be commanded by the Commissary of the Holy Office to give up the said doctrine, and not to teach it to others, nor defend it, nor treat of it; and that, if you did not acquiesce in this command, you should be thrown into prison. And in execution of the same decree, on the following day, in the Palace, before the above-mentioned Most Eminent Lord Cardinal Bellarmine, after you had been gently admonished by the same Lord Cardinal, you were commanded by the Lord Commissary of the Holy Office then in office, in

the presence of a notary and witnesses, to desist altogether from the said false opinion, and that in future it should not be lawful for you to defend or teach it in any way, neither by word nor in writing; and when you had promised obedience, you were dismissed.

And so that so pernicious a doctrine might be removed entirely and creep no further to the grave detriment of Catholic truth, a decree issued from the Sacred Congregation of the Index by which the books treating of a doctrine of this kind were prohibited; and that doctrine was declared false and altogether contrary to Sacred and Divine Scripture. And since this book, published at Florence in the year just past, has lately appeared, whose inscription showed that you were its author — its title being *Dialogo di Galileo Galilei delle due massime Sisteme del Mondo, Tolomaico, e Copernicano* (Dialogue of Galileo Galilei on the two chief systems of the world, Ptolemaic and Copernican) — and since the Sacred Congregation learned at the same time that, through the printing of the said book, the false opinion of the motion of the Earth and the stability of the Sun was gaining strength more and more every day, the said book was diligently examined, and in it was found an open transgression of the said command that had been intimated to you, in that in the same book you had defended the said opinion, already condemned and declared to be such in your presence. For in the said book, by various circumlocutions, you take pains to persuade that it is left by you as undecided and expressly probable; and this too is a most grave error, since an opinion that has already been declared and defined to be contrary to divine Scripture can in no way be probable.

Therefore, by our order, you were summoned to this Holy Office, where, examined under oath, you acknowledged the said book as written by you and committed by you to print. Likewise you confessed that about ten or twelve years ago, after the command had been given you as above, you began to write the said book. Likewise, that you sought licence to publish it, without however indicating to those who gave you that permission that you had been commanded not to hold, defend or teach such a doctrine in any way.

You confessed likewise that the writing of the said book is composed in many places in such a way that a reader might think that the arguments brought for the false side were so phrased as to be more able to constrain the intellect by their efficacy than to be easily refuted. You excused yourself on the ground that you had fallen into an error so foreign (as you said) to your intention because you had written in the form of a dialogue, and through the natural complacency that everyone takes in his own subtleties, and in showing himself cleverer than men commonly are in devising ingenious and apparently probable arguments even in favour of false propositions.

And when a suitable term had been assigned to you for making your defence, you produced a certificate in the hand of the Most Eminent Lord Cardinal Bellarmine, procured by you, as you said, to defend yourself from the calumnies of your enemies, who kept saying that you had abjured and had been punished by the Holy Office. In this certificate it is said that you had not abjured, nor been

punished, but only that the declaration made by Our Lord and promulgated by the Sacred Congregation of the Index had been notified to you, in which it is contained that the doctrine of the motion of the Earth and the stability of the Sun is contrary to the Sacred Scriptures, and that it can therefore be neither defended nor held. Therefore, since no mention is made there of two clauses of the command, namely *to teach* and *in any way*, it is to be believed that in the course of fourteen or sixteen years they had slipped from your memory, and that for this very reason you were silent about the command when you sought permission to have the book printed; and that you say this not to excuse your error, but so that it may be ascribed to vain ambition rather than to malice. But this very certificate, produced for your defence, has rather aggravated your case, since it says in it that the said opinion is contrary to Sacred Scripture, and yet you dared to treat of it, to defend it, and to urge it as probable. Nor does the permission artfully and cunningly extorted by you help you, since you did not disclose the command laid upon you.

But since it seemed to us that you had not stated the whole truth about your intention, we judged it necessary to proceed to a rigorous examination of you, in which (without any prejudice to the things you had confessed, and to those that had been brought against you above concerning your said intention) you answered as a Catholic. Therefore, having seen and maturely considered the merits of this case of yours, together with your above-mentioned confessions and excuses, and everything else that was by law to be seen and considered, we have come to the definitive sentence written below against you.

Invoking, therefore, the most holy name of Our Lord Jesus Christ and of his most glorious Mother, Mary ever Virgin, by this our definitive sentence — which, sitting as a tribunal, on the counsel and judgement of the Reverend Masters of Sacred Theology and Doctors of both Laws, our Consultors, we deliver in these writings in the case and cases brought before us between the Magnificent Carolus Sincerus [Carlo Sinceri], Doctor of both Laws, Fiscal Procurator of this Holy Office, of the one part, and you, Galileo Galilei, the defendant here, inquired into, examined and confessed as above by the present written process, of the other — we say, pronounce, judge and declare that you, the above-mentioned Galileo, on account of the things brought out in the written process and confessed by you as above, have rendered yourself to this Holy Office vehemently suspect of heresy: that is, of having believed and held a doctrine false and contrary to the Sacred and Divine Scriptures, namely that the Sun is the centre of the world [orbis terræ] and does not move from east to west, and that the Earth moves and is not the centre of the world, and that an opinion may be held and defended as probable after it has been declared and defined to be contrary to Sacred Scripture; and that you have consequently incurred all the censures and penalties enacted and promulgated against delinquents of this kind by the Sacred Canons and by other constitutions, general and particular. From these it is our pleasure that you be absolved, provided that first, with a sincere heart and unfeigned faith, you abjure, curse and detest before us the

above-mentioned errors and heresies, and any other error and heresy contrary to the Catholic and Apostolic Roman Church, in the form that will be presented to you by us.

And so that this grave and pernicious error and transgression of yours may not remain altogether unpunished, and so that you may be more cautious in future and be an example to others, that they may abstain from offences of this kind, we decree that the book of the *Dialogues* of Galileo Galilei be prohibited by public edict; and we condemn you to the formal prison of this Holy Office for a period to be fixed at our discretion; and by way of salutary penance we enjoin that for the next three years you recite the seven penitential psalms once a week, reserving to ourselves the power of moderating, changing or taking away, wholly or in part, the above-mentioned penalties and penances.

And so we say, pronounce, and by sentence declare, ordain, condemn and reserve, in this and in every other better manner and form in which by law we can and ought.

So we, the undersigned Cardinals, pronounce.

F., Cardinal of Ascoli.
G., Cardinal Bentivolus.
F., Cardinal of Cremona.
Brother Antonius, Cardinal of St Onuphrius.
B., Cardinal Gypsius.
F., Cardinal Verospius.
M., Cardinal Ginettus.

ABIVRATIO GALILÆI.

The abjuration of Galileo.

I, Galileo, son of the late Vincenzio Galilei of Florence, aged seventy years, arraigned in person before this court, and kneeling before you, Most Eminent and Most Reverend Lord Cardinals, Inquisitors General throughout the whole Christian Commonwealth against heretical depravity, having before my eyes the most holy Gospels, which I touch with my own hands, swear that I have always believed, do now believe, and with God's help shall in future believe all that the Holy Catholic and Apostolic Roman Church holds, preaches and teaches. But because by this Holy Office — on the ground that, after I had been juridically enjoined by the same, with a command, to abandon altogether the false opinion that holds the Sun to be the centre of the world and immobile, and the Earth not to be the centre and to move, and that I might not hold, defend or teach the said false doctrine in any way, or in writing; and after it had been notified to me that the said doctrine was repugnant to Sacred Scripture, I wrote and committed to print a book in which I treat that same doctrine, already condemned, and adduce arguments of great efficacy in fa- vour of it, without offering any solution — I have for that reason been judged vehemently suspect of heresy, namely of having held and believed that the Sun is the centre of the world and immobile, and that the Earth is not the centre and moves.

Therefore, wishing to remove from the minds of Your Eminences, and of every Catholic Christian, this vehement suspicion rightly conceived against me, with a sincere heart and unfeigned faith I abjure, curse and detest the above-mentioned errors and heresies, and in general every other error and sect contrary to the said Holy Church; and I swear that in future I shall never again say or assert, by word or in writing, anything on account of which a similar suspicion could be held of me; but that, if I know of any heretic or anyone suspected of heresy, I shall denounce him to this Holy Office, or to the Inquisitor and Ordinary of the place where I may be. I swear moreover and promise to fulfil and observe entirely all the penances that have been imposed on me, or shall be imposed, by this Holy Office. And if it should happen that I contravene any of my said promises, protestations and oaths (which God forbid), I submit myself to all the penalties and punishments that have been enacted and promulgated against delinquents of this kind by the Sacred Canons and by other constitutions, general and particular. So help me God and his holy Gospels, which I touch with my own hands.

I, the above-mentioned Galileo Galilei, have abjured, sworn, promised and bound myself as above; and in witness of this I have subscribed with my own hand the present document of my abjuration, and have recited it word for word, at Rome, in the convent of the Minerva, on this day, 1633 June 22.

I, Galileo Galilei, have abjured as above, with my own hand.

CONCLVSIO Sectionis Huius.

Conclusion of this Section.

So much for the arguments on both sides, and for the censures against the assertors of the immobility of the Sun and the motion of the Earth. How justly and prudently these censures were passed, and how undeservedly some speak against them, or even do not yet acquiesce in them, is clear from what has been said in the whole of this section from chapter 4. This section, intended above all others as a part of this volume and of my work, I congratulate myself, with the greatest thanksgiving, on having brought with God's help to the desired end. For I wished it to be, as it were, an apology for the Sacred Congregation of Cardinals who pronounced the said censures as a tribunal — not so much because I thought that so lofty a summit of authority and eminence needed this labour of mine, especially among Catholics, as out of love for the truth, which is to be urged upon anyone whatever, even a non-Catholic; out of a certain signal zeal and eagerness to keep Sacred Scripture whole and intact; and lastly out of the reverence and observance that I owe, by my own particular Institute, to the holy Catholic and Apostolic Roman Church.

Let there be, therefore,

CONCLVSIO VNICA & Vnicè in hac controuerſia Complectenda.

The single conclusion, and the one alone to be embraced in this controversy.

It must be asserted absolutely that the Earth stands naturally immobile at the centre of the world, and that the Sun moves around it with both a diurnal and an annual motion.

This is proved, first, because the opposite is manifestly repugnant to Sacred Scripture understood according to the letter (as it must be, so long as there is no absurdity), as we have shown from chapter 36 to 39 inclusive; second, because the opposite was condemned as heretical — or, as regards the motion of the Earth, as at the least erroneous in faith — by the Sacred Congregation of Cardinals deputed by the Supreme Pontiffs Paul V and Urban VIII, as is clear from the preceding chapter 40; and finally, because the opposite is contrary to physical evidence and to certain physico-mathematical demonstrations, according to what has been said more than once, especially in chapter 35.

SECTIO QVINTA DE SYSTEMATE MVNDI HARMONICO.

Section Five: On the Harmonic System of the World.

CAPVT I.

Chapter 1.

De Neceſſitate huius Sectionis ac de Auctoribus, qui de Proportionibus Harmonicis tractauerunt.

On the necessity of this Section, and on the authors who have written on harmonic proportions.

I. No one with even a little learning in astronomy who has contemplated the order of the heavens fails to recognise a certain harmony in the intervals and the motions of the planets; and what kind of harmony it is, and how great, cannot be neglected by anyone who professes an accurate treatment of the system of the world and of the heavens. There are, however, many things necessary or useful to the theory and practice of music that are not at all required for this dissertation on the harmonic system. Yet, so that no one's desire and curiosity may seem too little satisfied, I shall at least point out a good number of authors from whom, as from springs, a reader may quench this thirst, importunate though it may be.

These authors were: Aristotle, section 19 of the *Problems*, and there Blancanus, on the mathematical passages of Aristotle, from marginal number 359; Nicomachus in the *Enchiridion* of harmonics; the musical fragments of Heraclides Ponticus in Athenaeus; Aristoxenus in three books of *Harmonic Elements*, translated by Antonius Gogavinus [Antonio Gogava]; Euclid in the *Musical Elements*; Panaetius in his book on geometrical and musical ratios; Vitruvius, book 5, chapter 4, and on that passage Daniel Barbarus [Daniele Barbaro] and Gulielmus Philander [Guillaume Philandrier]; Pliny the Elder, book 2, chapter 22, and on that passage his commentators; Plutarch in the short work *On Music*, with the exposition of Carolus Valgulius [Carlo Valgulio]; Ptolemy in three books of *Harmonics*, translated by Antonius Gogavinus; Porphyry on Ptolemy's

Harmonics; Cassiodorus, *On the Disciplines*, under the heading "On Music"; St Augustine, *On Music*; Boethius in his book *On Music*, with the exposition of Franchinus Gaffurius [Franchino Gaffurio] and of Faber Stapulensis [Jacques Lefèvre d'Étaples]; Apuleius and Psellus [Michael Psellos] on music; Censorinus, *On the Birthday*, chapter 11; Isidore, book 3 of the *Origins*, in the chapter on music; Martianus Capella, book 9 of the *Philology*; Bede in the short work *On Music*; Macrobius, book 2 of the *Dream of Scipio*, from chapter 1 to 5; Guido Aretinus [Guido of Arezzo] in the *Introductorium* of music; Berno, abbot of Cluny; Io. Freschius; Petrus Aron [Pietro Aron]; Otho Theogerus, bishop [Theoger of Metz]; Othomarus Argentinas [Ottmar Luscinius] — all in books on music; Iodocus à Prato, otherwise called Iusquin [Josquin des Prez]; also Io. Richafort [Jean Richafort]; Nicolaus Bursius of Parma [Nicolò Burzio]; Io. Ghiselinus [Johannes Ghiselin]; Adamus Fuldensis [Adam of Fulda]; Iacobus Obrecht, a Netherlander [Jacob Obrecht]; Sixtus Dietrich; Gherardus à Salice; Andreas Sylvanus; Nicolaus Craën; Vincentius Lusitanus [Vicente Lusitano]; Horatius Tigrinus [Orazio Tigrini] in his musical compendium; Antonius à Vinea; Petrus Pontius [Pietro Ponzio]; Stephanus Vanneus [Stefano Vanneo] and Petrus Vanneus, *On the Power of Music*; Io. and Georgius Valla [Giorgio Valla]; Alypius in the *Isagoge* of music; Artusius [Giovanni Maria Artusi], *On the Imperfection of Modern Music*; Damianus Goës [Damião de Góis]; Gregorius Meyer; Io. Spadarus of Bologna [Giovanni Spataro]; Nicolaus Vicentinus [Nicola Vicentino]; Theodoricus Augustanus; Hieronymus Diruta [Girolamo Diruta]; Henricus Glareanus in his *Dodecachordon*; Ludovicus Folianus of Modena [Lodovico Fogliano] in *Musica theorica*; Franchinus Gaffurius; Iosephus Zarlinus [Gioseffo Zarlino] in the *Harmonic Institutions*; Vincentius Galilaeus [Vincenzio Galilei] in the *Dialogues on Music*; Marsilius Ficinus in the compendium of Plato's *Timaeus*, from chapter 27 to 35; Scipio Cerretus of Naples [Scipione Cerreto]; Io. Petrus Aloysius Palestrina [Giovanni Pierluigi da Palestrina]; Ludovicus Zacconus [Lodovico Zacconi]; Aloysius Denticus [Luigi Dentice]; Felix Anerius [Felice Anerio]; Franciscus Salinas [Francisco de Salinas], doctor of the school of Salamanca; Sebastianus Ravallius [Sebastián Raval]; Illuminatus Ayguinus [Illuminato Aiguino]; Augustinus Pisa [Agostino Pisa], on the beat in music; Clavius, in book 5 of the *Elements*, where he treats harmonic proportions; Robertus Flud [Robert Fludd], or de Fluctibus, in the *Microcosm* and the *Macrocosm*, each of which he contends was founded on harmonic laws; Johannes Kepler in five books of *Harmonics*, in the *Mysterium Cosmographicum*, chapter 12, and in the *Epitome of Copernican Astronomy*, book 6, from page 840 and 900; Pierre Hérigone in tome 5 of the *Cursus mathematicus*, from page 573, and more fully in Euclid's *Music*, in the same tome 5, from page 802; Marinus Mersennius on chapter 4 of Genesis, from verse 21, and in the paralipomena of the same work, from page 1854; Marius Bettinus [Mario Bettini], *Apiarium* 10, Progymnasma 1; and, most recently and most learnedly, Athanasius Kircher in the ten books of his *Musurgia*.

II. [Margin: The principal authors on the praises of music.] On the praises of music, and on its admirable power for many things, but above all for stirring and calming the emotions of the mind, and so on: Plutarch, the short work *On Music*; Petrus Vanneus, *On the Power of Music*; Martianus Capella, book 9 of *The Marriage of Philology and Mercury*, chapter 1; Zarlinus, part 1 of the *Harmonic Institutions*, from chapter 2 to 7, and part 2, from chapter 4 to 9; Mersennius on chapter 4 of Genesis, verse 21; Athanasius Kircher passim, but above all books 9 and 10 of the *Musurgia*.

CAPVT II.

Chapter 2.

De Concentu Cælorum In Communi.

On the concert of the heavens in general.

I. We have the most ancient testimony to the concert [concentus] of the heavens from God himself, the founder and harmonizer [Harmoſte] of the heavens, speaking thus with Job: [Margin: Job, chapter 38, verse 37.] *Who shall tell out the reckoning of the heavens, and who shall make the concert of heaven to sleep?* Various interpreters interpret this passage variously, but many refer it to the harmony that shines forth in the motions, the intervals and the arrangement of the stars. [Margin: The concert of heaven from Sacred Scripture.] So the Chaldean paraphrast: *Who has set the stars of heaven in wisdom?*, or: *Who has set the weeks of heaven in wisdom, and who has dwelt in the revolution of heaven?* The Zurich version, on the other hand: *Who by his wisdom will dictate to the aether what it is to do? And who will stay the bottles of heaven?* And Pagninus: *Who has numbered the heavens in wisdom, and who has made the things that come down from heaven to rest?* Again, Caietanus and Vatablus interpret it thus: *Who made the heavens so wisely, in the number in which they are?* And Philippus, cited by our own Pineda on that passage, interprets the concert of heaven as the arrangement and beauty of the heavens, for which men or angels praise God; so the concert is taken there objectively, for the object that rouses the rational creature to song and to the praises of God — as is said in Psalm 18: *The heavens tell the glory of God.*

Thomas Aquinas and Lyranus add, moreover, that the saying can be referred to the preceding verse, in which God had said: *Who gave the cock understanding?* For he goes on: *Who shall tell out the reckoning of the heavens?* — as if he were saying: who will tell the cock the proportion of the heavenly motions, so that from it he may discern the hours fixed for his singing? [Margin: The praises of the cock.] For with his song he seems to mark off, at every three unequal hours, the four watches of the night, but above all the fourth. On this see the praises of the cock in Pliny, book 10, chapter 21. The word *Concentus*, moreover, is in Hebrew *Nebel*, from the root *Nabal*, which means "to flow down", and, by synecdoche, a vessel in which flowing water is caught and carried, such as wineskins are; but since from little vessels of this kind there were made certain

musical instruments, the word is therefore taken for the psaltery, or for the *Nablum*, from the same root *Nabal*, and hence for concert, as the Vulgate has it; or, as Symmachus has it: *Who will adorn the organs of heaven?*; or, with St Augustine: *Who has bent down the organs of heaven to the earth?* Most of the rabbis cited by Pineda, however, interpret it as clouds full of water, or as the wineskins and bottles of heaven, and the Royal Bible as *the down-flowing of the heavens* — above all when stormy rains fall with a great noise, which God suddenly makes to sleep when he abruptly brings back fair weather. Furthermore, that passage of Joshua, chapter 10, *Sun, do not move*, and *the Sun stood still*, is in Hebrew *dom* and *vaijdom*, that is, as the Royal Bible has it, *be silent* and *it was silent*: there the motion of heaven is signified metaphorically by sound or voice, and its rest by silence; for the fabrications that the rabbis invent on that passage have been sufficiently refuted there by our own Serarius.

[Margin: The symphonism of the elements.] Also relevant to our subject are those words of Wisdom 19, verse 17: *For while the elements are changed into one another, as in an organ the sound of the quality is changed, and all keep their own sound; from which it can be judged with certainty by the very sight.* Among our own writers, Io. Lorinus and Io. Pineda interpret this passage admirably; but it is illustrated most of all by what Father Athanasius Kircher teaches in book 10 of the *Musurgia* on the symphonism of the elements, from page 367 to 373. Among many other things he adduces the tetrachord of Orpheus, in which, on the testimony of Brienius [Manuel Bryennios], Orpheus referred the Hypate to Earth, the Parypate to Water, the Paranete to Air and the Nete to Fire.

II. [Margin: The harmony of the world and of the heavens, from the Fathers.] Nor indeed are the Fathers out of tune with the Scriptures. On the contrary, [Margin: St Augustine.] St Augustine, on the harmony of the whole world, said in book 11 of the *City of God*, chapter 18: *God adorned the order of the ages like a most beautiful poem, with certain antitheses, as it were; and just as contraries set against contraries give beauty to speech, so the beauty of the age is composed by a certain eloquence, not of words but of things, through the opposition of contraries.* On that verse of Psalm 148, *His confession is above heaven and earth*, he also says: *What is the confession of God? That he himself confesses? No — but that all things confess him, all things cry out; the beauty of all things is, in a manner, the voice of those who confess God. Heaven cries out to God: you made me, not I; the earth cries out: you founded me, not I*, and so on. [Margin: St Ambrose.] St Ambrose chimes in with him in book 4 of the *Hexaemeron*, chapter 1, and in the preface on the Psalms, saying: *The angels praise the Lord, the powers of the heavens sing psalms to him; and a more explicit account holds that the very axis of heaven turns with a certain sweetness of perpetual concert, so that its sound is heard at the farthest parts of the earth, where certain secrets of nature lie; nor does this seem foreign to the usage of nature.*

[Margin: Philo.] Before him, Philo, in his book *On Dreams*, wrote most eloquently: *Heaven, by the perpetual concert of its motions, gives forth a most sweet harmony. If it could reach our ears, it would rouse in us uncontrollable loves and a*

mad desire; goaded by it, we would forget the things necessary for life, giving up food and drink, but would be refreshed, like candidates for immortality, by the divine songs of consummate music. Moses, having heard such songs when he was rapt out of the body, is said to have tasted neither bread nor water for forty days and as many nights. And a little later: *Thus heaven, the archetypal instrument of music, seems to me to have been fashioned for no other purpose than that hymns might be sung skilfully and musically to the parent of all things.* [Margin: Boethius.] After Philo let Severinus Boethius follow, most learned in musical proportions, in book 1 *On Music*, chapter 2. There he divides music three ways, namely into mundane, human and instrumental, comprehending under the mundane the admirable order and consonance of divine providence, especially in the arrangement of the heavens; and among other things he says: *How can it be that so swift a machine of heaven should move in a silent and noiseless course, even if that sound does not reach our ears?* [Margin: St Isidore.] What of Isidore, bishop of Seville, in book 3 of the *Origins*, chapter 16? Does he not say: *Without music no discipline can be perfect, for nothing exists without it. For the world itself is said to be composed by a certain harmony of sounds, and heaven itself revolves under the modulation of harmony*? [Margin: Bede.] But Bede ascribes much more to this music, in tome 1, in the *Musica theorica*, page 406, where he says: *While the celestial music is made up of the subtler things, it is rendered most sonorous without any incongruity; for it is poured secretly from the higher things down to the lower, as far as our hearing, although through habit we do not perceive it — as is the case with those who live near the* καταβαθμὸν *[Greek: katabathmon, "the descent"], that is, the descent of the Nile. But if someone were born in another world (if that were possible), as St Augustine asserts, and afterwards came into this world, he would hear it without any impediment, and it would please him beyond measure.*

[Margin: St Anselm.] St Anselm says similar things in book 1 of *De Imagine Mundi*: *The seven orbs of the heavens revolve with the sweetest harmony, and the sweetest concerts are produced by their circling. This sound does not reach our ears because it is made beyond the air, and its magnitude exceeds our narrow hearing.* [Margin: Licentius the poet.] To these must be added Licentius, a Christian poet and disciple of St Augustine, who, as is found in St Augustine, letter 39, and in Sixtus Senensis, book 5 of the *Bibliotheca*, annotation 105, sang thus of God:

He fitted numbers to the heavens, and bade them ply their sounding modes and lead out matching dances.

III. Let us now hear those outside the Church [exteros]. The most ancient of them, Pythagoras, is said to have won such fame precisely because he taught that the whole world is harmonically arranged, [Margin: Athenaeus.] as Athenaeus asserts, book 14, chapter 13; but so did Plato and Archytas, [Margin: Plutarch.] of whom Plutarch said at the end of his short work *On Music*: *But now, friends, you have passed over what is the greatest of all, and what shows most clearly that music is to be cultivated. For Pythagoras, Archytas, Plato and the rest of the ancient philosophers declared that the motions of all things and the revolutions of the stars*

could neither come to be nor subsist without music; for they contend that God the craftsman fashioned all things with harmony. [Margin: Plato.] Certainly Plato, in book 10 of the *Republic*, said that a single Siren sits on each of the celestial orbs; [Margin: Cicero.] and from Platonic springs flowed that saying of Cicero in book 1 of the *Tusculans*: *When Archimedes bound the motions of the Moon, the Sun and the five wandering stars into a sphere, he did the same as the God of Plato's Timaeus who built the world, so that a single revolution governed motions most unlike in slowness and swiftness.* But he says it more fully in the *Dream of Scipio*, where Scipio himself says: *What is this, I said, what is this sound, so great and so sweet, that fills my ears?* His father Paulus answers him at once: *This is the sound that, joined by unequal intervals which are yet marked off in fixed proportion, is produced by the impulse and motion of the orbs themselves; tempering high notes with low, it evenly produces concerts. For such great motions cannot be set going in silence, and nature brings it about that the extremes sound low at one end and high at the other.* [Margin: The praise of the number seven.] *For this reason that highest course of the starry heaven, whose revolution is swifter, moves with a high and rapid sound, but this lunar and lowest course with the lowest sound. For the ninth, the Earth — of the spheres, that is, or globes — remaining immobile, always clings to the lowest seat, embracing the middle place of the world. But those eight courses, in which the force of the modes is the same, produce seven sounds distinguished by intervals — a number that is the knot of almost all things. Learned men, imitating this with strings and songs, have opened for themselves a way back to this place, as have others who, with outstanding gifts, have cultivated divine studies in human life. Filled with this sound, the ears of men have grown deaf (nor is there any duller sense in you), as where the Nile rushes down from the highest mountains at the place called the Catadupa: the people who live near that place lack the sense of hearing because of the greatness of the noise. But this sound, from the most rapid revolution of the whole world, is so great that men's ears cannot take it in, just as you cannot look straight at the Sun, and your sight and sense are overcome by its rays.*

[Margin: Macrobius.] Subscribing to this, Macrobius, book 2 on the *Dream of Scipio*, chapter 1, speaks of that sound as a real one, in this world: *For sound must arise from the very circling of the orbs, because air that is struck, set in motion by the very intervention, gives off from itself the force of a crash, nature herself compelling the violent collision of two bodies to end in sound.* And after a few words: *From these things it is gathered by unassailable reasoning that musical sounds proceed from the revolution of the spheres: for sound must arise from motion, and the reason that is in divine things becomes in the sound the cause of melody. Pythagoras, first of all men of the Greek nation, conceived this in his mind, and understood that something composed sounds from the spheres.* He goes on to relate by what means Pythagoras, hearing the blows of hammers in a blacksmith's workshop, discovered the harmonic proportions. And in chapter 3: *Hence Plato in his Republic, when he treated of the rotation of the celestial spheres, says that Sirens sit on each of the orbs, signifying that by the motion of the spheres song is offered to the divinities; for Siren, in its Greek sense, means "singing to God". The theologians, too,* [Margin: The nine Muses.]

the nine Muses — the musical songs of the eight spheres, and the one greatest concord, which consists of them all — held to be. He adds, moreover, from Hesiod, that the eighth of the Muses, who presides over the starry sphere, is Urania, and that the ninth is Calliope, the concert arising from the sound of all the spheres, called Calliope from the beauty of her voice; and he concludes: *That the Muses are the song of the world even the Etruscans know, who called them Camenae, as if Canenae, from singing* [canendo]. *Therefore the theologians too, approving that the heaven sings, applied musical sounds to sacrifices*, and so on; and soon after: [Margin: Strophe and antistrophe, an imitation of the twofold motion of heaven.] *In the very hymns of the gods, too, metres were applied in tuneful verses by strophe and antistrophe, so that by the strophe the direct motion of the starry orb, and by the antistrophe the contrary regression of the wandering stars, might be proclaimed; from these two motions the first hymn in nature, to be dedicated to God, took its beginning.* The half-line of Angelus Politianus [Angelo Poliziano] alludes to this passage of Macrobius and of Plato:

To each its harmless Siren.

[Margin: Pliny.] Further, Pliny, book 2, chapter 3, speaking of the motion of the stars, says: *Whether the sound of so great a mass, whirling in unceasing rotation, is immense and therefore easily exceeds the capacity of our ears, I for my part could not easily say — any more, by Hercules, than whether the tinkling of the stars carried round together, as they revolve their orbs, is a concert of sweet and incredible charm. To us who live within it, the world glides by silently, day and night.* In the same book, chapter 22, he relates the Pythagorean distribution of the celestial intervals according to the musical canons, of which more below. [Margin: Psellus.] Michael Psellus, at the beginning of his *On Music*, says: *The ancients say that music contains all things.* [Margin: Censorinus.] Censorinus, who is older than he, in *On the Birthday*, chapter 11, towards the end, said of Pythagoras: *Moreover, he related many things that musicians treat of: he showed that the stars and this whole world are* ἐναρμόνιον *[Greek: enarmonion, "harmonious"].* [Margin: Dorylaus.] *That is why Dorylaus wrote that the world is the organ of God.* The rest concerning Pythagoras we shall report from Censorinus in chapter 7, number 2.

[Margin: Martianus Capella.] Fittingly, then, Martianus Capella, in *The Marriage of Philology and Mercury*, after book 8, which is entirely on astronomy, immediately adds book 9, which is on music and is so entitled; there he introduces Harmony speaking thus of herself: *Long since, indeed, hating the earth-born and disdainful of mortals, I strike the starry orbs of heaven, in which it is forbidden to expound the precepts of art, since the very rapidity of the revolving machine sings and recognises a melody consonant with the all-sounding beats of the measures.* [Margin: Ptolemy.] But we had almost forgotten our Ptolemy, who in book 1 of the *Harmonics*, chapter 2, lays down: *It is the aim of the harmonist everywhere to preserve the rational positions of the canon, in no way conflicting with the senses, according to the opinion of the majority; just as it is the astronomer's aim to preserve positions of the celestial motions consonant with the observed revolutions.* In book 3, chapter

8, he measures the configurations of the celestial aspects against musical laws, and in chapters 9, 10, 11 and 12 he compares the celestial motions to harmonic ones. [Margin: Caelius Rhodiginus.] Caelius Rhodiginus [Lodovico Ricchieri], book 5 of the *Antiquae lectiones*, chapter 25, asks, or wonders: *How does it come about that the whirling rotation of such great orbs is carried round in a silent and noiseless circuit — even if, with us not hearing it, a wonderful delight of sounds passes by?* [Margin: Petrus Gregorius Tholosas.] Similarly Petrus Gregorius Tholosas [Pierre Grégoire], book 12 of the *Syntaxes*, chapter 7, defining celestial music, says: *Celestial music is that which arises from the disposed order of the orbs and planets, by a concordant and meeting motion, in a defined space.* [Margin: Zarlinus.] Iosephus Zarlinus, too, in part 1 of the *Harmonic Institutions*, chapter 6, brings forward with his learning many things on the sound of heaven — unheard by us though it is, through habituation — and on the harmony in the motions and distances of the heavens. It now remains to settle, from what has been said, the question whether the sound and concert of the heavens is to be taken properly or metaphorically.

An Cæleſtia corpora Realem Sonitum ſuo motu producant?

Whether the celestial bodies produce a real sound by their motion.

IV. The affirmative opinion is attributed to Pythagoras by Macrobius, as we have already seen, book 2 on the *Dream of Scipio*, chapter 3; but long before that by Aristotle, who treats this very controversy in book 2 of *De caelo*, from text 52. For in text 54 he says: *That about which doubt has been raised, and which led the Pythagoreans to say that a consonance arises from these bodies being carried*, and so on — that is, from the stars, although at the beginning he did not name them, namely in text 52, where he says: *It is clear from this that the saying that a harmony arises from these bodies being carried, as though the sounds became consonant, was said wittily and finely by those who asserted it; yet the truth is not so.* Censorinus, too, very eloquently attributes the same to Pythagoras, in the book *On the Birthday*, chapter 11; we shall bring forward his words below, chapter 7, number 2.

[Margin: Authors for a real sound of the heavens.] This persuasion of Pythagoras about celestial music — to speak with the Conimbricenses, book 2 of *De caelo*, chapter 9, question 1 — took hold of the minds of very many by its sweetness, so much so that most, especially among the pagans, asserted that a sound is roused by the mutual collision of the celestial bodies, which we do not perceive, whether because of the distance, or because of habituation, or because our hearing has been dulled from infancy. Among them were — openly, indeed — Philo, in the book *On Dreams*; Cicero, in the *Dream of Scipio*; Pliny, book 2, chapter 3, although he seems to have doubts; Macrobius, book 2 on the *Dream of Scipio*, chapters 1 and 3; Martianus Capella, book 9 of the *Marriage of Philology*; Bede, in the *Musica theorica*; St Anselm, book 1 of *De Mundi imagine*; Caelius Rhodiginus, book 5 of the *Antiquae lectiones*, chapter 25; and Iosephus Zarlinus, part 1 of the *Harmonic Institutions*, chapter 6 — as is clear from their words reported in numbers 2 and 3. Not a little in favour of the same

opinion, too, are St Ambrose, in the preface on the Psalms; St Isidore, book 3 of the *Origins*, chapter 16; Plutarch, at the end of his short work *On Music*; and finally reason itself, by an induction made from what we experience in other bodies. [Margin: An argument for a real sound of the heavens.] Aristotle did not conceal this argument, *De caelo* 2, text 52: *It seems to some*, he says, *necessary that a sound should arise from the carrying of such great bodies, since it arises also from the carrying of those that are among us, which nevertheless have neither so great a mass nor such a speed as the Sun and the Moon have. How much more, then, when so many stars, so great in multitude and magnitude, are carried with such speed, is it impossible that some immense sound should not arise?* Nor is it an obstacle that this sound is not perceived by us. For the cause is that the sound falls upon us as soon as we are born and occupies our ears, and by its perpetual habituation does not allow itself to be distinguished from its contrary, namely the privation of sound, which never occurs. *Since, however*, Aristotle continues in text 52, *it seemed unreasonable that we do not hear this voice, they say the cause of this is that this sound is present to us as soon as we are born, so that it cannot be manifest by comparison with the contrary silence; for voice and silence are discerned each by the other.* He adds, moreover, the comparison with the ears of smiths, accustomed to the noise; by this he seems to allude to that workshop in which Pythagoras learned the harmonic proportions from the sound of hammers, on the testimony of Macrobius, book 2 on the *Dream of Scipio*, chapter 1. Aristotle's words at the end of text 52 are: *Therefore, just as to blacksmiths, because of habituation, it seems to make no difference, the same also happens to all men. These things, however, as was said at the beginning, are said elegantly and musically; but it is impossible that this should in reality be so.* The Ciceronian comparison, drawn from those who went deaf at the Catadupa because of the roar of the Nile, and to which Bede and Zarlinus subscribe, was already adduced in number 3.

V. [Margin: Authors against a real sound of the heavens.] The contrary opinion, however, which excludes a real sound from heaven, was followed, together with the Philosopher, by the Peripatetics, *De caelo* 2, from text 53 to 56; by the Conimbricenses, *De caelo* 2, chapter 9, question 1; Amicus, treatise 5 on *De caelo*, question 6, doubt 10; Abulensis [Alonso Tostado] on chapter 10 of Joshua, question 14; Vallesius, *De sacra philosophia*, chapter 36; Kepler, *Harmonics*, book 5, chapters 4 and 8; Serarius on chapter 10 of Joshua, question 13; Lorinus on Psalm 18, at verse 5, *Their sound has gone out into all the earth*; likewise Sixtus Senensis, book 5 of the *Bibliotheca sancta*, annotation 105; and Sanctius [Gaspar Sánchez] on chapter 38 of Job, verse 37; and not a few of the Fathers, especially St Basil, in the scholia on Psalm 18, where, explaining *There are no speeches nor words*, he adds: *Neither do they utter speech nor bring forth any word, but by the mere display of their order they call the whole earth and the sea to the praise of God*; and in homily 1 on the *Hexaemeron* he calls the opinion of Pythagoras a crafty imposture, flabby with ruinous decay. But St Ambrose treats it more fully in book 2 of the *Hexaemeron*, chapter 2. Having reported the opinion of the philosophers, who asserted that a most sweet sound is given forth

by the impulse and motion of the celestial globes but is not perceived by us, just as the roar of the Nile is not perceived by the inhabitants of the Catadupa, he adds: *But the truth itself answers them easily. For we who hear thunder, produced by the collision of clouds — would we not hear the revolutions of such great orbs, which, just as they are thought to be carried with a greater motion, so would rouse more vehement sounds?* Although this holy Doctor brings forward a different reason, for this sound's not being imperceptible, and does not resolve it, while he adds: *They add, moreover, that this sound does not reach the earth so that men, captivated by its sweetness and charm — which that most swift motion of the heavens produces from the eastern parts all the way to the west — should not abandon their own business and works, and everything here remain idle, through a certain rapture of the human mind towards the heavenly sounds.* We have already brought forward this reason, drawn from the final cause, from Philo in number 2. The same St Ambrose, in the book *On Isaac and the Soul*, chapter 7, on Aquila's version "Sounding like the Sun", adds: *By this the turning of the heavenly axis, and the courses of the Sun, Moon and stars — the concert of the globes — seem to be expressed. It is held even by some of our own; and since it has not found belief, it does not seem out of place, at least for the charm of its sweetness.* And in the preface to the Psalms of David he says: *The talk of certain people has it that the very axis of heaven turns with a certain sweetness of perpetual concert, so that, if habituation allowed, its sound would be heard in the farthest parts of the earth*, and so on. From this it is clear that he speaks from another's opinion. Besides these, St Irenaeus in his book *Against Heresies*, and St Epiphanius in book 1 of the *Panarion*, also list this among the heresies of the Marcosians: that they ascribed, that is, a real sound to the heavens.

VI. [Margin: Arguments against a real sound of the heavens.] Aristotle's arguments, for their part, are these. In *De caelo* 2, texts 53 and 54, he says: *If the heavens gave forth as great a sound as would befit them, then, even though we did not perceive it by the sense of hearing, we would still perceive it by touch, so to speak, because excessive sounds destroy even inanimate bodies — as the sound of thunder shatters certain stones, or makes them tremble and shakes them. Since, therefore, we perceive such a sound neither by hearing nor by any other sense, we more reasonably say that there is no such sound.* Again, in texts 54, 55 and 56, he teaches that the stars themselves do not produce a sound, because they are not moved of themselves but with the motion of their orbs, as a sailor moves with the motion of his ship; that the orbs themselves are not in air or in fluid fire, or in any medium suited to sound; and, finally, that *in that which is carried continuously and makes no blow, it is impossible for a sound to arise*. For not just any mutual rubbing of two bodies suffices for sound, especially if their surfaces are very highly polished; what is required is a cleaving of air or water, or of some intervening fluid body, struck by an interrupted motion. The Conimbricenses add that, in that case, those who had lacked the use of hearing for some years, through an injury to the organ corrupted by some disease, would perceive the sound of the heavens when they recovered their hearing. I add, for my part, that just as the perpetuity of the stars' motion does not prevent the eye from discerning it, so neither

would the perpetuity of a sound prevent us from hearing it; nor is silence or rest required for this. It seems to me, however, that if any sound were after all produced in the fluid aether, which extends as far as the sphere of the fixed stars — whether by the Firmament itself or by the bodies of the planets themselves — it could not reach us, both because of the thinness of the aether itself, which yields to their motion with almost no resistance, and because of their huge distance from us. Kepler, however, who holds the sphere of the fixed stars to be immobile, settles the matter of the others thus in book 5 of the *Harmonics*, chapter 4: *Now there are no sounds in heaven, nor is the motion so turbulent that a whirring is drawn out of the friction of the heavenly air.*

CAPVT III.

Chapter 3.

De Proportionibus, & præcipuè de Harmonicis.

On proportions, and especially on harmonic proportions.

I. [Margin: Aliquot and aliquant parts.] A PART, according to Euclid, book 5, is a magnitude that measures a greater magnitude as its whole. If it measures it perfectly, so that when repeated some number of times it exactly equals its whole, it is called an *aliquot part* [pars aliquota]: as 2 is with respect to 8. But if, when repeated, it exceeds its whole or falls short of it, as 2 does with respect to 9, it is called an *aliquant part* [pars aliquanta]; for the number two taken four times falls short of nine, but taken five times exceeds it.

[Margin: What ratio and proportion are.] A *ratio* is the mutual relation [habitudo] of two magnitudes of the same kind with respect to quantity. A *proportion*, on the other hand — which the Greeks call ἀναλογίαν [Greek: analogian, "analogy"] and some Latin writers *proportionalitas* — is a likeness of ratios. Thus the relation of 2 to 4 taken by itself, or of 3 to 6, is called a ratio; but the likeness of relation between the ratio of 2 to 4 and the ratio of 3 to 6 — that is, the fact that 2 is to 4 as 3 is to 6 — is called a proportion. It has, however, now become customary for a ratio itself to be called a proportion as well.

[Margin: Rational and irrational proportion.] Proportion is divided, first, into *rational* and *irrational*. A rational proportion is one that can be expressed in numbers, such as the proportion of a line three palms long to a line of six palms, since it can be expressed by the numbers 3 and 6. Hence such a proportion holds between two commensurable quantities, that is, quantities having some common aliquot part which can measure each of them exactly — as unity is such a part with respect to any whole number. And therefore between numbers, or discrete quantities, there cannot fail to be commensurability and rational proportion. An irrational proportion is one that cannot be expressed in numbers; it is found only between continuous quantities. Euclid demonstrates, at the end of book 10, that such a proportion, or incommensurability, holds between the diagonal and the side of any square: for no aliquot part can be

assigned common to those lines, nor can their proportion be expressed in any numbers.

[Margin: Proportion of equality and of inequality, greater or lesser.] Second, proportion is divided into the proportion of *equality*, such as holds between 20 and 20 or between 100 and 100, and of *inequality*, which holds between two unequal quantities, as between 20 and 10. The latter is subdivided into the proportion of *greater* and of *lesser inequality*, according as the greater quantity is compared with the lesser, as antecedent with consequent — as 4 with 2 — or the lesser with the greater, as 2 with 4, putting 2 in the antecedent of the proportion and 4 in the consequent.

[Margin: The 5 kinds of rational proportions of inequality.] Third, rational proportion, of greater as well as of lesser inequality, is subdivided into five kinds, of which the first three comprise the simple and the other two the compound. The simple kinds of greater inequality are the *multiple*, the *superparticular* and the *superpartient*; the compound are the *multiple superparticular* and the *multiple superpartient*. If you add to these the prefix *sub*, you will have as many kinds of rational proportion of lesser inequality, and they will be, and will be called, the *submultiple*, *subsuperparticular*, *subsuperpartient*, *submultiple superparticular* and *submultiple superpartient*.

II. [Margin: Multiple proportion.] A *multiple* proportion is the relation of a greater quantity to a lesser which measures that greater exactly, such as the proportion between 4 and 2, between 20 and 4, between 100 and 5. Its species are determinate and run on to infinity — namely double, triple, quadruple and so on — according as the greater quantity contains the lesser twice, three times, four times, and so on.

[Margin: Superparticular proportion.] A *superparticular* proportion is when the greater quantity contains the lesser once only, and in addition one aliquot part of that lesser — whether this part is a half, a third or a fourth, and so on to infinity. The species of these proportions are distinguished by the particle *sesqui*, as their characteristic mark, with the number of the aliquot part added. Thus a proportion is called *sesquialtera* when the greater contains the lesser once and in addition half of the lesser, as is the proportion of 3 to 2, or 9 to 6, or 30 to 20. In Greek it is called ἡμιόλιος [Greek: hēmiolios, "half-and-whole"], because ἥμη [recte: ἡμι-] [Greek: hēmi-, "half"] means half and ὅλος [Greek: holos, "whole"] means whole, as if you were to render it *totimedia* or *totidimidia*, "whole-and-a-half". But if the greater contains the lesser once and besides a third, or a fourth, a fifth, a hundredth or a thousandth part of the lesser, the proportion is called *sesquitertia*, *sesquiquarta*, *sesquiquinta*, *sesquicentesima*, *sesquimillesima*, and so on for the rest. It is worth setting out here some examples of them, comparing the upper number with the lower.

Superparticularium Proportionum Exempla.

Examples of superparticular proportions.

Proportion					
Sesquialtera, ἡμιόλιος [hēmiolios]	3 / 2	9 / 6	15 / 10	36 / 24	45 / 30
Sesquitertia, ἐπιτρίτη [epitritē]	4 / 3	12 / 9	20 / 15	24 / 18	100 / 75
Sesquiquarta	5 / 4	15 / 12	30 / 24	60 / 48	100 / 80

Reſiduum Tabulæ Præcedentis.
The rest of the preceding table.

Proportion					
Sesquiquinta	6 / 5	18 / 15	30 / 25	48 / 40	90 / 75
Sesquisexta	7 / 6	21 / 18	35 / 30	70 / 60	98 / 84
Sesquiseptima	8 / 7	24 / 21	40 / 35	72 / 63	96 / 84
Sesquioctava	9 / 8	27 / 24	45 / 40	72 / 64	99 / 88
Sesquinona	10 / 9	30 / 27	40 / 36	80 / 72	100 / 90
Sesquidecima	11 / 10	44 / 40	77 / 70	121 / 110	132 / 120
Sesquicentesima	101 / 100	202 / 200	303 / 300	404 / 400	505 / 500

III. [Margin: Superpartient.] A *superpartient* proportion is when the greater quantity contains the lesser quantity once only and, in addition, several aliquot parts of the lesser which, taken together, do not make up a single aliquot part, unity excepted; otherwise it would turn out to be superparticular. Such is the proportion between 8 and 5. The species of this proportion are usually distinguished by two characteristic marks. One of them, expressed by the particles *bi-*, *tri-*, *quadri-*, *quintu-*, *sextu-*, *septu-*, *octu-* and so on, indicates the number of aliquot parts that the greater quantity contains; the other names the proportion of those aliquot parts to the lesser quantity, which they measure. For example, the proportion of the number 8 to 5 is called *supertripartiens quintas* [supertripartient of fifths], because 8 contains 5 once and, besides, three fifth parts of five, which are three units; and so for the rest. Look at some examples of them in the following table, comparing the upper number with the lower.

Exempla Proportionis Superpartientis.
Examples of superpartient proportion.

Proportion				
Superbipartiens tertias	5 / 3	20 / 12	50 / 30	100 / 60
Superbipartiens quintas	7 / 5	35 / 25	63 / 45	98 / 70
Supertripartiens quartas	7 / 4	21 / 12	70 / 40	98 / 56
Supertripartiens quintas	8 / 5	40 / 25	80 / 50	96 / 60
Superquadrupartiens quintas	9 / 5	27 / 15	49 / 35	99 / 55
Superquintupartiens sextas	11 / 6	44 / 24	77 / 42	99 / 54
Supersextupartiens septimas	13 / 7	65 / 35	91 / 49	130 / 70
Superseptupartiens octavas	15 / 8	60 / 32	90 / 48	120 / 64
Superoctupartiens nonas	17 / 9	51 / 27	85 / 45	170 / 90
Supernoncupartiens decimas	19 / 10	57 / 30	95 / 50	190 / 100

Proportiones Compoſitæ.

Compound proportions.

IV. [Margin: Multiple superparticular.] A *multiple superparticular* proportion is when the greater quantity contains the lesser some number of times — say twice, three times or four times, and so on — and in addition one aliquot part of the lesser. Such is the proportion of 9 to 4: for nine contains four twice and, besides, a fourth part of four. It is therefore called *dupla sesquiquarta* [double sesquiquartal]: double because it contains the lesser twice, *sesquiquarta* because it contains in addition a fourth part of the lesser. The species of this proportion are therefore determinate and run on to infinity, compounded from the species of the multiple — double, triple, quadruple and so on — and from the species of the superparticular, namely *sesquialtera*, *sesquitertia*, *sesquiquarta* and so on. When these are combined, the result is the proportion *dupla sesquialtera*, *dupla sesquitertia*, *dupla sesquiquarta* and so on, or *tripla sesquialtera*, *tripla sesquitertia*, *tripla sesquiquarta* and so on, and likewise for the rest. Look at some examples of them in the following small table, comparing the upper number with the lower.

Exempla Proportionis Multiplicis Superparticularis.

Examples of multiple superparticular proportion.

Proportion				
Dupla sesquialtera	5 / 2	25 / 10	60 / 24	100 / 40
Dupla sesquitertia	7 / 3	35 / 15	70 / 30	98 / 42
Tripla sesquialtera	7 / 2	35 / 10	70 / 20	98 / 28
Tripla sesquitertia	10 / 3	40 / 12	60 / 18	100 / 30
Tripla sesquiseptima	22 / 7	66 / 21	110 / 35	176 / 56
Decupla sesquitertia	31 / 3	93 / 9	248 / 24	341 / 33

V. [Margin: Multiple superpartient.] A *multiple superpartient* proportion is when the greater quantity contains the lesser some number of times and, in addition, aliquot parts of the lesser that do not make up a single aliquot part. Such is the proportion of 11 to 3: for eleven contains three three times and, besides, two third parts of three, which do not make one aliquot part of three; otherwise the proportion would be multiple superparticular. The species of this kind are determinate and run on to infinity, and they take their names partly from the species of the multiple proportion — namely from double, triple, quadruple and so on — and partly from the species of the superpartient proportion. Combining the names in this way gives *dupla superbipartiens tertias*, *dupla supertripartiens quartas*, *dupla superquadripartiens quintas* and so on; likewise *tripla superbipartiens tertias*, *tripla supertripartiens quartas* and so on. See a specimen of them in the following table, comparing the upper number with the lower.

Exempla Proportionis Multiplicis Superpartientis.

Examples of multiple superpartient proportion.

Proportion				
Dupla superbipartiens tertias	8 / 3	32 / 12	80 / 30	96 / 36
Dupla supertripartiens quartas	11 / 4	44 / 16	110 / 40	220 / 80
Dupla superquadrupartiens quintas	14 / 5	42 / 15	140 / 50	280 / 100
Tripla superbipartiens tertias	11 / 3	33 / 9	110 / 30	220 / 60
Tripla supertripartiens quartas	15 / 4	60 / 16	90 / 24	120 / 32
Dupla superquintupartiens sextas	17 / 6	51 / 18	85 / 30	170 / 60
Quintupla supertripartiens quintas	28 / 5	56 / 10	84 / 15	280 / 50

VI. That there cannot be more rational proportions than the five already mentioned, of greater as well as of lesser inequality, is established as follows. Any commensurable quantities whatever (between which there is a rational proportion) have to one another the proportion that a number has to a number, as Euclid demonstrated in book 10 of the *Elements*, proposition 5; and a greater number cannot be compared with a lesser in any ways other than the five already mentioned. For either the greater contains the lesser some number of times exactly, that is, with no remainder; or it contains it once and, besides, a single aliquot part of the lesser; or it contains it once and several aliquot parts of the lesser which do not make one aliquot part; or it contains the lesser several times and a single aliquot part of the lesser; or, finally, it contains the lesser several times and, besides, several aliquot parts of the lesser which do not make one aliquot part. As for the denominators of proportion, see our Clavius on book 5 of Euclid, from page 540 in my copy, of the Roman edition of the year 1589.

De Proportionalitate Arithmetica, Geometrica, & Harmonica.

On arithmetic, geometric and harmonic proportionality.

VII. Boethius, Iordanus Nemorarius [Jordanus de Nemore] and many other arithmeticians call the proportionalities already mentioned *medietates* [means].

[Margin: Arithmetic proportionality.] ARITHMETIC proportionality, or mean, is when three or more numbers proceed by the same difference, as do these numbers: 4, 7, 10, 13, 16; for each of them exceeds its antecedent by three. If this happens continuously, it is called continuous proportionality; but if the numbers are set with a jump and an interruption — for example 4, 7 and 8, 11 and 30, 33 — it is called discrete.

[Margin: Geometric proportionality.] GEOMETRIC proportionality, or mean, is when three or more numbers keep the same proportion among themselves; and this is properly an *analogia* [analogy], or proportionality. Such is the subtriple in these numbers: 2, 6, 18, 54, 162. If it proceeds continuously in this way it is called continuous; but if it is interrupted it is called discrete, as in these: 2, 6 — 54, 162.

[Margin: Musical proportionality.] HARMONIC, or musical, proportionality or mean is when three numbers are so arranged that the proportion of the greatest to the least is the same as that of the difference between the two greater

to the difference between the two lesser. Such is the case in these numbers: 3, 4, 6. For the proportion of 6 to 3 is double, while the difference of the greatest is 2 and of the least 1, between which the proportion is likewise double. But the numbers already mentioned proceed neither by the same difference, as happens in arithmetic proportionality, nor by the same proportion, as in geometric. Another example of harmonic proportionality is in these numbers: 42, 12, 7. It is called musical, or harmonic, because it mostly contains those proportions in which the musical consonances consist. For in the first example, between 6 and 4 there is the *sesquialtera* proportion, which makes the consonance called *diapente*, or the fifth; between 4 and 3 there is the *sesquitertia* proportion, which makes the consonance called *diatessaron*, or the fourth; and finally, between the extreme numbers 6 and 3 there is the double proportion, which makes the consonance called *diapason*, or the octave; and so with most of them. Kepler, however, in book 3 of the *Harmonics*, chapter 3, contends that the definition of harmonic proportion already mentioned is empty, because he takes the cause of harmony from the division of the circle into aliquot parts, as will be said in chapter 4.

VIII. [Margin: Properties of the three proportionalities already mentioned.] Further, the three proportionalities already mentioned are distinguished from one another by several notable properties, which Clavius lists on book 5 of Euclid, from page 555. [Margin: 1st property.] The *first* is that in the geometric the proportion of the greatest of the three numbers [?] to the middle is the same as that of the middle to the least; in the arithmetic, by contrast, the proportion of the greatest to the middle is less than that of the middle to the least; while in the musical the proportion of the greatest to the middle is greater than that of the middle to the least. [Margin: 2nd property.] The *second* is that the arithmetic has equal differences between its terms but unequal proportions; the geometric, on the contrary, unequal differences between its terms but equal proportions; and the harmonic, lastly, neither equal differences nor equal proportions. [Margin: 3rd property.] The *third* is that in the arithmetic the sum of the extremes is double the middle; in the geometric and harmonic, however, the sum of the extremes exceeds double the middle by the amount by which the difference of the greater exceeds the difference of the lesser. [Margin: 4th property.] The *fourth* is that in the geometric the number produced by multiplying the first into the third is equal to the square of the middle; in the arithmetic the extremes multiplied together produce a number that falls short of the square of the middle by the number made by multiplying the difference of the lesser into the difference of the greater. [Margin: 5th property.] In the harmonic, finally, the number produced by multiplying the extremes together exceeds the square of the middle by the number made by multiplying the difference of the lesser by the difference of the greater. For the rest, see Clavius: he on page 597, and likewise Kircher in book 3 of the *Musurgia*, chapter 2, teach how to find three numbers in harmonic proportionality, as follows.

CAPVT III.

Tres Numeros in Proportionalitate Harmonica reperire.

To find three numbers in harmonic proportionality.

From three numbers in arithmetic proportionality, multiply the middle by the extremes, and you will have the extremes of a harmonic proportionality; the extremes of the arithmetic, multiplied by each other, produce the middle of the harmonic, as you see in the four following examples.

Arithmet.	1 2 3	3 7 11	4 6 8	10 60 110
Harmon.	2 3 6	21 33 77	24 32 48	600 1100 6600

How such proportions are continued, and how other problems bearing on this are solved, are set out in the same places by Clavius and Athanasius Kircher; by Zarlinus, part 1 of the *Harmonic Institutions*, from chapter 31 to 44; and by Ludovicus Folianus [Lodovico Fogliano], *Musica theorica*, section 1, especially from chapter 9. For we are not doing that now; we are only pointing out the sources from which one may judge whether harmonic proportion or proportionality — the musical mean — is found, or is to be sought, in the motions and intervals of the stars. For, as Petrus de Apono [Pietro d'Abano] said on the *Problems* of Aristotle, *the mean is what produces harmony*: of three strings, the middle one, stretched according to the ratios of the extreme ones, produces a concert most sweet to the ears. I am pleased, however, to add at the end of the chapter, in each of the five kinds of proportion, three examples of harmonic proportionality set up among three terms, as can be seen in the following table.

		Radices	Proportionalitates Harmonicæ
In the multiple genus, from	*Dupla*	1 2	3 4 6

CAPVT IV.

Chapter 4.

De Conſonantiarum ac Diſſonorum Interuallorum Inuentoribus, Inuentione, Numero, & Nomenclatura : deq. Monochordi ſimplici diuiſione.

On the inventors, the discovery, the number and the naming of the consonances and of the dissonant intervals; and on the simple division of the monochord.

I. How close a kinship there is between the pastoral art, the hammering or smith's art, and the art of music can be traced back to their very first origin, since it is agreed that these three arts were born in one and the same house, that of Lamech, who was of the line of Cain, in births close together, if not in a single birth. For the sacred writer Moses relates of Lamech in Genesis 4: [Margin: The origin of music from Jubal.] *Who took two wives, the name of the one Adah, and the name of the other Zillah. And Adah bore Jabal [?], who was the father of those who dwell in tents and of herdsmen; and his brother's name was Jubal, who was the father of those who sing to the harp and the organ. Zillah also bore Tubal-cain, who was a hammerer and smith in every work of brass and iron.* It is as though even then music were exerting its powers between the soft kind of songs and sounds that suits herdsmen and the hard kind that suits those who hammer metals; and we were given to understand that neither gentle nor fierce natures can be rightly ruled or tamed without some harmony. Although Berosus the Chaldean and Josephus the Hebrew affirm that the musical consonances were discovered by Jubal while he listened with an attentive ear to the sound of Tubal-cain's hammers, it is said that afterwards — whether that art was shipwrecked in the Flood or lay hidden among a few Hebrews — it arose again under Mercury, the inventor of the tortoise-shell lyre, as Diodorus Siculus and Lucian hold; or under Apollo, the inventor of the lyre, as Lactantius prefers; or from Amphion, as Pliny the Elder has it. At length, however, it was reborn at its original birthplace, in a smithy, and, as if half-buried, it was roused again by the sound of hammers and revived.

[Margin: Pythagoras, the second inventor of the consonances.] For, as *Macrobius* reports (book 2 on the *Dream of Scipio*, chapter 1), and Boethius after him, Pythagoras was passing by a workshop in which smiths were softening red-hot iron with blows, and heard something harmonious strike his ears from the sounds of the hammers answering one another in a fixed order and from the alternation of a high and a low sound. To find out where that consonance came from — whether from the strength of the hammerers' arms and their force, or from the weight of the hammers themselves — he ordered the smiths

to exchange hammers among themselves. When he heard the same harmony, he did not doubt that it was to be ascribed to the difference of the weights, especially since, when other weights were added, he had obtained different sounds that were not so consonant. Having therefore examined the weights of the hammers, he found that sound stands to sound as weight stands to weight of the same material. Then, turning from the hammers to strings made of sheep's gut and ox sinews, he hung weights on them in the proportion he had detected in the hammers; and when these too gave back a similar consonance, he laid down that universal axiom: [Margin: The musical axiom.] *As magnitude is to magnitude in matter of the same species, so is sound to sound.*

II. Further, among the many consonances that Pythagoras found by the device we have described, he accepted only those that are simplest; for, as Heraclides says in his *Introduction to Music*, he wished to remove rashness and inconstancy from things and, like a bee, to sip the purest and choicest dew of concords. He therefore held that the consonances of voices were to be sought not from the untrustworthy and inconstant judgement of the ears, but from fixed causes and from the laws of numbers: for he thought simplicity the mother of constancy, and composition and mixture the seedbed of inconstancy and uncertainty. Hence it came about that he received into the canon only those consonances that arise from multiple or superparticular proportion, up to the quadruple inclusive and no further: namely those between 2 and 1, between 3 and 2, between 4 and 3, between 3 and 1, and between 4 and 1. Boethius too lists almost only these consonances (book 2, from chapter 16), with the tone added — not as a consonance, as he himself affirms in book 1, chapter 16 — namely in the ratio of 9 to 8, or 18 to 16, and so on. Further, from that quaternary of numbers within which Pythagoras confined himself arose the *Tetractys*, or Pythagorean Quaternary, by which, as by a perennial fountain of the intellectual beauty of the soul, they used to swear — or rather, by him who through the Tetractys displayed the perpetual perfection of the soul. On this Zarlinus [Gioseffo Zarlino] writes much and learnedly in part 2 of the *Harmonic Institutions*, chapter 2, and Kepler in book 3 of the *Harmonics*, from page 4.

[Margin: Musicians called Canonists and Harmonists.] From the same source arose the sect of those musicians who were called *Canonici* [Canonists], because in determining the harmonic intervals and consonances they gave more weight to the ratios of numbers than to the senses; they were also called Pythagoreans. Opposed to this sect was the sect of the Harmonists, or Aristoxenians, who attributed more to the sense of hearing than to the ratios of numbers abstracted from sensible matter. Between them *Ptolemy*, taking a middle way, gave as much to the senses as Aristoxenus did and as much to reason as Pythagoras did, and therefore approved more consonances than Pythagoras, but not all those that Aristoxenus approved. So Ptolemy, in book 1 of the *Harmonics*, chapter 1, having said that the harmonic faculty of the soul consists in discerning the difference of lowness and highness of sounds, and that sound is an affection of struck air, adds: [Margin: Ptolemy, the reconciler of sense with reason.]

Hearing and reason, then, are the judges of harmony, but not on the same terms: hearing is related to the affection as a whole and as it is in itself, reason to its form and its cause. For in general it is proper to the senses to find the approximate and to receive the exact, whereas reason, on the contrary, receives the approximate and finds the exact. Then, from chapter 6, he examines and corrects the Pythagoreans; from chapter 9, the Aristoxenians; and from chapter 13, Archytas the Pythagorean; and from chapter 15, and through the whole of book 2, he labours to reconcile reason with hearing. The same author, in book 1, chapter 2, having compared the harmonist with the astronomer in this respect — that each must investigate a priori the reasons of the apparent motions in such a way that what appears to the senses is preserved — adds: *But first of all, both the Pythagoreans and the Aristoxenians were deceived. For the Pythagoreans, not following the comparison made by the ears in all the cases where they ought to have, fitted to the differences of sounds ratios that agree very poorly with some experiments made by the senses; and so they brought calumny upon this judge, that is, upon reason, among the men of the other sect. The Aristoxenians, on the other hand, giving very great weight to what they had received through the senses, as it were misused reason in passing, and so on.*

III. But not even Ptolemy himself emended Pythagoras and Aristoxenus in such a way as to satisfy later musicians. For since the Pythagoreans received only five consonances, called *diapason*, *dia-* tessaron*, *diapente*, *diapason diapente* and *disdiapason* — or, as the moderns say, the octave, fifth, fourth, twelfth and fifteenth — and the Aristoxenians had added the *ditonus*, the *semiditonus*, and the major and minor *hexachord* — that is, the major third, the minor third, the major sixth and the minor sixth — Ptolemy rejected these last as discordant, although all musicians with good ears accept them. [Margin: Ptolemy's errors, and the cause of the errors.] Conversely, he admitted among the consonances the diapason with the semiditonus, the diapason with the ditonus, and the diapason diatessaron — that is, to speak with the practitioners, the minor tenth, the major tenth and the eleventh, which are concordant. But besides these he added the interval between 6 and 7, and the one between 7 and 8, and others like them, which the ears and the practice of singing abhor; and he omitted the minor and major thirteenth, which all musicians accept today. Kepler (book 3 of the *Harmonics*, page 8) holds that the cause of Ptolemy's error was that he sought the principles of the consonances from abstract numbers, insofar as they are numbers; and yet no precise reason can be given by numbers why these numbers 1, 2, 3, 4, 5, 6, and so on, concur in the harmonic intervals, while 7, 11, 13 and the like do not. For what delights the hearing in music comes from sound, and sound is produced from the continuous, not the discrete, quantity of bodies. Therefore, as Zarlinus notes (part 1, chapter 41), and Valgulius [Carlo Valgulio] on Plutarch's *Music*, and Kepler (book 3 of the *Harmonics*, page 9), the causes of the consonances must be sought from continuous quantity, since number is not their proximate cause, but the proportion between high and low sounds — granted that this proportion, being rational, is expressed by numbers,

and that the differences of sounds are found more exactly by numbers than by dividing a continuous quantity with compasses.

IV. [Margin: From what source Kepler determined the consonances.] For the reasons already mentioned, therefore, Kepler, searching for the cause of the consonances in continuous quantity, sought it from the divisions of the circle into aliquot parts that are made geometrically and scientifically — that is, from regular plane figures that can be demonstrated — in such a way that those sides of the figures which are knowable and have their own demonstration are consonant when compared with the whole circumscribed circle; as we shall set out in the Scholia of this chapter. Meanwhile let us set out the more common doctrine.

Definitiones & Axiomata Quædam ad Harmonicen ſpectantia.

Some definitions and axioms bearing on harmonics.

V. [Margin: What consonance is.] *Consonance*, in Greek συμφωνία [symphōnia, "sounding together"], is a ratio of number between a high and a low sound, pleasant to hear, as is gathered from section 19 of the *Problems* of Aristotle; or, as *Severinus Boethius* defines it (book 1, chapter 8): *it is a mixture of a high and a low sound, falling sweetly and uniformly on the ears.* To this definition subscribe *Glareanus* (book 3 of the *Dodecachordon*, chapter 9), *Zarlinus* (part 2 of the *Harmonic Institutions*, chapter 12) and *Kircher* (book 3 of the *Musurgia*, in the preface). *Boethius*, however, said otherwise: *Consonance is the concord, brought into one, of voices unlike one another.* He did this, as some think, so that by the first definition he might adhere to Plato, who referred consonance to likeness, and by the second to Nicomachus, who referred it to unlikeness. But *Daniel Barbarus* [Daniele Barbaro], on book 5 of Vitruvius, chapter 4, said: *Consonance, or concent, is a tempered mixture of low and high sounds which reaches the ears with pleasure, arising from a comparison either multiple or superparticular.* [Margin: Dissonance.] According to Boethius and Kircher, *dissonance*, in Greek ἀσυμφονία [asymphonia, "not sounding together"], *is the harsh and unpleasant striking upon the ear of two sounds mixed with each other.*

[Margin: What a phthongus is.] *Phtongus*, in Greek φθόγγος [phthongos, "note"], is, according to Boethius, Glareanus and Kircher in the places cited above, *the fall of the voice*; or a certain definite sound of a single string, which, if it is tuneful and suited to melody, is called ἐμμελὲς [emmeles, "melodic"], and if otherwise, ἐκμελὲς [ekmeles, "unmelodic"]. For Euclid it is *a concordant fall of the voice upon one pitch*; but for Proclus it is *a sound lacking interval*.

[Margin: Unison.] The *unison*, in Greek ἰσόφωνος [isophōnos, "equal-sounding"], is a sound entirely equal to itself or to another; or the repetition of the same sound or voice; or the twin sound of equal strings or voices. As such, it is incapable of slackening and tightening, because it is in music what unity is in arithmetic and the point in geometry.

[Margin: Harmonic space and interval [?].] *Harmonic space* is a body of sounds compared with another similar body that is tighter or slacker. A harmonic *interval*, in Greek διάστημα [diastēma, "interval"], is a certain mutual relation of the spaces of the low and the high; or the distance between a low and a high sound.

[Margin: What a high and a low sound are.] A *high sound* is one produced by the frequent and quick vibration of air compressed through the collision of bodies; a *low* one, by the slow and sluggish vibration of slack air through the collision of bodies. This causal definition can be taken only comparatively, since not even the high and the low are said absolutely, but comparatively, just like large and small, fast and slow, and so on. On this occasion those skilled in music agree on the four following axioms. [Margin: Four musical axioms on the high and the low.] 1. *A part, compared with the whole, gives a higher sound.* 2. *A harmonic whole, compared with its part, gives a lower sound*: namely because the air is struck more tightly by the part than by the whole, and vibrates more frequently. 3. *A high sound consists of more motions than a low one.* 4. *The slack, compared with the taut, gives a lower sound.*

[Margin: Tension of the voice, intension, and so on.] *Tension*, in Greek τάσις [tasis, "tension"], is the state of a voice or string set at a pitch fit for singing. *Intension* of a voice or string, in Greek ἐπίτασις [epitasis, "tightening"], is the motion from a low to a high sound; *remission*, in Greek ἄνεσις [anesis, "slackening"], is the motion from high to low. *Elevation*, in Greek ἄρσις [arsis, "raising"], is the pronunciation of a syllable or word with the acute accent; *deposition*, or θέσις [thesis, "setting down"], is pronunciation with the grave accent.

[Margin: What a simple consonance is.] A *simple consonance* is one that does not resolve into another consonance; a *composite* one is one that resolves into two consonances. On this account the *diapason*, *diapente* and *diatessaron*, and also the *ditonus*, the *semiditonus* and the major and minor *hexachord*, are called simple; whereas the *diapason diapente*, the *disdiapason*, the *ditonus* with the *diapente*, and others of this kind are called composite.

[Margin: Perfect consonance.] A *perfect consonance* is one that so delights the hearing that the appetite comes to rest in it and desires nothing further; an imperfect one, when it does not delight so much as to keep the hearing from desiring something further — as *Folianus* teaches (section 2 of the *Musica theorica*, chapter 5). Further, among the perfect consonances themselves there are certain degrees. Those that arise from multiple or superparticular proportion, do not exceed the number three, and are simple, are the most perfect of all and in the first degree: namely the *diapason*, whose proportion is 2 to 1, and the *diapente*, whose proportion is 2 to 3 — although of these two the diapason is the more perfect. Those that arise from the multiple or superparticular genus, but extend to the number four, or stay within three but are composite, are in the second degree: namely the *diatessaron*, whose proportion is 4 to 3, the *diapason diapente*, that is 3 to 1, and the *disdiapason*, that is 4 to 1. Lastly, in the third

degree are those that are simple and arise from the superparticular genus of proportion, but extend beyond four up to six inclusive: such are the *ditonus*, whose proportion is 5 to 4, and the *semiditonus*, whose proportion is 6 to 5. All the rest are imperfect, either because they do not arise from the multiple or superparticular genus, or because they lie outside the senary. For although not all the proportions of numbers contained within the senary produce perfect consonances, all perfect consonances, considered in their least and radical terms, are nevertheless contained within the senary; [Margin: Praises of the senary.] which is why *Zarlinus* (part 1 of the *Harmonic Institutions*, chapters 15 and 16) and *Athanasius Kircher* (book 4 of the *Musurgia*, chapter 4, from page 186) deservedly extol them. Among the perfect consonances, those that are simple arise from the proportions between the numbers of the senary taken in order, as you see in the following small table — granted that Zarlinus later excludes the ditonus and semiditonus from the perfect, that is, from the more perfect, consonances.

Consonance	Numbers
Diapason	(1 2
Diapente	(2 3
Diatessaron	(3 4
Ditonus	(4 5
Semiditonus	(5 6

But Kepler (book 3 of the *Harmonics*, chapter 2) sets the perfect consonances at only 6, or 7 with the unison, and (chapter 12) the imperfect at 6.

[Margin: What a dissonant interval is.] Dissonant intervals that are nonetheless musical and concordant are the differences of the consonances, or parts of them, which, although considered in themselves they are not consonances, are nevertheless steps by which one ascends or descends from one consonance to another; and they serve aptly for distinguishing and composing the consonances, as cartilages serve the bones. [Margin: How the difference of consonances is investigated.] Further, to find the difference between two consonances and assign to it its species of proportion, the greater number of one consonance must be multiplied by the lesser number of the other, and again the greater number of the other consonance by the lesser of the other; for the two numbers so produced will be the terms of the proportion sought, that is, the difference of those consonances. For example, let the difference be sought between the diapente, that is 3, 2, and the diatessaron, that is 4, 3. Multiplying 3 by 3 gives 9; multiplying 2 by 4 gives 8. This proportion of 9 to 8, then — the sesquioctave — is the difference between the diapente and the diatessaron, and it is the one we shall show below to be called the major tone; and so with the others.

VI. It remains for us to gather into a table the perfect and the imperfect consonances, and then the dissonant but concordant intervals, omitting the unison, which is the principle of the consonances, not a consonance. [Margin: Explanation of the following tables.] In this table we shall set the Graeco-Latin,

Greek and Italo-Latin names; then the numbers of the proportions in their least and radical terms. If each of these two numbers is multiplied by the same number, other consonances of the same species can be had, finite but without end: thus if you multiply the terms of the diapente, 3, 2, by 10, they will make 30, 20, between which there is likewise the same species of proportion and the same consonance. Finally we shall add both the denomination of the species of each proportion and the genus of the proportion itself, indicated by these five marks: M, S, s, MS, Ms. Of these, M signifies *multiple*; capital S, *superparticular*; small s, *superpartient*; MS, *multiple superparticular*; and Ms, *multiple superpartient*.

[Margin: Points to note in the nomenclature of the consonances.] Care must be taken, however, not to treat the words *diapason*, *diapente* and *diatessaron* as nominative cases of the singular number and inflect or decline them, as some unskilled people do, thus: diapason, diapasondos; diatessaron, diatessarondos; diapente, diapentes. For in Greek they are genitive cases of the plural number with the preposition διὰ [dia, "through"]; and so in Greek they are written διὰ πασῶν [dia pasōn]; διὰ πέντε [dia pente]; διὰ τεσσάρων [dia tessarōn]. The first of these means *through all*, or *around all*; the second, *through five*; and the third, *through four*. For the diapason goes through all the concords and contains radically within itself all the more perfect consonances; and because after seven strings we return to it, the practitioners call it the *octave*. The diapente is called the *fifth* because it lies between notes that stand five degrees of the strings apart, as will be clear from the diatonic system, which we shall set out in chapter 6, numbers 3 and 5; just as the diatessaron is called the *fourth*, the disdiapason the *fifteenth*, and so on. Finally, in the judgement of Macrobius (book 2 on the *Dream of Scipio*, chapter 1), the diapason consists of six tones; the diapente of three tones and a hemitone; the diatessaron of two tones and a semitone; the diapason diapente of nine tones and a hemitone; and the disdiapason of twelve tones. *Censorinus* agrees with him (*De die natali*, chapter 11); and that this is true will be clear from what is to be said in chapter 6, number 3, at the end of the diatonic system. With these things explained, here now is the table.

I. TABVLA CONSONANTIARVM.

Table 1: The consonances.

	Ordo	Græcolatina	Græca	Italo-latina	Termini in minimis num.	Species	Genus

II. TABVLA. INTERVALLA DISSONA, Sed Concinnitati feruientia continens.

Table 2, containing the dissonant intervals that nevertheless serve concinnity [concinnitas].

Nomenclatura varia	Termini minimi	Species	Genus
Tonus maior [major tone], ἐπόγδοος [epogdoos, "one-eighth over"]; to the practitioners the major or perfect second. It is the difference between the diapente and the diatessaron	9 8	Sesquioctava	S
Tonus minor [minor tone]; the imperfect second. It is the difference between the diatessaron and the semiditonus, or between the diapente and the major hexachord	10 9; 20 18	Sesquinona	S
Semitonium maius [major semitone]: the difference of the minor tone and the semiditonus. By some it is called ἀποτομὴ [apotomē, "a cutting-off"]	54 50	Superbipartiens vigesimasquintas	s
Semitonium minus [minor semitone]: the difference between the ditonus and the diatessaron, or between the diapente and the minor hexachord	16 15	Sesquidecimaquinta	S
Semitonium minimum [least semitone]: the difference between the ditonus and the semiditonus, or between the major and the minor hexachord. It is also called δίησις [diēsis], or the Pythagorean diesis, or the Pythagorean λεῖμμα [leimma, "remnant"], as in Boethius and Glarean. To Vitruvius and Capella it is the fourth part of a tone; to Aristotle, the smallest element of music	25 24	Sesquivigesimaquarta	S
Semitonium medium [middle semitone], in Herigone, following Euclid, and in Mersenne: namely, what remains if you subtract the major semitone from the major tone	135 128	Superseptupartiens centesimas vigesimasoctavas	s
Semitonium maximum [greatest semitone], in the same Herigone, in Euclid's *Music*	27 25	Superbipartiens vigesimasquintas	s

Nomenclatura varia	Termini minimi	Species	Genus
Diesis enharmonica [enharmonic diesis], so called by the same Herigone; but to Mersenne it is the major apotome. In Aristotle and Suidas it is written δίεσις [diesis]; but Boethius and Glarean write δίησις	128 125	Supertripartiens centesimas vigesimasquintas	s
Limma Platonicum [Platonic limma], or the Pythagorean semitone and Pythagorean diesis, to Macrobius; but by Daniele Barbaro and Herigone it is called the Pythagorean semitone, while to Kircher it is the Pythagorean limma	256 243		s
Apotome Platonica [Platonic apotome]: what is left when the limma is taken from the major tone; Mersenne calls it the minor apotome	2187 2048		s
Comma maius [major comma], Κομμα [komma]: the difference of the major and the minor tone	81 80	Sesquioctogesima	S
Comma minus [minor comma], in Herigone	10240 10125		s
Schisma, σχίσμα [schisma]: half of a comma	4352 4330		s
Diaschisma, διὰ σχίσμα [dia schisma]: half of the diesis, or a diesis improperly so called	162 160		s

From what has been said it is clear that *diesis* is a highly equivocal name, since some have used it for one species of semitone and others for another. Macrobius, moreover (book 2 on the *Dream of Scipio*), says that in the usage of more recent writers the diesis is a sound smaller than a semitone. Practitioners nowadays, wherever they want half a note to be used, set the sign of the diesis.

Quæſtio 1. Quas nam Conſonantias acceptarint Authores infraſcripti ?

Question 1. Which consonances did the authors listed below accept?

VII. To answer the question more briefly, in place of names we shall set numbers as indices of the consonances, to be looked up in column 1 of Table 1. Besides the consonances, almost all admitted the tone, the semitones, and the diesis or limma, and not a few the apotome.

- The Pythagoreans, Boethius, Martianus Capella, Macrobius: 1.2.3.4.5.
- Aristoxenus and Vitruvius, according to Daniele Barbaro: 1.2.3.4.5.8.9.19.
- Vitruvius himself, book 5, chapter 4: 1.2.3.4.5.12.
- Daniele Barbaro himself: 1.2.3.4.5.6.7.8.9.10.11.12.18.
- Ptolemy: 1.2.3.4.5.12.20.21.
- Euclid, and Herigone following him: 1.2.3.6.7.8.9.
- Iosephus Zarlinus [Gioseffo Zarlino]: 1.2.3.4.5.6.7.8.9.10.22.23.
- Ludovicus Folianus [Lodovico Fogliano]: 1.2.3.4.5.6.7.8.9.10.11.12.13.14.
- Marinus Mersennius [Marin Mersenne]: 1.2.3.5.6.7.8.9.18.19.
- Athanasius Kircher: 1.2.3.4.5.6.7.8.9.15.16.17.18.19.

- Johannes Kepler, in his musical scale: 1.2.3.4.5.6.7.8.9.10.11.12.13.14, as will be clear from what is to be said in chapter 6, number 5 — granted that earlier he had counted among the perfect consonances the unison and six other consonances, namely 1.2.3.4.5.8.22, as is clear from his book 3, chapter 2.

Quæſtio 2. Cur Conſonantiæ oriantur magis à Proportionibus Maioris, quàm Minoris inæqualitatis ?

Question 2. Why do consonances arise from proportions of greater rather than of lesser inequality?

VIII. For it is commonly said by musicians that the diapason arises from the double proportion rather than from the subdouble, and the diapente from the sesquialter rather than from the subsesquialter, although between the same terms 2 and 1 there is both the proportion of 2 to 1, the double, and that of 1 to 2, the subdouble, and so on. Ludovicus Folianus (section 2 of the *Musica Theorica*, chapter 3) and Zarlino (part 2 of the *Harmonic Institutions*, chapter 50) reply that the cause is this: in a proportion of greater inequality the greater term is compared with the lesser in a more perfect manner, namely as the container, which has the character of form, with the contained, which has the character of matter; and also that the relation of excess, or majority, is positive and real, whereas the relation of defect, or minority, is nothing but a privation, and is not a real relation but a relation of reason.

Quæſtio 3. An Tonus diuidi poſſet in duo Semitonia æqualia.

Question 3. Whether the tone could be divided into two equal semitones.

IX. Most deny it: first of all Macrobius (book 2 on the *Dream of Scipio*, chapter 5), Boethius (at the beginning of book 3), Glarean (book 1 of the *Dodecachordon*, chapter 10), Daniele Barbaro (on book 5 of Vitruvius, chapter 4), and Kircher (book 3 of the *Musurgia*, axiom 10). For just as a semivowel is not so called because it divides a vowel into two equal parts, so the semitone is so called because it lies between the extremes, not, however, because it is the exact half of the tone. The reason is that the tone belongs to the superparticular genus, since its proportion is 9 to 8, and no superparticular proportion can be divided into two equal parts. Barbaro therefore reproaches Aristoxenus because, following the judgement of the ears rather than the reasons of numbers, he divided the tone into two equal parts; and Barbaro says that it is cut into two unequal parts, of which one is called the major hemitone, or apotome, and the other the minor hemitone, or diesis. But Carolus Valgulius [Carlo Valgulio], on Plutarch's *Music*, defends Aristoxenus, and teaches that although the unit lying between 9 and 8 cannot be cut into two whole parts, yet the string itself, or chord, on which, as on a rule, concords are formed by divisions duly made, can be cut anywhere, because magnitude is continuous, and so into two equal parts. Nor, he teaches, was Aristoxenus so unskilled in arithmetic, or ignorant of the

doctrines of the Pythagoreans, since he wrote whole volumes on arithmetic and had as his teacher Xenophanes, a noble Pythagorean. But Father Athanasius Kircher (book 3 of the *Musurgia*, chapter 12, propositions 1 and 2) teaches that the tone can be divided into two equal parts in irrational numbers, but not in rational ones. He adds, moreover, that whoever, with Philolaus and Boethius, posit a half of the comma, namely the schisma, cannot deny a half of the tone. Consult him if you want more on this matter.

Quæſtio 4. Quare Diapaſon totam diuerſitatem Conſonantiarum in ſe contineat, aut terminet, & ſit Regina Conſonantiarum.

Question 4. Why the diapason contains within itself, or bounds, the whole diversity of the consonances, and is the queen of the consonances.

X. The diapason, in Greek διὰ πασῶν [dia pasōn], that is "through all", or "to all", or "around all", is so called because all the consonances are either contained within it or bounded by it. For although various harmonic proportions are found beyond it, yet according to sense, and judged by the ears, they seem to have almost no difference from those contained within the diapason — indeed, not even from the diapason itself; nor is any wholly new consonance found in which something of the diapason is not felt. For the ditonus seems to affect the sense in the same way as the diapason ditonus, and the semiditonus as the diapason semiditonus; so too the diatessaron and the diapason diatessaron, and so with the other consonances. Hence it comes about that, once the seven simple consonances, set apart from one another by a perceptible difference, are complete — namely the diapason, diapente, diatessaron, ditonus, semiditonus, and the major and minor hexachord — there is a repetito [?] of the consonances, and their whole diversity is bounded by the diapason. And because everyone easily discerns it and is refreshed by it, Aristotle (section 19, problem 35) calls it καλλίστη συμφωνία [kallistē symphōnia], that is, the most beautiful consonance. [Margin: The diapason, the most beautiful of the consonances.] Moreover, this too belongs to it uniquely: added to a like consonance, it generates other consonances without end, for example the didiapason [recte: disdiapason], the trisdiapason, the quaterdiapason, and so on. But if you add a diapente to a diapente, no consonance is produced, just as none is produced from others of the same species added together, as Aristotle teaches (section 19, problem 42). For the rest in praise of the diapason, read Aristotle, section 19, problems 17 and 32.

Quæſtio 5. Quo Artificio Diſcerni poſſint ipſo auditu Conſonantiæ omnes : & quomodo Monochordi Diuiſio ſit facienda.

Question 5. By what art all the consonances can be discerned by hearing itself, and how the division of the monochord is to be made.

XI. We learned above from Macrobius that Pythagoras hunted out the consonances from the sound of different hammers, and afterwards from chords — that is, strings or gut strings — stretched and hung with different weights, in the proportion he had detected in the hammers, so that the tensions of strings of the same species and thickness came out different according to the difference of the weight hung on them. But the monochord is in every way superior, because it is difficult to find several strings exactly alike in species, thickness and uniformity, or to stretch them with precisely as great a difference as the exact distinction of the consonances requires. [Margin: Notion and definition of the monochord.] The monochord is so called from μόνος [monos], which means single or solitary, and from χορδὴ [chordē], which means string, because it is an instrument containing a single stretched string; Ptolemy and Boethius call it the harmonic rule [Regula Harmonica]. Suidas calls this instrument *Magadea*, from the nominative Μαγὰς [Magas], and says that it is a squared piece of wood, hollow inside, containing strings fitted for grasping the variety of notes; for it can consist of two strings, one of which always gives the whole, and the other the part due to the consonance. But because the method with a single string is simpler, Guido Aretinus [Guido of Arezzo] defined it thus: *The monochord is a long squared piece of wood, hollow within, with a string drawn over it, by whose sound we grasp the varieties of notes.* [Margin: What the magas is.] However, the *magas* — or, as others have it, in Glarean above and in Kircher (book 4, chapter 1), the *magadis* — is mostly taken both for the twin fixed support, or little hemispherical bridge, that bounds and holds up the ends of the whole string, and for a third little bridge, or movable stool, that is set under the string at the point where the division of the string has been made by marking, according to the proportion due to the consonance sought. More recent writers call it the *cursor*, because it is moved forwards and backwards while we hunt for the consonances. The *pectis*, or plectrum, is what we strike the string with, so that by its vibration it gives out its sound. From *magas*, moreover, is formed the verb μαγαδίζειν [magadizein], which means to play on a string, forming various consonances on it.

[Margin: The first way of dividing the monochord.] The first use of the monochord, then, is for us to explore by it the individual consonances separately, or even the dissonant intervals, by a simple division of the string into only two parts — a division, I say, not real, but equivalent to a real one: namely by marking on a straight line set beneath the stretched string itself and of the same length, so that the place of the movable *magas* may be known. The string is to be divided into as many equal parts as the sum of the two numbers that determine the proportion due to the consonance. Thus, if you wish to explore the *diapason*, whose proportion is between 2 and 1, then since 2 and 1 make 3 you must divide the string into three equal parts; for if you strike the part of the string containing two parts, and immediately the other, containing a single such part, you will hear this consonance. So, if you wish to discern the *diapente*, whose proportion is as 3 to 2, then since 3 and 2 make 5 you will divide the

whole string into 5 equal parts; and with the *magas* placed where two parts end on one side and three on the other, by striking each you will learn this consonance. And so with the rest, as the following small table will show. In it the first column contains the number of equal parts into which the whole string is to be divided by marking, with the help of compasses or of folded paper; the second, the number of parts of the longer partial string; and the third, of the shorter. Struck together, or immediately one after the other, they will present to purified ears the consonance [?] sought, or else a dissonant interval that nevertheless serves concinnity [?].

Monochordi Diuiſio Pro Conſonantijs
Division of the monochord for the consonances.

Consonantiae	Equal parts of the whole string	Parts of the divided string: longer	Parts of the divided string: shorter
Diapason	3	2	1
Diapente	5	3	2
Diatessaron	7	4	3
Diapason diapente	4	3	1
Disdiapason	5	4	1

Schisma	8682	4352	4330
Diaschisma	322	162	160

[Margin: The second way.] The second way is when a single string is divided into equal parts in such a manner that the same division serves, if not all, at least several consonances — say the seven simple ones. In that case you will divide the string into 120 equal parts. For if you strike the whole string, and then its half, namely the partial string consisting of 60 parts, you will hear

the *diapason*; and you will hear the same thing another way if you strike on one side the string having 80 parts and on the other the one having 40. If, however, you strike the whole string and then the partial one having 80 parts, you will perceive the *diapente*. But if you strike the whole string, and immediately the partial one having 90 parts, you will hear the *diatessaron*. If, however, you strike the whole string and then the partial one having 96 parts, you will hear the *ditonus*. But if you strike the whole string, and immediately the partial one having 100 parts, you will perceive the *semiditonus*. Again, if you strike the whole string and then the partial one that has 72 parts, you will hear the *major hexachord*. Finally, if you strike the whole string, and immediately that one of the partial strings that has 75 parts, you will perceive the *minor hexachord*. And so your ear will become master of the seven simple consonances, which Virgil calls the "seven distinctions of notes" [Septem discrimina vocum]. For these, see the synopsis in the following small table.

Diuiſio Monochordi pro 7. Conſonantijs Simplicibus.

Division of the monochord for the 7 simple consonances.
The whole string is to be divided into 120 equal parts.

	Parts	For the consonance
The whole string is to be struck, and immediately with it or after it is to be struck the string of	100	*Semiditonus*
	96	*Ditonus*
	90	*Diatessaron*
	80	*Diapente*
	75	*Major hexachord*
	72	*Minor hexachord*
	60	*Diapason*

We shall speak below about monochords in the diatonic, chromatic and enharmonic genera, after the difference of these genera has been explained, namely in chapter 6, numbers 3 and 4. There you will learn that a diatonic monochord suited to the consonances and to the dissonant but concinnous intervals is to be divided into 9216 equal parts according to Boethius, Glarean and Zarlino; or into 3600 parts according to Folianus; or into 2160 or 720 parts according to Kepler.

[Margin: The third way.] The third way is by the figure that Ptolemy (book 1 of the *Harmonics*, chapter 11) calls the *Helicon*, that is, by the square ABCD. Divide its side BD in half at F, and CD in half at E. Then divide the side BD into four equal parts, BG, GF, FH, HD. Again, divide the same side BD into three equal parts, BK, KI, ID. From the points of division of the side BD draw, to the opposite side AC, perpendiculars parallel to the sides: GL, KM, FN, IO, HP. And finally, from B draw the straight line BE to E, the midpoint of the side CD. For if the parallels just mentioned, together with the

sides to which they are parallel, are strings of the same species and tension, and the chordotomum, or magas, makes BE a continuous line, you will find the consonances or concinnous intervals written below.

Diagram. The square of the Helicon, set into the right column. A square with A at the top left, B at the top right, C at the bottom left and D at the bottom right. Five horizontal lines cross it, parallel to AB and CD; they meet the left side AC at L, M, N, O, P and the right side BD at G, K, F, I, H, from top to bottom. A straight line runs from B down to E on the bottom side CD, crossing the five horizontals at Q, R, S, T, V, from top to bottom.

- A (top left corner): A
- B (top right corner): B
- L, M, N, O, P (left side, top to bottom): L, M, N, O, P
- C (bottom left corner): C
- G, K, F, I, H (right side, top to bottom): G, K, F, I, H
- D (bottom right corner): D
- Q, R, S, T, V (on the line from B to E, top to bottom): Q, R, S, T, V
- E (on the bottom side): E

TABELLA PRO HELICONE.

Table for the Helicon.

- *Unison*: CE with ED.
- *Diapason*: AB with CE; or OT with TI.
- *Diapente*: CE with TI; or NS with CE; or AB with OT.
- *Diatessaron*: TI with SF; or CE with VH; or AB with NS.
- *Ditonus*: PV with CE; or MR with OT.
- *Semiditonus*: NS with PV; or AB with MR.
- *Major hexachord*: PV with VH; or MR with CE.
- *Minor hexachord*: AB with PV.
- *Diapason diapente*: AB with VH; or ED with QG; or NS with SF.
- *Disdiapason*: AB with SF; or OT with QG.
- *Diapason with the ditonus*: MR with TI; or PV with SF.
- *Diapason with the diatessaron*: AB with TI; or OT with SF.
- *Diapason with the major hexachord*: MR with SF.
- *Major tone*: VH with TI; or MR with OT.
- *Minor tone*: MR with NS.
- *Major semitone*: OT with PV.

I pass over the remaining methods as suited to fewer consonances: namely the mesolabe [Mesolabrum], about which Zarlino (part 2, chapter 25); and the square divided into eight parallelograms with an oblique line such as BE, about which

Athanasius Kircher (*Musurgia*, book 4, chapter 5, Lemma 2); and others pointed out by Glarean (*Dodecachordon*, book 1, chapters 17 and 18) or by Ludovicus Folianus (section 2, chapters 14 and 15).

I add only this. When one string is struck, another string — not struck, but in unison with it or akin to it in consonance — vibrates, provided it lies within the sphere of the first string's vibrations. You can test this by laying a bent slip of straw [paleola] on the second string: you will see it jump. This effect was known to Macrobius (book 2 on the *Dream of Scipio*), and Kepler tries to give its cause (*Harmonics*, book 3, page 14); so too Fracastorius [Girolamo Fracastoro] (*De Sympathia*, chapter 11), and the natural philosophers [Physiologi] in the question of action at a distance.

SCHOLIA.

Scholia.

[Margin: Kepler's doctrine of the origin of the consonances.]

I. Kepler, then, setting out to investigate the origin of the consonances from the divisions of the circle, lays down at the start of book 1 of the *Harmonics* that the demonstration of a figure in a circle is the derivation of a quantity to be known — that is, measured or described — from the diameter, through the possible intermediate steps.

[Margin: Proper and improper demonstration of figures in a circle.]

The *proper* demonstration of such a figure is when the number of its angles, or of the angles of a kindred figure with double or half [?] the number of sides, becomes the middle term for determining the ratio of the side to the diameter. The *improper* demonstration is when the ratio of the side to the diameter cannot be determined geometrically from the number of angles applied directly, unless one brings in the side of another figure that has neither double nor half the number of sides.

[Margin: Several degrees of knowability, both of the expressibles and of the inexpressibles.]

He further establishes several degrees of knowledge [gradus scientiae]. The first degree of knowability [scibilitas] is when some line can be shown to be equal to the diameter, or a plane equal to the square of the diameter. The second degree is when, the diameter (or likewise its square) having been divided into some definite number of equal parts, the proposed line or plane is shown to be equal to such a part or parts. That plane is then called *expressible* [Effabile], and the line *expressible in length* [Effabilis longitudine]: for number is, so to speak, the language of geometers. The third degree is when a line is inexpressible in length but its square is expressible; the line is then also called *expressible in square* [effabilis potentia]. The remaining degrees he calls simply *inexpressible*, rather than irrational or surd.

Among these the fourth degree — though the first of the inexpressibles — is when neither the line nor its square is expressible, but the square can still be transformed into a rectangle whose sides are at least expressible in square. Such a line is called a *mese* [Mese, "medial"], because it is a mean proportional between two expressible lines commensurable in square only; its square is

called a *meson* [Meson, "medial area"], whether it has the form of a square or is transformed into a rectangle. From this kind of plane, and from the expressible plane, other species and degrees arise. The fifth degree of knowledge, then, is when two lines, neither of them expressible nor medial [mesae], and wholly incommensurable with each other, nevertheless make the sum of their squares, and their common rectangle, expressible. The sixth degree is when two lines that are neither expressible, nor medial, nor commensurable with each other nevertheless make one of the two expressible and the other a *meson* — that is, either the sum of the squares or the common rectangle. The seventh degree is when, of two inexpressible and incommensurable lines, neither is expressible — that is, neither the sum of the squares nor the common rectangle — yet each is a *meson*. For the other degrees, which arise from combinations of these, consult Kepler himself up to proposition 34, where he begins to determine the knowable sides of figures according to the degrees already mentioned.

[Margin: Tetragon.] [Margin: Octagon.] [Margin: Sixteen-sided figure.] [Margin: Triangle.] [Margin: Hexagon.] [Margin: Dodecagon.] [Margin: Figure of 24 sides.] [Margin: Decagon.]

He shows that the diameter of the circle is knowable in the 1st degree; the side of the tetragon inscribed in the circle in the 3rd degree, but its square [Quadratum] in the 2nd. The side of the octagon, and of the octagonal star, is knowable only in the 8th degree, but the sides of the two joined together in the 6th degree. The side of the sixteen-sided figure is knowable in degrees far below the 8th degree. The side of the triangle inscribed in the circle is knowable in the 3rd degree, and that of the hexagon in the 2nd; but their planes, or areas, are *mesa* and stand to each other in double ratio. The sides of the dodecagon and of the dodecagonal star, if joined together, are knowable in the 5th degree; if separated, in the 8th. The plane of the dodecagon, however, is expressible. Likewise the regular figure of 24 sides, and all the figures that arise from it by continually doubling the number of sides, together with their stars, have knowable sides, but in a degree below the 8th. Further, the sides of the decagon and of the decagonal star joined together are knowable in the 5th degree, but separated in the 8th; joined with the diameter of the circle, in the 4th degree.

[Margin: Pentagon.] [Margin: Fifteen-sided figure.] [Margin: Heptagon.]

The sides of the pentagon and of the pentagonal star are knowable separately in the 8th degree, but joined, in the 4th as well as in the 6th degree. The planes of the decagon, the pentagon, the icosagon [Icosigonum] and the rest of this class fall either [?] into the remoter degrees of knowledge. The sides of the fifteen-sided figure, and of the star that arises from it, have no proper demonstration, just as those of the thirty-sided figure have none; and moreover the heptagon is not knowable, nor does it have a proper demonstration. Hence the division of arcs of the circle into 3, 5, 7, etc. equal parts, and in any ratio whatever that is not a continued doubling of those demonstrated before, cannot yield knowable sides of figures.

Having demonstrated this, he concludes that there are four classes of knowable figures: three having a proper demonstration, and a fourth having an improper one. In the division of the circle the diameter holds first place, as being expressible in length. In 2nd place is the hexagon, because its side, being equal to the semidiameter, is expressible in length. In 3rd place are the tetragon and the triangle, whose sides are expressible in square only. In 4th place are the sides of the dodecagon and the decagon, and of the stars of the same name, because they are among the lines inexpressible in square and the composites of the first species. In 5th place are the sides of the pentagon and the octagon, and also of the pentagonal and octagonal stars, etc.

[Margin: Congruent figures.]

In book 2 of the *Harmonics* he treats of the geometrical congruence or incongruence — or unsociability [insociabilitas] — of figures, and he concludes that the figures congruent in plane angles or in solid angles, or in plane and solid angles together (that is, those whose angles meet at one point in such a way as to leave no gap between the sides), are only the twelve listed below.

Left	Right
1 Triangle	7 Dodecagon
2 Tetragon	8 Icosagon
3 Pentagon	9 Pentagonal star
4 Hexagon	10 Octagonal star
5 Octagon	11 Decagonal star
6 Decagon	12 Dodecagonal star

[Margin: Kepler's doctrine of the origin and number of the consonances.]

II. In book 3 of the *Harmonics* he inquires into the origin of the harmonic ratios, and the nature and differences of the things that pertain to song, and he first lays down these axioms.

1. The diameter of the circle, and the sides of the radical figures explained by him in book 1 that have a proper demonstration, determine a part of the circle consonant with the whole circle, whether the circumference of the circle is stretched round in a circle or straight like a single string. And therefore the consonances are infinite, because the demonstrable figures are infinite — granted that some of them have been selected.
2. By whatever degree the demonstration of a side stands removed from the first, by that same degree the consonance with the whole circle of the part of the circle cut off by the side recedes from the most perfect consonance, that of the unison.
3. The indemonstrable sides of figures and of stars determine a part of the circle dissonant from the whole circle; and so do sides that are indeed demonstrable, but not by a proper demonstration.
4. Figures that have kindred demonstrations of their sides beget kindred harmonies.

5. Strings or arcs of the circle of equal tension, having to one another, by reason of their length, the same ratio as holds between a part or the remainder of the circle and the whole circle, also have the same consonance or dissonance, even if it is contained between other terms or sounds.
6. When two strings have given out identical sounds, a third voice consonant with one of them is consonant with the other too; or, if dissonant with one, it is dissonant with the other too.
7. When two strings or voices have given out identical sounds, a third voice that is identisonant [identisona] with one of them is also identically consonant with the other.

On these premises he affirms: 1. that after the unison, which he calls the most perfect consonance, the half with the whole circle begets the most perfect and simplest consonance, in the first degree — and an identical one on the opposite side — because it is made by the diameter of the circle. 2. If the greater part of the circle does not have a continued double ratio to the whole circle, and is consonant with the whole circle, the lesser part will be dissonant from the whole. 3. Strings in continued double ratio are all identically consonant with one another. 4. A string that is consonant with either of the multiples of a continued double ratio is consonant with the other as well; and if it is dissonant with one, it is dissonant with the other too.

In chapter 2, further, he deals with the harmonic section of a string — when, that is, the whole string is cut into parts such that each is consonant both with the whole and with the others. He teaches that there are only seven such sections, namely those whose ratio is indicated by the numbers below, and which he had treated in the *Mysterium Cosmographicum*, chapter 12.

Harmonic sections: if one part of the string is to the other part as

Vt	Ad	Vt	Ad
1	1	5	1
2	1	3	2
3	1	5	3
4	1		

After this, in chapter 3, he treats of the trinity of concordant sounds, or of harmonic means; in chapter 4, of the origin of the melodic [concinna] intervals; in chapter 5, of the natural division of the consonant intervals into melodic ones; in chapter 6, of hard and soft song; in chapter 7, of the division of a single octave in each kind of song; in chapter 8, of the number and order of the smallest intervals; in chapters 9 and 10, of the notes and characters of voices and strings, and of the syllables Ut, re, mi, fa, sol, la; in chapter 11, of the composition of systems; in chapter 13, of naturally melodious song; in chapters 14 and 15, of the Modes, or Tones, of melodies; and in chapter 16, of figured song.

CAPVT V.

Chapter 5.

De Muſicæ ac Melodiarum Cantuumque Diuiſionibus varijs, ac Generibus.

On the various divisions and kinds of music, of melodies and of songs.

[Margin: Divisions of music, 1 and 2.]

I. Music is twofold: one theoretical, the other practical. Theoretical music, on the authority of Boethius (book 1, chapter 2), is threefold. *Cosmic* [Mundana] music considers the harmony of the whole world and of its parts — the symphony [Symphonismus] and symmetry of the elements and of the heavens. *Human* music deals with the proportions of the body and the soul, with each other and with their own parts — that is, with the harmony of the microcosm. *Instrumental* [Organica] music contemplates the harmony that results from sounds and voices, whether in a natural or an artificial way. Zarlino, however (part 1, chapter 5), first divides music in two, into *animastic* [Animastica] and *instrumental*, and then subdivides the animastic into cosmic and human, and the instrumental into natural and artificial.

[Margin: Division 3.]

[Margin: What natural and artificial music are.]

The third division, then, is of instrumental music into the *natural*, which considers the sounds produced naturally by the force of the throat or larynx, the lungs, the palate, the tongue, the teeth and the lips — for these are the natural instruments of the sound and voice of animals — and into the *artificial*, which considers sound made, or able to be made, by various manufactured instruments.

[Margin: Division of musical instruments.]

Of these instruments the first kind comprises the pneumatic ones, or ἐμφυσώμενα [Greek: emphysōmena, "blown into"], that is, instruments that sound by the force of breath and are animated by air, whether it be the breath of living creatures or wind and air. Such are reed-pipes [calami], hemlock-stalk pipes [cicutae], syrinxes, shepherds' or soldiers' pipes, in Italian *subioli* or *cifoli*; pipes with three or six holes [tristomae, hexastomae], in Italian *flauti*; and *litui*, or horns; bagpipes [Cornamusae], in Italian *corni*, *cornetti*, *cornamuse*; and serpent horns, in Italian *biscioni*; and shawms [Tibiae], in Italian *piue* or *pifferi*; and bladder-pipes [Fistulae vtriculares], in Italian *piue sordine*; and trumpets, buccinas and war-trumpets [Classica], in Italian *trombe*; and slide trumpets [Tubae ductiles], in Italian *tromboni*; and *zooglossa* pipes, with which we imitate the various voices of animals; and *anthropoglossa* pipes, with which we imitate human speech and laughter. But first among them are the instruments that are called, by antonomasia [ἀντονομαστικῶς, antonomastikōs], *organs*, or by Vitruvius *musical canons* [Canones Musici]: built of many pipes or tubes of lead or of cypress wood, and blown by bellows.

The second kind comprises the instruments called ἔγχορδα [Greek: enchorda, "stringed"] or ἔντατα [Greek: entata, "strung taut"] — that is, chordal or sinew-strung instruments, consisting of one or more strings, which sound when struck with the fingers, the nails, plectra, etc. Such are psalteries, harps, lutes [Testudines], lyres, barbitons, *cheles*, sambucas, pandoras, mandoras, nablas, citterns [Cytharae], pectides, harpsichords [Clauicymbala], and the Turkish three-string, commonly *il colachon* or *colasson*. For lutes, pandoras and mandoras are called *leuti* in Italian; citterns, *cetre*; Spanish citterns, *chitariglie*; theorbos, *chitaroni*. The small four-string *chelys* is *il violino*; the six-string *chelys* is *la viola*; the larger four-string *chelys*, *il violone*;

the smallest *chelys*, or *lynterculus*, *il lirino*; the twelve-string *chelys*, or lyre, *lira* or *lirone*. The clavichord, or clavicymbal, or manichord, is called *clavicembalo*, *manacordo*, *spinetta*. Finally, the third kind comprises the percussion instruments, in Greek κρούστικα [Greek: kroustika, "struck"] or κρούστα [Greek: krousta, "struck"]: cymbals, sistrums, drums [Tympana], bells, clappers [Crotala], and xylorgans [Zylorgana], that is, instruments which have wooden cylinders in place of pipes. On musical instruments there have written excellently Mersennius (on Genesis, chapter 4, verse 21, question 56, or from page 1515), Othomarus Luscinius [Ottmar Luscinius] (*Musurgia*, book 1), and our own Kircher (book 2, chapters 3 and 6, and book 6 of the *Musurgia*). There Kircher also sets out, from his own experiments and Mersennius's, the proportions of strings, pipes, etc., and what voices strings of different metals, of gut and of thread give out; or what sounds different woods give when struck, and in what proportion.

[Margin: Division 4, from Isidore.]

Fourth, music is divided by Isidore (*Etymologies* [Origines], book 3) into the *harmonic*, which consists of the songs of voices; the *organic*, which arises from breath; and the *rhythmic*, which takes its numbers from the impulse of the fingers. Some, however, include under the rhythmic both the metrical art of syllables, for building verse, and the art of dancing; others separate the metrical from the rhythmic, as can be seen in Zarlino (part 1, chapter 5).

[Margin: Division 5, from Martianus Capella.]

Fifth, music is divided according to Martianus Capella (*On the Marriage of Philology*, book 9) into three kinds. The first is called εἰδικὸν [Greek: eidikon, "specific", "of form"], which is consonant from sound, numbers and words that are alike and persevering; the part of it that pertains to melody is called harmonic, the part that pertains to numbers rhythmic, and the part that pertains to words metrical. The second kind is ἐργαστικὸν [Greek: ergastikon], that is, operative; and the third ὑπερεργαστικὸν [Greek: hyperergastikon], that is, super-operative, or ἑρμηνευτικὸν [recte: ἑρμηνευτικόν] [Greek: hermēneutikon, "interpretive"], that is, enunciative. On these consult that author, for this division is very obscure and accepted by almost no one.

[Margin: Division 6, into the Dorian, Phrygian, Lydian modes, etc.]

II. Sixth, music is divided into various modes, but chiefly into the Dorian, Phrygian, Lydian, Aeolian, Ionian and Iastian, and into modes mixed from

these, according as these modes were invented by the Dorians, the Phrygians, etc., or were more in use in those regions — although Alypius in his *Isagoge* says the Dorian was invented by Thamyras, the Phrygian by Marsyas, the Lydian by Amphion, the Hypodorian by Philoxenus, the Hypolydian by Polymnastus, and the Mixolydian by Sappho. In assigning the difference between them, however, there is an astonishing and almost inextricable confusion. See, if you like, the interpreters of Aristoxenus and Ptolemy; Glarean (book 1 of the *decachordon*, chapters 2 and 7); Mersennius (on Genesis, chapter 4, verse 24, from page 1664); and Kircher (*Musurgia*, book 3, chapter 15, and book 7, page 554), who collect the opinions of others. Here it is enough to know that the Dorian was a grave and severe mode, in which Re–Sol reigned; the Phrygian religious and hard, in which Mi–La; the Lydian wanton, and the Ionian soft, in which Ut–fa. Hence Pliny the Elder (book 2, chapter 22) said that Saturn moves in the Dorian, Jupiter in the Phrygian, Mercury in the Lydian. Further, all the modes, simple and mixed, are brought down to 12 according to Kircher, or to 15 according to Euclid, Cassiodorus and Capella.

[Margin: The musical modes, 12.]

The *Dorian*: in Lucian δεμνὸς [recte: σεμνός] [Greek: semnos, "solemn"], sacred and grave; in Apuleius warlike, and most apt for setting heroic verse, on account of its gravity joined with briskness.

The *Hypodorian*, or plagal [subiugalis] of the Dorian: gloomy and too grave.

The *Phrygian*: in Lucian ἔνθεος [Greek: entheos, "inspired"], in Apuleius religious; full of severe indignation, and so also called σκόλιος [Greek: skolios, "crooked"]; fit for tragic iambics and for carrying minds out of themselves, as Plato has it (book 3 *On Justice*) and Aristotle (*Politics* 8, chapter 5).

The *Hypophrygian*: humble, and composed for weeping, on account of its sad lament.

The *Lydian*: cheerful, drunken, threatening, and suited to revellers; and so in Lucian βακχικὸς [Greek: bakchikos], that is, bacchic and mad. For that reason Plato rejected it (dialogue 5, *Republic*).

The *Ionian*, or Iastian: soft, dissolute, wanton.

The *Hypolydian*: tearful, devout, or, as others say, wailing.

The *Mixolydian*: soul-bending, and leading to various affections.

The *Hypomyolydian* [?]: full of natural delight.

The *Aeolian*: gentle and of wonderful sweetness, and fit for lyric poets; the more recent writers call it the "foreign" mode.

The *Hypoaeolian*: it too has a remarkable sweetness.

The *Ionian*: in Lucian γλαφυρὸς [Greek: glaphyros, "polished", "elegant"], in Apuleius wanton; apt for iambics and trochaics. Plato condemned it for its excessive softness (dialogue 5, *Republic*); our musicians call it the Fifth.

The *Hypoionian* corrects the softness of the Ionian and corresponds to the Sixth of the more recent writers.

But according to Euclid, Cassiodorus and Capella there are 15, and they are numbered thus: *Dorian, Iastian, Phrygian, Aeolian, Lydian, Hypodorian, Hypoiastian, Hypophrygian, Hypoaeolian, Hypolydian, Hyperdorian, Hyperiastian, Hyperphrygian, Hyperaeolian, Hyperlydian*. But on these Kepler says more (*Harmonics*, book 3, chapters 14 and 15).

[Margin: Division 7, into the diatonic, chromatic and enharmonic genus.]

III. Seventh, music is divided into three most celebrated genera, namely the diatonic, the chromatic and the enharmonic — in Greek διατονικὸν [Greek: diatonikon], χρωματικὸν [Greek: chrōmatikon], ἐναρμονικὸν [Greek: enarmonikon]. So Vitruvius has it (book 5, chapter 4), naming the three genera of modulation διάτονον [Greek: diatonon], χρῶμα [Greek: chrōma, "colour"] and ἁρμόνιαν [Greek: harmonian] — on which see Daniele Barbaro; so too Ptolemy (*Harmonics*, book 1, chapter 13), who attributes this division to Archytas the Pythagorean; Martianus Capella (*On the Marriage*, book 9, the chapter on the genera of tetrachords), where he calls these three genera of tetrachords or of modulations ἐναρμόνον [recte: ἐναρμόνιον] [Greek: enarmonon], χρῶμα and διάτονον; Boethius (book 5); Macrobius (book 2 on the *Dream of Scipio*, chapter 4); Zarlino (part 2, chapters 9 and 16); and Athanasius Kircher (*Musurgia*, book 3, page 119, and more fully in the whole of chapter 13). This division is taken from the different ways of ordering the tetrachords in the ascent from a low sound to a high one.

[Margin: The diatonic genus.]

The *diatonic*, on Plutarch's testimony, is the most ancient and the most natural; Zarlino attributes its invention either to Terpander of Lesbos [Therpandro Lesbio] or to Pythagoras. This genus ascends through two tones and a minor semitone; and because it proceeds by spaces a tone apart and abounds in tones, it is called *diatonum*, or diatonic. This genus is severe, grave and constant, displaying manly character and bearing; it is very much in use today, and was in use also in the times of Martianus Capella and Macrobius.

[Margin: The chromatic.]

The *chromatic* genus was invented by Timotheus of Miletus, the lyric poet, as Suidas and Boethius report; and for this reason Aristotle says in the *Metaphysics* that had there been no Timotheus, we should have been forced to do without many melodies. *Chroma*, further, means "colour" in Greek; the genus is so named because it brings various colours into the diatonic, and it stands between the diatonic and the enharmonic as variety of colour stands between white and black. It proceeds by two semitones, a major and a minor, and a semiditone, that is, three semitones. It is far more artful than the diatonic and suited to stirring various affections; hence Vitruvius says of it: *"Through subtle skill and the frequency of its measures it has a sweeter delight."* Barbaro, however, calls it soft and plaintive.

[Margin: The enharmonic.]

The *enharmonic* was invented by Olympus, on the testimony of Aristoxenus and of Plutarch (*On Music*). As it is the most excellent of all and the fullest of

authority, so it is of the highest art and skill, and on account of its difficulty it was used by very few; and for that reason it was called by antonomasia [ἀντονομαστικῶς] the *harmonic*, or enharmonic. It proceeds by a diesis and a ditone. Kepler, treating these matters lightly at the end of book 3, chapter 6 of the *Harmonics*, thinks that the diatonic corresponds to hard song and the chromatic to soft song; or that there were two species of the diatonic, the hard and the soft, which were mixed together in the chromatic; but that nothing in the music in use corresponds to the enharmonic, except the vibrations of the human voice, the tremulant of organs, the mordent on the strings of the pandora, and the like. Finally, Macrobius (book 2 on the *Dream of Scipio*, chapter 4) says: *"Since there are three genera of musical melody, the enharmonic, the diatonic and the chromatic, the first has fallen out of use because of its excessive difficulty, while the third is disreputable for its softness; hence the middle one, that is, the diatonic, is assigned to the music of the world in Plato's teaching."*

Aristoxenus, further, subdivided the diatonic into the soft and the intense [Incitatum], and the chromatic into the soft, the sesquialter and the tonic. These subdivisions, like those of Didymus, Archytas and Eratosthenes, are rejected by Ptolemy (*Harmonics*, book 1, chapters 12 and 13, and book 2, chapters 13 and 14), Boethius (book 5, chapters 15, 16 and 17) and Zarlino (part 2, chapter 16). Kircher, however (*Musurgia*, book 3, chapter 13), says that the more expert musicians accept five subordinate genera, or species, of the diatonic — namely the Pythagorean, the soft, the syntonic, the toniac and the equal; three species of the chromatic, the ancient, the soft and the syntonic; and finally two of the enharmonic, the ancient and the Ptolemaic. He sets out patterns of these in tetrachords, with their ratios, in larger and smaller numbers.

Here, however, on account of what is to be said in the next chapter, it should be noted beforehand that the lowest of the strings was called by the Greeks *hypate hypaton*; the second *parhypate hypaton* [hypathon]; the third *lichanos hypaton* [Lychanon]; and the highest *hypate meson*. We shall distinguish them in order by the initial numbers I, II, III, IV.

Tetrachordon Diatonicum Diatonum seu Pythagoricum (the diatonic, or Pythagorean, diatonic tetrachord)

Strings	Number
I.	6144
Tone: sesquioctava ratio, as 9 to 8	
II.	6912
Tone: sesquioctava ratio, as 9 to 8	
III.	7777 [?]
Minor semitone: 13-superpartient of 243 [tredecup. 243], as 256 to 243	
IV.	8192

Tetrachordum Diatonicum Molle (the soft diatonic tetrachord)

Strings	Number
I.	63
Sesquiseptima, 8 to 7	
II.	72
Sesquinona, 10 to 9	
III.	80—45
Sesquivigesima, 21 to 20	
IV.	84—48

Tetrachordum Diatonicum Incitatum seu Syntonum (the intense, or syntonic, diatonic tetrachord)

Strings	Number
I.	36
Minor tone: sesquinona, 10 to 9	
II.	40
Major tone: sesquioctava, 9 to 8	
III.	45
Minor semitone: sesquidecimaquinta, 16 to 15	
IV.	48

Tetrachordum Diatonicum Toniacum (the toniac diatonic tetrachord)

Strings	Number
I.	168
Tone: sesquioctava, 9 to 8	
II.	189
Sesquiseptima, 8 to 7	
III.	216
Sesquivigesimaseptima, 28 to 27	
IV.	224

Tetrachordum Diatonicum Aequale (the equal diatonic tetrachord)

Strings	Number
I.	9
Sesquinona, 10 to 9	
II.	10
Sesquidecima, 11 to 10	
III.	11
Sesquiundecima, 12 to 11	
IV.	12

Tetrachordum Chromaticum Antiquum (the ancient chromatic tetrachord)

Strings	Number
I.	6144
Trisemitone	
II.	7296
Semitone	
III.	7776
Minor semitone	
IV.	8192

Tetrachordum Chromaticum Molle (the soft chromatic tetrachord)

Strings	Number
I.	105
Sesquiquinta, 6 to 5	
II.	126
Sesquiquartadecima, 15 to 14	
III.	135
Sesquivigesimaseptima, 28 to 27	
IV.	140

Tetrachordum Chromaticum Syntonum, seu Incitatum (the syntonic, or intense, chromatic tetrachord)

Strings	Number
I.	66
Sesquisexta, 7 to 6	
II.	77
Sesquiundecima, 12 to 11	
III.	84
Sesquivigesimaprima, 22 to 21	
IV.	88

Tetrachordum Enharmonicum Antiquum (the ancient enharmonic tetrachord)

Strings	Number
I.	6144
Ditone	
II.	7776
Diesis	
III.	7984
Diesis	
IV.	8192

Tetrachordum Enharmonicum Ptolemaicum (the Ptolemaic enharmonic tetrachord)

Strings	Number
I.	276
Sesquiquarta, 5 to 4	
II.	345
Sesquivigesimatertia, 24 to 23	
III.	360
Sesquiquadragesimaquinta, 46 to 45	
IV.	368

These were the foundations of the other tetrachords, out of which the whole system, or musical scale, was composed: it consisted of five tetrachords, the fourth string of the first being the first of the second tetrachord, the fourth of the second the first of the third, and so on, as we shall set out in the examples of the next chapter, where we shall explain the names and order of the strings.

[Margin: 8. The division into hard and soft.]

IV. *Eighth*, the genus of melodies is divided into hard song and soft song [Cantum Durum ac Molle], a division well known among recent writers. Hard song is that in whose system the intervals are ordered from the lowest voice by the major third and major sixth, that is, by the consonances 5 to 4 and 5 to 3, which are also called hard and harsh. Soft song is that in which the intervals are ordered from the lowest voice by the minor third and minor sixth, that is, by the consonances 6 to 5 and 8 to 5, which are called the soft third and the soft sixth. Examples of these are in Kepler, book 3 of the *Harmonics*, chapter 6; anyone who wants them may consult him.

[Margin: 9. The division of song into plain and figured.]

V. *Ninth*, music is divided into plain song, or firm song, and figured, or harmonic, song. Plain song is that in which the passage from sound to sound is made by the simple raising and lowering of the voice, without any search for consonance as such and without variation of time; or, that in which the difference of high and low is attended to, but without a symmetry of several voices consonant in harmony through various durations of time. Figured song is that whose melody is made by several voices consonant with one another in harmony, and by durations of time fittingly ordered in voice or sound; and because this is done by means of certain notes and figures, this song is called *figured*. This kind is thought to have been invented in the last centuries. Plain music, moreover, is subdivided into the Boethian, the Gregorian and the Aretine; all of them, for their gravity and clarity, are very well suited to divine worship and to stirring devotion. Boethius, imitating the Greeks, set up 15 divisions on the monochord, distributing 15 strings into four tetrachords and admitting a semitone between the first and second point; among the Latins, Saints Ambrose and Augustine followed him. Later St Gregory the Great, about the year 594, devised the seven letters of the alphabet A B C D E F G, repeating them up to the number 15. But Guido Aretinus [Guido d'Arezzo], about the year of the Lord 1024, established the hand, or musical scale, with

20 letters and the six syllables *ut, re, mi, fa, sol, la*; of these, a little in the next chapter.

CAPVT VI.

Chapter VI.

De Chordis Vocibus ac Notis Musicis, earumq. nomenclatura, & distributione in Systemate Harmonico seu in Scala Musica.

On the strings, voices and musical notes, their nomenclature, and their distribution in the harmonic system, or musical scale.

I. In the modulation of voices or sounds three principal accidents are usually considered. *First*, the natural quality of the voice or sound, by which there are four notable species of voices: namely, *Discantus*, or *Cantus*; *Altus*, or *Contratenor*; *Tenor*; and *Basis* — in Italian *Soprano, Contralto, Tenore* and *Basso*; for Julius Pollux calls the last *Basis*. *Second*, the continuous quantity in the duration, or stay, of time that we dwell on in pronouncing some word or sustaining a sound. For this the notes serve that Ioannes de Muris [Johannes de Muris], or Muria, of Paris is said to have invented about the year of the Lord 1320. Their order is such that each preceding note requires a stay twice as long as the one following. For the value, name and properties of these notes, see the following small table, with the time of the primum mobile, which assumes the ordinary pace of the hand raised and lowered, from our own measurements made with a pendulum.

Musical notes	Times	Names	Properties	Time of the primum mobile
[note-shapes]	8	Maxima	It sleeps	18″ 40‴
[note-shapes]	4	Longa	It lies down	9″ 20‴
[note-shapes]	2	Breve	It sits	4″ 40‴
[note-shapes]	1	Semibreve	It walks	2″ 20‴
[note-shapes]	½	Minim	It hurries	1″ 10‴
[note-shapes]	¼	Semiminim	It runs	0″ 36‴
[note-shapes]	⅛	Chroma	It flies	0″ 18‴
[note-shapes]	1/16	Semichroma	It flies away	0″ 9‴
[note-shapes]	1/32	Biscroma	It vanishes	0″ 4½‴

Before notes of this kind, however, neither Guido Aretinus nor others had notes distinguishing durations; they used mere thickish points, or little circles. From this the art was also called *counterpoint* [Contrapuncti Ars]: as a note is now set against a note, so then a point was marked against a point.

II. *Third*, in sounds and voices one considers the raising and lowering from low to high or from high to low — that is, the change of the voices through certain steps, by which the voice as it were ascends or descends. To distinguish these steps the ancients used either different parts of the same string, some

longer and some shorter, or different strings of different tension, to which they also gave fixed names. They arranged them so that, out of 15, 16 or 18 strings, they nonetheless set up five tetrachords, because the last of the first tetrachord was the first of the second, and so on — except the first of the fourth tetrachord, which is not shared with the last of the third; and for that reason the fourth tetrachord is called that of the disjunct strings. And so they constituted the greatest diatonic system. Vitruvius, book 5, chapter 4, supplies us with the names of the five tetrachords, saying: *"There are five tetrachords: the first, the lowest, which in Greek is called* ὕπατον *[hypaton, "highest"]; the second, the middle, which is called* μέσον *[meson, "middle"]; the third, the conjunct, which is called* συνέμμενον *[synemmenon, "joined"]; the fourth, the disjunct, which is named* διεζέυγμενον *[diezeugmenon, "disjoined"]; the fifth, which is the highest, is called in Greek* ὑπερβόλεον *[hyperbolaeon, "exceeding"]."* Martianus Capella subscribes to this (book 9, in the chapter on the tones), as does Boethius (book 1, chapter 20). You have the names of the strings, the explanations of the names, and their number according to various authors in the following table, in which we have written ὑπατῶν [hypatōn] with Glarean, and not ὑπάτων [hypatōn], as some write it corruptly.

CHORDARVM, Nomina secundùm tropos Musicos (the names of the strings according to the musical modes)

Order	Greek names	Graeco-Latin	Meaning
18	νήτη ὑπερβολαίων	Nete hyperbolaeon	The last of the high strings, or of the exceeding
17	παρανήτη ὑπερβολαίων	Paranete hyperbolaeon	The second-to-last of the high, or of the exceeding
16	τρίτη ὑπερβολαίων	Trite hyperbolaeon	The third of the high, or of the exceeding
15	νήτη διεζευγμένων	Nete diezeugmenon	The last of the disjunct
14	παρανήτη διεζευγμένων	Paranete diezeugmenon	The second-to-last of the disjunct
13	τρίτη διεζευγμένον	Trite diezeugmenon	The third of the disjunct
12	παραμέση	Paramese	Next to the middle string, corresponding to *b durum*
11	νέτη συνεμμένων	Nete synemmenon	The last of the conjunct
10	παρανήτη συνεμμένων	Paranete synemmenon	The second-to-last of the conjunct
9	τρίτη συνεμμένων	Trite synemmenon	The third of the conjunct
8	μέση	Mese	The middle
7	λιχανὸς μεσῶν	Lichanos meson	The index finger, or the extended, of the middle strings
6	παρυπάτη μεσᾶν [recte: μεσῶν]	Parhypate meson	The one below the principal, or the second, of the middle strings
5	ὑπάτη μεσὼν	Hypate meson	The principal, or the low, of the middle strings

Order	Greek names	Graeco-Latin	Meaning
4	λιχανὸς ὑπατῶν	Lichanos hypaton	The index finger of the principal, or low, strings
3	παρυπάτη ὑπατῶν	Parhypate hypaton	The second, or the one below the principal, of the low strings
2	ὑπάτη ὑπατῶν	Hypate hypathon	The principal of the principal, or the low of the low
1	προσλαμβανόμενος	Proslambanomenos	The added, or acquired, note

So, in counting the strings of the Greek system, some list only 15: for example, Ptolemy (*Harmonics*, book 2, chapters 5 and 11), Glarean (*Dodecachordon*, book 1, chapter 19), Ludovicus Folianus (*Musica Theorica*, section 3, last chapter), Zarlino (*Harmonic Institutions*, part 2, chapter 28), Mersennius [Marin Mersenne] (on chapter 4 of *Genesis*, verse 24, page 1670), and Kepler (*Harmonics*, book 3, chapter 11). All of these leave out strings 9, 10 and 11 — that is, the third, second-to-last and last of the conjunct strings — and put the paramese immediately after the mese, numbering the rest in the same order as above. But Vitruvius (book 5, chapter 4), and on him Daniel Barbarus [Daniele Barbaro] and Philander [Guillaume Philandrier]; Euclid, and with him Hérigone (volume 5 of his *Cursus Mathematicus*, in the *Music* of Euclid); Martianus Capella (book 9, *On the Marriage of Philology and Mercury*, in the chapter on the modes); and Athanasius Kircher (*Musurgia*, book 3, chapter 13, page 144) list 18 strings, in the same order as I do — although Capella differs from us here and there in naming them, as is clear from the following small table; in the others he agrees with us.

Nomenclatura peculiaris Martiani Capellae (Martianus Capella's own nomenclature)

Order	Name
4	ὑπάτων διάτονος
7	μέσων διάτονος
9	τρίτη συνζευγμένων
10	συνζευγμένων διάτονος
11	νήτη συνζευγμένων
14	διεζευγμένων διάτονος
17	ὑπερβολαίων διάτονος

Biancani (*Loca mathematica Aristotelis*, on section 19 of the *Problems*) and Bettini (*Apiaria*, apiary 10, progymnasma 1, proposition 1), however, do not list all the strings but only the 8 principal ones in the common octachord: *hypate, parhypate, lichanos* [Lychanon]*, mese, paramese, trite, paranete, nete*. But before we add the Aretine notes to these strings and arrange the greatest system according to the three genera — namely the diatonic, the chromatic and the enharmonic — a few things must first be touched on about the notes of the strings that Guido Aretinus devised and increased up to the number of 22 strings.

[Margin: Guido Aretinus, the restorer of music.]

III. Before Guido Aretinus, most Europeans used to employ in church chant eight straight lines, as eight strings, whose beginnings were marked with Greek letters; and on those lines points were marked, as notes are now, but not in the spaces between them. So Vincenzo Galilei teaches in his dialogue on music, and our Kircher shows it from manuscripts of the Vatican Library and of the library of Messina (*Musurgia*, book 5, chapter 1). Later Guido Aretinus, a Benedictine monk from Arezzo in Etruria and master of the monastic choir, while he was at Pomposa, a town of the Duchy of Ferrara, in the year of the Lord 1024, devised and found a new manner of singing, easy and pleasant, which Europe still uses now, together with the harpsichords [clauicymbalis] that were also invented. He gained acceptance for it and taught it through the whole of Italy up to the year 1028, with the approval of the Supreme Pontiffs John XX and Benedict VIII, by whom he was summoned to Rome and received with honour.

First, since he saw that between the eight lines used by his predecessors the spaces were idle and empty of notes — every step went from line to line — he reduced the lines to 5, but set notes in the spaces, so as to take in more intervals with fewer lines. *Second*, to distinguish the three principal tetrachords he substituted for the Greek strings these six syllables, *ut, re, mi, fa, sol, la*, through which the ascent is made from the lowest, *ut*, to the highest, *la*. He chose them from that strophe of the hymn of St John the Baptist:

UT queant laxis RE-sonare fibris, MI-ra gestorum FA-muli tuorum; SOL-ve polluti LA-bii reatum, Sancte Ioannes.

("That your servants may with free voices sound out the wonders of your deeds, loose the guilt of their polluted lips, O holy John.")

Of these, the first tetrachord is expressed by *ut, re, mi, fa*; the second by *re, mi, fa, sol*; the third by *mi, fa, sol, la*. *Mi, fa*, or *fa, mi*, is a semitone; the others, next to one another, are major and minor tones. *Third*, he distributed these syllables over five tetrachords, corresponding to the five fingers of the hand and to as many keys [clauibus], in such a way that he constituted 20 strings and, with an admirable economy, represented every difference of tones and semitones. He nevertheless kept the seven letters devised earlier by St Gregory the Great, namely A B C D E F G; when these are completed the cycle returns to A. But before the first A he set Γ, that is, a capital gamma, to signify that the Greeks were the inventors of music, and to add a tone to complete the diapason, or octave, which two conjoined tetrachords do not fill.

On this hand, or musical scale, Guido himself wrote a book called *Micrologus*, or *Introductorium*, and dedicated it to Theobaldus, bishop of Arezzo. In the dedicatory letter he promises that from it as much skill in singing can be drawn within a month as anyone could scarcely acquire in many years by the old method; and at the end he adds this closing formula: *"End of the Micrologus of Guido, at the age of 34 years, under Pope John XX,"* etc.

Although the greater part of Europe has accepted those six syllables, some have nonetheless been content with four only, *ut, re, mi, fa*, as Mersenne reports

(on chapter 4 of *Genesis*, page 1679). Others have proposed seven, namely *ut, re, mi, fa, sol, la, bi*, as Ericius Puteanus [Hendrik van der Putte] in his *Musathena*, so as to distinguish the seven *phthongi* [phthógos], the notes that properly make up the octave, just as the Greeks are said once to have distinguished them by their seven vowels αιυεηοω. Some in the Low Countries, too, on Kepler's testimony (*Harmonics*, book 3, chapter 9), use these seven: *bo, ce, di, ga, lo, ma, ni*. Yet in the year 1547, on the testimony of Maillardus (chapter 10, *On the Tones*), these eight were in use in the Low Countries: *ut, re, mi, fa, sol, la, sy, o*.

With these things set out first, here now is the musical scale, or greatest musical system, corresponding to the Greek strings and tetrachords, with the ratios of the intervals; this system indeed we have compiled from what is handed down by Guido himself in the *Introductorium*; by Barbaro and Philander on book 5 of Vitruvius, chapter 4; by Folianus in the last chapter of section 3; by Zarlino, part 2 of the *Harmonic Institutions*, chapters 30, 33 and 36; by Glarean, book 1 of the *Dodecachordon*, chapters 5 and 19; by Hérigone in volume 5 of his *Cursus Mathematicus*, in the *Music* of Euclid; by Mersenne on chapter 4 of *Genesis*, from page 1668; and by Kircher, book 3 of the *Musurgia*, chapters 8, 9 and 13, and book 4, chapters 2 and 3. We have, moreover, supplied from others what some have omitted, and corrected what more than one writer confuses. Although Guido's scale could be fitted to the chromatic and enharmonic genera, it is usually adapted only to the diatonic. And although among the ancients the greatest system was contained within the disdiapason, or double octave, such as it is in the following scale from the string *proslambanomenos* to the string *nete hyperbolaeon* — since the number 9216 to 2304 is quadruple, which constitutes the double octave, just as 9216 to 4608, or 4608 to 2304, is double and constitutes the octave — Guido nevertheless added other strings and increased this system up to 22 strings.

SYSTEMA Maximum Diatonicum, cum Divisione Monochordi Diatonici, & cum Typo Scalae Musicae Guidonis Aretini (the greatest diatonic system, with the division of the diatonic monochord and with the pattern of the musical scale of Guido Aretinus)

		1	10368	Γ	ut	

Two ruled columns of the leaf carry labels that span several rows and are given here rather than in the body of the table:

- At the left, vertical labels for four tetrachords: *Tetrachord of the hyperbolaeon* (from Nete hyperbolaeon to Nete diezeugmenon); *Tetrachord of the diezeugmenon* (from Nete diezeugmenon to Paramese); *Tetrachord of the meson* (from Mese to Hypate meson); *Tetrachord of the hypaton* (from Hypate meson to Hypate hypaton).
- At the right, an unheaded column with the strings of the *Tetrachord of the synemmenon* (so labelled vertically): Nete synemmenon, Paranete synemmenon, Trite synemmenon, Mese — set against the rows from Paranete diezeugmenon down to Mese.

IV. Let us now examine this system: we shall find in it, besides the tones and semitones, the first five species of the more perfect consonances, as will at once be clear from the following table.

Consonance					Whole string of Boethius				Whole string of Guido			
Diapason	ut	2	to	1	thus 9216	to	4608	and	10368	to	5184	
Diapente	ut	3	to	1	thus 9216	to	6144	and	10368	to	6912	
Diatessaron	ut	4	to	3	thus 9216	to	6912	and	10368	to	7776	
Diapason diapente	ut	3	to	1	thus 9216	to	3072	and	10368	to	3456	
Disdiapason	ut	4	to	1	thus 9216	to	2304	and	10368	to	2592	

[Margin: 1. Corollary.]

From this it is clear, *first*, that in both scales the diapason ends at the eighth string, the diapente at the fifth and the diatessaron at the fourth string; but the diapason-diapente at the twelfth of Boethius and at the thirteenth of Guido, and the disdiapason at the fifteenth of Boethius but at the sixteenth of Guido. From this it is clear why these consonances have been called the octave, the fifth, the fourth, the twelfth and the fifteenth: namely because the strings are consonant with the whole string, which is set in first place, at the eighth position, the fifth and so on, if they are counted inclusively from the first.

[Margin: 2. Corollary.]

It is clear, *second*, that between strings 1 and 8, which make the diapason, there are five whole tones and two semitones, that is, 6 tones; between strings 1 and 5, which make the diapente, three tones with a semitone; between strings 1 and

4, which make the diatessaron, two tones and a semitone; and between strings 1 and 12 of Boethius, or 1 and 13 of Guido, which make the diapason-diapente, 9 tones and a semitone; and finally, between strings 1 and 15 of Boethius, or 1 and 16 of Guido, which make the disdiapason, 12 tones. This whole doctrine of the tones and semitones contained in the consonances already mentioned is set out expressly by Macrobius (book 2 on the *Dream of Scipio*, chapter 1), and in large part by Censorinus (*On the Birthday*, chapter 11) and by Pliny the Elder (book 2, chapter 22).

[Margin: 3. Corollary.]

It is clear, *third*, that the remaining eleven consonances, out of the 14 we enumerated in chapter 4, Table 1, are not found exactly in this scale. The reason is that this scale takes account of tones and semitones, and it is not so much a division of one string as a comparison of many different strings. If the remaining eleven consonances were to be found in Guido's scale, then the numbers you see in the small table below would have to be found in it.

	Interval								
For	the ditone	as	5	to	4	thus	10368	to	8294
For	the semiditone	as	6	to	5	thus	10368	to	8640
For	the major hexachord	as	5	to	3	thus	10368	to	6220
For	the minor hexachord	as	8	to	5	thus	10368	to	6485
For	the major tenth	as	5	to	2	thus	10368	to	6147
For	the minor tenth	as	12	to	5	thus	18368	to	4320
For	the eleventh	as	8	to	3	thus	10368	to	3891
For	the major thirteenth	as	10	to	3	thus	10368	to	3112
For	the minor thirteenth	as	16	to	5	thus	10368	to	3240

In the systems already mentioned, but especially in the diatonic, Martianus Capella (book 9, the chapter *What a system is*) considers eight perfect species of systems: 1. from Proslambanomenos to Mese; 2. from Hypate hypaton to Paramese; 3. from Parhypate hypaton to Trite diezeugmenon; 4. from Lichanos hypaton to Paranete diezeugmenon; 5. from Hypate meson to Nete diezeugmenon; 6. from Parhipate meson to Trite hyperbolaeon; 7. from Lichanos meson to Paranete hyperbolaeon; 8. from Mese to Nete hyperbolaeon. Each species thus comprises an octochord.

V. Kepler, however, constitutes his consonances differently. I would therefore like to add here, from the third book of his *Harmonices*, chapter 11, the Greatest System. It contains the perfect and imperfect consonances, with their intervals, through two diapasons or through the disdiapason, which Ptolemy also called the perfect system; and it contains both perfect and imperfect consonances. To tell these apart we have added another small table of our own.

The Keplerian system [SYSTEMA KEPLERIANVM.]

Key	Interval	Number	Guido's key and syllables	String

B e	Major hexachord	5	3	1296	e Sixth, major, hard
B dg	Minor hexachord	8	5	1350	dg Sixth, minor, soft
B hh	Diapason with the ditone	5	2	864	hh Major tenth
B bb	Diapason with the semiditone	12	5	900	bb Minor tenth
B cc	Diapason-diatessaron	8	3	810	cc Eleventh
B ee	Diapason with the major hexachord	10	3	648	ee Major thirteenth
B ddg	Diapason with the minor hexachord	16	5	675	ddg Minor thirteenth
B g	✠ ✠ ✠	3 432/576	1	576	g Most imperfect fourteenth

The same Kepler, moreover, in book 3 of the *Harmonices*, chapter 7, divided the whole string into 720 equal parts and determined the length of the remaining strings up to the octave, for the hard and the soft song, as you see in the first of the small tables that follow. And in chapter 8, dividing the whole string into 2160 parts, he determined the least intervals within one diapason, as you can see in the second small table below.

Table I. Of the length of the strings [Tabula I. Longitudinis Chordarum.]

Order of the strings	For the soft song	For the hard song
8	360	360
7	405	405
6	450	432
5	480	480
4	540	540
3	600	576

CAPVT VII.

Chapter VII.

An & Quo ordine Musarum voces, & Chordarum sonos Cælestibus sphæris accommodare oporteat.

Whether, and in what order, the voices of the Muses and the sounds of the strings should be fitted to the celestial spheres.

[Margin: Sirens and Muses, presiding over the celestial orbs.]

I. I shall begin with Macrobius, who in book 2 on the *Dream of Scipio*, chapter 3, says: "Plato, in his *Republic*, namely in book 10, when he treated of the revolution of the celestial spheres, says that a Siren sits on each of the orbs, signifying that by the motion of the spheres song is offered to the divinities; for *Siren*, understood in Greek, means 'singing to God'. The theologians, too, the nine Muses, etc." And a little below: "That the Muses are the song of the world even country people know" — or, as others read, "the Etruscans know" — "who called them Camenae, as if Canenae, from *canendo*, 'singing'. Therefore the theologians too, approving that heaven is tuneful, applied musical sounds to sacrifices, which among some peoples used to be performed with the lyre and the cithara, among others with pipes and other musical instruments. In the very hymns to the gods, too, metres were applied in tuneful verses through strophe and antistrophe, so that by the strophe the direct motion of the starry orb, and by the antistrophe the contrary regression of the wandering stars, should be proclaimed; and from these two motions the first, in nature, to be dedicated to God took its beginning."

[Margin: Strophe and antistrophe, the symbol of the two motions of the heaven.]

That strophe and antistrophe, together with motion in a circle, were used to represent the two motions of the heaven is attested also by Didymus and Victorinus in the scholia on Pindar, by the ordinary gloss on Pindar, and also by Triclinius on Sophocles' *Electra*. Their words are quoted by Mazzonus [Jacopo Mazzoni] in the *Defence of Dante*, book 2, chapter 34. He reconciles Didymus and Victorinus, who say that the strophe ran from right to left, so as to show the motion from east to west, with the Gloss and Triclinius, who say that the strophe ran from left to right: the former spoke of the right and left of the world, the latter of the right and left of a man.

[Margin: The number and names of the Muses.]

But to return to the Muses: writers agree neither on their number, nor on their names, nor on their order and offices. Phurnutus [Cornutus] reported that there were once two, on account of theory and practice. Three, however, are given by Ephorus (as reported by Arnobius), by M. Varro, by St Augustine, and by Zezes [Tzetzes] the grammarian on Hesiod, namely Cephison, Apollonida and Boristhenida, daughters of Apollo; Glareanus (book 2 of the *Dodecachordon*, chapter 14) says this was invented on account of the threefold sound, which is made by the voice, by breath, or by striking. Aratus, however (book 5 of the ἀστρικῶν [astrikōn, "astronomical matters"]), posits four Muses, daughters of Jupiter and the nymph Plusia, namely Archen, Meleten, Thelxinoën and Acœdem. Cicero likewise records four, in book 3 of *On the Nature of the Gods*, but calls them Thelxiopem, Mnemen, Aoeden and Meleten, born of the second Jupiter; and as many born of Jupiter Pierius and Antiopa. Epicharmus, however, in the *Marriage of Hebe*, lists seven Muses, daughters of Pierus and the nymph Pimpleis, namely Nilum, Tritonem, Asopum, Heptapolem, Acheloida, Tipoplum and Rhodian. The more common opinion, however, with Homer, Hesiod and Orpheus, holds that there were nine Muses, daughters of Jupiter and Mnemosyne. Phurnutus does not dissent, saying that the ternary multiplied by itself produces the novenary number of the Muses; nor does Zezes, although he says that their names were once Callichorem, Helicen, Eunicen, Telxinoen, Terpsichoren, Euterpen, Enceladen, Dian and Europen. But Hesiod, in the *Theogony*, lists their names in this order:

> Clio and Euterpe and Thalia and Melpomene, Terpsichore and Erato and Polyhymnia and Urania, and Calliope; and she it is who brings them all forth in order.

[Margin: The discoveries and offices of the Muses.]

Nor do all writers record their discoveries and functions in the same way. Our fellow-citizen Lilius Gregorius Gyraldus [Lilio Gregorio Giraldi], in syntagma 7 of *On the Gods of the Gentiles*, under the word *Musa*, reports the following. Clio discovered history; Thalia φυτουργίαν [phytourgian, "planting"], that is, the art of plants; Euterpe the pipes; Melpomene the ode, that is, song; Terpsichore the dance, that is, the *tripudium*; Erato wedding rites and

dancing; Polymnia agriculture; Urania astrology; Calliope poetry. Further on, however, he interprets them allegorically: Urania as the sublimity of the intelligence; Polymnia as the capacity of memory; Euterpe as the delight of the will; Erato as the love of like things; Melpomene as the depth of thought; Terpsichore as the exercise of the arts; Calliope as the beauty of eloquence; Clio as good fame and glory, which arises from the things already mentioned; and Thalia as the budding of virtues. The same author, however, gives this Greek epigram, rendered by him into Latin:

> Calliope showed the hero the art of song; Clio brought forth the measures of the sweet-sounding cithara; Euterpe the resounding song of the tragic chorus; Melpomene stirred the lyre with sweet harmony; and pleasing Terpsichore made ready to blow the reeds; but Erato found the delightful hymns of the gods; Polymnia joined harmony and dances to numbers; Urania the chorus of the stars and the turnings of heaven; comic life and manners, Thalia, were found by you.

[Margin: Apollo Musagetes.]

Apollo himself, moreover, is called Μουσήγετος [Mousēgetos, "leader of the Muses"], that is, the Leader and Choragus of the Muses, as Phurnutus, Macrobius (book 2 on the *Dream of Scipio*, chapter 3) and Proclus on Plato report. The words of this Proclus are: "Apollo is worshipped as Musagetes, and is the unity directed to harmony in the universe; here, in turn, is the chorus of the Muses of the whole novenary number; and by these two the whole world is bound together with indissoluble bonds."

II. As regards the order of the Muses in relation to the spheres

[Margin: The order of the Muses in the heavens.]

of heaven with which they are compared, different writers hold different views. Plato, for his part, determined nothing on this point. Nor did Cicero, in his book on the *Dream of Scipio*, although he indicated his mind obscurely in these words: "All things are joined together for you in nine orbs, or rather globes. One of them, the celestial and outermost, which embraces all the rest, is itself the supreme God, holding and containing the others; in it are fixed those eternal courses of the stars that revolve. Beneath it are set seven, which turn backwards with a motion contrary to that of the heaven, etc." And a little below: "And in the lowest orb the Moon, kindled by the rays of the Sun, revolves" — the lowest, that is, of the moving orbs, for shortly afterwards he adds: "For the one that is in the middle and ninth, the Earth, does not move and is the lowest, and towards it all weights are borne by their own inclination."

[Margin: Cicero's opinion.]

Therefore, according to Cicero's mind, the lowest of the Muses is to be assigned to the Earth, and the highest to the sphere of the fixed stars or to the whole heaven, as containing in itself all the motions of the others.

[Margin: And Macrobius's.]

This passage of Cicero is explained by Macrobius (book 2 on the *Dream of Scipio*, chapter 3). He teaches that the Muses are to be ascribed to the celestial spheres in exactly the order in which Hesiod listed them, so that Clio is assigned to the lowest sphere and Urania to the eighth, while Calliope is the most beautiful voice, as arising from the concord of all the spheres. Macrobius's words are these: "The theologians, too, held that the nine Muses are the musical songs of the eight spheres and the one greatest containment, which consists of them all. Hence Hesiod, in the *Theogony*, calls his eighth Muse Urania, because after the seven wandering spheres that lie beneath, the eighth, the starry sphere set above them, is called by its proper name heaven. And to show that the ninth and greatest is the one produced by the concordant totality of sounds, he added: Καλλιόπη θ' ἥ δε προφερεστάτη ἐστὶν ἁπασάων [Kalliopē th' hē de propherestatē estin hapasaōn, "and Calliope, who is the foremost of them all"]. By the name itself he shows that the very sweetness of the voice is called the ninth Muse, for Καλλιόπη [Kalliopē] is, in its Greek interpretation, 'of the best voice'. And to indicate more pointedly that she is the one that consists of all, he gave her a word of totality, namely προφερεστάτη ἁπασάων [propherestatē hapasaōn, "foremost of all"]."

[Margin: Glareanus's opinion.]

Glareanus held the same view of Calliope, in book 2 of the *Dodecachordon*, chapter 12, in these words: "But the ninth orb must be understood as the symphony blended from these eight phthongi, and for this reason called Calliope, as Plato philosophizes about the Muses in the *Republic* — not rashly, in the judgment of all the learned; Cicero's treatment in the *Dream of Scipio* is the same." And in chapter 14 he affirms that, according to Plato in book 10 of the *Republic*, the Sirens assigned to the individual spheres were called the eight Muses on account of the eight sounds, while the symphony blended from them was called by Plato the ninth Muse, and by Hesiod Calliope, as the most excellent of all. He also praises Christophorus Landinus [Cristoforo Landino], because he interpreted better than Servius, with reference to this totality and excellence of the voices comprised in Calliope, that verse of Virgil in *Aeneid* 9:

> You, O Calliope, I pray, breathe upon me as I sing.

Here the best of poets used the plural number in addressing Calliope, as being the one who comprehended all the others in herself or under herself — which in *Aeneid* 7 he did not dare to do when he invoked Erato. Then, in the system of the world, together with Hesiod, Glareanus assigns Clio herself to the Moon, Euterpe to Mercury, Thalia to Venus, Melpomene to the Sun, Terpsichore to Mars, Erato to Jupiter, Polhymnia to Saturn, Urania to the fixed stars, and Calliope to the last orb of all.

[Margin: The opinion of Marsilio Ficino.]

But Marsilius Ficinus [Marsilio Ficino], on Plato's dialogue on poetic frenzy — and with him, subscribing to his view, Iosephus Zarlinus, in part 2 of the *Harmonic Institutions*, chapter 29 — applies Thalia to the Moon; Euterpe to Mercury, Erato to Venus, Melpomene to the Sun, Clio to Mars, Terpsichore to

Jupiter, Polhymnia to Saturn, Urania to the sphere of the fixed stars; and he sets Calliope over the individual spheres and over all of them together, to indicate the harmony that arises from them all.

But Gyraldus, in syntagma 7 of *On the Gods of the Gentiles*, under the word *Musa*, attributes Thalia to the Earth, as silent and having no harmony; to the Moon, Clio and the Hypodorian mode; to Mercury, Calliope and the Hypophrygian; to Venus, Terpsichore and the Hypolydian; to the Sun, Melpomene and the Dorian; to Mars, Erato and the Phrygian; to Jupiter, Euterpe and the Lydian; to Saturn, Polhymnia and the Mixolydian; to the fixed stars, Urania and the Hypermixolydian. This opinion is subscribed to, in Marinus Mersennius on chapter 4 of Genesis, verse 21, page 1704, by an unnamed author in the following distichs:

> First of all Thalia, who lies deaf in the lap of the Earth, makes the silences of night bud forth with song. Persephone (a) and Clio breathe; the Hypodorian therefore is born; hence it begets the Prosmeledes (b), sprung from it. And the following string gives the Hypo-Phrygian, which Calliope herself brings forth; the interpreter (c) of the gods himself brings it forth. The third shows the beginnings of the Hypolydian on the strings: Terpsichore comes to meet it; kindly Paphis (d) sets it in order. Melpomene and Titan (e), believe me, establish the mode which is said to be the Dorian, in fourth place. Erato wishes to assign the fifth string to the Phrygian, and so does Mars, who loves not peace, but always battles. You will have the Lydian measure of Euterpe and of Jupiter, which the sixth string, holding it sweetly, bade to be. Saturn and Polyhymnia drive the seventh string, from which the Mixolydian takes its beginning. While Urania searches out the friendly eighth, the Hypermixolydian turns the pole with art.

[Margin: a. It is Lu[?].]
[Margin: b. Proslambanomenos.]
[Margin: c. Mercury.]
[Margin: d. Venus.]
[Margin: e. The Sun.]

It is pleasing, therefore, to gather these opinions into one synopsis in the following small table.

Spheres (Glareanus, after Hesiod, Plato, Cicero and Macrobius)	Muses (Glareanus, after Hesiod, Plato, Cicero and Macrobius)	Ficinus and Zarlinus (after Plato)	Gyraldus and others in Mersennius
The ninth, or the eight together	Calliope	Calliope	✠
✳ Of the fixed stars	Urania	Urania	Urania
♄ Of Saturn	Polyhymnia	Polyhymnia	Polyhymnia
♃ Of Jupiter	Erato	Terpsichore	Euterpe
♂ Of Mars	Terpsichore	Clio	Erato
☉ Of the Sun	Melpomene	Melpomene	Melpomene

Spheres (Glareanus, after Hesiod, Plato, Cicero and Macrobius)	Muses (Glareanus, after Hesiod, Plato, Cicero and Macrobius)	Ficinus and Zarlinus (after Plato)	Gyraldus and others in Mersennius
♀ Of Venus	Thalia	Erato	Terpsichore
☿ Of Mercury	Euterpe	Euterpe	Calliope
☾ Of the Moon	Clio	Thalia	Clio
The Earth	✠	✠	Thalia

Thus all agree in the assignment of three Muses — Urania, Polyhymnia and Melpomene; in the rest not all agree.

[Margin: Our opinion, and a critique from Aristotle and Pliny.]

III. You will now ask us for our own view. Our answer is that these analogies and harmonies were determined by the authors already mentioned "more prettily than truly", to use the words of Aristotle (book 2 of *De caelo*, text 52); or that, with Pliny (book 2, chapter 22), it is said "that Saturn moves in the Dorian, Mercury in the phthongus, Jupiter in the Phrygian, and similarly in the rest, with a subtlety more pleasing than necessary". And Macrobius himself, in book 2 on the *Dream of Scipio*, chapter 4, says that to pursue these matters more subtly "is the mark of one showing off, not of one teaching". Of the same opinion are Glareanus (book 2 of the *Dodecachordon*, chapter 13, at the end), Zarlinus (part 2 of the *Harmonic Institutions*, chapter 29, at the end), Mersennius (on chapter 4 of Genesis, page 1704) and Kircherus [Athanasius Kircher] (book 10 of the *Musurgia*, page 381).

[Margin: Our first reason.]

The reason that moves me, however, is not a single one. First, we made plain enough under number one how inconstant the tradition was about the number, the names and the properties of the Muses.

[Margin: 2nd reason.]

Second, the order of the celestial spheres among the older astronomers was itself also varied, as is clear from the variety of systems we have already set out in book 3, chapter 6, and book 9, section 3. So you would not satisfy even Macrobius by assigning Thalia and Euterpe to Venus and Mercury, since he admits that those planets are also carried above the Sun.

[Margin: 3rd reason.]

Third, if the Sun is the leader of the Muses, and is therefore called Musagetes, how does one of the Muses preside over his sphere — as his deputy, or helper? Again, if no ninth sphere distinct from the others is granted for the primum mobile, but each planet is moved by a single spiral motion, there will be no sphere to which Calliope or another ninth Muse may be assigned; and much less is a Muse of its own to be given to the Earth, since it does not move.

[Margin: 4th reason.]

Fourth, how do the Muses and the Sirens fit together in Plato's opinion, if elsewhere Greece told the fable that the Sirens were defeated by the Muses in a singing contest? It is better, therefore, to dismiss these fables and to recognize,

in place of the Muses, the Peripatetic Intelligences — which the theologians also recognize — as the governors of the heavens.

De Chordarum & Cælestium sphærarum Analogia.

On the analogy of the strings and the celestial spheres.

[Margin: The inventor of the lyre: Mercury, or Apollo?]

IV. Before we deal with the strings of the celestial lyre, we must briefly inquire who the inventor of the lyre was, and how many strings it had. For if we believe Diodorus Siculus, Mercury devised a three-stringed lyre, but Orpheus made it a tetrachord. Terpander, on the testimony of Plutarch in his short work *On Music*, added to it laws and names for the strings — granted that Suidas, Boethius (book 1, chapter 20) and Aristotle (section 19, problem 32) attribute a seven-stringed lyre to him. But Macrobius (book 1 of the *Saturnalia*, chapter 19) relates that the tetrachord was attributed to Mercury, to signify the same number of regions of the world, or seasons of the year; and he adds: "Just as the lyre of Apollo, of seven strings, gives us to understand the motions of as many celestial spheres, among which nature has set the Sun as governor." But Hyginus, in his *Poetic Astronomy*, affirms that Mercury was the inventor of the seven-stringed lyre, on account of the number of the seven Pleiades, or Atlantids; that when he had driven off Apollo's cattle, he complied with Apollo in order to satisfy him as he pursued him, and agreed that Apollo should name himself the inventor of the seven-stringed lyre; and that he was rewarded besides by Apollo with that rod with which Mercury, a little later, reconciling two serpents, used to carry the caduceus in return for the lyre. But even before Hyginus, Homer, in the hymn he dedicated to Mercury, recognizes him as the inventor of the seven symphonies through as many strings, made from the guts of birds, in this verse:

> Επτὰ δὲ συνφώνος ὀίων ἐτανύσατο χορδὰς [Hepta de synphōnos oiōn etanysato chordas, "and he stretched seven concordant strings of sheep"] — that is: "And he stretched seven consonant strings made from the guts of sheep."

Horace agrees with this (book 3 of the *Odes*, Ode 11), addressing Mercury and his tortoise-shell:

> And you, tortoise-shell, skilled to resound with seven strings.

In imitation of this, or to imitate the 7 symphonies, whether celestial or human, Pan is believed to have been the first to join seven reeds into one wind instrument. Ovid mentions a pipe of this kind in *Metamorphoses* 2, in this half-line:

> … a pipe unequal with its seven reeds:

And Corydon in Virgil, *Eclogue* 2:

> I have a pipe made of seven unequal hemlock stalks.

Granted that the well-known Menalcas in Theocritus boasts of a pipe of nine voices, or reeds, made by himself, in this verse:

> Συρίγγαν ἐπόησαν καλὰν ἐγω ἐννεάφωντον [recte: ἐννεάφωνον]
> [syringan epoēsan kalan egō enneaphōnton, "a fine pipe of nine voices"]

that is:

> I myself made a beautiful syrinx of nine voices.

But to return to the seven-stringed lyre: Glareanus (book 2 of the *Dodecachordon*, chapter 12) holds that its seven strings signify the seven species of consonances into which the diapason is divided, and which reign in the two octochord instruments; and to this he draws that line of Virgil in *Aeneid* 6:

> And the Thracian priest, too, in his long robe, answers the measures
> with the seven distinct notes.

[Margin: 7 species of the diapason.]

These species are: the diapason; the diapason-diapente; the disdiapason; the diapason with the ditone; the diapason with the semiditone; the diapason with the major hexachord; and the diapason with the minor hexachord — unless by these you understand the 7 simple consonances that we listed in chapter 4, table 1.

V. But whatever may be the case about the inventor and purpose of the seven-stringed lyre, or of the nine-stringed lyre or pipe, it is certain that some authors, not to be despised, recognized in the celestial spheres intervals and differences of deep and high notes, and therefore fitted to them the strings of the lyre or of the harmonic system. Cicero led the way for them from the Platonic source, in the *Dream of Scipio*. When Scipio asks, "What is this, I said, what is this sound, so great and so sweet, that fills my ears?", Cicero brings in his father Paulus answering in these words:

[Margin: Cicero's opinion on the high sound of the highest sphere.]

"It is the sound, he said, which, joined by unequal intervals, yet distinguished in a fixed proportion, is produced by the impulse and motion of the orbs themselves; tempering the high with the low, it produces harmonies evenly. For such great motions cannot be roused in silence, and nature brings it about that the extremes sound low at one end and high at the other. For this reason that highest course of the starry heaven, whose revolution is swifter, moves with a high, roused sound, while this lunar and lowest course moves with the deepest. For the Earth, the ninth, remaining immobile, always stays fixed in the lowest seat, embracing the middle place of the world. But those eight courses, in which two have the same power, produce seven sounds distinguished by intervals — a number that is the knot of almost all things. Learned men, imitating this with strings and songs, have opened for themselves a way back to this place."

[Margin: Macrobius's opinion.]

Explaining these words, Macrobius (book 2 on that *Dream*, chapter 4) teaches that a sharper sound comes from a great and rapid collision of the air, and a deeper one from a slow and more sluggish one. He confirms this both by the example of a rod swung through the air and by that of strings, which sound high if they are stretched with a tighter pull, and lower if with a looser one;

and of pipes and flutes, in which, he says, holes that are narrower, or farther from the mouth of the one blowing, give a deeper sound than those that are more open, or nearer the mouth. From this he concludes that the highest sound is owed to the supreme, starry orb, both on account of its size, by which it extends without measure, and on account of the very great speed of its daily motion towards the west; whereas the deepest sound is owed to the Moon, on account of the narrowness of its orb and the slowness of its motion. He also concludes that, of the 9 spheres described by Tullius [Cicero], the Earth is immobile and the other eight are mobile, but that there are only seven sounds, because Mercury and Venus are moved with the same motion as the Sun; and that for this reason Cicero said that two have the same power.

[Margin: Glareanus's exposition of Cicero's text.]

Glareanus, however (book 2 of the *Dodecachordon*, chapter 13), thinks that the passage of Cicero is corrupt and was not well enough understood by Macrobius; and that the word *Septem*, "seven", is to be referred not to the sounds but to the intervals, so that the eight courses produce as many sounds, but sounds separated from one another by seven intervals. Or rather, it should be read thus: "But those eight courses, in which the power of the extremes is the same, produce seven intervals with distinct sounds." For by the laws of music eight phthongi, or principal notes, produce seven intervals, or seven species of the diapason.

[Margin: The cause of the diversity of opinions on this.]

VI. Now, from the sources of Plato and Cicero, three different opinions have flowed. The first assigns to the supreme sphere the highest of the strings — that is, either the *mese*, which is the highest of the first nine strings in the harmonic system, or the *nete hyperbolaeon*, which is the highest in the ancient system of 15 strings. The second assigns to the supreme sphere the deepest of the strings, namely the *proslambanomenos*, or at least the *hypate hypaton*. The third, finally, either adheres to both under different respects, or strives to reconcile both — granted that it leans towards one rather than the other. The reason for these different opinions is both the twofold motion that appears in the heaven, and the differing distance and size of the orbs. For if one considers the common motion, called that of the primum mobile, towards the west, the fixed stars move faster than Saturn, and Saturn faster than the remaining lower planets; and on that account the highest sound is owed to the sphere of the fixed stars. But if one considers the apparent proper motion towards the east, the sphere of the fixed stars is the slowest, then Saturn, and so on; so, on account of this cause of motion, the deepest sound seems to be allotted to them. Conversely, since the length of a string and the size of bodies give a deeper sound than shortness and smallness, as Aristotle teaches (section 19, problem 8), a deeper sound seems to be attributed to the spheres and stars more remote from the Earth. It is disputed besides whether the string giving the deepest sound ought to be placed in the lowest place of the musical system and of the tetrachords, and the highest string in the highest place; or rather the deepest in the highest

place and the highest in the lowest. Glareanus discusses this question learnedly in book 1 of the *Dodecachordon*, chapter 5, and book 2, chapter 8.

[Margin: 1st opinion: of Cicero, Macrobius and Guido Aretinus.]

VII. The first opinion is that of Guido Aretinus, whom many have followed. As is clear from the systems set out in chapter 5, after number 3, he put in the lowest place the deepest string, Gamma-ut, which the proslambanomenos follows, and in the highest degrees of the scale the higher sounds. This agrees with Cicero (book 6 of the *Republic*, or the *Dream of Scipio*) and with Macrobius: namely, that the upper bodies, as being swifter in the daily motion, give a higher but smaller sound, while the lower bodies, being slower, give a greater but deeper so- und. This opinion was followed by Gulielmus Philander [Guillaume Philandrier] on Vitruvius, book 5, chapter 4, who attributes it to the ancients; by Gyraldus, in syntagma 7 of *On the Gods of the Gentiles*, under the word *Musa*; by Valla on Pliny, book 2, chapter 22; by Father Athanasius Kircher, book 10 of the *Musurgia*, page 393; and by the unknown author in Mersennius on chapter 4 of Genesis, verse 21, page 1704. For they give the deepest string to the Moon or to the Earth, and the highest to Saturn or to the sphere of the fixed stars.

[Margin: Of Philander, Gyraldus, Valla, Kircher.]

These writers are certainly supported, on the one hand, by the order of the strings on the cithara, which is the reverse of the order of the strings on the lyre. For on the lyre the deepest and thickest string is in the highest place, whether the lyre is a trichord, a tetrachord or a hexachord; but on the cithara the deepest and thickest of the strings is in the lowest seat, and the highest in the highest — an order that our organs still keep, in which the thicker pipes are placed in the lower row and the more slender in the upper. And, on the other hand, the human voice too begins more often not from the highest but from the lowest, and from a deeper sound, and rises little by little, by a natural transition, to a higher one. For the deeper voice is, as it were, the foundation, without which the upper and higher voices seem to degenerate into chatter, unless they are sustained by the strength and firmness of a deeper voice. Although the highest voice may seem to soothe the hearing more sweetly, yet, as Glareanus noted above, no song is more pleasing than when the lowest voice sounds firmly; and the upper voices achieve almost nothing without the Bass of the lower voices — for so Julius Pollux names the deeper voices. Nor today is the consonance of the diatessaron admitted unless it is propped up from below by the support of the diapente, that is, the fifth, or else of the third. Mersennius, too, although on chapter 4 of Genesis, page 1704, he rejects fictions of this kind, nevertheless on page 1705 describes, from the secrets of the Cabbalists, the ten-stringed cithara of David with the following analogy, in which he assigns the higher sound to the highest spheres and spirits. Here it is in a table.

[Margin: The strings of the Davidic cithara according to the Cabbalists.]

Strings	Names of the strings	Notes	Bodies	Spirits
1	Parhypate meson	F fa ut	The elements	The blessed soul
2	Lichanos meson	G sol re ut	☾	Angels
3	Mese	A la mi re	☿	Archangels
4	Paramese	B fa b mi	♀	Principalities
5	Trite diezeugmenon	C sol fa ut	☉	Virtues
6	Paranete diezeugmenon	D la sol re	♂	Powers
7	Nete diezeugmenon	E la mi	♃	Dominations
8	Trite hyperbolaeon	F fa ut	♄	Thrones
9	Paranete hyperbolaeon	G sol re ut	✳	Cherubim
10	Nete hyperbolaeon	A la mi re	The first moved ("1. Mobile")	Seraphim

[Margin: 2nd opinion.]

VIII. The second opinion assigns the deeper sound to the upper spheres: either because it takes them to be slower, when their proper motion is considered, or because, even if the greater speed of the common motion confers sharpness on them, the length of the interval and the size of the bodies nevertheless produce a deeper and greater sound — just as with the strings of many-stringed instruments, in which the thicker and larger string produces a deeper but more sonorous voice.

[Margin: Of Nicomachus.]

This was the opinion of Nicomachus in the *Enchiridion of Harmonics* — as Boethius and Philander report — who accordingly assigned the hypate to Saturn and the nete to the Moon. Servius Honoratus, too, explains Virgil's phrase "through the friendly silences of the silent Moon" in this way: "'Of the silent Moon': either he means night, in the poetic manner, or he spoke on a physical account. For there are seven circles: of Saturn, Jupiter, Mars, the Sun, Venus, Mercury and the Moon. And the first, that is, Saturn, sounds vehemently, the rest less according to their order, as we have heard in the cithara, whose last string sounds less."

[Margin: And of Servius the grammarian.]

There, by the last string of the cithara, Servius means the one that is nearer to our ears, and in this respect he compares it with the Moon — not according to the order of upper and lower position, for the Moon is below and Saturn above, whereas on the cithara the highest and thinnest string, of least sound, is above, and the deepest below. Therefore Angelus Politianus [Angelo Poliziano], in the last chapter of the *Miscellanea*, neither understood Servius nor justly censured him, when he says: "This, then, will at last hold good, if he takes the last not for the lowest but for the highest, which in Greek is called the hypate, from which a deeper sound is roused; just as from the other, outermost and thinnest string — which I for my part would gladly call the last — a high voice is brought forth, because it is stretched forward."

But Politianus is more justly censured by Glareanus (book 2 of the *Dodecachordon*, chapter 8), where he teaches that Servius spoke truly and according to the nature and series of the celestial orbs (if there were any sound there), and

indeed according to the strings of the cithara as well; for on it the hypate, the deepest of the strings, holds the lowest place, and the highest string the last, which, even if it is stretched to the utmost, is not for that reason heard the most. "For granted," says Glareanus, "that in one and the same string its sharpness strikes the hearing more when it is stretched hard than its depth does when it is stretched more loosely; yet among different strings, the one that is larger and thicker is heard more, and makes a greater sound, than one that is more slender, even if the latter is stretched more and sounds higher — just as the sound of a man with a good voice is heard more than the wailing or crying of a little boy. Hence too it is that the higher voices achieve almost nothing without the base and firmness of the deeper ones."

[Margin: And of Angelo Poliziano.]

It appears, however, that Politianus judged rightly as far as this goes, in granting the deeper sound to the hypate; and that, by putting it in the highest place, he subscribed to Servius, who attributes it to Saturn.

[Margin: And of Boethius.]

Of the same opinion, finally, was Severinus Boethius. For he not only recognized the hypate as the deepest of the strings, but also assigned it to the upper spheres. In book 1 of his *Music*, chapter 20, he says of the strings: "And among these, the one that was the deepest was called hypate, as being greater and more venerable; hence they also call Jupiter Hypatos. They call a consul, too, by the same name, on account of the excellence of his dignity; and it was attributed to Saturn on account of the slowness of his motion and the depth of his sound." So too, in book 4, chapter 10, he puts the proslambanomenos in the highest place and the nete in the lowest.

[Margin: Glareanus's opinion.]

And Glareanus, a follower of Boethius, absolutely denies that there is sound in the heavens, or any true account of symphony, as is clear from book 2 of the *Dodecachordon*, chapter 14, from the paragraph *Ceterum* to the end. Yet on the supposition either that there were some sound in the heaven, or that one should philosophize about the celestial bodies as about terrestrial sounding ones, he inclines to Boethius's view. For in book 1 of the *Dodecachordon*, chapter 5, he says: "I am not unaware that to many this order of the strings laid down by Guido seems inverted, and entirely contrary to the natural course of the heaven from which this formula was taken, since the upper bodies of the celestial orbs give a deeper sound, as being greater. And the divine Severinus Boethius, too, seems to have observed this everywhere in his demonstrations." And a little later: "Whether, then, we also invert them, so that the upper are the deeper — namely so that we put the tetrachord hypaton in the highest place, with the proslambanomenos, which Severinus sometimes does — either on account of the name [?] hypatos, which means 'principal', or because it so seemed to the first teachers of this art. For many old instruments, too, such as trichords, tetrachords and hexachords, still have it so, etc." And in book 2, chapter 8, he says that Servius spoke "both truly and according to the nature and series of the

celestial orbs (if there is any sound there)"; and it is clear from what has been said that Servius gave Saturn the deepest and most vehement sound. And in chapter 13, after recounting Cicero's opinion, he departs from it and adds: "Others, on the contrary, ascribed the higher sounds to the lower bodies, and the deeper, or greater, to the upper, because larger bodies also give a greater sound and smaller ones a smaller — an opinion that seems to me far more probable, since bodies in the heaven are as they are in this sensible world." And he adds a twofold type: one Ciceronian, in which he assigns the shorter and higher strings to the upper spheres; the other Boethian, in which he assigns the longer and deeper strings to the upper spheres. We shall display these types within a table, together with others. In chapter 14, however, he chose the Boethian type alone — as does Mario Bettini in the *Apiaria*, apiary 10, progymnasma 1, proposition 1, inasmuch as he applies the hypate to the fixed stars, the parhypate to Saturn and the nete to the Moon.

[Margin: And of Bettini.]

This opinion is favoured, moreover, by the order of the lyre, in which the thicker string, of deeper sound, holds the highest place, and the string of higher sound holds the lowest — as is also kept, for the most part, in other instruments.

[Margin: 3rd opinion.]

IX. The third opinion shows itself indifferent. Zarlino holds it, in part 2 of the *Harmonic Institutions*, chapter 29, where he sets out two systems: one according to Cicero, but assigning the mese to the fixed stars and the proslambanomenos to the Moon; the other according to Boethius. Within the three opinions already mentioned, however, there is still some variety as regards the whole order of the strings, as will appear more clearly from the following tables.

CHORDARVM CÆLESTIVM ORDO

The order of the celestial strings

	According to Cicero and Macrobius: Glareanus, Zarlino and Gyraldus	According to Cicero and Macrobius: Gulielmus Philander	According to Cicero and Macrobius: Father Athanasius Kircher	According to Nicomachus and Boethius: Glareanus and Zarlino	According to Nicomachus and Boethius: Mario Bettini

The Earth			Proslam-banomenos	Nete synemmenon a la mi re	

Foot of the table: Add to these what I reported from the Cabbalists at the end of number 7.

[Margin: The author's opinion.]

X. What our own opinion on this matter is can already be clear from what was said at the beginning of number 3: namely, that these things are investigated more charmingly than truly, or with a subtlety more pleasing than necessary, as we said there with Aristotle and Pliny. And Macrobius, very prudently, in book 2 on the *Dream of Scipio*, chapter 4, when he had this controversy in hand, concluded with these words:

[Margin: An excellent sentence of Macrobius.]

"To illuminate, as I think, the obscurity of Cicero's words, the treatise on music that we have given succinctly, with such brevity as was permitted, will suffice. For to search out the netes and hypates and the names of the other strings, and to stitch together the minute subtleties of tones or limmas, and what in sounds is taken for a letter, what for a syllable, what for a whole word, is the part of one who makes a display, not of one who teaches. Nor, because Cicero made mention of music in this place, must we on this occasion go through all the treatises that there can be about music — treatises which, as far as my opinion goes, I do not think have any end."

[Margin: Glareanus's absolute sentence.]

Imitating him, I believe, Glareanus concluded near the end of chapter 13 of book 2 of the *Dodecachordon*: "Not without reason did this fiction seem to Aristotle more pleasing to tell than likely to be true"; and a little later: "But this indulgence is granted to antiquity, which thought that human minds were to be raised in any way it could to the contemplation of celestial things." Zarlino himself too, at the end of chapter 29 of part 2, concludes with Pliny that these things are investigated with a pleasure more subtle than necessary; and Marinus Mersennius, on chapter 4 of Genesis, verse 21, page 1704, rejects all these fictions

as put forward without sufficient proof. And long before them, St Ambrose, in the book *On Isaac and the Soul*, chapter 7, denied that fictions of this kind about the harmony of the heavens find credence, although on account of the pleasantness of the discourse they are heard with favour and delight — as we showed in chapter 2 from his own words.

[Margin: Our 1st reason.]

Nor am I moved only by the reason that there is no real sound in the heavens — what I thought about this I said in the same chapter 2. First, rather: even if there were some sound, the truer order of the planets is not the one that the authors already mentioned suppose. And it may indeed seem astonishing that Fathers Mersennius and Kircher, more recent astronomers, place Mercury nearer the Moon than Venus, unless you say they spoke according to the opinion of the ancients. But since these two planets are carried now below and now above the Sun, do they not measure out by their motions the whole portion of that system which runs from their apogee to their perigee? Similarly Mars too, which at times becomes nearer the Earth than the Sun: does he not occupy in great part, by his own ascent and descent, that interval through which the Sun, Venus and Mercury ascend and descend, and mingle himself with them, so that you cannot ascribe to him a distinct string or interval?

[Margin: [?] Reason.]

Second: since it is more probable that the planetary heavens are fluid, and that the planets move in them of themselves and not by the motion of orbs, as was said in section 1, chapter 2, question 2, and chapter 7, a greater sound could indeed be attributed to the sphere of the fixed stars, as being solid, as to a greater body; but a greater sound could not be attributed to Saturn, Jupiter and Mars than to the Sun, since the Sun is greater than those three planets.

[Margin: 3rd reason.]

Third: since there are eight different species of harmonic systems, as I showed from Martianus Capella in chapter 5, at the end of the chromatic and enharmonic system, it is very uncertain which of them should be assigned to the celestial system.

[Margin: 4th reason.]

Fourth: if one were free and had the leisure to play at these things, account would have to be taken both of the satellites of Saturn and Jupiter, and of the differing position that the planets hold at the apogee and perigee of the eccentric and of the epicycle, and of the differing altitude that the fixed stars hold.

[Margin: 5th reason.]

Fifth: as regards speed and slowness of motion — since in reality they are not moved by any other real motion than toward the west, although because of their slowness the lower ones seem to recede toward the east — a higher sound would certainly have to be assigned to the upper ones, as being absolutely swifter in this motion, except when they become retrograde. On the other hand, the three upper planets, because of the greater mass of their bodies, would

require a deeper sound than the three lower ones. Thus one reason destroys the other; and therefore this analogy, sung up with a charm rather oratorical and academic, loses all its harmony through its very discord — to say nothing of the disagreement among the authors themselves in distributing the strings over the heaven.

CAPVT VIII.

Chapter 8.

An & Qua ratione Distantijs Siderum Interualla Systematis Harmonici debeant accommodari.

Whether, and by what method, the intervals of the harmonic system should be fitted to the distances of the stars.

Achilles Tatius, in the *Isagoge* to Aratus's *Phaenomena*, in the chapter on the order of the spheres, 7, says: "Of their harmonic motion, as has been said, Aratus treats in the *Canon*, and Eratosthenes in the *Mercurius*, and also Hypsicles, Thrasyllus and Adrastus of Aphrodisias; the authors of this doctrine were the Pythagoreans, who think that all things are moved in harmony and order." Boulliau, too, at the end of the Prolegomena to the *Astronomia Philolaica*, names the *Harmonicon caeleste* of Franciscus Vieta [François Viète], which Petrus Puteanus [Pierre Dupuy] had lent for use to Father Marinus Mersennius, from whom, how- ever, it was stolen. But since we do not know their opinion, we shall come down to the views of others.

[Margin: 1st opinion, of the Pythagoreans.]

I. The first opinion was that of the Pythagoreans, which we shall try to fish out from Pliny, Plutarch and Censorinus. Pliny, then, in book 2, chapter 21, says: "Many have tried to track down the intervals of the stars from the Earth, and they have reported that the Sun is distant from the Moon nineteen parts, each as great as the distance of the Moon itself from the Earth. But Pythagoras, a man of shrewd mind, inferred that from the Earth to the Moon is one hundred and twenty-six thousand stadia; from the Moon to the Sun double that; and from there to the twelve signs triple; and our own Gallus Sulpicius was of this opinion too."

[Margin: The distance of the Moon from the Earth and from the Sun according to the ancient mathematicians.]

Partly twin to this passage is the one in Plutarch, book 2 of the *De placitis* (*On the Opinions of the Philosophers*), chapter 31, where he says: "Empedocles: that the Moon is twice as far from the Sun as from the Earth. The mathematicians: that the Moon is distant from the Sun nineteen parts, each as great as its own distance from the Earth. Eratosthenes: that the Moon is seven hundred and eighty thousand stadia distant from the Earth." I should think, however, that these mathematicians, who determined the distance of the Moon from the Sun as nineteen times the distance of the Moon from the Earth, were Aristarchus

and Hipparchus and their followers. For Aristarchus, in the book *On the Sizes and Distances of the Three Bodies*, proposition 7, had already demonstrated "that the distance by which the Sun is distant from the Earth is greater than eighteen times the lunar distance from the Earth, but less than twenty times": that is, about nineteen times. And Hipparchus put the distance of the Moon at about 64 terrestrial semidiameters, and that of the Sun at 1200, which is to 64 about as 19 to 1.

It is surprising, then, that Eratosthenes gave the lunar distance only 780,000 stadia, that is, 97,500 Italian miles. For, from what was said in book 2, chapter 7, Eratosthenes put 80,181 stadia in the diameter of the Earth and 40,090½ in the semidiameter; and when 780,000 stadia are divided by 40,090½, there come out, for the lunar distance, 19 whole terrestrial semidiameters.

[Margin: Pythagoras's earlier opinion, most absurd.]

But Pythagoras must have blundered far more shamefully, since he granted this distance no more than 126,000 stadia, which, divided by 8, make 15,750 Italian miles — that is, scarcely 4 semidiameters of the Earth. The lunar parallax protests against this, for we have already proved, in book 4, chapter 14, that it requires more than 51 semidiameters of distance from the Earth. If this distance were doubled, the distance of the Sun would come out at 8 terrestrial semidiameters, and if tripled, the distance of the fixed stars would be 12 semidiameters of the Earth. So if we followed this ancient opinion of Pythagoras, the Sun and the fixed stars would be subject to a parallax of several degrees, against the evidence of observations. With these rudiments set out first, however, let us pass on to his other opinion.

[Margin: Pythagoras's later opinion.]

II. Having finished chapter 21, then, Pliny, in book 2, chapter 22, goes on to say: "But Pythagoras at times, on a musical principle, calls the distance of the Moon from the Earth a tone; from the Moon to Mercury, half of that space; and from Mercury to Venus about as much; from Venus to the Sun one and a half; from the Sun to Mars a tone, that is, as much as to the Moon from the Earth; from Mars to Jupiter a half, and from Jupiter to Saturn a half, and from there one and a half to the zodiac [Signiferum]: so that seven tones are made, which they call the diapason harmony, that is, the universality of concord. In it Saturn is moved in the Dorian, Mercury in the phthongus, Jupiter in the Phrygian, and similarly in the rest" — a subtlety more pleasing than necessary.

Censorinus, in the book *De die natali*, chapter 11, sets out this view more explicitly indeed, but in the distance of Saturn from the fixed stars he differs from Pliny unless the text is corrected. For he says: "Pythagoras taught that this whole world was made on a musical principle, and that the seven stars wandering between heaven and Earth, which govern the births of mortals, have a well-proportioned motion [Greek: ἔυρυθμον (eurythmon, "well-rhythmed")] and intervals suited to the musical diastemata, and give out various sounds, each according to its altitude, so concordant that they make indeed a most sweet melody, but one inaudible to us because of the greatness of the sound, which

the narrowness of our ears could not take in." And a little after: "Pythagoras indicated how many stadia there were between the Earth and each of the stars. By the stadium in this measurement of the world is to be understood chiefly the one they call Italian, of 625 feet" — that is, of 125 paces, which make an eighth part of an Italian mile. He then goes on to say: "Thus he thought that from the Earth to the Moon is about 126 thousand stadia, and that this is the interval of a tone; from the Moon to the star of Mercury, which is called Stilbon [Greek: στίλβων (stilbōn, "the Gleamer")], half of that, as it were a hēmitonion [Greek: ἡμιτόνιον (hēmitonion, "half-tone")]; from there to Phosphoros [Greek: φόσφορον (phosphoron, "the Light-bearer")], which is the star of Venus, about as much, that is, another hēmitonion; from there further to the Sun, three times as much, as it were a tone and a half; and so the star of the Sun is three tones and a half distant from the Earth, which is called the diapente, and from the Moon two and a half, which is called the diatessaron; and from the Sun to the star of Mars, whose name is Pyroeis [Greek: πυρόεις (pyroeis, "the Fiery")], there is as much interval as from the Earth to the Moon, and this makes a tone [Greek: τόνον (tonon, "a tone")]; from there to the star of Jupiter, which is called Phaethon [Greek: φαέθων (phaethōn, "the Radiant")], half of that, which makes a hēmitonion; as much from Jupiter to the star of Saturn, whose name is Phainon [Greek: φαίνων (phainōn, "the Shiner")], that is, another hēmitonion; from there to the highest heaven, where the signs are, likewise a hēmitonion [?]. And so from the highest heaven to the Sun the diastema is a diatessaron, that is, of two tones and a half; and to the summit of the Earth from the same heaven there are six tones, in which is the symphony of the diapason [Greek: διὰ πασῶν (dia pasōn, "through all")]."

Zarlino, too, described the numbers and proportions of Censorinus in part 1 of the *Harmonic Institutions*, chapter 6, putting six tones from the Earth to the highest heaven — not on his own opinion, but on that of Pythagoras. For he himself denies that there is a tone from the Earth to the Moon, since the Earth, being immobile, is unfit to render any sound, and so to sound in concert with the Moon.

[Margin: Pliny to be corrected.]

Georgius Valla, in book 1 of his *Music*, chapter 2, refers that "sesquiplum" in Pliny not to a tone but to a semitone, so that from Saturn to the fixed stars there are three quarters of a tone. Glareanus, however, in book 2 of the *Dodecachordon*, chapter 13, affirms that all the old codices of Pliny have not *seven* but *six* tones, and that accordingly "semitonium" should be read for "sesquiplum"; he denies, moreover, that the diapason can arise from seven tones on any opinion of the musicians, and much less on that of Aristoxenus. Certainly, if we consult Guido's scale, taken from Boethius but enlarged and corrected, which we set out in chapter 6, number 3, we shall see that from the first string to the eighth, which make the consonance of the diapason, there are indeed seven intervals, but only 6 tones, namely 5 whole ones and two semitones [hemitonia]. Finally, Censorinus, a most diligent author, cannot be reconciled with Pliny in any

other way. Since he affirms that the Pythagorean stadia are equal to the Italian, and so Pythagoras puts no more than 126,000 stadia from the Moon to the Earth, that is, 15,750 Italian miles, which are about 4 semidiameters of the Earth, we shall easily construct the following small table, with parallaxes agreeing with the Pythagorean intervals.

PYTHAGORICA INTERVALLA

The Pythagorean intervals, from Pliny corrected, and from Censorinus

Body	Distances of the planets from one another: interval	Distances of the planets from one another: semid. of the Earth	And from the Earth: semid. of the Earth	Horizontal parallax

✳	—	—	24	2° 23′

[Margin: 2nd opinion, of the Platonists.]

III. The second opinion was that of the Platonists rather than of Plato himself. They rejected the distances of the planets determined by Archimedes for no other reason than that these did not preserve the proportions due to music, as Macrobius relates in book 2 on the *Dream of Scipio*, chapter 3, where he has this: "Rightly, then, everything that lives is captivated by music, since the celestial soul by which the universe is animated took its origin from music. While it drives the body of the world to its spherical [?] motion, it produces a sound which is separated by unequal intervals, yet intervals distinguished by reason in due proportion, just as it was woven together from the beginning. But these intervals, which in the soul, being incorporeal, are judged by reason alone, not by sense — it must be asked whether this balanced measurement has also been preserved in the very body of the world. And Archimedes indeed believed that he had found out the number of stadia by which the Moon was distant from the surface of the Earth; Mercury from the Moon; Venus from Mercury; the Sun from Venus; Mars from the Sun; Jupiter from Mars; Saturn from Jupiter. And he thought he had also measured by reason the whole space from the

orb of Saturn up to the starry heaven itself. This measurement of Archimedes, however, was rejected by the Platonists, as not preserving the double and triple intervals. And they laid down that this is to be believed: that as great as the distance is from the Earth to the Moon, twice that is from the Earth to the Sun; and as great as it is from the Earth to the Sun, three times that is from the Earth to Venus; and as great as from the Earth to Venus, four times that is from the Earth to the star of Mercury; and as great as it is to Mercury from the Earth, nine times that is from the Earth to Mars; and as great as from the Earth to Mars, eight times that is from the Earth to Jupiter; and as great as it is from the Earth to Jupiter, twenty-seven times that is from the Earth to the orb of Saturn. Porphyry inserted this Platonic conviction into the books in which he shed some light on the obscurities of the *Timaeus*; and he says that they believe these intervals to be in the body of the world after the image of the weaving of the soul — intervals which are filled out with epitrites, hemiolii and epogdoi, with semitones and the limma — and that so the harmony comes about."

Marsilius Ficinus [Marsilio Ficino] also reports these proportions, in the *Compendium* on Plato's *Timaeus*, chapter 34, and asserts that they seem to him the more probable, and in keeping with Plato's mind in the *Timaeus* and in books 8 and 10 of the *Republic*. To weigh these intervals, then, we shall take the lunar distance from the Earth as very nearly 60 terrestrial semidiameters, according to what was said in book 4, chapter 4. With this posited, the Platonic intervals will be as can be seen in the following small table.

INTERVALLA PLATONICA.

The Platonic intervals

Body	Ratio to the distance from the Earth immediately preceding	Distance from the Earth, in units of which the lunar distance is one	Distances from the Earth, in units of which the lunar distance is 60
The Earth			
☾	1	1	60
☉	Double the lunar	2	120
♀	Triple the solar	6	360
☿	Quadruple the Venerean	24	1440
♂	Ninefold the Mercurial	216	12960
♃	Eightfold the Martial	1728	103680
♄	Twenty-sevenfold the Jovial	46656	2799,360

[Margin: The absurdity of the Platonic intervals.]

The distance of the Sun from the Earth, then, would be only 120 terrestrial semidiameters, which conflicts with what we demonstrated in book 3, chapter 7; and the distance of Saturn from the Earth would be about 2,799,360 semidiameters of the Earth, that is, in the ratio of 23,328 to 1 to the solar distance, whereas it ought to be only as 10 to 1, or about tenfold, from what was said in book 7, section 6, chapters 1 and 2. So farewell to this Pythagorean and

Platonic harmony, which does not reconcile reason with the experience of the senses and with observations, although it ought to have been reconciled, as Ptolemy rightly decides in book 1 of the *Harmonics*, chapters 1 and 2. For it is not enough that these proportions agree with reason even if they cannot be approved by sense, as Zarlino seems to have admitted in part 1, chapter 6.

[Margin: 3rd opinion, Bettini's.]

IV. The third opinion is that of our Father Mario Bettini, to be read in the *Apiaria*, apiary 10, progymnasma 1, propositions 1 and 3, with their scholia. He supposes, first, that the Sun is distant from the centre of the Earth by 1145 terrestrial semidiameters and is in the middle of the planetary system; and that its distance, together with the remaining distance to the Empyrean, makes a diapente, so that the Sun's distance from the Earth is to be tripled to obtain the semidiameter of the whole world, as an entire monochord: namely 3435 terrestrial semidiameters. From this it follows that, ascending from the Earth to the Sun, the Sun occupies the place of the fifth string, and the note befits it that is called *Sol* in Guido's musical scale, matching the name of the Sun.

Next he determines the distances of the planets, and indeed of the heavens above the planets, according to the consonances of the more recent musicians admitted in the common use of the octochord — but of an octochord purely Dorian and having a diatonic depth. Further, to serve the ease of the arithmetical operation and the order of the planets found by the more recent astronomers, and at the same time so that the harmonic consonances should depart as little as possible from the observations, he takes some planets at their mean distance, some at apogee, some at perigee. With these things supposed, he determines the intervals of the planets and of the heavens from the Earth in semidiameters of the Earth, as you see in the following table.

In it, as I said, the distance of the Empyrean from the centre of the Earth, or the whole string, is 3435 terrestrial semidiameters. The distance of the Moon at apogee from the Earth, so that it may be the major tone according to the ancients, which is the ninth part of the whole string, is 381 6/9 terrestrial semidiameters. The distance of Venus at perigee from the Earth makes the consonance of the ditone, namely the fifth part of the whole string, which is 687 terrestrial semidiameters; so it comes about that between the Moon at apogee and Venus at perigee he puts the minor tone. The distance of Mercury at perigee from the Earth makes the consonance of the diatessaron, which is the fourth part of the whole string, or 858 3/4 terrestrial semidiameters; so it comes about that between Mercury and Venus, both at perigee, he puts the major semitone, or apotome. The mean distance of the Sun from the Earth, moreover, is, as has been said, 1145 semidiameters of the Earth, and with the remainder of the whole string, which is 2290, it makes a diapente, and with the whole string a diapason-diapente; hence it comes about that between Mercury and the Sun there is a major tone, as he himself thinks.

The mean distance of Mars from the Earth occupies the end of the major hexachord, that is, two fifths of the whole string, and so 1374 terrestrial

semidiameters. To hunt down the distance of Jupiter, he subtracts the major hexachord, which is 1374, from the whole string of 3435, and 2061 remain; of this he takes the ninth part as a major tone, namely 229, and adds it to the distance of Mars, and the distance of Jupiter from the Earth becomes 1603 terrestrial semidiameters. The distance of Saturn he makes half of the whole semidiameter of the world, or of the whole string, that is, 1717½ terrestrial semidiameters, so that it acquires the consonance of the diapason with the whole string. The distance of the fixed stars he makes two thirds of the whole string, so that they too sound a diapente. The distance of the crystalline heaven he determines by the consonance of the diatessaron, but in such a way that from the Earth to the crystalline there are three quarters of the whole string, that is, 2574 3/4 semidiameters of the Earth. Hence it comes about that the distance between the Empyrean and the crystalline is to the whole string as 1 to 4, which is the disdiapason. From these figures we have put together the following table, taken from his express words, but with many consonances added that arise from his intervals, which he appends.

HARMONICA INTERVALLA EX P. MARIO BETTINO

Harmonic intervals according to Father Mario Bettini, shown on the line AB as the entire string of the monochord of the world

	Bodies	Distance from the Earth, in semidiameters of the Earth	Proportions with consonances or concinnous intervals	Proportions with consonances or concinnous intervals (continued)

[Margin: Father Bettini's 1st error.]

V. Although the symmetry just described is far more concinnous than either the Pythagorean or the Platonic, it nevertheless contains many inconsistencies and fallacies, and introduces a very great and altogether dissonant discord between astronomy and harmonics. *First*, he assigns the Moon so great a distance as no astronomer has ever assigned or can assign while the parallaxes are preserved. For no one has ever found, or will detect, in the Moon a horizontal parallax greater than 1° 43′ or less than 51 1/5′; the former of these implies a distance from the Earth of 33 1/2 terrestrial semidiameters, the latter about 67, as is certain from geometry and from what was said in book 4, chapter 14. And Father Bettini himself approves this way of determining the distances of the stars by parallaxes, in the *Apiaria*, apiary 8, progymnasma 3, proposition 9, and progymnasma 4, and in volume 2 of the *Aerarium Philosoph.*, page 73.

[Margin: 2nd error.]

Second, from the distance of the Moon of 381 6/9 terrestrial semidiameters that he lays down, it would follow that the Moon could never be eclipsed by the shadow of the Earth. This is contrary to the experience of every age, and contrary to all who are even lightly versed in astronomy; indeed it is contrary to what the same Father teaches, very learnedly, on lunar eclipses caused by the Earth's shadow, in the *Apiaria*, apiary 8, progymnasma 2 and progymnasma 3, proposition 11. For no one has ever carried the height of the Earth's shadow beyond 282 semidiameters of the Earth, as is clear from what was said in book 3, chapter 11, problem 8. Nor may you say that this removes only the eclipse of the Moon at apogee, and not below the apogee. For when the 282 semidiameters, which at the most belong to the shadow, are taken from the lunar distance of 381, there remain 99 terrestrial semidiameters — and no one has laid down so great a difference between the Moon's perigee and apogee. And yet we know that the Moon, even at apogee, has at times run into a total eclipse, and so has been far below the apex of the Earth's shadow.

[Margin: 3rd error.]

Third, not even a total eclipse of the Sun could occur if the Moon were 381 and the Sun 1145 semidiameters of the Earth distant from the Earth, as he lays down; for while the apparent diameters of the luminaries are preserved, such an eclipse would be impossible, as is clear from book 5, chapter 9. And yet Father Bettini himself admits a total eclipse of the Sun, in the *Apiaria*, apiary 8, progymnasma 2, proposition 10, and he is bound to admit it from the history of eclipses, which we treat in book 5, chapter 20.

[Margin: 4th error.]

Fourth, the Moon's distance of 381 semidiameters of the Earth cannot hold together with the distance of the Sun of 1145 that he posits, as is proved by Aristarchus's problem founded on the dichotomy phase of the Moon, which Father Bettini himself praises in volume 1 of the *Aerarium*, page 629. For if the Moon's distance is set at 381 6/9, or nearly 382, it follows that the Sun is distant from the Earth by at least 7299 terrestrial semidiameters, and in reality by much more, if the angle observed by us at the time of dichotomy is taken, as is clear from what was demonstrated in book 3, chapter 7, problem 3.

[Margin: 5th error.]

Fifth, he puts Jupiter and Saturn much nearer to the Sun and the Earth than the prosthaphaereses and the commensurations of the orbs demonstrated by Copernicus and others require. For these require that the distance of Jupiter be very nearly fivefold the distance of the Sun from the Earth, and that of Saturn about tenfold the Sun's distance from the Earth, as we showed in book 7, section 1, chapters 1 and 2. Yet according to Father Bettini the distance of Jupiter is to the distance of the Sun less than as 14 to 11, and that of Saturn less than as 16 to 11.

[Margin: 6th error.]

Sixth, he assigns to the fixed stars a distance from the Earth of 3435, so small that no astronomer could ever ascribe it, since from it there would follow a horizontal parallax of one whole minute and a half, which all astronomers know to be false. All these errors arose from his wanting the Sun's distance both to stand in the fifth place and to give out the note *Sol*, and to make a diapente from the highest heaven with the whole semidiameter of the world; and wanting the Moon to make a tone, that is, to contain in its distance one ninth of that whole interval, and so on.

[Margin: Other incongruities.]

I pass over the fact that he assigns no worthy consonance to Jupiter, certainly not the least of the planets; and that no definite consonance answers to 4 planets outside their perigee position, to the Moon outside apogee, or to the Sun and Mars outside their mean distance — as though in fact for the most part they did not keep the harmony. This is hardly consistent in one who has taken upon himself to demonstrate harmonic proportions kept by God in the intervals of the planets. Finally, so that the Sun may occupy the place of the fifth string, he

has taken the Earth as the first string; yet the Earth, like the Empyrean, is unfit to represent a sound because of its immobility.

[Margin: 4th opinion, Kepler's.]

VI. The *fourth* opinion is that of *Johannes Kepler*, in book 5 of the *Harmonics* [Kepler's *Harmonice Mundi*], chapter 4. There he sets out the extreme intervals from Tycho's observations, that is, the distances of the planets from the Sun when they are at aphelion, that is, most distant from the Sun, and when they are at perihelion. And if the two extreme intervals of the same planet are considered, he admits that harmony is found in none of the planets except Mars and Mercury, as is clear from the table he gives, as here below. To understand it one must suppose, from chapter 3 of the same book, that the *extreme convergences* of two planets are when their apsides are nearest, namely at the perihelion of the upper and the aphelion of the lower planet; and that the *extreme divergences* are the opposite apsides of two planets, namely the aphelion of the upper and the perihelion of the lower. Now here is the table.

INTERVALLA COMPARATA CVM HARMONICIS.

The intervals compared with the harmonic ones

Planet	Apsis	Distance, in units of which the radius of the annual orb is 1000	Letter	Proportions of each
Saturn	Aphelion	10052	a	More than a minor tone: 10000/9000
	Perihelion	8968	b	Less than a major tone: 10000/8935
Jupiter	Aphelion	5451	c	No concinnous proportion, but
	Perihelion	4949	d	about as 11 to 10, or half of 6/5
Mars	Aphelion	1665	e	If it were 1665/1388, it would be the harmonic 6/5
	Perihelion	1382	f	If it were 1665/1332, it would be the harmonic 5/4

RESIDVVM TABVLÆ PRÆCEDENTIS.

The remainder of the preceding table

Planet	Apsis	Distance, in units of which the radius of the annual orb is 1000	Letter	Proportions of each
The Earth	Aphelion	1018	g	If it were 1020/980, it would be the diesis 25/24;
	Perihelion	982	h	so it does not possess the diesis
Venus	Aphelion	729	i	Less than a sesquicomma
	Perihelion	719	k	More than a third part of the diesis
Mercury	Aphelion	470	l	More than an overflowing diapente,

Planet	Apsis	Distance, in units of which the radius of the annual orb is 1000	Letter	Proportions of each
	Perihelion	307	m	243/160; less than the harmonic 8/5

[Margin: Use of the table.]

So the extreme intervals of no single planet allude to harmonies, except those of Mars and Mercury. For in Mars, if its perihelion of 1382 were 1388, it would be to its aphelion of 1665 as 5 to 6, and so it would be the consonance of the semiditone, or minor third; yet it is not far from it. In Mercury, however, although to Kepler they seem to allude to the diapente, or to the harmony 8/5, which is the minor hexachord, to me its extreme intervals seem rather to allude to the diatessaron, which is between 4 and 3; or else this interval is to be disregarded.

"But if you compare the extreme intervals of different planets with one another," says Kepler, "some light of harmony shines out," as is clear to anyone who studies the first column of the preceding table and the letters marking its extremes. a to d, that is, the aphelion of Saturn to the perihelion of Jupiter, has the proportion of 10,052 to 4949, that is, nearly 2 to 1; so their extreme divergences make a little more than a diapason. But their convergences, that is, b to c, or the perihelion of Saturn to the aphelion of Jupiter, have the proportion of 8968 to 5451, which is not indeed as 5 to 3, but midway between this and 8 to 5, that is, between the major sixth and the minor sixth. Thus the extreme divergences of Jupiter and Mars, c f, embrace nearly a disdiapason, or the proportion 4 to 1; and their convergences, d, e, nearly a diapente with a diapason, or 3 to 1. Again, the extreme divergences of the Earth and Mars, e and h, have somewhat more than 5 to 3, which is the major sixth; and their convergences, f and g, have an overflowing diatessaron, since the diatessaron is as 4 to 3. Again, the extreme convergences of the Earth and Venus, g and k, have an overflowing diatessaron. Between Venus and Mercury, however, the divergence, i and m, is a little less than a diapason with a semiditone, that is, than 12 to 5; and the convergence, k and l, is a little more than a diapente, or than 3 to 2.

[Margin: Kepler's absolute judgement on the harmony of the intervals.]

Kepler, however, adds that these intervals, insofar as they are lengths without motion, are not fitly examined for harmonies, whose subject is rather motion itself, as to its speed and slowness. Therefore, if we seek harmonies, they are not to be sought in the intervals insofar as these are the semidiameters of the orbs, but insofar as they are the measure of the motions, that is, rather in the motions themselves — especially since for the semidiameters of the orbs only the mean intervals, or the mean distances from the Sun, can be taken, and among these harmony shines out less than in the extremes of the aphelia and perihelia. For this reason Kepler absolutely denies that harmonic proportions are to be sought among the intervals of the planets as such, and apart from motion.

Quinta & Nostra Opinio, & Authoritates pro illa.

The fifth opinion, which is ours, and the authorities for it.

[Margin: 5th and true opinion.]

VII. The fifth opinion, not unlike the preceding and truer, is that the distances of the planets and of the fixed stars, whether from the Earth, from the Sun, or from one another, are not to be determined from harmonic proportions or musical intervals. Beyond doubt this was the opinion of Aristotle [Margin: Aristotle's.], in book 2 of *De caelo*, text 52, where, speaking of the Pythagoreans who required harmony in the motion and intervals of the heavens, he said: "This is said prettily indeed and elegantly, yet the truth is not so." It was the opinion, too, of Pliny the Elder [Margin: Pliny's.], book 2, chapter 22, where, after reporting Pythagoras's opinion on the intervals of the stars according to tones, semitones and tones-and-a-half, he concludes that these and similar things said by him are "a subtlety more pleasant than necessary."

[Margin: Macrobius's.]

Macrobius too was of the same opinion, in book 2 on the *Dream of Scipio*, chapter 4, judging this inquiry to belong "to one who makes a show, not to one who teaches." We drive home their judgements as often as the opportunity comes back to us. [Margin: Zarlino's. Glareanus's.] In this, moreover, Zarlino subscribed to Aristotle and Pliny, in part 2 of the *Harmonic Institutions*, chapter 29, and so did Glareanus, in book 1 of the *Dodecachordon*, chapter 5, and book 2, chapter 13, where he says: "But that the intervals of the celestial orbs in the heaven itself stand in the same ratio as the notes in the diapason, in whatever kind of modulation we may finally set them, does not seem likely to me." And after some intervening matter he adds: "Boethius, a true judge of this business, when he saw these things so wonderfully varied among the ancients, and Pliny not afraid to call them a subtlety more pleasant than necessary, so tempered these matters as nevertheless to set both opinions before the reader's eyes." Finally, declaring his own opinion, he says: "But to confess at last what we hold for certain, we say in general: not without reason did this fiction seem to Aristotle more pleasant to tell than likely to be true. For if anyone should wish to apply these things, so to speak, he will not, by Hercules, find the intervals of the planets agreeing with the musical spaces, nor will he detect that any definite ratio of sound is present, either in the subject or in the efficient cause, as the physicists hold. But this indulgence is granted to antiquity, which thought that human minds were to be raised by any means whatever to the contemplation of heavenly things."

[Margin: Mersennius.]

Nor is there any doubt that Mersennius, on chapter 4 of Genesis, verse 21, page 1558, was of the same opinion, since he says there: "I know there is no need for the distance of the planets, both from one another and from the Earth, to be as exact as it is in their motions and sizes, in order that music may represent their economy; and yet I wish it could be done exactly, so that through voices

and instruments we might have some commerce with the heavenly bodies." And on page 1559 he sets little value on those very allusions to consonances that we reported from Kepler in the preceding number, because the opinions of astronomers on the distances of the stars, among which a musician might choose, are diverse. Again, on page 1703, he reported the opinion of certain astrologers — whose, I do not know — who say that the diapason and the disdiapason are ruled by the Sun, the diapente by Venus, the diatessaron by Mercury, and the diapason-diapente by Jupiter; and on the following page he says that he rejects all of this, and adds: "In vain, therefore, will the harmonists labour if they seek a tone from the Earth to ☾; a semitone from the Moon to ☿, and as much from it to ♀; a diapente from the Earth to the Sun; a diatessaron from the Moon to the Sun; a tone from the Sun to ♂, from there a semitone to Jupiter, as much from ♃ to ♄, and from ♄ to the firmament; and consequently a diatessaron from the Sun to the firmament, and a diapason from the Earth to the firmament. For the experience of geometrical astronomy teaches well enough that those spaces are wrongly set up, as is plain from article 3 and from what is said elsewhere on the distance of the heavens from one another. And the same is to be concluded about the proportion of the motions."

[Margin: Father Athanasius's praise of music, and his opinion.]

Most recently our Father Athanasius Kircher — who has deserved best of all in exalting music to the heavens, and as reigning in the whole of nature, especially in book 10 of the *Musurgia*, which he entitles *Decachordon Naturae*, register 2, paragraph 2, or page 381 — inquiring what the music of the celestial bodies is and in what it consists, concludes that their harmonic concent consists "not in the periodic numbers of the motions, not in that perceptible collision of the celestial bodies, but in nothing else than their admirable disposition and a certain ineffable proportion conspiring into union, by which these bodies of the world so correspond to one another that, if one were removed or changed, the harmony of the whole would rightly perish, etc. This harmony, as we have said, consists both in a certain admirable disposition and a most well-proportioned spacing of one bo- dy of the world from another; and in the most exact analogy of the quantity or size of each, fitted to the attaining of its end." The end intended by God, however, was not the delight, perceptible to the hearing, of a sound excited by the heavens, but the production, preservation and advancement to its final end of sublunary nature, especially of living things, each in its own way — which Kircher goes on to expound there excellently and at length — and therefore so great a distance was assigned to the planets that they might produce effects suited to sublunary natures. For if the Moon or the Sun were much nearer than they are, the former would moisten and chill too much, the latter would dry and heat too much. And had Jupiter, wholesome and most temperate, with its four companions, not been set between Saturn and Mars, dissonant, pestilent and malign planets, or the beneficent Sun and Venus on this side of them, great and intolerable harms would have followed.

Pliny the Elder had noted this before Kircher, in book 2, chapter 8. Having said that the star of Saturn is "of a cold and stiffening nature", and a little after that "the third star, that of Mars, which some call the star of Hercules, fiery and burning from the nearness of the Sun, revolves in about two years", he at once adds: "And so Jupiter, set between the two, is tempered by each of them, by the excessive heat of the one and the cold of Saturn, and is made wholesome." And Cicero's famous Paulus hints at this very thing in the *Dream of Scipio*, when he says: "of which one globe is held by the star that on earth they call Saturn's. Next comes that brightness, favourable and wholesome to the human race, which is called Jupiter's; then the ruddy one, dreadful to the lands, which you call Mars's." What we stammer about these things, as a sample to point out divine Providence, is to be understood also — if indeed it can be understood by us — of innumerable other ratios and proportions chosen by God as ordered to an end.

Rationes pro Quinta & Nostra Opinione.

Reasons for the fifth opinion, which is ours.

[Margin: 1st reason.]

VIII. *First*: the intervals and motions of the celestial bodies either produce no sound at all — especially in the planetary system, where the planets travel in a fluid and most tenuous aether — or at any rate they produce no sound perceptible to us, as experiment shows. And so Pliny the Elder said truly, in book 2, chapter 3: "To us who live within it, the world glides by in silence, alike by day and by night." Therefore they are not ordered by God to that end, and consequently those harmonic proportions that sound in concord to our ears in human voices, so as to produce a concinnity pleasant to the ears, are not to be sought in them. For when the end is removed, the order and proportion owed to it is removed; and much more so in the intervals themselves taken apart from motion, since, as Kepler rightly said, the proper subject of harmony is not immobile quantity but mobile quantity, that is, the very motion of the bodies.

[Margin: 2nd reason.]

Second: even if the celestial bodies gave out by their motion a sound perceptible to us, the consonances of those sounds would still not stand within the bounds and limits within which the consonances of human voices stand — which, because of either our weakness or the necessity of nature, we confine within the bounds of the Boethian system or of Guido's scale. For since the lungs, throat, palate, tongue, teeth and lips are not ordered to this end alone, that we may modulate sweetly in forming the voice, but to many other ends as well, these organs had to be so formed that they could descend in depth, or rise in height, only to a definite limit. But among other animals there are some that can form a deeper or a higher voice than we can; and in strings and in organ pipes many more and subtler differences can be found. How much

more in the motions of the stars, intermingled with so great a variety! In vain, therefore, would we hold the laws of that concent to the far too curtailed and slender standard of our harmony; it would be just as if we wished to confine to our measures the songs of angels in the innumerable bodies which, God permitting, they could assume.

[Margin: 3rd reason.]

Third: if harmonic proportion is to be sought in the celestial intervals or motions, it is chiefly because some symmetry can be found in them, or even a proportion double, triple, quadruple, quintuple, etc., if not most exactly, then at least with fractions that spoil that proportion little. But granting (though not yet conceding) the proportions just mentioned, harmony still does not follow from them as such, but only as they are in the qualities of voices and sounds. For Panaetius rightly said, in his book on the ratios of geometry and music: "The faculty of consonances is observed not in the magnitudes of voices but in their qualities." Otherwise, wherever quantities are found, discrete or continuous but reduced to discrete by division or marking off, in which there are, besides unity, the numbers 2, 3, 4, 5, 6, 8, 12 — by which all 14 consonances listed in the first table of chapter 4 are contained — harmony would reign there, taken properly or quasi-properly; and so very many arts would be confounded with one another.

Nor indeed must every symmetry be weighed against the canon of the musical monochord, or against the standard of harmonic ratios. For who would demand this of an architect in buildings, of an apothecary in compounding drugs, of a commander-in-chief in drawing up a battle line, of a shipbuilder in putting ships together, or of God himself and of Nature in the structure of the human body, or of animals or plants? It would surely be ridiculous to require that the nerves, the intestines and the tendons should have in the body of animals the measure that harmonic proportions require; or that the five principal vessels or instruments of the soul — namely the brain, the heart, the liver, the kidneys and the spleen — should be so commensurate with one another as to quantity or motion that, for example, the brain, in itself or with another member, should make a diapason, the heart a diapente, the liver a diatessaron, the kidneys a diapason-diapente, the spleen a disdiapason. For a proportion of this kind would be unsuited to the end to which they are ordered, which is far different from the delight of the ears. The same judgement, then, applies to those who pursue in the celestial intervals and motions the symmetry proper to music, that is, symphonism. Nor is there any doubt that many proportions unsuited to producing consonances, such as those that arise from the numbers 7, 9, 14 compared with others, are nevertheless most suited to other effects intended by God and by Nature in the heaven and in other bodies.

[Margin: 4th reason.]

Fourth: either harmonic proportions are to be sought in any intervals of the planets whatever — and not this, for most of them do not have them, and so for the most part the work of the divine Harmost would lack the harmony that the

followers of the Pythagoreans commend so highly — or in the more notable intervals, for instance in the greatest, mean and least distance of the stars from one another, or from the Sun, or from the Earth, or from all of these. Neither can this be maintained. First, the diversity of opinions about these intervals of the stars among the more recent astronomers stands in the way. Second, not even in the opinion of a single astronomer are all the greatest, mean or least intervals of the planets so tempered together that the commonly accepted musical consonances are found in them. Finally, the apogees of the planets have never all concurred with apogees, nor perigees with perigees, in one place under the fixed stars; or if this has ever happened or will happen, it does not suffice for a harmony worthy of God, for it would have to happen always or for the most part. In the same way it does not suffice for the excellence of some arch-musician if the voices and tones are so ordered by him that they are consonant twice or three times and dissonant a thousand times. And I say nothing for the present of the variety of the genera and modes of music indicated in chapter 5, which is so great that it is not certain which genus suits the heavens.

[Margin: 5th reason.]

Fifth, finally: no one is so senseless, or of so stubborn and brazen a brow, as not to grant to Ptolemy, in book 1 of the *Harmonics*, chapters 1 and 2, that sense and reason must be the judges of harmony — but in such a way that sense, a posteriori, first finds what is near the truth, while reason, considering the causes, finds and determines a priori what is exact; or, if reason has first found what is exact, that must still be received by sense and approved as concinnous. So we shall not, with the Pythagoreans, attribute too much to reason, nor, with the Aristoxenians, too much to the senses. And that judgement of his from book 1, chapter 2, must be driven home once more, where he says: "It is the harmonist's purpose everywhere to preserve the rational positions of the canon, in no way ever conflicting with the senses, according to the opinion of the majority; just as it is the astronomer's to preserve the positions of the celestial motions, consonant with the observed revolutions, and these too taken, indeed, from things evidently and universally more apparent." But if we should wish the intervals of the planets, from harmony's rules to determine, they will often conflict with observations made evidently by the senses; nor will the commensurations of the orbs, or the prosthaphaereses resting on them, represent such places of the planets as are detected through astronomical instruments and accurate observations. And they will conflict so far as to be a long way from the closeness that this business would require, for reason to have a foundation for the view that God willed to attain other ends through the celestial intervals and motions in such a way that He nevertheless also set before Himself this end too — namely, the beauty of harmonic ratios, to be wrought by Himself and to be contemplated by the intellectual creature. [Margin: Objections are dissolved.] Since, then, the observations repeatedly protest against the harmonic laws and are dissonant with them, it must be said either that those ends could

not be attained together through these means, or vertè [?] that God did not will it. Accordingly, the assertions of Scripture, of the Fathers and of the wise concerning the harmony and concent of the heavens are not to be taken in a proper or quasi-proper sense — as though nothing else of harmonic ratio were lacking to the heavens except a sound perceptible to us — but in a metaphorical sense, according to analogy and a certain accommodation. In this way too, in political and household government, that saying of Ecclesiasticus 32 is to be understood: "Have they made you ruler? Do not be lifted up, etc., and do not hinder music" — that is, the order and subordination of offices, or the peace and concord of citizens or of the members of a household.

CAPVT IX.

Chapter IX.

An Magnitudo & Densitas Corporum Cælestium ex Harmonicis Proportionibus Determinata fuerit.

Whether the size and density of the celestial bodies were determined from harmonic proportions.

I. This too we deny, for the reasons adduced in chapter 8 from number 8, if what we said of the intervals is applied to the sizes and densities of the planets — with the exception, however, of the argument a posteriori, taken from sensible experiment, concerning their density; for we have no such experiment by which we could convict of falsity those who would fashion the density and rarity of the planets from harmonic proportions. Nor indeed did Kepler, in book 4 of the *Epitome of Astronomy*, define those from harmonic ratios, but only from geometrical ones, as is clear from his pages 484 to 489. He said only that Saturn is twice as high as Jupiter, one and a half times heavier, and one and a half times rarer, and thus twice as high as it is heavier, and twice as ample as it is rarer, and so proportionally for the others; and that the Sun is the densest of all. The proportions of density that he devises we have already reported in book 7, section 1, chapter 1, number 7; and his various propositions bearing on this we reviewed in book 7, section 6, chapter 8, number 16, to which we refer the reader — on condition that he consults scholium 2 of the same chapter. The same author, moreover, in book 5 of the *Harmonice*, chapter 4, expressly denies that the proportions of the bodies of the planets are harmonic.

Father Antonius Maria de Reita [Anton Maria Schyrleus de Rheita], in his *Oculus Enoch et Eliae*, book 4, chapter 2, member 4, asserts that the Earth is to the Sun as a square root is to its square, that is, as 10 to 100, so that the Sun is a hundred times larger than the Earth, and things like this, on which see our book 7, section 6, chapter 8, scholium 3; and from this Father Athanasius Kircher, in book 10 of the *Musurgia*, page 379, says that, if these things were true, certain harmonic proportions could be gathered. That, I say, by no means agrees with the more exact observations of the diameters and distances obtained

by us and by others, as is clear from what was said in book 7, section 6, from chapter 10. And Kircher himself, on the same page and on page 381, holds suspect the observations of Rheita on which he built those proportions, and says: "But I very much doubt whether Rheita did not choose, for the quantity of the said apparent diameters assumed at pleasure, so beautiful and handsome a proportion, rather than actually observe it."

CAPVT X.

Chapter X.

An & Qua Ratione Motus Planetarum ex Proportionibus Harmonicis Determinati fuerint à DEO.

Whether, and in what way, the motions of the planets were determined by God from harmonic proportions.

I. Here, to be sure, Kepler triumphs: in book 6 of the *Epitome of Copernican Astronomy*, pages 477, 501 and 900; in the *Mysterium Cosmographicum*, chapters 14, 20, 21; but above all in book 5 of the *Harmonice*, in whose proem he says that he had begun to speculate about this business 22 years before, and had spent the best part of his life in astronomy to this end, namely to show that "the whole nature of harmony, however great it is, with all its parts explained in book 3, is found among the celestial motions". From Kepler, moreover, Petrus Herigonius [Pierre Hérigone] selected a very few things in volume 5 of his *Cursus Mathematicus*, from page 573; Mersennius, on chapter 4 of Genesis, pages 1558 and 1704; and Athanasius Kircher more, in book 10 of the *Musurgia*, from page 376. But before Kepler, Ptolemy, in book 3 of the *Harmonics*, from chapter 9, took up this very argument to demonstrate, and it is therefore fair to hear him first.

[Margin: The teaching of Ptolemy on the harmony of the celestial motions.]

II. Thus Ptolemy, in book 3 of the *Harmonics*, chapter 9. As regards the motion in longitude, he likens the risings and settings of the stars to the deepest voices, and their meridian ascents to the highest. This is, first, because just as those who practise the voice begin from the deepest notes and, when they have ascended to the highest, descend until they end in the deepest, and so move from silence through the highest voice to silence, so the stars, from rising through the meridian to setting, pass from privation of appearance to privation of appearance; and second, because the lower places, to which the limits of rising and setting are likened, give out the deepest sounds, while the upper ones, resembling the meridians, give out the highest. In chapter 10, as regards the motion in altitude, he says that in the motion toward the greatest distance from the Earth the diatonic genus reigns, because in it two intervals are not smaller than the remaining one; in the motion of least distance, the enharmonic, because in it both of the two intervals become smaller than the remaining one; and finally, in the motion of mean distance, the chromatic, because in

it the lichanos, or index string, cuts the tetrachord in the middle and stands midway between the diatonic and the enharmonic. In chapter 11 he compares the motion in latitude to the changes that take place in the tones without passing from one genus to another; and he compares the Mixed Lydian and the Hypodorian, as the extreme modes of the tones, with the greatest latitude to the north and the south, and the Dorian, as the middle one, with the planets when they lack either latitude, being in the ecliptic, or declination, being in the equator. In chapter 12 he likens the remaining order of the tetrachords to the remaining aspects to the Sun: namely, the tetrachords of the disjunct strings, that is, the diezeugmenon, to the intervals running from occultation to the appearances of the stars, and also to the oppositions with the Sun, such as acronychal risings and full moons; and the tetrachords synemmenon to the quadratures; and so on for the rest. In chapter 13, the whole circle having been divided into 360 parts, he assigns to the trine aspect 120 parts, to the quadrate 90, to the sextile 60, and to the opposition 180; and so, taking from this 180 parts for the proslambanomenos, he gives 20 to the highest of the mediae, 90 to the last of the diezeugmenon, and 60 to the last of the hyperbolaeon. In chapter 14 he investigates the consonances diapente, diatessaron and some others through the division of the circle into 360 parts, according as certain aspects have, to the whole circle or to a portion of the circle owed to another aspect, a sesquitertian, sesquialter, etc., proportion. Finally, in chapter 15, he says that the sound of Saturn and Mars, the maleficent planets, makes the consonance diatessaron with each of the beneficent ones: that is, the last of the excellentes of Saturn is consonant with the last of the disjunct of Jupiter, and the last of the conjunct of Mars with the mese, or middle, of Venus; and that the sound of Saturn belongs rather to the solar sect, that of Mar- s, to the lunar sect; and that therefore all the configurations of Saturn with Jupiter are beneficent, while of the configurations, or aspects, of Saturn with the Sun only the trines are beneficent, as being more consonant than the rest. So too, of the configurations of Mars with Venus and the Moon, only the triangular are beneficent; further, the configurations of Saturn with the Moon and Venus are bad, and all those of Mars with the Sun dangerous. Let it suffice for us to have pointed these things out, so that it may appear that Ptolemy in these matters partly plays, rather, in a poetic vein — as it seemed to Kepler too, in the appendix to the *Harmonice* — and partly hunts out a harmony in the heaven from the astrological faculty, or vanity.

III. Kepler, however, in book 4 of the *Epitome of Copernican Astronomy*, page 477, and in book 3 of the *Harmonice*, chapter 6, teaches that the least number suitable for determining all the parts of the monochord, so as to constitute the double diapason system — that is, of the soft and the hard song — is one of 720 parts. And since, from the ancient observations of Aristarchus and from more recent ones, the apparent diameter of the Sun at apogee subtends 30′ ("which", he says, "is the 720th part of the whole circle"), this diameter was determined at so great a quantity in order that the first body, that is, the Sun, the chorus-leader of celestial music, might divide the circle for the earth-dwellers

and the contemplating creature according to the harmonic laws, that is, into 720 parts. This number can be divided into very many aliquot parts, namely by two, three, four, five, six, eight, nine, ten, twelve, fifteen, sixteen, eighteen, twenty, twenty-four and forty-eight; that is, in order, into parts of 360, 240, 180, 124, 90, 80, 72, 60, 48, 45, 40, 36, 30, 15. The consonances he determines from the sides of the figures that can be inscribed in a circle and demonstrated, we have already taught in chapter 4, scholia 1 and 2. In book 4 of the *Harmonice*, chapters 5 and 6, and in book 6 of the *Epitome of Astronomy*, page 901, he teaches that sublunary nature is sensibly aroused and stimulated to greater activity as often as the planets are configured with one another harmonically, that is, as often as their aspects and radiations occur at such a distance from one another under the zodiac as the harmonic proportions require. Of these aspects we shall speak in the following chapter; for now we are dealing with the motions themselves. On these Kepler writes in book 6 of the *Epitome*, from page 90, and in the whole of book 5 of the *Harmonice*, especially from chapter 3, in which he affirms as a most certain matter that the proportion between the periodic times of any two planets is precisely the sesquialter of the proportion of their mean distances from the Sun, provided that the arithmetical mean between the two diameters of the elliptical orbit is a little less than the longer diameter.

[Margin: The proportion [?] between the periods [?] and the distances [?] of the planets [?].]

Thus if, for example, from the period of the Earth, which is one year, and from the period of Saturn, which is 30 years, you take the third part of the proportion, that is, the cube roots, and make the double of this proportion by squaring the roots, the most exact proportion of the intervals of Saturn and the Earth from the Sun will come out. For the cube root of 1 year is 1, and its square is 1; but the cube root of 30 years is a little more than 3, and the square number a little more than 9; therefore the mean distance of Saturn from the Sun is a little more than nine times the mean distance of the Earth from the Sun. This Keplerian proposition is accepted by Hérigone as well, in volume 5 of the *Cursus Mathematicus*, page 573; and Wendelen noted the same proportion between the periods and the intervals of the satellites of Jupiter from Jupiter, in a most learned letter that he wrote out to me. Kepler goes on, and in chapter 4 admits that in the periodic times of the planets compared with one another there are no harmonic proportions; and to this Mersennius, on chapter 4 of Genesis, page 1558, and Athanasius Kircher, in book 10 of the *Musurgia*, page 377, readily subscribe. The periodic motions of the planets about the Sun, gathered from all the times spent in all the degrees of the whole circuit, long, middling and short, are, according to Kepler in the same place, as below.

Period	Days	Sixtieths of a day	Hence mean daily motion ′	″	‴
Saturn	18769	12	2	0	27
Jupiter	4332	37	4	59	8
Mars	686	59	31	26	33

Period	Days	Sixtieths of a day	Hence mean daily motion ′	″	‴
Earth with ☾	365	15	59	8	11
Venus	224	42	96	7	39
Mercury	87	58	245	32	25

Again, in the same chapter 4, he admits that the daily journeys of any two planets, whether the slowest or the fastest are taken, have no harmonic proportion if their true journeys in the aethereal air are considered; but if their apparent motions are taken, as seen from the Sun itself, and how great a daily arc in the ecliptic the angle made at the Sun subtends, he says that the following consonances, or concinnous intervals, are found. He takes the daily motions from the Tychonic astronomy.

Harmonies of pairs: Diverg.		Con-verg.		Apparent daily motions		Mo-tion	Let-ter	Proper harmonies of each: between		Ra-tio	Har-mony
				♄	Aphe-lion	1′ 46″	a	between	1′ 48″	is 4/5	major
a		b			Per-ihe-lion	2′ 15″	b	and	2′ 15″		third
d	1/3	c	1/2	♃	Aphe-lion	4′ 30″	c	between	4′ 35″	is 5/6	minor
c		d			Per-ihe-lion	5′ 30″	d	and	5′ 30″		third
f	1/8	e	1/5	♂	Aphe-lion	26′ 14″	e	between	25′ 21″	is 2/3	diapente
e		f			Per-ihe-lion	38′ 1″	f	and	38′ 1″		
h	5/12	g	2/3	Earth	Aphe-lion	57′ 3″	g	between	57′ 28″	is 15/16	semi-
g		h			Per-ihe-lion	61′ 18″	h	and	61′ 18″		tone
k	3/5	n	5/8	♀	Aphe-lion	94′ 50″	n	between	94′ 50″	is 24/25	diesis
n		k			Per-ihe-lion	97′ 37″	k	and	98′ 47″		
m	1/4	l	3/5	☿	Aphe-lion	164′ 0″	l	between	164′ 0″	is 5/12	diapason
					Per-ihe-lion	384′ 0″	m	and	394′ 0″		with the minor third

[Margin: Explanation of the preceding table.]

In the preceding little table, then, the first column indicates the harmonic proportions between the daily motions of two planets about the Sun, either

diverging — that is, comparing the aphelion of the higher planet with the perihelion of the lower — or converging — that is, comparing the perihelion of the higher with the aphelion of the lower. To signify this, letters of the alphabet have been added which, when looked up in the second column, signify the motion of a planet at aphelion or at perihelion. For example, in the first column, under the title "diverging", you see a and d, and set against them this fraction, 1/3. Now a in the second column signifies Saturn's aphelion motion, and d Jupiter's perihelion motion; therefore between Saturn's daily aphelion motion, which is 1′ 46″, and Jupiter's perihelion motion, which is 5′ 30″, the proportion is like that between 1 and 3. For when the motions are resolved into seconds, the daily motion of Saturn is 106″, and of Jupiter 330″, between which the proportion is as 1 to 3. But between b and c, that is, between the converging daily motions of Saturn's perihelion and Jupiter's aphelion, the proportion is the one indicated by this fraction, 1/2, namely double, or as 2 to 1; for the motion of Saturn's perihelion is 135″ in seconds, and that of Jupiter's aphelion 270″, between which there is a most perfect diapason. In the others, however, except Jupiter with Mars, the proportions of the motions are so close to harmonic ones that, if strings were stretched so, the ears could not easily discern the imperfection of the consonance. He therefore concludes that there are perfect harmonies: between ♄ perihelion and ♃ aphelion, the diapason; between ♃ perihelion and ♂ aphelion, the diapason with the soft third, nearly; between ♂ perihelion and the Earth's aphelion, the diapente; between the perihelia of these same, the soft sixth; between the aphelia of the Earth and ♀, the hard sixth; between the peri- helia, the soft sixth; and between ♀ aphelion and ☿ perihelion, or also between the perihelia, the disdiapason. From these and other considerations — though not without many cautions — he tries in chapter 5 to draw the proportions of the planetary motions to the places of the system, that is, to the keys of the musical scale, in the genus of the hard and of the soft song. In chapter 6 he contends that musical tones, or modes, are in a certain way expressed by God in the extremes of these same motions; and in chapter 7, that universal harmonies of all six planets are given, fourfold, like common counterpoints. And in chapter 8, although he admits that there are no sounds in the heaven, that the motions in which he considers the harmonies are not true but only apparent from the Sun, and that there is no solid natural cause for comparing the apparent motions of the planets with human voices, he nevertheless, by I know not what lure of congruence and analogy, assigns the bass to Saturn and Jupiter, the tenor to Mars, the alto to the Earth and Venus, and the descant to Mercury.

Stepping from here to the eccentricities, in chapter 9 — a very long one — with many axioms devised and ingeniously coordinated to his purpose, he tries to show that the eccentricities of the orbs must have been determined from harmonic ratios, so that the extremes of the aphelion and perihelion motions could represent the harmonic proportions discussed above; that therefore the inscriptions and circumscriptions of the orbs in the five bodies, or about the five

Regular bodies, had to give way to these harmonic ratios; and that the intervals of the planets could not have been built so exactly from the Regular bodies, lest the harmonies of the extreme motions about the Sun should perish. Finally, in chapter 10, since he seems to himself to have detected a harmony between the extreme motions of the planets — not the true ones, but those apparent to the Sun, that is, seen from the Sun — he concludes that the Sun is the palace of the whole of nature, and that there is in it some mind hidden from us which can perceive those harmonies, since they arise only from motions subtending angles at the Sun. From this he tries to confirm the rest of the Sun and the motion of the Earth, without which a great part of those harmonies perishes.

The same author, however, taught how to investigate harmonic proportions in the motions as seen both from the Sun and from the Earth, in book 6 of the *Epitome of Astronomy*, page 901. We have given that teaching of his on another occasion, in book 7, section 5, chapter 8, number 7, so that we have no need to repeat it here.

[Margin: The author's opinion.]

IV. *Our* opinion, however — from which Mersennius, on chapter 4 of Genesis, from page 1558 and 1704, and Kircher, in book 10 of the *Musurgia*, are not far removed — is that Kepler's efforts already mentioned contain more ingenuity than solid learning or true doctrine. *First*, a great part of them rests on the immobility of the Sun at the centre of the world, on a certain mental power of the Sun that apprehends the harmonies, and on the annual motion of the Earth about the Sun — a hypothesis we have already rejected in the last chapters of the preceding section. *Second*, the first three reasons adduced in chapter 8, number 8, tell against it here. *Third*, harmony properly so called, or harmonic proportions, are not found as exact as was fitting and possible for God, had He set harmonic ratios before Himself in the archetype in determining the motions: not in the periods of the planets compared with one another, nor in most of the daily motions as seen from the Earth — where the creature that contemplates the divine works, accustomed to sensible harmonies, dwells — nor in the motions as regards latitude, nor between the extreme motions themselves as apparent from the Sun; and finally, those extreme motions of two planets, for instance Saturn's perihelion and Jupiter's aphelion, very rarely concur, and for the most part those motions proceed without these harmonies. Since this is so, it seems rather that we must assert that the harmony which Scripture, the Fathers and very many of the wise recognize in the heaven is to be understood only analogically and metaphorically, through a certain accommodation and likeness. Just as, namely, in sensible harmony a concent pleasing to the ears nevertheless arises from unequal and diverse sounds and voices, so from the motions of the celestial bodies, though diverse and unequal, there nevertheless follows an admirable order toward the end sought by God, and a conspiring of the means toward that same end — most pleasing to the angelic and human intellect that contemplates these things more deeply.

The rest, however, which has been sought out with such ingenuity by Kepler and others to establish in the heavens some harmony of such a kind that nothing else is lacking to it but a sensible sound, seems to be mere symbolism, poetic or oratorical rather than philosophical. So Kepler himself, in the appendix to the *Harmonice*, page 253, judged of the symbolisms of Ptolemy and of Robert Flud [Robert Fludd], or de Fluctibus; and Mersennius, on Genesis chapter 4, page 1558, judged the very same of Kepler's analogies, calling them symbolisms that are at most oratorical, that is, such as orators may use to amplify, by metaphors of this kind, the divine providence in celestial things. And he adds that the eternal geometry of God is no more concerned with harmonic proportions than with the temperings of figures, colours, flavours and odours. Just as we cannot, from the image of the divine geometry impressed on our mind, give a reason why this figure or mixture of colours rather than another delights the eyes, and why these flavours or odours rather than others are pleasant to the palate or the nostrils — nor in these matters must we have recourse to the image of geometry — so neither in giving a reason why these sounds rather than others delight the hearing; and much less is the reason for the celestial motum [?], and for their intelligible beauty, to be given from these things which are pleasant to the hearing alone.

CAPVT XI.

Chapter XI.

An Siderum Aspectus vim habeant ac determinationem ex Configurationibus Harmonicis.

Whether the aspects of the stars have their force and determination from harmonic configurations.

I. I taught much on this argument in book 7, section 5, chapter 8, since aspects are affections of the planets in longitude, which that section dealt with; and meanwhile I seemed to report Kepler's teaching on this matter in such a way that, by not disapproving it, I approved it, because the divisions of the circle by aspects seem to have a greater kinship with harmonic consonances than the motions of the planets have. Moreover, Kepler, in book 4 of the *Harmonice*, chapter 5, propositions 1, 2, 3 and 4, says that the kinship of the radiations, or aspects, with the circle and its arcs, and with the regular figures, is greater than that of the consonances; that the congruence of the figures inscribable in a circle can do more toward constituting efficacious configurations than toward the consonances; and that toward the same, congruence can do more than scibility. What congruence is, and what the scibility of figures is, has been sufficiently indicated here in the scholia of chapter 4.

[Margin: What is an efficacious configuration?]

Further, in the same chapter 5, an efficacious configuration is defined by Kepler: "When the rays of two planets make such an angle as is apt to stimulate

sublunary nature and the inferior faculties of living beings, so that each becomes busier about its own work at the time of the configuration." He then assumes a twofold axiom: namely, that the arc of the circle of the zodiac cut off by the side of a congruent and scible figure or star measures the angle of the efficacious configuration; and that the angle of a scible and congruent figure or star is the module, or measure, of the efficacious configuration. With these laid down — since he had demonstrated in book 1 that the diameter of the circle, the tetragon and the trigon, the hexagon, the octagon and the octagonal star, the dodecagon and the dodecagonal star, and the pentagon and the decagon with the pentagonal and decagonal star, are scible, and in book 2 that they are congruent — he therefore constitutes 13 efficacious configurations. Among them the most efficacious is the conjunction, and to it corresponds the whole circle of 360°. Next comes the opposition, because the two rays concur in the same line, which is the most perfect congruence, and to it corresponds the semicircle of 180°. Next, the quadrate aspect, to which corresponds the quadrant of the circle, of 90°; after it the trine, or trigonal, aspect, to which corresponds a third of the circle, that is, 120°; next the sextile, or hexagonal, aspect, to which corresponds a sixth of the circle, that is, 60°; and then the remaining Keplerian aspects, in the order of efficacy that we represent at once in the little table below.

Efficacious configurations, from Kepler, book 4 of the Harmonice, chapter 5.

Arc of the zodiac intercepted (degrees)	Names of the aspects	Sign	Scible and congruent figures, from whose sides the aspects arise	Harmonies once believed by Kepler
0 or 360	Conjunction	☌		
180	Opposition	☍	Diameter of the circle	diapason
90	Quadrate	□	Tetragon	diatessaron
120	Trine	△	Trigon	diapente
60	Sextile	✶	Hexagon	semiditone
45	Octile, or Sequadrus		Octagon	minor hexachord
135	Trioctile, or Sesquadrus		Octagonal star	
30	Semisextile		Dodecagon	
150	Quincunx		Dodecagonal star	
72	Quintile		Pentagon	ditone
108	Sesquintile, or Tridecile		Decagonal star	
144	Biquintile		Pentagonal star	major hexachord
36	Semiquintile, or Decile		Decagon	

[Margin: Kepler's old axiom condemned by Kepler.]

II. In book 4 of the *Harmonice*, chapter 6, Kepler likewise recounts the occasion for introducing new aspects into astrology. He had treated it in his book *De stella nova*, chapters 8, 9 and 10, and in his replies to the physicians

Helisaeus Roslinus [Helisäus Röslin] and Philippus Feselius [Philipp Feselius], who attacked these new aspects; and finally in what he had said about these aspects in the *Ephemerides*, from page 33 to 36. For in the year 1606 he had taken as an axiom *that God the Creator either took the laws for ordering the aspects from the harmonies of song below the octave, or tempered the ears of man, the judges of those concords, to the celestial aspects.* This axiom, which was coined by no one else but himself, as is clear from page 34 of the *Ephemerides*, he now refutes, on the ground that there would then have to be as many aspects as there are simple consonances up to the diapason. For the quadrate aspect would have to correspond to the diatessaron itself; the trine to the diapente; the opposite to the diapason; the quintile to the major third, or ditone; the sextile to the minor third, or semiditone; the biquintile to the major sixth, or major hexachord; and the Sequadrus to the minor sixth, or minor hexachord. For if you take away from the whole string as great a portion as any of the aspects already mentioned takes away from the circle, the remainder of the string makes with the whole string the consonance already mentioned that is assigned to each aspect. But, Kepler says, it has been found by meteorological observations that sublunary nature is stimulated also by the semisextile aspect, which intercepts a twelfth part of the circle, although, when a twelfth portion is taken from the string, the remainder of eleven parts does not sound in consonance with the whole string; and, on the contrary, that it is not stimulated sensibly or manifestly by the sesquadrus, which intercepts three eighths of the circle, or 135°, although, when three eighths are taken from the string, the remaining five parts are consonant with the whole. Roused by this, he corrects his axiom in this place and teaches that the harmonic proportions are not the causes of the aspects, and that their efficacy does not come from the harmonic section of the circle as such. For granted that the harmonies have a great kinship with the aspects, and that the origin of both is from the figures inscribable in a circle, yet the harmonies arise from them in one way and the aspects in another. For in however many ways the circle is divided demonstratively, all those ways can be transferred to a straight line, that is, to the string, and to any part of it, and so the consonances are distinguished. But not every demonstrative division of the circle, made, say, into three or four arcs, can be transferred to any arc of it whatever. For a straight line, whether cut short or prolonged, remains straight; but a circle cut short does not remain straight. From this it follows that there is a proportional section of any two straight lines whatever, and yet there is none of any two arcs whatever of one circle.

[Margin: The falsity of the axiom already mentioned.]

III. Kepler, having become more cautious than his former self, teaches these and other things in that chapter 6. Among them the following are notable, which I am pleased to set out in his own words, with a little explanation of our own added. *For a true mathematical and causal comparison of the concords with the aspects to exist, the axiom must be overturned completely, since it is not only insufficient but also diametrically contrary to the truth. For no aspect properly*

corresponds to any lesser concord, except that the opposite corresponds to the concord diapason; but each corresponds to the greater concords, the companions of the lesser, out of the triad of each section. That is, the aspects are defined by the same segments of the circle as the greater concords also are, while the lesser concords are defined by the residues of the circle. For example, the trigonal aspect does not correspond to the concord diapente but to the diapason epidiapente. That is, the trine aspect is between two planets a third part of the zodiac, or 120°, apart, and not by the residue, or 240°; and between 3 and 1 is the consonance diapason epidiapente. He goes on: *The quadrate does not correspond to the diatessaron but to the disdiapason; the quintile not to the major third, but to the one compounded of it and the diapason.* For the quadrate aspect is between things 90°, or one quarter, apart, and not by the residue, or three quarters of the zodiac; and between 4 and 1 is the consonance disdiapason. Likewise the quintile aspect is between planets 72°, or one fifth, apart, and not by two fifth parts of the zodiac; and between 5 and 1 is the consonance diapason with ditone, which not everyone accepts among the true consonances. He likewise continues, saying: *The sextile corresponds not to the minor third but to the disdiapason epidiapente; the biquintile not to the major sixth, as we supposed above, but to the one compounded of the major third and the diapason; the sesquadrus not to the minor sixth but to the one compounded of the diatessaron and the diapason, as is clear from the same proportion of part to whole in each case.* That is, the sextile aspect is between bodies a sixth part of the zodiac apart; the biquintile between bodies two fifth parts of the zodiac, that is 144°, apart; and the sesquadrus between bodies three eighth parts of the zodiac, that is 135°, apart. Now between 6 and 1 is the consonance disdiapason with diapente; between 5 and 2 lies the diapason with ditone; and between 8 and 3 the diapason diatessaron. Let the preceding table, therefore, be corrected as in the following table, to which we have added three consonances omitted by Kepler.

Aspect	Degrees of the zodiac intercepted	Consonances with the whole circle
Opposition	180	diapason
Quadrate	90	disdiapason
Trine	120	diapason epidiapente
Sextile	60	disdiapason epidiapente
Octile	45	✠
Sesquadrus	135	diapason diatessaron
Semisextile	30	✠
Quincunx	150	diapason with semiditone
Quintile	72	disdiapason with ditone
Sesquintile	108	diapason with major hexachord
Biquintile	144	diapason with ditone
Semiquintile	36	✠

Consult now the first table of consonances in our chapter 4, and you will see that there are not a few consonances to which no aspect is assigned here,

and conversely that there are some aspects here against which the crosses set beside them, ✠, indicate that no consonance corresponds.

IV. These and similar considerations compelled Kepler to admit, in the same book 4, chapter 6, that harmonic consonances and aspects do have something in common as regards their origin from the divisions of the circle, but that music and meteorology are nevertheless born from these divisions in different ways, for different causes concur in constituting the aspects; and that nature makes a choice of those aspects that are furnished with more prerogatives. But let his words, I ask, be noted: *What, then, is it that sets a limit to the number of aspects? And why is no semiquadrate, or octile, and no decile or tridecile introduced, except only after the principal ones? Why is the sesquadrus, ennobled by a musical kinship, either omitted or held cheap. The semisextile, a stranger in music, is not merely inserted but even displayed among the first?* He answers himself at once: *Because it is not music that forms the aspects; geometry forms both kinds, though the one by some laws and the other by others. For whatever comes from a noble figure, one that has some singular privileges in geometry, is both harmonic in music and efficacious in meteorological things. But meteorology and music are like different peoples, sprung from the same fatherland, geometry.* And he adds that the harmonic proportions, though they arose from the circle, went out from the circle and founded colonies, while the aspects remained within their fatherland, the circle, and use no laws other than the circle's, taken from the regular and congruent plane figures inscribed in a circle. The rest of what he says in chapter 7 about the faculty of sublunary nature, about a certain soul of the whole universe, and about a soul of the Earth that perceives the force of the aspects and is stimulated to act, neither belongs to this place nor is to be admitted by Catholics without correction. Here, however, we must select from book 6 of the *Epitome of Copernican Astronomy* the aspects that Kepler finally accepted, and in the degree of dignity that he later recognized in them by the very observation of meteorological effects.

[Margin: The dignity of the aspects.]

V. In book 6 of the *Epitome of Astronomy*, then, page 843, he teaches that in the first degree of the aspects are placed: the *conjunction*, as the beginning of all; the *opposition*, as occurring in all three divisions of the circle; the *quadrate*, as occurring in two, the area of its figure being expressible; the *sextile*, because its side is expressible; the *semisextile*, because its side is among the inexpressibles of the more perfect order, and because, repeated twelve times, it encloses a stable plane; and the *trine*, since its side is expressible in square [potentia]. On these, consult what was said in scholium 1 of chapter 4.

In the second order, he says, are the *quintile* and the *biquintile*, because, although their sides are inexpressibles of a lower order, they nevertheless share among themselves in the divine proportion, which he explained in book 1 of the *Harmonice*, and the figures themselves excel in congruence into solid figures; and the *quincunx*, because its figure is fruitful in the congruence of planes. He says, however, that the *decile* and *tridecile* already fall short of congruence, and that the *octile* and *sesquadrus* are the most worthless, because they are formed

from sides that are neither expressible nor use the divine proportion, nor in turn are they raised up by any notable congruence of the figure. He therefore places them in the third degree, in book 4 of the *Harmonice*, chapter 6. To the other demonstrable figures he assigns no aspects, because their efficacy vanishes and has no support from observation, since not even all the aspects of the third degree are wholly beyond doubt. Let this, however, be the final table of the aspects according to Kepler's mind.

The order of the aspects in force and dignity

Orders of the aspects	Names of the aspects	Sign	Degrees of the zodiac intercepted	Consonances
I.	Conjunction	☌	0 or 360	unison
	Opposition	☍	180	diapason
	Quadrate	□	90	disdiapason
	Sextile	✶	60	disdiapason epidiapente
	Semisextile		30	none
	Trine	△	120	diapason epidiapente
II.	Quintile		72	disdiapason with ditone
	Biquintile		144	diapason with ditone
	Quincunx		150	diapason with semiditone
III.	Decile		36	none
	Tridecile		108	diapason with major hexachord
	Octile		45	none
	Sesquadrus		135	diapason diatessaron

It deserves consideration, however, that the other consonances to which some aspects correspond are either the beginning or species of the consonance diapason, which Kepler did not notice; and that, of the consonances that belong to the diapason and are enumerated in the first table of chapter 4, there is none that does not have its aspect in the zodiac, except the one compounded of the diapason and the minor hexachord, such as is between 16 and 5. This is so, first, because the number 360 is not divided into 16 whole parts, since a sixteenth part of that number is 22½; and second, because these parts, taken five times, make 112½, a number too near to the number 108, which belongs to the diapason with the major hexachord, so that it is no wonder if the efficacies of the two cannot be distinguished. Yet I do not think that this affinity with the diapason was set before God as a motive for determining those aspects, since even without it, indeed without any consonance at all, there are three aspects, namely the *semisextile*, the *decile* and the *octile*. For the rest: in the mixtures of colours, flavours and odours, and of the temperaments owed to innumerable plants and animals, in the climacteric years, in the rhythms of the pulse, in the species of fevers and in very many other things, there are definite degrees, mostly expressible by numbers, if their nature were perfectly known. And yet, because those degrees can have proportions owed to harmonic numbers, we must not on that account be anxious to search out music in them beyond the

bounds of metaphor and of a somewhat looser analogy; and so too neither in the aspects of the planets, nor in their motions, nor in their sizes, nor in their intervals. As though nothing had been made wisely by God that He had not subjected to the laws of harmony.

LIBRI NONI FINIS.

End of the Ninth Book.

LIBER DECIMVS PROBLEMATVM ASTRONOMICORVM COMMVNIVM.

The Tenth Book: Of Common Astronomical Problems.

SECTIO PRIMA DE TRIANGVLORVM ANALYSI.

The First Section: On the Analysis of Triangles.

PROHOEMIVM.

Preface.

Although it is our purpose, God willing, to hand down in Volume 2 of this *Almagest*, and in its first book, the whole theory and practice of measuring triangles according to the various forms of trigonometrical analysis, together with the tables needed for it, it has nevertheless seemed good, in this vestibule, as it were, of the common problems, to set out first an epitome of this practice by means of logarithms and mesologarithms, not, however, neglecting sines, tangents and secants, with examples for each, by which each precept is illustrated. The reader can then have recourse to them, and we shall not need to explain by examples the problems to be handed down in the remaining sections; instead a single example of the same rule can serve for very many problems to be solved by it. We suppose here, moreover, that the reader has procured for himself the logarithmic tables of arcs or angles of Adrianus Vlacq [Adriaan Vlacq], or of Father Bonaventura Cavalieri, principal professor of mathematics in this University of Bologna, which he published again in a new form at my urging, at Bologna in the year 1643. For the logarithms of absolute numbers, however, one must have the tables of John Napier, reformed by Henry Briggs and enlarged by Adriaan Vlacq of Gouda, which give logarithms for all numbers increasing in natural series from unity up to 100000; or at least the tables of Henriconis, which go up to 20000. If anyone lacks these tables, however, let him by all means use the old form, and the tables of sines, tangents and secants, which are indeed found everywhere. But the most correct are those published by our Clavius, or by Franciscus Scothen, or by Philippus Lansbergius [Philips van Lansbergen]; and the most minute, running to every ten seconds of each minute of the first and last degrees of the quadrant, are those of Georgius Ioachimus Rheticus [Georg Joachim Rheticus] in his great *Canon* and of L. Valentinus Otho [Valentin Otto] in the *Opus Palatinum*; and finer still are those

that Bartholomaeus Pitiscus [Bartholomäus Pitiscus] has in his great *Canon*, since they contain the sines, tangents and secants for every single second of the first minute, and so on. Finally, we suppose the reader already practised in the doctrine of triangles, and we offer here nothing other than an epitome of the rules, especially of those in which logarithms are substituted in place of sines, tangents and secants.

CAPVT I. In Quo Definitiones, & Præcepta quædam generalia pro vſu Logarithmorum.

Chapter 1. In which are given definitions and certain general precepts for the use of logarithms.

[Margin: What logarithms are, and how many kinds there are.]

LOGARITHMS are artificial numbers substituted for natural ones, suited to performing multiplication by addition alone and division by subtraction alone; indeed, if the residue of a logarithm is employed, they are suited to performing multiplication and division, and hence the rule of three, or of proportions, by addition alone, which is a huge saving of labour and gain of time. Further, some logarithms are for natural numbers taken absolutely; others are logarithms of arcs of the circle, or of the angles that the arcs of the circle measure. For example, in the tables of Father Bonaventura Cavalieri the logarithm of the number twelve is 10 791 812. But the logarithm of twelve minutes is 75 429 065, and that of twelve degrees is 93 178 789. Now those that are substituted in place of sines are called logarithms; those in place of tangents[50], mesologarithms; and finally those in place of secants, tomologarithms. Thus the second logarithm is substituted for the second sine, and the second mesologarithm for the second tangent. Granted, the whole trigonometry of arcs or angles can be completed by logarithms and mesologarithms alone.

[Margin: The logarithm of the radius.]

The *logarithm of the radius* is the artificial number substituted for the natural number of the radius, or whole sine, or semidiameter of the circle; or it is unity followed by as many ciphers as the assumed radius has ciphers and unity together. Therefore, if the radius assumed in the tables of sines is 10,000,000, that is, unity with seven ciphers, as most tables have it, the logarithm of the radius will be unity with eight ciphers, thus: 100,000,000. And so the logarithm of the radius always exceeds the radius by a single cipher. But when logarithms of absolute numbers are employed in rectilinear triangles, the logarithm of the radius is supposed to have as many ciphers as in the logarithms of arcs or angles.

[Margin: What the residue of a logarithm is.]

The *residue of a logarithm* (understand: of the radius), or arithmetical complement, is the residue that remains when the logarithm is subtracted from the logarithm of the radius. For example, since the logarithm of the number 12 taken absolutely is, as we said, 10 791 812, if you subtract this number from the logarithm of the radius, which is 100,000,000, there re-

[50] printed *Tagentium*, for *Tangentium*

mains this residue: 89 708 188. Likewise, since the logarithm of 12°, or of an angle subtending an arc of 12°, is, as we said, 93 178 789, when this is likewise subtracted from the logarithm of the radius, 100 000 000, there remains this residue: 06 821 211. For a cipher must be written at the beginning of any logarithmic series if no other numerical figure has to be put in its place. You see, then, that the residue of a logarithm is obtained very easily: the last figure of the given logarithm, on the right, is subtracted from ten, but all the others always from nine, since by the rules of subtraction all the ciphers of the logarithm of the radius have to be changed into nines. Further, for brevity, we shall indicate the residue of a logarithm by these marks, *Res.L.*, just as we indicate a logarithm by the letter L alone and a mesologarithm by the letter M; and the second logarithm, or logarithm of the complement, by this mark, L2, and the second mesologarithm, or mesologarithm of the complement, by this mark, M 2.

[Margin: Prior knowledge of the species.]

The *species* of an angle is said to be known when it is known whether it is right, acute or obtuse; the species of an arc, when it is known whether it is a quadrant of the circle, or greater or less than a quadrant.

PRÆCEPTA.

Precepts.

[Margin: 1st precept.]

I. In the addition as much as in the subtraction of logarithms, if at the beginning of the sum or of the remainder, on the left, one or more ciphers come out in place of units or of numbers, they must be written nonetheless, even if no figure of a unit or of a number stands before them, as in the two following examples.

ADDITION			
Numbers	2	Log.	03010300
	4	Log.	06020600
Sum		Log.	09030900

SUBTRACTION		
Logarithm of the radius		100000000
Of degrees 12	Log.	93178789
Residue	R.	06821211

One series must always be written above the other in such a way that the last figure of the one stands above the last figure of the other, on the right, in the way usually done in the rule of addition, by which a sum is collected from several numbers set one above another.

[Margin: 2nd precept.]

II. If, after the addition of any logarithms, or mesologarithms, or tomologarithms, or of these mixed together, the sum is to be called a logarithm, it must not contain more terms or figures than there are ciphers in the logarithm of the radius. So if any figure is surplus, it must be thrown away from the beginning of the sum, whether that figure is a one, or a two, or any number at all. Therefore, since in our tables and those of Father Cavalieri the logarithm of the radius contains eight ciphers after the unit, a logarithmic sum must not contain more than 8 figures, as you see in the examples written below; in the first two of them a two is thrown away from the left-hand place, and in the third a one.

	L2 89471612	M 105713821	M2 117581222
	L 91184134	L 91147332	L 72637773
	L 99938612	L 89196231	
Uncorrected sum	L 280594358	L 286057384	L 190218995
Corrected sum	L 80594358	L 86057384	L 90218995

[Margin: 3rd precept.]

III. If the said sum after addition is to be called a double logarithm, or a doubled logarithm, then a single one must be kept in the first place of the sum. Thus if, in the first of the three examples given above, the sum 280594358 were to be called, in the rules to be given below, not the logarithm of some arc or angle but the double logarithm, indicated by these marks, LL, the sum would have to be 180 594 358. But in the third example no change would need to be made; instead the sum 190 218 995 would have to be kept for the double logarithm. It is called the double logarithm, however, not because it is double the sum that would remain once the one or the two had been thrown away from the first place, but because it is double the logarithm that is to be used to find some arc or angle, which must be doubled to obtain the arc or angle sought, as will be shown in the examples of the rules.

[Margin: 4th precept.]

IV. If the said sum after addition is to be called a mesologarithm, or a second mesologarithm, and it contains more figures than there are ciphers in the logarithm of the radius, then the second figure either exceeds 3 or does not exceed 3. If it exceeds it, whatever figure is surplus beyond the number of the said ciphers must be thrown away from the first place; if it does not exceed it, a single one must be kept in the first place, which holds the surplus figure, as in the examples written below.

M 10892371	L 9995841	T 102030402
M 104719922	M 82158137	L 92562314
L 92606330	T 117728665	

Uncorrected sum	M 306249963	M 2 299845213	M 194592716
Corrected sum	M 106249963	M 2 99845213	M 94592716

You see that in the first sum a 1 has been kept in place of the 3, because the second figure, 0, does not exceed 3; but in the others the surplus two or one has been thrown away, because the second figure is 9, which exceeds three.

[Margin: 5th precept.]

V. Finally, if after addition the said sum is to be called a tomologarithm, a single one must be kept before figures equal in number to the ciphers that the logarithm of the radius has, as you see in the following examples.

	T 135362739	L 99931420
	L2 99623978	L 93157900
		M 102163024
Uncorr. sum	T 234986717	T 295252344
Corrected sum	T 134986717	T 195252344

[Margin: 6th precept.]

VI. When a logarithm is smaller than would allow another logarithm to be subtracted from it, a single one must be added before the first figure, on the left, of the smaller logarithm. This is the same as if you had set the logarithm of the radius above the smaller one. For example, since the logarithm of forty, which is 16 020 600, cannot be subtracted from the logarithm of twelve, which is 10 791 812, then in place of 10 791 812 one must use the logarithm increased on the left by a one, thus: 110 791 812; and then, after 16 020 600 has been subtracted, there will be left the residue 94 771 212.

[Margin: 7th precept.]

VII. If the given arc or angle is greater than 90°, use in its place its supplement to 180°, and for this supplement look up its logarithm, or sine, and so on.

[Margin: 8th precept.]

VIII. If the sum of the logarithms of absolute numbers ought not to be the logarithm of a whole unit, but it is certain

from elsewhere that, after the solution of the triangle, some quantity less than a unit must come out, say less than one foot, or a fraction, then one will have to use a privative logarithm according to the cossic rules, and subtraction must be employed instead of addition, so that the numerator and denominator of the fraction to be found may be had. Choose, then, 10, or 100, or 1000 as your denominator, and look up its logarithm; from this subtract the logarithmic sum found before. For the residue, then, look up the corresponding number in the table of logarithms of absolute numbers: it will be the numerator of the fraction, to be set above the denominator. But the matter will become clearer by an example. Let the logarithmic sum be 12 041 200, which in the

tables corresponds to the number 16, and yet let it be certain from elsewhere that the side of the triangle sought ought not to be, say, 16 feet, but not even one whole foot. Choose, then, the denominator 1000, whose logarithm is 30 000 000. If you subtract from this 12 041 200 (which was the sum collected), there remains 17 958 800, which is the logarithm of the number 62. So when the numerator 62 has been written above the chosen denominator 1000, this fraction results: 62/1000. It signifies that the side sought is not, say, of one foot, but contains sixty-two thousandth parts of one foot; and the same holds for the other measures.

[Margin: What the base is.]

Further, in the following rules, by the name *base*, or hypotenuse, is to be understood the line subtending, or opposite, the right angle, when the triangles are right-angled; in the others, however, the third side after the two others that have been named.

CAPVT II. In Quo Regulæ 13. Triangulorum Planorum ſeu Rectilineorum, RECTANGVLORVM, vt eſt

Chapter 2. In which are 13 rules for plane, or rectilinear, triangles that are RIGHT-ANGLED, as is

Diagram. A right triangle set in the left column under the chapter title, completing its closing words "as is". The base runs horizontally from A on the left to C on the right; a vertical side rises from C to B; the hypotenuse joins A and B. The right angle is at C.

- A (lower left): end of the base and vertex of the hypotenuse
- C (lower right): vertex of the right angle
- B (top right): top of the vertical side

I. Regula. Datis Baſi, & Angulo Adiacente, Quærere Latus oppoſitum angulo dato. *Rule 1. Given the base and an adjacent angle, to find the side opposite the given angle.*

[Margin: By logarithms.]

To the logarithm of the base add the logarithm of the given angle, and the sum will be the logarithm of the side sought.

EXEMPLVM. *Example.*

Let base AB be 600 feet; its logarithm is	L	27781513
Let angle A be 30°; the logarithm of these is	L	96989700
The sum of these, with the unit taken away according to what was said in chapter 1, precept 2, is	L	24771213

Look up, then, in the tables of Vlacq or of Cavalieri, or in ours, the logarithm 24 771 213, and opposite it there will correspond 300. Therefore side BC,

opposite angle A, is 300 feet, of such feet as base AB is 600 feet. Likewise, in all the rules for plane triangles, the sides or bases sought will be found with the help of the logarithmic table, by looking up, opposite the logarithm that has been found, the number that corresponds to it.

If angle B were given, A would nevertheless also be given, because A is the complement of B to the remaining right angle, by proposition 32 of the first book of Euclid's *Elements*.

[Margin: By sines.]

OR: Let it be done that as the radius, or whole sine, is to the base, so is the right sine of the given angle to the side opposite the given angle.

EXEMPLVM. *Example.*

Let angle A be 30°; its right sine is	5 000 000
Let base AB, by which the sine is to be multiplied, be of feet	600
The sum from the sine multiplied by the base is	3 000 000 000
Which, divided by the radius	10 000 000
Gives the quotient, that is, side BC, of feet	300

II. Regula. Datis Basi & vno Laterum, Quærere Angulum oppositum Lateri dato. *Rule 2. Given the base and one of the sides, to find the angle opposite the given side.*

[Margin: By logarithms.]

To the residue of the logarithm of the base add the logarithm of the given side, and the logarithm of the angle sought will result. How the residue of a logarithm is obtained was explained in chapter 1.

EXEMPLVM. *Example.*

Let base AB be 600 feet; its logarithm is	L	27781513
When this is subtracted from the logarithm of the radius, that is, from 100 000 000	—	—
There remains the residue of the logarithm of the base	RL	72218487
Let side BC be 300 feet; the logarithm of these is	L	24771213
The sum of these two is the logarithm	L	96989700

Look up, then, among the logarithms of arcs, arealiter [?], the logarithm 96 989 700: for you will see that opposite it, in the first column of the tables, there corresponds 30°. You will conclude, then, that angle A is of so many degrees.

[Margin: By sines.]

OR: Let it be done that as the base is to the radius, or whole sine, so is the given side to the right sine of the angle sought.

EXEMPLVM. *Example.*

Let radius AB be	10 000 000
Let side CB be of feet	300
When the radius is multiplied by the side, let the sum be	3 000 000 000
Which is to be divided by base AB, taken to be of feet	600
The quotient will be the right sine BC	5 000 000
To this sine corresponds angle A, of degrees	30

III. Regula. Datis Latere & Angulo Adiacente, Quærere Basim. *Rule 3. Given a side and an adjacent angle, to find the base.*

[Margin: By logarithms.]

To the logarithm of the given side add the residue of the second logarithm belonging to the given angle, and the logarithm of the base will result.

EXEMPLVM. *Example.*

Let angle A be 30°; its second logarithm is	L 2.	99375306
When this is taken away from the logarithm of the radius, there remains the residue	RL 2.	00624694
Let side AC be 520 feet; the logarithm of these is	L	27160033
The sum of these two is the logarithm	L	27784727
To this logarithm corresponds base AB, of 600 44/100 feet		

[Margin: By sines.]

OR: Let it be done that as the radius is to the given side, so is the secant of the given angle to the base sought.

EXEMPLVM. *Example.*

Let angle A be 30°; its secant will be	11 547 005
Let side AC be of feet	520
When the secant is multiplied by the side, let the sum be	6 004 442 600
When this is divided by the radius	10 000 000
The base AB, or quotient, is of feet 600 44426/100000	

IV. Regula. Datis Latere & Angulo adiacente, Quærere Latus alterum. *Rule 4. Given a side and an adjacent angle, to find the other side.*

[Margin: By logarithms.]

To the logarithm of the given side add the mesologarithm of the given angle, and the logarithm of the side sought will result.

EXEMPLVM. *Example.*

Let side AC be 520 feet; its logarithm is	L	27160033
Let angle A be 30°; the mesologarithm of these is	M	97614394
The sum, with the unit taken away from the first place, is the logarithm to which there corresponds in the tables side BC, of 30 [recte: 300] feet	L	24774427

[Margin: By sines.]

OR: Let it be done that as the radius is to the given side, so is the tangent of the given angle to the other side.

EXEMPLVM. *Example.*

The tangent of angle A, 30°, is	5 773 503
Side AC is of feet	520
When the tangent is multiplied by the side, let the sum be	3 002 221 560
Which, divided by the radius	10 000 000
Gives the quotient, or side BC, of feet	300 1/5

V. Regula. Datis Laterib. ambobus, Quærere Angulum vtrumq Acutorum.
Rule 5. Given both sides, to find each of the acute angles.

[Margin: By logarithms.]

To the logarithm of the side opposite the angle sought add the residue of the logarithm of the other side, and the sum will be the mesologarithm of the said opposite angle. When this angle is subtracted from 90°, the remainder will be the other acute angle.

EXEMPLVM pro Angulo A. *Example for angle A.*

Let side BC be 300 feet; its logarithm is	L	24771213
Let side AC be 520 feet; the residue of its logarithm is	RL	72839967
The sum is the mesologarithm	M	97611180

To which there corresponds in the tables of arcs the angle 29° 59′.

[Margin: By sines.]

OR: Let it be done that as the side adjacent to the angle sought is to the radius, so is the side opposite the same angle to the tangent of the opposite angle.

EXEMPLVM. *Example.*

The radius is for us of parts	10 000 000
Side BC is of feet	300
When the radius is multiplied by the side, let the sum be	3 000 000 000
When this is divided by side AC, of feet	520

The quotient comes out as the tangent 5 769 230 4/5, namely that of angle A, 29° 59″.

VI. Regula. Datis Latere & Angulo Oppoſito Quærere Baſim. *Rule 6. Given a side and the opposite angle, to find the base.*

[Margin: By logarithms.]

To the logarithm of the given side add the residue of the logarithm of the given opposite angle, and the logarithm of the base will result.

EXEMPLVM. *Example.*

Let side BC be 300 feet; its logarithm is	L	24771213
Let angle A be 30°; the residue of the logarithm of these is	RL	03010300
Therefore base AB is 600 feet, because the sum is the logarithm	L	27781513

[Margin: By sines.]

OR: Let it be done that as the radius is to the given side, so is the second secant of the given angle to the base sought.

EXEMPLVM. *Example.*

The second secant of angle A, 30°, is	20 000 000
Side BC is of feet	300
When the second secant is multiplied by the side, let the sum be	6 000 000 000
Which, divided by the radius	10 000 000
There remains the quotient, or base AB, of 600 feet	

VII. Regula. Datis Latere & Angulo Oppoſito Quærere Latus alterum. *Rule 7. Given a side and the opposite angle, to find the other side.*

[Margin: By logarithms.]

To the logarithm of the given side add the second mesologarithm of the given angle, and the logarithm of the other side will result.

EXEMPLVM. *Example.*

Let side BC be 300 feet; its logarithm is	L	24771213
Angle A, 30°; the second mesologarithm of these is	M2	102385606
The sum (with the unit taken away from the beginning) is the logarithm	L	27156819

To which there corresponds side AC, of 520 feet.

[Margin: By sines.]

OR: Let it be done that as the radius is to the second tangent of the given angle, so is the given side to the other side sought.

EXEMPLVM. *Example.*

The second tangent of angle A, 30°, is	17 320 508
Side BC is of feet	300
When the second tangent is multiplied by the side, the sum is	5 196 152 400
Which, divided by the radius	10 000 000
The quotient is, approximately, 520 feet, or 519 6/10	

VIII. Regula. Datis Lateribus, Quærere Baſim. *Rule 8. Given the sides, to find the base.*

Find the acute angles by the fifth rule, and then find the base by the sixth. OR: the sum of the squares of the sides will be a square whose square root will be the base. For example, if side AC is 520 feet, its square, when that number is multiplied by itself, is 270 400; and if side BC is 300 feet, its square is 90 000. The sum of these squares is 360 400, and its nearest square root is 600. Therefore base AB is approximately 600 feet. The foundation of the rule is proposition 47 of the first book of Euclid.

IX. Regula. Datis, Baſi & Latere, Quærere Latus alterum. *Rule 9. Given the base and a side, to find the other side.*

Find by rule 2 the angle opposite the given side, and from there, by rule 7, the other side. Or subtract the square of the side from the square of the base: there will be left a square number whose square root will be the side sought.

X. Regula. Datis Baſi & Angulo adiacente, Quærere Latus adiacens Angulo dato. *Rule 10. Given the base and an adjacent angle, to find the side adjacent to the given angle.*

Find by rule 1 the side opposite the given angle, and from this, by rule 7, the side adjacent to it.

XI. Regula. Datis Baſi & vno Laterum, Quærere Angulum adiacentem Lateri dato. *Rule 11. Given the base and one of the sides, to find the angle adjacent to the given side.*

Find by rule 2 the angle opposite the given side, and subtract the angle found from 90°: for the angle sought will be left.

XII. Regula. Dato vno Angulorum Acutotorum, eoque ſubtracto à Gradibus 90. notus ſit alter Acutorum. *Rule 12. When one of the acute angles is given and is subtracted from 90°, the other of the acute angles becomes known.*

XIII. Regula. Datis tantummodo duobus acutis angulis in Triangulo rectilineo Rectangulo, non poteſt concludi certa quantitas Baſis aut Laterum; quia ſaluis prædictis angulis poteſt Triangulum Rectangulum eſſe maius ac maius in infinitum. *Rule 13. When only the two acute angles of a rectilinear right-angled triangle are given, no definite size of the base or of the sides can be concluded, because, with the said angles unchanged, the right-angled triangle can be larger and larger without limit.*

CAPVT III. In quo Regulæ 9. Triangulorum Planorum OBLIQVANGVLORVM, Quorum Schema ſit

Chapter 3. In which are 9 rules for plane OBLIQUE-ANGLED triangles, whose diagram is

Diagram. A plain triangle set in the left column under the chapter title, completing its closing words "whose diagram is". The base runs from A on the left to B on the right; the third vertex, C, stands at the top, nearly above B.

- A (lower left): end of the base
- B (lower right): end of the base
- C (top, above B): the vertex opposite the base

I. Regula. Datis Lateribus duobus & Angulo vni eorum Oppoſito, Quęrere Angulum Oppoſitum reliquo dato Lateri, priùs tamen ſpecie præcognitum. *Rule 1. Given two sides and an angle opposite one of them, to find the angle opposite the other given side, its species, however, being known beforehand.*

[Margin: By logarithms.]

To the logarithm of the given angle add the residue of the logarithm of the side opposite it, and the logarithm of the remaining side; the result will be the logarithm of the angle sought, if the angle is to be acute, or of the angle to be subtracted from 180° so that an obtuse angle results, if the angle sought is to be obtuse.

EXEMPLVM. *Example.*

Let the given angle A be 60° 36′; their logarithm is	L	99401248
Let the opposite side BC be 2240 feet; the residue of their logarithm is	RL	66497520
Let side AB be 1800 feet; their logarithm is	L	32552725
The sum (with the unit taken away from the beginning) is the logarithm	L	98451493

To this corresponds the acute angle C, 44° 26′.

[Margin: By sines.]

OR: Let it be done that as the side opposite the given angle is to the sine of the given angle, so is the other given side to the sine of the angle sought.

EXEMPLVM. *Example.*

The sine of angle A, of 60° 36′, is	8 712 138
Side AB is of feet	1800
The sine multiplied by side AB gives the sum	15 681 848 400
Which, divided by side CB, which is of feet	2240
Gives the quotient 7000 825 40/224, which is the sine of angle C, 44° 26′.	

II. Regula. Datis Latere & duobus Angulis, quorum vnus ſit Oppoſitus lateri dato, Quęrere Latus Oppoſitum alteri angulo dato. *Rule 2. Given a side and two angles, one of which is opposite the given side, to find the side opposite the other given angle.*

If the angles to be used are acute, proceed as below.

[Margin: By logarithms.]

To the logarithm of the given side add the residue of the logarithm of the angle opposite it, and the logarithm of the other given angle; the result will be the logarithm of the side sought.

EXEMPLVM. *Example.*

Let side AB be 1800 feet; their logarithm is	L	32552725
Let angle C be 44° 26′; the residue of its logarithm is	RL	01548530
Let angle A be 60° 36′; their logarithm is	L	99401248
The sum (with the unit taken away) is the logarithm	L	33502503

To this corresponds side CB, of 2240 feet.

[Margin: By sines.]

OR: Let it be done that as the sine of the given angle opposite the given side is to that same side, so is the sine of the other given angle to the side sought.

EXEMPLVM. *Example.*

The sine of the remaining angle A, of 60° 36′, is	8 712 138
Side AB is of feet	1800
The sine multiplied by side AB gives the sum	16 681 848 400
Which, divided by the sine of angle C, of 44° 26′	7 000 789
The quotient gives side CB, of 2240 feet.	

But if the angle opposite the side to be found is obtuse, proceed as below.

Diagram. A triangle set in the right column beside the paragraph on triangle GAC. Its base runs from G on the left to C on the right, with the vertex A above, nearer G. Two dotted lines descend from A to the base, ending at P and at E; P and E are lettered below the base, P nearer G.

- A (top): vertex of the angle GAC
- G (lower left): end of the base
- P (below the base, left of centre): foot of the first dotted line from A
- E (below the base, right of P): foot of the second dotted line from A
- C (lower right): end of the base

Consider triangle GAC, in which, from the given angle GAC, which is obtuse, the greatest side, GC, is to be found. For since angle G or C is given, the sum of angle GAC and G or C, subtracted from 180°, will leave the third angle, G or C. Now suppose side AC is given; drop the perpendicular AP, and in triangle APC, right-angled at P, with the base AC and the angle C, find side AP by rule 1 for right-angled triangles. Then, C being subtracted from 90° and angle CAP thus obtained, find side PC with the base AC by the same rule 1. Next, in triangle APG, with side AP, now found, and with angle G, which is known, find side GP by rule 7 for right-angled triangles; joined to side CP, it will make up the side sought, GC.

[Margin: In this figure angle A should have been obtuse.]

[Margin: Otherwise.]

But if the sides comprehending angle GAC are given: G being subtracted from 90°, GAP is known. With it, and with the base GA, find side GP by rule 1 for right-angled triangles; and with the base AC and the angle CAP, known as above (that is, by subtracting angle C from 90°), find side PC by the same rule 1 for right-angled triangles. For the sum of the sides GP and PC will be the side sought, GC, opposite the obtuse angle.

III. Regula. Datis Lateribus duobus & Angulo Verticali, hoc eſt à datis Lateribus comprehenſo, Quærere Angulum quemuis Baſi adiacentem. *Rule 3. Given two sides and the vertical angle, that is, the angle comprehended by the given sides, to find either angle adjacent to the base.*

[Margin: Preparation for the calculation.]

[Margin: Use the figure placed at the beginning of the chapter.]

Three things must first be prepared: namely, the *sum of the given sides*; then their *difference*, by subtracting the smaller from the greater; and lastly the *half-sum of the angles at the base*, which is obtained by subtracting the vertical angle from 180° and dividing the remainder by 2. Thus if side AC is 1800 feet and CB 2240 feet, the *sum of the sides* is 4040 feet, and their difference is 440. And if the vertical angle C is 74° 58′, this, subtracted from 180°, leaves the sum of angles A and B taken together, 105° 2′; half of this, or the half-sum, is 52° 31′. With these prepared, proceed by logarithms or by sines, as below.

[Margin: By logarithms.]

To the residue of the logarithm of the sum of the sides add the logarithm of the difference of the sides and the mesologarithm of the half-sum of the angles at the base; the result will be the mesologarithm of the angle that is to be added to the already mentioned half-sum of the angles, so that the greater angle results, or subtracted from it, so that the smaller angle at the base remains.

EXEMPLVM. *Example.*

Let the sum of the sides be 4040 feet; the residue of their logarithm is	RL	63936186
The difference of the sides, 440 feet; their logarithm is	L	26434527
The half-sum of the angles at the base, 52° 31′; their mesologarithm	M	10115281 1
The sum (with the unit taken away, according to chapter 1, precept 4) is the mesologarithm	M	91523524

To this corresponds the angle 8° 4′ 45″, which, added to the half-sum, 52° 31′, makes angle A, 60° 35′ 45″; but subtracted from it, it makes angle B, 44° 26′ 15″.

[Margin: By sines.]

OR: Let it be done that as the sum of the given sides is to their difference, so is the tangent of the half-sum of the angles adjacent to the base to the tangent of the angle that is to be added to that same half-sum, so that the greater angle results, or subtracted from it, so that the smaller remains.

EXEMPLVM. *Example.*

The tangent of the half-sum of the angles, 52° 31′, is	13 040 106
The difference of the sides is	440
The tangent multiplied by the difference of the sides gives the sum	5 737 646 640
Which, divided by the sum of the sides	4040
Gives the quotient, that is, the tangent of the angle of 8° 4′ 45″	1 420 011 ½

This, added to the half-sum of the angles or subtracted from it, gives the same as above.

IV. Regula. Datis Lateribus tribus, Quærere Angulum quemlibet. *Rule 4. Given the three sides, to find any angle.*

[Margin: Use the figure set out just before.]

First, onto the greatest side, GC, drop from the opposite angle A the perpendicular AP; then, taking PE equal to GP, draw the straight line AE from A to E. Two triangles thus arise, APG and APC, right-angled at P. In each of them, besides the right angle, the base is known, AG and AC respectively, since these are given sides of triangle GAC. Therefore, if side GP, and side PC in the other triangle, were known, the angles G and C could be found by the rules for plane right-angled triangles; and their sum, subtracted from 180°, will leave angle GAC. But for sides GP and PC to become known, one must find the segment EC — namely the segment in whose remainder, GE, the perpendicular AP falls at the half, P. For once EC has been found and subtracted from the whole greatest side GC, the remainder GE will be left known; its half, GP, will be one side of triangle APG, while the other half, PE, added to the line EC, will make up side PC. In this way you will have data sufficient to solve each of the two right-angled triangles. The whole effort of this rule, then, is directed to finding the segment EC; for which proceed as follows.

[Margin: By logarithms.]

To the residue of the logarithm of the greatest side, GC, add the logarithm of the sum of the smaller sides, AC and AG, and the logarithm of the difference of those same smaller sides; the result will be the logarithm of the segment EC.

EXEMPLVM. *Example.*

Let side GC be 2483 feet; the residue of its logarithm is	RL	66050233
Side AC, 2240 feet, and AG, 1800 feet; their sum, 4040; its logarithm	L	36063814
The difference of the sides is 440 feet; its logarithm	L	26434527
The sum (with the unit taken away from the beginning) is the logarithm	L	28548574

To this corresponds the segment EC, of 716 feet. When these are subtracted from side GC, of 2483 feet, GE remains, of 1767 feet, whose half, GP, is 883½, and PE is just as much. Therefore, when PE, 883½, and EC, 716, are added together, side PC comes to 1599½. So, to solve the right-angled triangle APG and to find angle G by rule 11 for right-angled triangles, there are given the base AG, of 1800 feet, and the side GP, of 883½ feet. And to solve the right-angled triangle APC and to find angle C by the same rule, there are given the base AC, of 2240 feet, and the side PC, of 1599½ feet.

[Margin: By sines.]

The same segment EC will be obtained if it is done that as the greatest side is to the sum of the smaller sides, so is the difference of the smaller sides to the segment EC — that is, to the segment of the greatest side at the half of whose remainder the perpendicular falls.

V. Regula. Datis Lateribus duobus, & Angulo Verticali, Quærere Latus tertium ſeu Baſim. *Rule 5. Given two sides and the vertical angle, to find the third side, or base.*

First find the angles at the base by rule 3, then the third side by rule 2.

VI. Regula. Datis Lateribus duob. & Angulo vni eorum Oppoſito, Quærere Latus tertium, dummodo nota ſit ſpecies reliquorum angulorum. *Rule 6. Given two sides and an angle opposite one of them, to find the third side, provided the species of the remaining angles is known.*

First find, by rule 1 of this chapter, the angle opposite the other of the given sides, and then the third side by rule 2.

VII. Regula. Datis Angulis duobus, & Latere vni eorum Oppoſito, Quærere Latus Oppoſitum tertio angulo. *Rule 7. Given two angles and a side opposite one of them, to find the side opposite the third angle.*

The third angle is known, because it is the supplement of the other two, taken together, to two right angles. Therefore, if the sum of the two given angles is subtracted from 180°, the third side can then be found by rule 2 of this chapter.

VIII. Regula. Datis Angulis duobus, & Latere vni eorum Adiacente, Quærere Latera reliqua. *Rule 8. Given two angles and a side adjacent to one of them, to find the remaining sides.*

Since the third angle becomes known when the sum of the two given angles is subtracted from 180°, the remaining sides can certainly be found by rule 2 of this chapter.

IX. Regula. Omnia Quæſita in Regulis præcedentibus, inueniri poſſunt per regulas Triangulorum Rectangulorum, reducto Triangulo Obliquangulo ad duo Triangula Rectangula, vt fuſiùs explicabo in Libro Trigonometrico. *Rule 9. Everything sought in the preceding rules can be found by the rules for right-angled triangles, by reducing the oblique-angled triangle to two right-angled triangles, as I shall explain more fully in the Trigonometric Book.*

CAPVT IV. In Quo Regulæ 16. Triangulorum Sphæricorum RECTANGVLORVM, Cuiuſmodi eſt Triãgulum infraſcriptum ABC, Rectangulum ad A, in quo arcus BC, ſubtenſus angulo recto A; vocetur Baſis.

Chapter 4. In which are 16 rules for spherical RIGHT-ANGLED triangles, such as the triangle ABC drawn below, right-angled at A, in which the arc BC, subtending the right angle A, is to be called the base.

Diagram. A spherical triangle in the right column under the chapter title. B stands at the top, A at the lower left, C at the lower right; the side BC is a long curved arc, AC a shallower curve, and AB a short, nearly straight side. Two small dots and a comma-like mark stand inside the angle at A.

- B (top): vertex
- A (lower left): vertex of the right angle
- C (lower right): vertex

I. Regula. Datis Baſi & Angulo Adiacente, Quærere Latus Oppoſitum Angulo dato. *Rule 1. Given the base and an adjacent angle, to find the side opposite the given angle.*

[Margin: By logarithms.]

To the logarithm of the base add the logarithm of the given angle, and the result will be the logarithm of the side sought — with the unit, however, taken away in the leftmost place, according to what was said in chapter 1, precept 2.

EXEMPLVM. *Example.*

Let the base BC be 60° 30′; its logarithm is	L	99396968
Let angle B be 23° 30′; its logarithm is	L	96006997
Therefore AC is an arc of 20° 18′ 27″, since the sum of the logarithms is	L	95403965

[Margin: By sines.]

OR: Let it be done that as the radius is to the sine of the base, so is the sine of the given angle to the sine of the side sought.

EXEMPLVM. *Example.*

The sine of the base BC, of 60° 30′, is	8 703 557
The sine of angle B, of 23° 30′, is	3 987 491
One sine multiplied by the other gives the sum	34705 345 205 487
Which, divided by the radius, or whole sine	10 000 000
Gives the quotient 3 470 534 521/1000, namely the sine of the arc AC, 20° 18′ 27″.	

II. Regula. Datis Baſi & Angulo Adiacente, Quærere Latus Adiacens angulo dato. *Rule 2. Given the base and an adjacent angle, to find the side adjacent to the given angle.*

[Margin: By logarithms.]

To the second mesologarithm of the base add the residue of the second logarithm of the given angle, and the result will be the second mesologarithm of the side sought.

EXEMPLVM. *Example.*

Let the base BC be 66°; its second mesologarithm is	M 2.	96485831
Let angle C be 35°; the residue of its second logarithm is	RL 2.	00866355
Therefore AC is 61° 28′ 30″, since the sum is the second mesologarithm	M 2.	97352186

[Margin: By sines.]

OR: Let it be done that as the radius is to the secant of the given angle, so is the second tangent of the base to the second tangent of the arc, or side, sought.

EXEMPLVM. *Example.*

The secant of angle C, of 35°, is	12 207 746
The second tangent of the base BC, of 66°, is	4 452 287
The secant multiplied by the tangent gives the sum	54352 388 813 102
Which, divided by the radius	10 000 000
Gives the quotient 5 435 238 88/100, that is, the second tangent of side AC, 61° 28′ 30″.	

III. Regula. Datis Baſi & Angulo Adiacente Quadrante minoribus; Quærere Angulum alterum Baſi Adiacentem. *Rule 3. Given the base and an adjacent angle, each less than a quadrant, to find the other angle adjacent to the base.*

[Margin: By logarithms.]

To the second logarithm of the base add the mesologarithm of the given angle, and the result will be the second mesologarithm of the angle sought. But if the data are greater than a quadrant, consult the scholia of this chapter.

EXEMPLVM. *Example.*

Let the base BC be 60° 30′; its second logarithm is	L 2.	96923388
Let angle B be 23° 30′; its mesologarithm is	M	96383019
Therefore angle C is 77° 54′ 53″, since the sum, with the unit taken away according to chapter 1, precept 4, is the second mesologarithm	M 2.	93306407

[Margin: By sines.]

OR: Let it be done that as the radius is to the second sine of the base, so is the tangent of the given angle to the second tangent of the angle sought.

EXEMPLVM. *Example.*

The second sine of the base BC, of 60° 30′, is	4 924 236
The tangent of angle B, of 23° 30′, is	4 348 124
The second sine multiplied by the tangent gives the sum	21 411 188 693 264
Which, divided by the radius	10 000 000
Gives the quotient 2141118 87/100, that is, the second tangent of angle C, 77° 54′ 53″.	

IV. Regula. Datis Baſi & Latere, Quærere Angulum Oppoſitum Lateri dato. *Rule 4. Given the base and a side, to find the angle opposite the given side.*

[Margin: By logarithms.]

To the logarithm of the given side add the residue of the logarithm of the base, and the result will be the logarithm of the angle sought — with the unit taken away, if it is surplus, according to chapter 1, precept 2.

EXEMPLVM. *Example.*

Let the base BC be 60°; the residue of its logarithm is	RL	00624694
Let side AB be 20°; its logarithm is	L	95340517
Therefore angle C is 23° 15′ 42″, since the sum is	L	95965211

[Margin: By sines.]

OR: Let it be done that as the radius is to the second secant of the base, so is the sine of the given side to the sine of the angle sought.

EXEMPLVM. *Example.*

The second secant of the base BC, of 60°, is	11 547 005
The sine of side AB, of 20°, is	3 420 202
The second secant multiplied by the sine gives the sum	39 493 089 595 010
Which, divided by the radius	10 000 000
Gives the quotient 3 949 308 9595/10000, that is, the sine of angle C, 23° 15′ 42″.	

V. Regula. Datis Baſi & Latere Quadrante minoribus: Quærere Angulum Adiacentem Lateri dato. *Rule 5. Given the base and a side, each less than a quadrant, to find the angle adjacent to the given side.*

[Margin: By logarithms.]

To the second mesologarithm of the base add the mesologarithm of the given side, and the result will be the second logarithm of the angle sought. What is to be done when the base or the side is greater than a quadrant will be stated in the scholia of this chapter.

EXEMPLVM. *Example.*

Let the base BC be 60° 30′; its second mesologarithm is	M 2.	97526420
Let side AB be 30°; its mesologarithm is	M	97614394
Therefore, of angle B, 70° 56′ 5″, on account of the second logarithm	L 2	95140814

[Margin: By sines.]

OR: Let it be done that as the radius is to the tangent of the given side, so is the second tangent of the base to the second sine of the angle sought.

EXEMPLVM. *Example.*

The second tangent of the base BC, of 60° 30′, is	5657728
The tangent of side AB, of 30°, is	5773 503
One tangent multiplied by the other gives the sum	32 664 909 581 184
Which, divided by the radius	10 000 000
Gives the quotient 3 266 490 96/100, that is, the second sine of angle B, 70° 56′ 5″.	

VI. Regula. Datis Baſi & Latere Quadrante minoribus, Quærere Latus alterum. *Rule 6. Given the base and a side, each less than a quadrant, to find the other side.*

[Margin: By logarithms.]

To the second logarithm of the base add the residue of the second logarithm of the given side, and the result will be the second logarithm of the side sought. But if the data are greater than a quadrant, consult the scholia of this chapter.

EXEMPLVM. *Example.*

Let the base BC be 60°; its second logarithm is	L 2.	96989700
Let side AB be 20°; the residue of its second logarithm is	RL 2.	00270142
Therefore side AC is 57° 51′ 15″, since the sum is the second logarithm	L 2.	97259842

[Margin: By sines.]

OR: Let it be done that as the radius is to the second sine of the side, so is the secant of the base to the secant of the side sought.

EXEMPLVM. *Example.*

The secant of the base BC, of 60°, is	20 000 000
The second sine of side AB, of 20°, is	9 396 926
The secant multiplied by the second sine gives the sum	187 938 520 000 000

which, divided by the radius	10 000 000
gives the quotient 18 793 852, that is, the secant of side AC, 57° 51′ 15″.	

VII. Regula. Datis Latere & Angulo Adiacente, Quadrante minoribus, Quærere Latus Alterum. *Rule 7. Given a side and an adjacent angle, each less than a quadrant, to find the other side.*

[Margin: By logarithms.]

To the logarithm of the given side add the mesologarithm of the given angle, and the result will be the mesologarithm of the side sought. But if the data are greater than a quadrant, consult the scholia of this chapter.

EXEMPLVM. *Example.*

Let side AB be 20°; its logarithm is	L	95340517
Let angle B be 50° 10′; its mesologarithm is	M	100787534
Therefore side AC is 22° 17′ 18″, since the sum, with the unit taken away according to chapter 1, precept 4, is	M	96128051

[Margin: By sines.]

OR: Let it be done that as the radius is to the sine of the given side, so is the tangent of the given angle to the tangent of the remaining side.

EXEMPLVM. *Example.*

The sine of side AB, of 20°, is	3 420 202
The tangent of angle B, of 50° 10′, is	11 988 184
The sine multiplied by the tangent gives the sum	41 002 010 893 168
Which, divided by the radius	10 000 000
Gives the quotient 4 100 201 [?]89/1000, that is, the tangent of side AC, 22° 17′ 19″.	

VIII. Regula. Datis Latere & Angulo Adiacente, Quærere Angulum Oppositum Lateri dato. *Rule 8. Given a side and an adjacent angle, to find the angle opposite the given side.*

[Margin: By logarithms.]

To the second logarithm of the given side add the logarithm of the adjacent angle, and the result will be the second logarithm of the angle sought.

EXEMPLVM. *Example.*

Let side AB be 20°; its second logarithm is	L 2	99729858
Let angle B be 50° 10′; its logarithm is	L	98853109
Therefore angle C is 43° 48′ 46″, for its second logarithm is	L 2	98582967

[Margin: By sines.]

OR: Let it be done that as the radius is to the sine of the given angle, so is the second sine of the given side to the second sine of the angle sought.

EXEMPLVM. *Example.*

The second sine of side AB, of 20°, is	9 396 926
The sine of angle B, of 50° 10′, is	7 679 110
One sine multiplied by the other gives the sum	72 160 024 415 860
Which, divided by the radius	10 000 000
Gives the quotient 7 216 002 44/106[51], that is, the second sine of angle C, 43° 48′ 46″.	

IX. Regula. Datis Latere & Angulo Adiacente, Quadrante minoribus, Quærere Baſim. *Rule 9. Given a side and an adjacent angle, each less than a quadrant, to find the base.*

[Margin: By logarithms.]

To the second logarithm of the given angle add the second mesologarithm of the given side, and the result will be the second mesologarithm of the base. But if the data exceed a quadrant, consult the scholia of this chapter.

EXEMPLVM. *Example.*

Let angle B be 50°; its second logarithm is	L 2	98080675
Let side AB be 36°; its second mesologarithm is	M 2	101387390

[51] so printed; a second reading of the page confirms the denominator's third figure as 6. The product 72 160 024 415 860 divided by the radius gives 7 216 002.44…, so the denominator should be 100; the printed 6 may be a foul sort.

Therefore the base BC is 48° 30′, since the sum, with the unit taken away according to chapter 1, precept 4, is the second mesologarithm	M 2	99468065

[Margin: By sines.]

OR: Let it be done that as the radius is to the second sine of the given angle, so is the second tangent of the given side to the second tangent of the base.

EXEMPLVM. *Example.*

The second sine of angle B, of 50°, is	6 427 876
The second tangent of side AB, of 36°, is	13 763 819
The sine multiplied by the tangent, and the sum divided by the radius	10 000 000
Gives the quotient 8 847 253, that is, the second tangent of the base BC, 48° 30′.	

X. Regula. Datis Latere & Angulo Oppoſito, ſingillatim Quadrante minoribus, Quærere Latus alterum ſpecie tamen præcognitum. *Rule 10. Given a side and the opposite angle, each singly less than a quadrant, to find the other side, its kind, however, being known beforehand.*

[Margin: By logarithms.]

To the mesologarithm of the given side add the second mesologarithm of the opposite angle, and the result will be the logarithm of the other side, less than a quadrant. But if you are certain from elsewhere that this side must be greater than a quadrant, then subtract the side found from 180°, and the remainder will be the side sought. When, however, one of the data is greater than a quadrant, consult the scholia of this chapter.

EXEMPLVM. *Example.*

Let the given side AC be 40° 10′; its mesologarithm is	M	99263778
Let angle B be 40° 30′; its second mesologarithm is	M 2	100685011
Therefore side AB is 81° 13′ 6″, since the sum is the logarithm	L	99948789

[Margin: By sines.]

OR: Let it be done that as the radius is to the second tangent of the given angle, so is the tangent of the given side to the tangent of the side sought.

From here on, for brevity's sake, we shall refrain from examples by sines: for it is clear enough from what has been said so far how one is to work with them.

XI. Regula. Datis Latere & Angulo ipſi Oppoſito, Quærere Baſim ſpecie tamen præcognitam. *Rule 11. Given a side and the angle opposite it, to find the base, its kind, however, being known beforehand.*

[Margin: By logarithms.]

To the logarithm of the given side add the residue of the logarithm of the opposite angle, and the result will be the logarithm of the base, less than a quadrant. Or, if the base must be greater than a quadrant, you will obtain it by subtracting the arc found from 180°.

EXEMPLVM. *Example.*

Let the given side AB be 20°; its logarithm is	L	95340517
Let angle C be 23° 20′; the residue of its logarithm is	RL	04022173
Therefore BC is 59° 42′ 30″, on account of the logarithm	L	99362690

[Margin: By sines.]

OR: Let it be done that as the radius is to the second secant of the given angle, so is the sine of the given side to the sine of the base sought.

XII. Regula. Datis Latere & Angulo Oppoſito, Quærere Angulum reliquum ſpecie notum: dummodo ſingula Datorum ſint Quadrante minora. *Rule 12. Given a side and the opposite angle, to find the remaining angle, known in kind, provided that each of the data is less than a quadrant.*

[Margin: By logarithms.]

To the residue of the second logarithm of the given side add the second logarithm of the opposite angle, and the result will be the logarithm of the remaining angle, if acute. But if it must be obtuse, you will obtain it by subtracting the angle found from 180°. And if any of the data is greater than a quadrant, consult the scholia of this chapter.

EXEMPLVM. *Example.*

Let side AB be 20° 30′; the residue of its second logarithm is	RL2	00284124
Let angle C be 24° 10′; its second logarithm is	L 2	99601655
Therefore angle B is 76° 55′, on account of the logarithm	L	99885779

[Margin: By sines.]

OR: Let it be done that as the radius is to the secant of the given side, so is the second sine of the given angle to the sine of the angle sought.

XIII. Regula. Datis Lateribus, Quærere Baſim. *Rule 13. Given the sides, to find the base.*

[Margin: By logarithms.]

To the second logarithm of one given side add the second logarithm of the other side, and the result will be the second logarithm of the base.

EXEMPLVM. *Example.*

Let side AB be 20°; its second logarithm is	L 2	99729858
Let side AC be 70° 10′; its second logarithm is	L 2	95340517
Therefore the base BC is 71° 15′ 10″, on account of the second logarithm	L 2	95070375

[Margin: By sines.]

OR: Let it be done that as the radius is to the second sine of the given side, so is the second sine of the other side to the second sine of the base.

XIV. Regula. Datis Lateribus Quadrante minoribus, Quærere Angulum Oppoſitum cuiuis Laterum. *Rule 14. Given the sides, each less than a quadrant, to find the angle opposite either of the sides.*

[Margin: By logarithms.]

To the mesologarithm of the side opposite the angle sought add the residue of the logarithm of the remaining side, and the result will be the mesologarithm [?] of the angle sought. And if any of the data is greater than a quadrant, consult the scholia of this chapter.

EXEMPLVM. *Example.*

Let side AB be 20°; its mesologarithm is	M	95610659
Let side AC be 70°; the residue of its logarithm is	RL	00270142
Therefore angle C is 21° 10′ 38″, on account of the mesologarithm	M	95880801

[Margin: By sines.]

OR: Let it be done that as the radius is to the tangent of the side opposite the angle sought, so is the second secant of the remaining given side to the tangent of the angle sought.

XV. Regula. Datis Angulis duobus obliquis Quadrante minoribus, Quærere Baſim. *Rule 15. Given the two oblique angles, each less than a quadrant, to find the base.*

[Margin: By logarithms.]

Add together the second mesologarithms of the oblique angles, and the result will be the second logarithm of the base. And if the data are singly greater than a quadrant, consult the scholia of this chapter.

EXEMPLVM. *Example.*

Let angle C be 36°; its second mesologarithm is	M 2	101387390
Let angle B be 55° 20′; its second mesologarithm is	M 2	98398377
Therefore the base BC is 72° 9′ 8″, on account of the second logarithm	L 2	99785767

[Margin: By sines.]

OR: Let it be done that as the radius is to the second tangent of either given angle, so is the second tangent of the other given angle to the second sine of the base.

XVI. Regula. Datis Angulis obliquis, Quærere Latus cuiuis angulorum Oppoſitum. *Rule 16. Given the oblique angles, to find the side opposite either of the angles.*

[Margin: By logarithms.]

To the second logarithm of the angle opposite the side sought add the residue of the logarithm of the remaining oblique angle, and the result will be the second logarithm of the side sought.

EXEMPLVM. *Example.*

Let angle C be 23° 10′; its second logarithm is	L 2	99634877
Let angle B be 78° 0′; the residue of its logarithm is	RL	00095956
Therefore side AB is 19° 58′, on account of the second logarithm	L 2	99730833

[Margin: By sines.]

OR: Let it be done that as the radius is to the second sine of the angle opposite the side sought, so is the second secant of the remaining given angle to the second sine of the side sought.

SCHOLIA. *Scholia.*

Diagram. A small woodcut at the head of the scholia, right column. Two arcs meet at A on the left and C on the right, forming a lens. R stands at the upper arc, towards the right; B at the lower arc, left of centre. A third arc runs from R down to B, dividing the lens into a left part lettered P and a right part lettered V.

- A (left point of the lens): vertex

- P (inside the left part): the triangle ARB
- R (upper arc, right of centre): vertex
- V (inside the right part): the triangle RCB
- C (right point of the lens): vertex
- B (lower arc, left of centre): vertex

[Margin: The use of the vicarious triangle.]

I. We have said more than once in the preceding rules that the data are each required to be less than a quadrant. Otherwise, if one or both of them is greater than a quadrant, that is, of more degrees than 90, those rules do not hold for the given triangle unless they are transferred to another triangle, its vicarious triangle [Triangulum Vicarium]; once that triangle is solved, the given triangle will also remain solved. First, therefore, one must continue two sides, or a side and the base, until they complete a semicircle, and so the vicarious triangle arises. For example, in the figure set out above, suppose the proposed triangle is the spherical triangle ARB, right-angled at R, to be solved by rule 2 of the preceding chapter, which requires the base AB to be less than a quadrant and the adjacent angle ABR likewise acute, that is, less than a quadrant; and yet AB is, say, 100°, and angle ABR 120°. Let the base AB and the side AR be continued as far as C, so that ABC and ARC are both semicircles. Then triangle V will be the vicarious triangle of triangle P. And by the very fact that, besides the right angle R, two other data are given in P, two other data will also be given in V. For if angle A is given, angle C is also given, since the two opposite angles made by semicircles of equal circles are equal. If side AR is given, then, when it is subtracted from 180°, side RC will be given. Similarly, if the base AB is given, then, when it is subtracted from 180°, the base BC will be given. Finally, if angle ABR is given, then, when it is subtracted from 180°, angle RBC will be given. And so in the vicarious triangle V sufficient data are had to solve it by the same rule by which the proposed triangle P was ordered to be solved. Thus in our case the base BC would be 80°, and the adjacent angle RBC 60°. Therefore, by rule 2 for spherical right-angled triangles, the side BR, adjacent to angle B, can be sought.

[Margin: The solution of the proposed triangle from the solution of the vicarious triangle.]

II. Once the vicarious triangle V is solved, the other triangle P, the one first proposed, remains solved. For if the common side BR was sought, then once it is found in V it is also found for triangle P, because the side is the same. But if side AR was sought, then once side RC is found and subtracted from 180°, side AR becomes known. If, on the other hand, AB was sought, then once BC is found and subtracted from 180°, the base AB will become known. But if angle ABR was sought, then once RBC is found and subtracted from 180°, angle ABR will be known. Finally, if angle A was sought, it is enough to find angle C, for C is equal to angle A. The whole skill lies in continuing the sides, or the base and one of the sides, so that in the vicarious triangle you have sufficient data to solve it, and from its solution the proposed triangle remains solved. For

this continuation we shall indeed give some rules in our *Trigonometry*, God willing; but practice itself and the drawing of the figure will easily instruct a skilful geometer in this matter. And from this you will learn how you should use the vicarious triangle in spherical oblique-angled triangles too, where there is need.

CAPVT V. In quo Regulæ 14. Triangulorum Sphæricorum OBLIQVANGVLORVM, Cuiuſmodi eſt ABR; vel eius Vicarium V, ſeu BRC, in ſequenti Schemate.

Chapter 5. In which are 14 rules for spherical OBLIQUE-ANGLED triangles, such as ABR, or its vicarious triangle V, that is, BRC, in the following figure.

Diagram. A small woodcut in the left column under the chapter title, the same design as the figure at the head of the scholia on the previous page. Two arcs meet at A on the left and C on the right, forming a lens; a third arc runs from R on the upper arc down to B on the lower arc, dividing the lens into a left part lettered P and a right part lettered V.

- A (left point of the lens): vertex
- P (inside the left part): the triangle ABR
- R (upper arc, right of centre): vertex
- V (inside the right part): the vicarious triangle BRC
- C (right point of the lens): vertex
- B (lower arc, left of centre): vertex

I. Regula. Datis Lateribus duobus, & Angulo vni eorum Oppoſito, Quærere Angulum alteri Oppoſitum, ſed ſpecie præcognitum. *Rule 1. Given two sides and the angle opposite one of them, to find the angle opposite the other, its kind, however, being known beforehand.*

[Margin: By logarithms.]

To the residue of the logarithm of the side opposite the given angle add the logarithm of the given angle and the logarithm of the remaining side, and the result will be the logarithm of the angle sought.

EXEMPLVM. *Example.*

Let side BR be 40° 20′; the residue of its logarithm is	RL	01889391
Let angle C be 36° 15′; its logarithm is	L	97718150
Let side RC be 50°; its logarithm is	L	98842540
Therefore angle RBC is 44° 24′ 55″	L	98450081

[Margin: By sines.]

OR: Let it be done that as the sine of the side opposite the given angle is to the sine of the given angle, so is the remaining given side to the sine of the angle sought, if acute. And if you were certain from elsewhere that the angle

sought must be obtuse, you will obtain it by subtracting the angle found from 180°.

II. Regula. Datis Lateribus duobus ſingillatim Quadrante minoribus, & Angulo vni eorum Oppoſito, ac Specie anguli oppoſiti reliquo dato Lateri, Quærere Baſim. *Rule 2. Given two sides, each singly less than a quadrant, the angle opposite one of them, and the kind of the angle opposite the remaining given side, to find the base.*

[Margin: By logarithms.]

First, to the residue of the second logarithm of the given angle add the second mesologarithm of the side adjacent to it, and the result will be the second mesologarithm of a certain arc, which is to be called the First.

Then, to the residue of the second logarithm of the side adjacent to the given angle, add the second logarithm of the First Arc and the second logarithm of the remaining given side, and the result will be the second logarithm of the Second Arc.

Third, if the angles opposite the given sides are of the same kind, that is, both acute or both obtuse, the sum of the First and Second Arcs will make up the base sought. But if they are of different kinds, subtract the smaller of the arcs found from the larger, and the remainder will be the base sought. If the data are greater than a quadrant, use the vicarious triangle, according to what was said in the scholia of chapter 4.

EXEMPLVM. *Example.*

[Margin: Step 1.]

Let angle C be 54° 34′; the residue of its second logarithm is	RL2	02367553
Let side RC be 40°; its second mesologarithm is	M 2	100761875
Therefore the First Arc is 25° 56′ 30″	M 2	103129418
The residue of the second logarithm of side RC, of 40°, is	RL2	01157460
The First Arc, of 25° 56′ 30″; its second logarithm is	L 2	99538755
The second logarithm of side RB, of 60°, is	L 2	96989700
Therefore the Second Arc is 35° 56′ 24″	L 2	97685915

[Margin: Step 2.]

[Margin: Step 3.]

Now the angles C and RBC are both acute; therefore the sum of the arcs, the First of 25° 56′ 30″ and the Second of 35° 56′ 24″, which is 61° 52′ 54″, makes the base BC.

[Margin: By sines.]

OR: Let it be done that as the radius is to the secant of the given angle, so is the second tangent of the side adjacent to the given angle to the second tangent of the First Arc. Then let it be done that as the second sine of the side adjacent

to the given angle is to the second sine of the remaining given side, so is the second sine of the First Arc to the Second Arc, which is to be added to the first arc if the angles opposite the given sides are of the same kind, so that the base is obtained; otherwise the difference of the arcs found will give the base.

III. Regula. Datis Lateribus duob. ſingillatim Quadrante minoribus, & Angulo vni eorum Oppoſito, & Specie anguli oppoſiti reliquo Lateri, Quærere Angulum Verticalem, ſeu comprehenſum à Lateribus datis. *Rule 3. Given two sides, each singly less than a quadrant, the angle opposite one of them, and the kind of the angle opposite the remaining side, to find the vertical angle, that is, the angle contained by the given sides.*

[Margin: By logarithms.]

First, to the mesologarithm of the given angle if it is acute, or of its supplement to 180° if it is obtuse, add the second logarithm of the side adjacent to this angle, and the result will be the second mesologarithm of a certain angle, which is to be called the First Angle.

Then, to the mesologarithm of the side adjacent to the given angle, add the second mesologarithm of the other side and the second logarithm of the First Angle found, and the result will be the second logarithm of an angle, which is to be called the Second Angle.

Third, if the angles opposite the given sides are of the same kind, the sum of the First and Second Angles will make up the vertical angle sought; but if they are of different kinds, the difference of the angles found will be the size of the vertical angle. But if the given sides are greater than a quadrant, use the vicarious triangle, which is treated in the scholia of chapter 4.

EXEMPLVM. *Example.*

Let angle C be 54° 34′; its mesologarithm is	M	101478013
Let side RC be 80°; its second logarithm is	L 2.	92396702
Therefore the First Angle is 76° 17′	M 2.	93874715
The mesologarithm of side RC, of 80°, is	M	1075[?]6812
The second mesologarithm of side RB, of 60°, is	M 2.	97614394
The second logarithm of the First Angle, of 76° 17′, is	L 2.	93749696
Therefore the Second Angle is 39° 4′	L 2.	98900902

Now the angles C and RBC, opposite the given sides, are both acute; therefore the sum of the First and Second Angles found, that is, of 76° 17′ and 39° 4′, which is 115° 21′, makes the vertical angle BRC.

[Margin: By sines.]

OR: Let it be done that as the radius is to the tangent of the given angle, so is the second sine of the side adjacent to the given angle to the second tangent of the First Angle. Then let it be done that as the tangent of the side adjacent

to the given angle is to the second tangent of the remaining given side, so is the second sine of the First Angle found to the second sine of the Second Angle. Now if the angles opposite the given sides are of the same kind, the sum of the First and Second Angles found will be the vertical angle; otherwise the difference of the angles found will be the vertical angle.

IV. Regula. Datis Lateribus duobus, quorum ſaltem vnum ſit Quadrante minus, & dato Angulo Verticali acuto, Quærere Baſin. *Rule 4. Given two sides, at least one of which is less than a quadrant, and the vertical angle, acute, to find the base.*

[Margin: By logarithms.]

First, to the second mesologarithm of the smaller of the given sides add the residue of the second logarithm of the acute vertical angle, and the result will be the second mesologarithm of an arc, which is to be called the First Arc.

Then, to the residue of the second logarithm belonging to the First Arc found, add the second logarithm of the smaller of the given sides and the second logarithm of the difference between the other side and the First Arc found; and the result will be the second logarithm of the base. The base must agree in kind with the difference already mentioned; otherwise the supplement of the supposed base to 180° must summi [?], so that the true base is obtained. But if the vertical angle is obtuse, or both of the given sides are greater than a quadrant, use the vicarious triangle, which is treated in the scholia of chapter 4.

EXEMPLVM. *Example.*

Let angle BRC be 37° 13′; the residue of its second logarithm is	RL2	00988938
Let side RB be 60°; its second mesologarithm is	M 2	97614394
Therefore the First Arc is 54° 3′ 30″, for the sum is	M 2	98603332
The residue of the second logarithm of the First Arc, of 54° 3′ 30″, is	RL2	02312166
Side RC, of 80°, and its difference from the First Arc is 25° 56′ 30″; the second logarithm of this is	L 2	99538755
The second logarithm of side BR, of 60°, is	L 2	96989700
Therefore the base BC is 40° 1′ 49″	L 2	98840621

That is, less than a quadrant, just as the difference of the First Arc and side RC was less than a quadrant.

[Margin: By sines.]

OR: Let it be done that as the radius is to the sine of the smaller of the given sides, so is the sine of the remaining side to an arc, which is to be called the First. Then let it be done that as the radius is to the First Arc, so is the versed sine of the vertical angle to the Second Arc; add this to the versed sine of the difference of the sides, and the result will be the versed sine of the base sought.

V. Regula. Datis Lateribus duobus, quæ ſimul ſumpta ſint minora Semicirculo; & dato Angulo Verticali, Quærere Angulum vtrumq. ad Baſim. *Rule 5. Given two sides which taken together are less than a semicircle, and the vertical angle, to find each angle at the base.*

[Margin: By logarithms.]

To the residue of the second logarithm of the half-sum of the sides add the second logarithm of their half-difference and the second mesologarithm of half the vertical angle, and the result will be the mesologarithm of the half-sum of the angles at the base.

Then, to the residue of the logarithm of the half-sum of the sides add the logarithm of their half-difference and the second mesologarithm of half the vertical angle, and the result will be the mesologarithm of the half-difference of the angles sought. This, therefore, added to the half-sum of the angles at the base, will give the larger angle, and subtracted from the same half-sum it will leave the smaller angle. But if the given sides together are greater than a semicircle, employ the vicarious triangle, which is treated in the scholia of chapter 4.

EXEMPLVM. *Example.*

Let side RC be	40°	0′	
And side RB	60°	0′	
The sum of the sides will be	100°	0′	half-sum 50°
And the difference of the sides	20°	0′	half-difference 10°
The vertical angle BRC	112°	0′	half-angle 56°

The residue of the second logarithm of the half-sum, 50°, is	RL2	01919325
The second logarithm of the half-difference, 10°, is	L 2	99933515
The second mesologarithm of half the vertical angle, 56°, is	M 2	98289874
Therefore the half-sum of the angles at the base is 45° 56′ 30″, a single unit being kept in the mesologarithm, according to precept 4 of chapter 1	M	100142714
Then		
The residue of the logarithm of the half-sum of the sides, 50°, is	RL	01157460
The logarithm of the half-difference of the sides, 10°, is	L	92396702
The second mesologarithm of half the vertical angle, 56°	M 2	98289874
Therefore the half-difference of the angles is 8° 41′ 35″	M	91844036

Add this to the half-sum, 45° 56′ 30″, and the larger angle C becomes 54° 38′ 5″. Subtract it, and RBC, the smaller, becomes 37° 14′ 55″.

[Margin: By sines.]

OR: Let it be done that as the second sine of the half-sum of the sides is to the second sine of their half-difference, so is the second tangent of half the

vertical angle to the tangent of the half-sum of the angles sought. Then let it be done that as the sine of the half-sum of the sides is to the sine of their half-difference, so is the second tangent of half the vertical angle to the tangent of the half-difference, which is to be added to the half-sum of the angles itself to make the larger angle, and subtracted from it to leave the smaller of the angles sought.

VI. Regula. Datis Lateribus duobus, Quorum alterum ſaltem ſit Quadrante minus, & Angulo Verticali acuto; Quærere Angulum quemuis ad Baſin. *Rule 6. Given two sides, at least one of which is less than a quadrant, and the vertical angle, acute, to find either angle at the base.*

[Margin: By logarithms.]

First, to the residue of the second logarithm of the vertical angle add the second mesologarithm of the side opposite the angle sought, and the result will be the second mesologarithm of the First Case [Primus Casus]. Then, to the residue of the logarithm of the First Case add the second mesologarithm of the vertical angle and the logarithm of the difference between the First Case and the other given side, and the result will be the second mesologarithm of the angle sought.

EXEMPLVM. *Example.*

Let the vertical angle BRC be 50°; the residue of its second logarithm	RL2	01919325
Let side BR be 36°; its second mesologarithm is	M 2	101387390
Therefore the First Case is 25° 2′, for the sum is	M 2	103306715
Side RC, 70°		
The First Case, 25° 2′; the residue of its logarithm	RL	03735102
The difference of the First Case and side RC, 44° 58′, whose logarithm is	L	98402322
The second mesologarithm of angle BRC, 50°	M 2	99238135
Therefore angle C is 36° 3′ 26″, for	M 2	101375559

[Margin: By sines.]

OR: Let it be done that as the radius is to the secant of the vertical angle, so is the second tangent of the side opposite the angle sought to the second tangent of the First Case. Then let it be done that as the second tangent of the vertical angle is to the second secant of the First Case, so is the sine of the difference between the First Case and the other side to the second tangent of the angle sought.

VII. Regula. Datis Angulis duobus & Latere vni eorum Oppoſito, Quærere Latus alteri angulo dato Oppoſitum, ſpecie tamen præcognitum. *Rule 7. Given two angles and the side opposite one of them, to find the side opposite the other given angle, its kind, however, being known beforehand.*

[Margin: By logarithms.]

To the residue of the logarithm of the angle opposite the given side add the logarithm of the given side and the logarithm of the

remaining given angle, and the result will be the logarithm of the side sought, less than a quadrant. But if it must be greater than a quadrant, subtract the side found from 180° and you will have the side sought.

EXEMPLVM. *Example.*

Let angle C be 38° 10′; the residue of its logarithm is	RL	02090459
Let side RB be 42°; its logarithm is	L	98255109
Let angle RBC be 54° 15′; its logarithm is	L	99093281
Therefore side RC is 61° 29′ 17″, for the sum is	L	99438849

[Margin: By sines.]

OR: Let it be done that as the sine of the angle opposite the given side is to the sine of the given side, so is the sine of the remaining given angle to the sine of the side sought, less than a quadrant; or (if it must be greater than a quadrant) of the side to be subtracted from 180°, so that the side sought is obtained.

VIII. Regula. Datis Angulis duobus acutis, & Latere vni eorum Oppoſito, nec non Specie Lateris oppoſiti alteri angulo, Quærere Baſim adiacentem datis angulis. *Rule 8. Given two acute angles and the side opposite one of them, and also the kind of the side opposite the other angle, to find the base adjacent to the given angles.*

[Margin: By logarithms.]

To the residue of the second logarithm of the angle adjacent to the given side add the second mesologarithm of the given side, and the result will be the second mesologarithm of the First Arc.

Then, to the logarithm of the First Arc add the mesologarithm of the angle adjacent to the given side and the second mesologarithm of the remaining given angle, and the result will be the logarithm of the Second Arc.

Third, if the given side is less than a quadrant, the sum of the First and Second Arcs found will make up the base sought. But if the given side is greater than a quadrant, the sum made of the Second Arc and of the supplement of the First Arc to a semicircle will make up the base sought.

EXEMPLVM. *Example.*

Let side RB be 40°; its second mesologarithm is	M 2	100761865
Angle RBC, 35° 25′; the residue of its second logarithm	RL2	00888641

Therefore the First Arc is 34° 22′, for	M 2	101650506
The logarithm of the First Found, 34° 22′, is	L	97516538
The mesologarithm of angle RBC, 35° 25′, is	M	98519312
The second mesologarithm of angle C, 52°, is	M 2	98928098
Therefore the Second Arc is 18° 16′ 30″, for	L	94963948

Added to the First Arc, this makes the base BC 52° 38′ 30″.

[Margin: By sines.]

OR: Let it be done that as the radius is to the secant of the angle adjacent to the given side, so is the second tangent of the given side to the second tangent of the First Arc. Then let it be done that as the tangent of the angle adjacent to the given side is to the second tangent of the remaining given angle, so is the sine of the First Arc to the sine of the Second Arc, which agrees in kind with the side not given. Let the rest, as regards the sum of the arcs, be done as above.

IX. Regula. Datis duobus Angulis acutis, & Latere Oppoſito vni eorum, ac Specie Lateris oppoſiti alteri angulo dato, Quærere Angulum Tertium. *Rule 9. Given two acute angles and the side opposite one of them, and the kind of the side opposite the other given angle, to find the third angle.*

[Margin: By logarithms.]

To the second logarithm of the given side add the mesologarithm of the angle adjacent to it, and the result will be the second mesologarithm of an angle, which is to be called the First Angle.

Then, to the logarithm of the First Angle add the second logarithm of the remaining given angle and the residue of the second logarithm of the angle adjacent to the given side, and the result will be the logarithm of an angle, which is to be called the Second Angle; and it must agree in kind with the remaining side.

Third, if the given side is less than a quadrant, the sum of the first and second angles found will make up the third angle sought. But if the given side is greater than a quadrant, then to have the angle sought use the sum made of the Second Angle and of the supplement of the First Angle to 180°.

EXEMPLVM. *Example.*

Let side RB be 40°; its second logarithm is	L 2	98842540
Let angle RBC be 54° 34′; its mesologarithm	M	101478013
Therefore angle 1 is 42° 53′, a unit being removed, etc.	M 2	100320553
The logarithm of angle 1, 42° 53′, is	L	98328331
The second logarithm of angle C, 37° 13′, is	L 2	99011062
The residue of the second logarithm of angle RBC, 54° 34′	RL2	02367553
Therefore angle 2 is 69° 12′, for the sum is	L	99706946

[Margin: Remember precept 4 of chapter 1.]
Therefore, when angles 1 and 2 are joined, angle BRC becomes 112° 5′.
[Margin: By sines.]
OR: Let it be done that as the radius is to the second sine of the given side, so is the tangent of the angle adjacent to the same side to the second tangent of the First Angle. Then let it be done that as the second sine of the angle adjacent to the given side is to the second sine of the remaining given angle, so is the sine of the First Angle to the sine of the Second Angle, which agrees in kind with the side not given. Therefore, when the angles found are joined as above, the result will be the third angle sought.

X. Regula. Datis Angulis duobus, quorum vnus ſaltem ſit acutus, & Baſi ijs adiacente, quæ ſit Minor quadrante, Quærere Angulum Baſi Oppoſitum.
Rule 10. Given two angles, at least one of which is acute, and the base adjacent to them, which is less than a quadrant, to find the angle opposite the base.
[Margin: By logarithms.]
To the mesologarithm of the acute angle, or (if both are acute) of the smaller of the acute angles, add the second logarithm of the base, and the result will be the second mesologarithm of the First Angle.
Then, to the residue of the logarithm of the First Angle add the second logarithm of the smaller of the given angles and the logarithm of the difference between the larger of the given angles and the First Angle found, and the result will be the second logarithm of the angle sought. But if the base is greater than a quadrant, use the vicarious triangle, as in the scholia of chapter 4.

EXEMPLVM. *Example.*

Let angle A be 37° 13′; its mesologarithm is	M	98805277
Let the base AB be 60°; its second logarithm is	L 2	96989700
Therefore the First Angle is 69° 12′, for	M 2	95794977
The residue of the logarithm of angle 1, 69° 12′	RL	00292694
Angle A, 37° 13′; its second logarithm	L 2	99011062
Angle ABR, 112° 6′, and its difference from angle 1 is 42° 54′, whose logarithm	L	98329691
Therefore the vertical angle ARB is 54° 24′ 30″, for	L 2	97633447

But if the First Angle found were greater than the remaining angle, the larger of the acute ones, then the vertical angle, that is, the angle sought, must be obtuse; therefore, to obtain it, subtract the angle found second from 180°.
[Margin: By sines.]
OR: Let it be done that as the radius is to the sine of the smaller of the given angles, so is the sine of the remaining given angle to the First Found [Inventum primum]. Then let it be done that as the radius is to the First Found, so is the versed sine of the base to the Second Found. Third, add the Second Found to

the versed sine of the difference between either of the given angles and the supplement of the other to 180°, and the result will be the versed sine of the vertical angle sought.

XI. Regula. Datis Angulis duobus ſimul duos rectos non excedentibus, & Baſi adiacente ipſis, Quærere Latus vtrumq. vnico actu. *Rule 11. Given two angles which together do not exceed two right angles, and the base adjacent to them, to find each side in a single operation.*

[Margin: By logarithms.]

First, collect the sum of the angles at the given base and their difference, and finally half the given base. Then, to the residue of the second logarithm of the half-sum of the angles add the second logarithm of their half-difference and the mesologarithm of the half-base, and the result will be the mesologarithm of the half-sum of the sides sought.

Third, to the residue of the logarithm of the half-sum of the given angles add the logarithm of their half-difference and the mesologarithm of half the given base, and the result will be the mesologarithm of the half-difference; this, added to the half-sum of the sides, will make the larger side, and subtracted, the smaller.

EXEMPLVM. *Example.*

Let angle ARB be	54°	34′	
Let angle C be	37°	13′	
Their sum	91°	47′	half-sum 45° 53′ 30″
Their difference	17°	21′	half-difference 8° 40′ 30″
The base AR, 80°			half-base 40°

The residue of the second logarithm of the half-sum of the angles, 45° 53′ 30″, is	RL2	01573149
The second logarithm of the half-difference of the angles, 8° 40′ 30″, is	L2	99950126
The mesologarithm of the half-base, 40°, is	M	99238135
Therefore the half-sum of the sides is 50° 38′ 44″, on account of the mesologarithm	M	100861410
Then		
The residue of the logarithm of the half-sum of the angles, 45° 33′ 30″, is	RL	01438600
The logarithm of the half-difference, 8° 40′ 30″, is	L	91784810
The mesologarithm of the half-base, 40°, is	M	99238135
Therefore the half-difference of the sides is 9° 59′ 47″	M	92461545

This half-difference, added to the half-sum of the sides, makes side AB 60° 38′ 31″; subtracted, it leaves the smaller side BR, 40° 38′ 57″.

[Margin: By sines.]

OR: Let it be done that as the second sine of the half-sum of the given angles is to the second sine of their half-difference, so is the tangent of the half-base to the tangent of the half-sum of the sides. Then let it be done that as the sine of the half-sum of the given angles is to the sine of their half-difference, so is the tangent of the half-base to the tangent of the half-difference of the sides, which is to be added to the half-sum of the sides itself to make the larger side, and subtracted to make the smaller.

XII. Regula. Datis Angulis duobus, quorum ſaltem vnus ſit Acutus, & Baſi Adiacente, quæ ſit minor Quadrante, Quærere Latus vtrumuis. *Rule 12. Given two angles, at least one of which is acute, and the base adjacent to them, which is less than a quadrant, to find either side.*

[Margin: By logarithms.]

To the second logarithm of the base add the mesologarithm of the angle that is given and is opposite the side sought, and the result will be the second mesologarithm of the First Arc, for so the first quantity found is to be called. Then, to the residue of the second logarithm of the First Arc found add the second mesologarithm of the base, and the second logarithm of the difference between the second given angle and the First Arc found, when the side sought is opposite an acute angle; or the second logarithm of the sum made of the second of the given angles and the First Arc found, when the side sought is opposite an obtuse angle; and the result will be the second mesologarithm of the side sought. But if the difference or sum already mentioned is greater than a quadrant, subtract the side found from 180° to have the side sought. But if both of the given angles are greater [?] than an acute angle, or the base is greater than a quadrant, have recourse to the vicarious triangle, which is treated in the scholia of chapter 4.

EXEMPLVM. *Example.*

Let angle ARB be 112° 6′, and let side AB be sought.		
Its complement to 180° is 67° 54′, whose mesologarithm	M	103914120
Let the base AR be 40°; its second logarithm is	L 2	98842540
Therefore the First Found is 27° 55′ 38″, for	M 2	102756660
Then		
Let angle A be 54° 3[?]′; the sum of it and the First Found is 82° 29′ 38″, whose second logarithm is	L 2	91161800
The residue of the second logarithm of the First Found, 27° 55′ 38″, is	RL2	00537750
The second mesologarithm of the base, 40°, is	M 2	100761865
Therefore side AB is 80° 15′, on account of the second mesologarithm	M 2	92461415

[Margin: By sines.]

OR: Let it be done that as the radius is to the tangent of the angle opposite the side sought, so is the second sine of the base to the second tangent of the

First Found. Then let it be done that as the second tangent of the base is to the secant of the First Found, so is the second sine of the difference between the First Found and the second of the given angles, if the side sought is opposite an acute angle — or the second sine of the sum made of the First Found and the other of the given angles, if the side sought is opposite an obtuse angle — to the second tangent of the side sought (if the said sum or difference does not exceed 90°), or of its supplement to 180° (if it does exceed it).

XIII. Regula. Datis Angulis tribus, Quærere Latus quoduis tanquam baſis.
Rule 13. Given the three angles, to find any side as a base.

First, you must determine which side it is that you want to find, and call it the base, and the angle opposite it the vertical angle. Once these are determined, subtract the vertical angle from 180°, and let the remainder be called the Complement of the Vertical. Further, subtract the smaller of the remaining angles from the larger, and let the remainder be called the Difference of the angles. Add this to the Complement of the Vertical, and the result will be the Mystic Sum [Summa mystica], for so I call it for the sake of distinction. Subtract the same difference from the same Complement of the Vertical, and the Mystic Difference will result. Take half of each, and you will have the Mystic Half-sum and also the Mystic Half-difference, which are to be used as we shall say shortly.

[Margin: By logarithms.]

Second, add together these four: the logarithm of the Mystic Half-sum, the logarithm of the Mystic Half-difference, and the residue of the logarithm of each given angle singly; and the result will be a doubled second logarithm, that is, a certain sum, in which the redundant unit will have to be kept, according to what was said in chapter 1, precept 2.

Third, take half of the doubled logarithm, and you will have the second logarithm of half the side sought, as of a half-base; therefore double this will be the whole side sought, that is, the whole base.

EXEMPLVM. *Example.*

In the triangle P, set out at the beginning of the chapter, let the base AR be sought.

Let the vertical angle ABR be	120°
Its complement to two right angles	60°
Let angle BRA be	45° 20′
And angle A	37° 10′
The difference of the angles is	8° 10′
Joined to the complement of the vertical, 60°, this gives the Mystic Sum	68° 10′
Subtracted from the same, it gives the Mystic Difference	51° 50′
Therefore the Mystic Half-sum is	34° 5′

And the Mystic Half-difference	25° 55′

With these prepared,

The logarithm of the Mystic Half-sum, 34° 5′, is	L	97484967
The logarithm of the Mystic Half-difference, 25° 55′, is	L	96405445
The residue of the logarithm of angle BRA, 45° 20′, is	RL	01480030
The residue of the logarithm of angle A, 37° 10′, is	RL	02188656
Therefore the double of the second logarithm is	L L2	197559098
Its half is the second logarithm	L 2	98779549

To this corresponds in the tables the arc 40° 58′ 20″; doubled, therefore, it gives the side AR, that is, the base, 81° 56′ 40″.

[Margin: By sines.]

OR: Let it be done that as the radius is to the second secant of either of the angles adjacent to the base sought, so is the second secant of the other of the said angles to an arc, which is to be called the Found [Inventum]. Then let it be done that as the radius is to the arc found, so is the difference of two versed sines, of which more shortly, to the versed sine of the base sought. One of the said versed sines is to be the versed sine of the vertical angle; the other, the versed sine of the difference between either of the two angles adjacent to the base and the supplement to 180° of the other angle, likewise adjacent to the base.

XIV. Regula. Datis Lateribus Tribus, Quærere Angulum quemlibet tanquam Verticalem. *Rule 14. Given the three sides, to find any angle as the vertical angle.*

First, determine which of the three angles you want to know, and call it the vertical angle; call the side opposite it the base; the others keep the common name of sides. Then add the base to the aggregate of the sides, and let the sum of these be called the Mystic Sum; from the same aggregate of the sides take away the base, and let the remainder be called the Mystic Difference. Take half of each of them, and you will have the Mystic Half-sum and also the Mystic Half-difference, whose use I shall teach shortly.

[Margin: By logarithms.]

Second, then, collect these four into one sum: namely the logarithm of the Mystic Half-sum, the logarithm of the Mystic Half-difference, and the residue of the logarithm of each side taken singly; and the result will be the double of the second logarithm, of which more shortly.

Third, take half of the double of the second logarithm, and you will have the second logarithm of the half vertical angle; doubling it, you will have the vertical angle sought.

EXEMPLVM. *Example.*
In triangle V, in which angle C is sought.

Let side BC be	60°	20′	
Let side RC be	40°	20′	
Their aggregate is	100°	40′	
Let the base BR be	50°	20′	
The Mystic Sum	151°	0′	and the Mystic Half-sum 75° 30′
The Mystic Difference	50°	20′	and the Mystic Half-difference 25° 10′

With these prepared,

The logarithm of the Mystic Half-sum, 75° 30′	L	99859416
The logarithm of the Mystic Half-difference, 25° 10′	L	96286472
The residue of the logarithm of side BC, 60° 20′	RL	00610204
The residue of the logarithm of side RC, 40° 20′	RL	01889391
The sum, the double of the second logarithm	LL 2	198645483
Its half is the second logarithm	L 2	99322721

To this corresponds the half-angle 31° 10′ 34″. Therefore the whole angle C is 62° 21′ 8″.

[Margin: By sines.]

OR: Let it be done that as the radius is to the second secant of one side containing the angle sought, so is the second secant of the other side containing the same angle to the First Found. Then let it be done that as the radius is to the First Found, so is the difference of the versed sines (namely of the base and of the difference of the sides) to the versed sine of the angle sought.

INDEX REGVLARVM PRÆDICTARVM TRIGONOM. *Index of the trigonometric rules already given.*

SECTIO SECVNDA PROBLEMATVM PRIMI MOBILIS.

Section Two: Problems of the Primum Mobile.

PROHOEMIVM. *Preface.*

We call Problems of the Primum Mobile those that are general and common to all stars, whether fixed or wandering, and also to the points or parts themselves of the ecliptic, the equator, the meridian, the horizon, the vertical, and the other great circles that are usually marked out in the highest heaven, and to the angles arising from the intersection of the circles already mentioned with one another — whether that highest heaven is in reality the primum mobile or not. Further, for the notions of the terms, and for the definitions of the arcs or angles to be used below, the definitions we gave in Book 1 of this work, chapter 22, should be read again.

[Margin: Advice for the practice of the following problems.]

As for the order of the problems, although it can vary, we shall follow the one that can, as it were, lead the reader by the hand from simpler and better-known phenomena to others less known and more involved. And although, on the occasion of figures explained once for one or a few problems, we think it right to give other related problems as well, so that we are not forced to insert and explain the same figure too often, everyone will nevertheless be satisfied if they consult the alphabetical index of the problems already explained at the end of this book, so that they may be readily at hand without confusion of order. In

place of the examples that someone might want, the general examples given in the first section for solving any triangles will suffice — especially in chapter 4, where we taught how to solve spherical right-angled triangles, and in chapter 5, where we taught how to solve spherical oblique-angled ones; nor will there be any need except to send the reader to the rules given there, or else to the examples given in other books of this work of ours — apart from a very few cases, very frequent in astronomy, which we shall illustrate with examples. Finally, we shall teach the construction of the Tables of the Primum Mobile from the problems proper to them, in such a way, however, that we add the principal authors who have already constructed the tables already mentioned.

[Margin: Order of the problems.]

[Margin: Order of the problems.]

Auctores, vnde aliqua ſequentium Problematum. *Authors from whom some of the following problems come.*

Although, God granting, we are going to present many new problems devised by us, it is nevertheless right to praise those authors who have handed down to us not a few of the following problems, granted that they did so in another and not infrequently more perplexing way. Such are Ptolemy, books 1 and 2 of the *Almagest*; Geber [Jābir ibn Aflaḥ], books 1 and 2 of his *Astronomy*; Copernicus, books 1 and 2 of the *Revolutions*; Regiomontanus, in 63 problems of the Primum Mobile and 31 precepts of Directions; Erasmus Reinholdus [Erasmus Reinhold], in 60 precepts of Directions; Petrus Apianus, in 100 propositions of the Primum Mobile; Erasmus Osualdus, in 70 propositions of the primum mobile; Daniel Santbech, in 159 propositions of Astronomical and Geometrical Problems; Io. Antonius Maginus, from book 5 to book 12 of the *Primum Mobile*, where he has 199 problems, besides 55 canons in his work on Directions; Longomontanus, book 2 of the *Spherics*, giving 59 problems; Clavius, here and there in the *Astrolabe*; Bonaventura Cavalieri, in the *Centuria* of problems; Hérigone, in the common problems; Petavius [Denis Pétau], in the *Uranologion*; Bartholomaeus Pitiscus [Bartholomäus Pitiscus], book 1 of the *Astronomical Problems*, where see problem 16, and the single book of *Geographical Problems*; Villebrordus Snellius [Willebrord Snellius], at the end of his doctrine of triangles, where he solves 8 spherical problems — besides others who have inserted some problems of this kind here and there in their works, such as Tycho in volumes 1 and 2 of the *Progymnasmata*, and those who have treated comets trigonometrically.

1. Problema. Meridianam Lineam, & Poli atque Aequatoris Altitudinem Inuenire. *Problem 1. To find the meridian line, and the altitude of the pole and of the equator.*

[Margin: Problem 1.]

I taught the finding of the meridian line sufficiently in Book 1 of this *Almagest*, chapter 10, and the finding of the altitude of the pole in the same book, chapter

12; so go back there. It was right, however, to mention them here first, since these two are the most universal foundations of astronomical observations and of most problems. The other methods, less necessary but still useful, or very ingenious, we shall give in the Section of Geographical Problems. Now if you subtract the altitude of the pole from 90°, you will have the distance of the pole from the vertex, which is always as great as the elevation of the equator; just as the distance of the equator from the vertex, that is, from the zenith, is as great as the altitude of the pole.

2. Probl. Declinationem Solis Maximam vel Minimam Obſeruare, & ex vtraq. vel vtralibet Obliquitatem Eclipticæ deducere, Quæ ſemper tanta eſt, quanta Diſtantia Tropicorum ab Aequatore; quantaq Diſtantia Polorum Eclipticæ & Aequatoris. *Problem 2. To observe the greatest or the least declination of the Sun, and from both, or from either, to deduce the obliquity of the ecliptic, which is always as great as the distance of the tropics from the equator, and as great as the distance between the poles of the ecliptic and of the equator.*

[Margin: Problem 2.]

In the adjoining figure, let the horizon be HR, and the equator the circle AQ, whose axis is BP; and let the meridian be HZRN, in which the zenith, that is, the vertex of the observer, is Z, and the nadir N; and the poles of the equator B and P.

Diagram. A small woodcut in the left column beside the text of problem 2: a circle (the meridian HZRN) with the horizontal diameter HR, the equator AQ drawn through the centre, the axis BP drawn through the centre, and a further chord from C towards the lower right. Small stars stand on the circle at K, G, C and M, marking the stars and solar positions discussed in problems 2–4. Labels, clockwise from the top:

- K (top, left of Z): the Sun's place at the summer solstice, a star at K
- Z (top): zenith
- G (top, right of Z): a star at G
- B (upper right): pole of the equator
- M (right, above R): a star at M
- R (right): horizon
- Q (lower right): equator
- N (bottom): nadir
- P (lower left): pole of the equator
- H (left): horizon
- C (left, above H): the Sun's place at the winter solstice, a star at C
- A (upper left): equator

First, then, suppose you have observed the Sun's greatest meridian altitude HK — namely the one it has at noon on the day of the summer solstice — and have corrected it by subtracting the refraction and adding the solar parallax. If from the Sun's altitude so corrected, that is, its true altitude, you subtract the altitude of the equator HA, the arc AK will be left, that is, the greatest

declination of the Sun. I gave examples of this practice in Book 3, chapter 27, number 3.

Second, you will obtain the same result even without the altitude of the equator, by two meridian altitudes of the Sun: the greatest, namely at noon of the summer solstice, when the Sun is at K, and the least at noon of the winter solstice, when it is at C, correcting both by adding the parallax and subtracting the solar refraction. For if you subtract the least, HC, from the greatest, HK, the distance of the tropics CK will remain; half of it, AK or AC, will be the greatest declination sought, as I taught with examples in Book 3, chapter 27, number 2. Indeed, if you add this, that is CA, to the least true altitude of the Sun, HC, you will have the altitude of the equator HA.

3. Probl. Declinationem quamlibet Solis & cuiuſuis ſideris ex Altitudine Meridiana; 4. Probl. Vel Altitudinem Meridianam ex Declinatione deducere. *Problem 3. To deduce any declination of the Sun and of any star from the meridian altitude; Problem 4. Or the meridian altitude from the declination.*

[Margin: Problem 3.]

Observe the meridian altitude of a star with an astronomical quadrant, or any other instrument for altitudes, and correct it if need be by adding the parallax and subtracting the refraction, and you will have the true altitude. Then go back to the figure of problem 2. For if the star observed was between your vertex and the part of the horizon farther from the visible pole of the world, the altitude of the equator HA, subtracted from the greater altitude HK of the star standing at K, will leave the northern declination of the star, AK, if the observer is northern, or the southern, if southern. Conversely, if the star is at C, and its true altitude HC is less than the altitude of the equator HA, the former taken from the latter will leave the declination of the star AC — southern if the observer is northern, northern if southern. But if the star was between the vertex and the part of the horizon nearer the visible pole of the world, as if it is at G or at M, the altitude of the pole RB, taken from the true altitude RG of the higher star, will leave GB, its distance from your pole, which taken from 90° will leave the declination AG of star G, towards the same pole. But if the altitude RM of star M is less than the altitude of the pole RB, then, the former being subtracted from the latter, BM will be left, the distance from the pole, which, again taken from 90°, will leave the declination QM of star M, likewise towards your pole. See the example in Book 6, chapter 11, problem 1. The declination, and indeed also the right ascension, of a star, even one placed outside the meridian, can also be observed with equatorial armillae set in a position analogous to the celestial sphere; but the method given above is much easier and more evident.

[Margin: Problem 4.]

But if the true declination of a star were known, not changed about noon — say the arc CA or AK — then, by subtracting the former and adding the latter to the altitude of the equator HA, the true meridian altitude of the star would

become known; and by taking the parallax from it and adding the refraction, the apparent meridian altitude will be known; and so for the rest.

Probl. Solis Locum in Ecliptica inquirere Data ipſius 5. Declinatione Meridiana, & Obliquitate Eclipticæ. 6. Declinatione Meridiana & Aſc. Recta Solis. 7. Obliquitate Eclipt. & Aſc. Recta Solis. *Problem. To find the place of the Sun in the ecliptic, given its: 5. meridian declination and the obliquity of the ecliptic; 6. meridian declination and the right ascension of the Sun; 7. the obliquity of the ecliptic and the right ascension of the Sun.*

[Margin: Problem 5.]

In the adjoining diagram, let the equator be AIL, and the ecliptic AVLPA; and let the arcs of the meridians by which the declination of the points of the ecliptic, and so of the Sun, is measured be GDP, ♋IV♑ and VHS.

Diagram. A woodcut in the right column: a lens-shaped figure formed by the straight equator AIL and the two arcs of the ecliptic, the upper arc through G, ♋ and V and the lower arc through P, ♑ and S, crossed by three meridian arcs GDP, ♋IV♑ and VHS. Labels:

- A (left point), with ♈ below it: beginning of Aries
- L (right point), with ♎ beside it: beginning of Libra
- G, ♋, V (upper arc, left to right): points of the ecliptic; ♋ the beginning of Cancer
- P, ♑, S (lower arc, left to right): points of the ecliptic; ♑ the beginning of Capricorn
- D, I, H (on the equator, left to right): feet of the three meridian arcs

First, then, if the declination is nil, the Sun is at the beginning of Aries, A, or of Libra, L, which you will tell apart from the difference of season. But if the declination is the greatest and summer one, ♋I, the Sun will be at the beginning of Cancer; if the winter one, ♑I, at the beginning of Capricorn. Outside these cases one must know beforehand in which quadrant of the ecliptic

[Margin: Order of the problems.]

[Margin: Order of the problems.]

it lies — whether in the first, AG♋, namely between the vernal equinox and the summer solstice, as when the Sun is at G. For then, in triangle ADG, right-angled at D, from the given declination GD and the angle of the obliquity of the ecliptic GAD, you will gather the Sun's longitude from the beginning of Aries, AG, that is, the base, by Rule 11 of spherical right-angled triangles. But if it is in the 2nd quadrant, as at V, find by the same rule the base VL in triangle VHL, right-angled at H, since the Sun's declination VH and the obliquity of the ecliptic HLV are given; for when the base VL is taken from 180°, the Sun's elongation from the beginning of Aries, AGV, will be left, and so its place in the ecliptic. Here, however, we suppose the straight lines AIL, GP, VS, etc., to be substituted for arcs of great circles. If the Sun is at S, a point of the third quadrant, look likewise for the base SL in triangle SHL, right-angled at H, in which the declination SH and the obliquity HLS are given; add this base to

180°, and the result will be the Sun's longitude from the beginning of Aries. Finally, if the Sun is at P, a point of the fourth quadrant of the ecliptic, look by the same rule for the base AP in triangle ADP, right-angled at P [?]; for the declination DP and the obliquity DAP are given. Take this base from 360°, and what is left will be the Sun's longitude from the beginning of Aries, reckoned according to the succession of the signs.

[Margin: Problem 6.]

But if the Sun is at G, and the declination GD and the right ascension AD are given, you will gather the base AG, that is, the longitude of the Sun, by Rule 13 of spherical right-angled triangles, since in triangle ADG, right-angled at D, two sides are given. Or, if the Sun is at V, its right ascension AH, taken from 180°, will leave the side HL; with it and with the declination VH you will gather, by the same Rule 13, the base VL, which, taken from 180°, gives its longitude; and so for the other cases.

Diagram. A woodcut in the left column, of the same design as the figure of problem 5 on the preceding page: a lens-shaped figure formed by the straight equator AIL and the two arcs of the ecliptic, the upper arc through G, ♋ and V and the lower arc through P, ♑ and S, crossed by three meridian lines GDP, ♋I♑ and VHS. Labels:

- A (left point), with ♈ beside it: beginning of Aries
- L (right point), with ♎ beside it: beginning of Libra
- G, ♋, V (upper arc, left to right): points of the ecliptic; ♋ the beginning of Cancer
- P, ♑, S (lower arc, left to right): points of the ecliptic; ♑ the beginning of Capricorn
- D, I, H (on the equator, left to right): feet of the three meridian lines

[Margin: Problem 7.]

But if the Sun is at G, and the obliquity GAD and the Sun's right ascension AD are given, you will gather the base AG by Rule 9 of spherical right-angled triangles. The rest you now understand.

Probl. Aſcenſionem Rectam Solis, ſeu Puncti Eclipticæ, in quo reperitur Sol, inueſtigare, Datis 8. Longitudine Solis, & Obliquitate Eclipticæ 9. Declinatione, & Longitudine Solis 10. Obliquitate Eclipticæ, ac Declinat. Solis *Problem. To find the right ascension of the Sun, or of the point of the ecliptic in which the Sun is found, given: 8. the longitude of the Sun and the obliquity of the ecliptic; 9. the declination and the longitude of the Sun; 10. the obliquity of the ecliptic and the declination of the Sun.*

[Margin: Problem 8.]

First, in the figure of problem 5, let the Sun be at G, a point of the first quadrant, and let its longitude be given, that is, the base AG, together with the obliquity of the ecliptic GAD. Then in triangle ADG, right-angled at D, you will gather the side AD, that is, the Sun's right ascension, by Rule 2 of spherical right-angled triangles. But if the Sun is in the 2nd quadrant, as at

V, its longitude AV, taken from 180°, will give the base VL; with it and with the obliquity VLH, by the same Rule 2, you will gather the side HL, which, taken from 180°, leaves the Sun's right ascension AH. If, however, the Sun is in the 3rd quadrant, as at S, take 180° from the longitude and the base SL will remain; with it and with the obliquity HLS, look by the same Rule 2 for the side HL, which, added to 180°, makes the Sun's right ascension. Lastly, if the Sun is in the 4th quadrant, as at P, the Sun's longitude taken from 360° will give the base AP; with it and with the obliquity DAP, look for the side AD, which, taken from 360°, leaves the right ascension of ☉.

[Margin: Problem 9.]

Second, let the declination and the longitude be given. In all four cases already mentioned, the base will be given from the longitude, and from the declination the side adjacent to the base, say the side GD, or VH, etc.; with these, by Rule 6 of spherical right-angled triangles, find the other side, which will be either the right ascension itself or its argument, as was said in the three later cases of problem 8.

[Margin: Problem 10.]

Third, let the obliquity of the ecliptic be given, and the side opposite it, that is, the declination — say the angle GAD and the side GD. Then by Rule 10 of spherical right-angled triangles you will have the other side, which will be the right ascension, as AD, or its argument, as in the other three cases already mentioned.

Probl. Obliquitatem Eclipticæ explorare, Datis 11. Declinatione, ac Longitudine Solis 12. Declinatione, & Aſc. Recta Solis 13. Longitudine & Aſcenſ. Recta Solis *Problem. To find out the obliquity of the ecliptic, given: 11. the declination and the longitude of the Sun; 12. the declination and the right ascension of the Sun; 13. the longitude and the right ascension of the Sun.*

[Margin: Problem 11.]

The first method is if the declination of the Sun is given, say the side GD (namely in the figure of problem 5), and the longitude, that is, the base AG, from astronomical tables or ephemerides, or from elsewhere. For by Rule 4 of spherical right-angled triangles you will obtain the angle GAD, that is, the obliquity of the ecliptic; and you will work in the same way when the Sun's place is in the other quadrants of the ecliptic, for you will always know from the longitude which base is to be used.

[Margin: Problem 12.]

The second method is, given the Sun's declination GD and right ascension AD — that is, two sides: for then by Rule 14 of spherical right-angled triangles you will learn the angle of the obliquity of the ecliptic; and so in the other three cases, which have been dealt with more than once above.

[Margin: Problem 13.]

The third method is if the Sun's longitude AG, that is, the base, and the right ascension AD are given: for by Rule 5 of spherical right-angled triangles you

will obtain the angle of the obliquity of the ecliptic; and you will proceed in the same way in the other three cases.

We pass over the remaining methods by which the distance of the poles could be verified from the declination and latitude of other stars, or from their longitude or right ascension, since that distance is rather presupposed for those properties, as being much more certain.

14. Probl. Angulum Eclipticæ & Meridiani determinare, Datis Eclipticæ Graau quouis, & Obliquitate; ipſiuſq. Tabulam conſtruere. Idem verò Angulus vocatur quoque Eclipticæ & Circuli Horarij, vel Declinationis. *Problem 14. To determine the angle of the ecliptic and the meridian, given any degree*[52] *of the ecliptic and the obliquity; and to construct its table. This same angle is also called the angle of the ecliptic and the hour circle, or the circle of declination.*

[Margin: Problem 14.]

The meridian, cutting the ecliptic at the solstitial points, makes four right angles with it; but at the equinoctial points it makes two acute angles, vertically opposite each other, and two other, obtuse, ones. Any one of the acute angles is found by subtracting the obliquity of the ecliptic from 90°; the obtuse, by adding it to 90°. Outside these positions trigonometry is needed; but it is enough to find this angle for any degree of the first quadrant of the ecliptic — namely, in the figure of problem 5, for any degree of the arc AG♋. Let there be, then, the spherical triangle ADG, right-angled at D, in which the obliquity of the ecliptic, that is, the angle GAD, is given, and the longitude AG of the given point G, namely the base. Then by Rule 3 of spherical right-angled triangles you will find the angle AGD that the meridian, of which GD is a portion, makes with the ecliptic; and the supplement of this angle to 180° will be the angle DGV. The same angle could be found given the obliquity of the ecliptic and the declination of the given point of the ecliptic; or from the distance from the nearer equinox and the declination; or from the distance and the right ascension; but the way I have taught is simpler and comes first. Scheiner, however, in the *Rosa Ursina*, from page 356 to 363, suggests two other methods, mechanical ones: one by the analemma, from the astrolabe of Io. Roias [Juan de Rojas]; the other by an instrument he devised himself.

[Margin: The table's construction, and its authors.]

Once a table of this angle has been constructed, then, for every degree of the quadrant AG♋, it will serve the three remaining quadrants; for that angle is of the same size at any four degrees of the ecliptic equally distant from the nearer equinoctial or solstitial point — say at the degrees G, V, S, P. Moreover, a table of this kind is given by Copernicus, book 2, chapter 3; by Lansbergen, page 99 of the *Tables*; by Io. Antonius Maginus, in the *Directions of the Primum Mobile*, page 199; by Boulliau, in the *Philolaic Tables*, page 140; and by Scheiner, in the *Rosa Ursina*, page 355,

[52] printed *Graau*, for *Gradu*

[Margin: Order of the problems.]
[Margin: Order of the problems.]
supposing an obliquity of 23° 30′; Kepler, in the *Rudolphine Tables*, folio 24; and Longomontanus, in the *Astronomia Danica*, book 1 of the *Spherics*, folio 60, from Tycho's obliquity. Five other methods could have been added, of which we shall speak from problem 76 on; but this one is simpler and more common.

15. Probl. Declinationem Solis, aut cuiuſuis puncti aut gradus Eclipticæ Inquirere, Datis Obliquitate & Gradu quouis Eclipticæ, ac Tabulam Declinationum harum conſtruere. *Problem 15. To find the declination of the Sun, or of any point or degree of the ecliptic, given the obliquity and any degree of the ecliptic; and to construct a table of these declinations.*

[Margin: Problem 15.]

Let the figure of problem 5 be repeated here, in which the spherical triangle ADG is right-angled at D; and in it let the base AG be given, from the given degree of the ecliptic in the first quadrant, and also the angle of the obliquity GAD. Then by the first rule of spherical right-angled triangles you will find the side GD, that is, the declination belonging to the degree G; and so for the other degrees of the first quadrant A♋. For this it will be enough to construct a table, since it will serve the remaining quadrants: the declination of any four points of the ecliptic equally distant from the nearer equinoctial or solstitial point is equal.

[Margin: The table's construction, and its authors.]

Moreover, a table of the declination of the Sun, and so of the points of the ecliptic, has already been constructed and handed down to us by Ptolemy, book 1 of the *Almagest*, chapter 13; Orontius [Oronce Finé], book 2 of the *Cosmographia*, chapter 4; Copernicus, book 2, chapter 2; Reinhold and Regiomontanus, in the *Tables of Directions*, page 1 or 2 of the tables; Clavius, in the *Sphere*, page 264; Maginus, in the *Tables of Directions*, page 34; Tycho, volume 1 of the *Progymnasmata*, page 80; Longomontanus, book 1 of the *Spherics*, folio 55; Boulliau, in the *Philolaic Tables*, page 140; the *Rudolphine Tables*, folio 24; Lansbergen, page 94; and Griembergerus [Christoph Grienberger], in Scheiner's *Rosa Ursina*, page 391. This last table is worked out to every 5′ of the degrees, whereas those of Reinhold, Clavius and Tycho go to every 10′, and the rest to single degrees — each of them, however, according to the obliquity of the zodiac that its author thought had held, or held, in his own time.

16. Probl. Aſcenſionem Rectam cuiuſuis Puncti Eclipticæ Inueſtigare, Datis Eclipticæ Obliquitate, ac puncto, Eiuſque Tabulam componere. *Problem 16. To find the right ascension of any point of the ecliptic, given the obliquity of the ecliptic and the point; and to compose its table.*

[Margin: Problem 16.]

Above, in problem 8, we taught how to derive the Sun's right ascension from the Sun's longitude, that is, from the given point of the ecliptic, and from

the obliquity of the ecliptic. In exactly the same way the right ascension of any degree of the first quadrant of the ecliptic, AG♋, is gathered, and so a table is constructed which serves for the whole ecliptic. For, given a point of the ecliptic in the 2nd quadrant, ♋L — say V — and hence its distance from the solstitial point ♋, the right ascension AD of the point G, equally distant from the same point ♋, is sought; and this (that is, HL, which is equal to it), subtracted from 180°, the degrees of the whole semicircle AIL, leaves AH, namely the right ascension of the point V; and so for the rest, as was said in problem 8.

[Margin: The table's construction.]

Tables of this kind have been supplied to us by Ptolemy, book 2 of the *Almagest*, chapter 8; Orontius, book 2 of the *Cosmographia*, chapter 3; Regiomontanus, in the *Directions*, page 52; Copernicus, book 2, chapter 3; Reinhold, in the *Tables of Directions*, from page 86, and in the *Prutenic Tables*, page 1; Clavius, in the *Sphere*, from page 330; Maginus, in the *Tables of Directions*, page 54; Boulliau, in the *Philolaic Tables*, page 141; Tycho, volume 1 of the *Progymnasmata*, page 86; Lansbergen, page 97 of the *Tables*; Longomontanus, book 2 of the *Spherics*, folio 57; Santbech, page 103; the *Rudolphine Tables*, folio 24; and Grienberger, in Scheiner's *Rosa Ursina*, page 391, a different table for each different obliquity of the ecliptic. Grienberger's goes to every 5′ of the degrees; Reinhold's and Tycho's to every 10′; the others', except Ptolemy's, to single degrees.

Probl. Aſcenſionem Rectam Sideris Obſeruare 17. More antiquo per Clepſydras 18. Per diſtantiam Lunæ à Sole, & Sideris à Luna 19. Per diſtantiam Veneris à Sole, & Sideris à Venere 20. Per Diſtãtiam Sideris à Saturno, aut Ioue 21. Per diſtantiam ipſius Sideris à Sole 22. Per Aſc. Rectam Solis, & tempus inter eam ac tranſitum Sideris per medium cæli 23. Per Aſc. Rectam vicinæ ſtellæ, & tranſitum Sideris per M. C. *Problem. To observe the right ascension of a star: 17. in the ancient manner, by water clocks; 18. by the distance of the Moon from the Sun, and of the star from the Moon; 19. by the distance of Venus from the Sun, and of the star from Venus; 20. by the distance of the star from Saturn or Jupiter; 21. by the distance of the star itself from the Sun; 22. by the right ascension of the Sun, and the time between it and the star's transit through mid-heaven; 23. by the right ascension of a neighbouring star, and the star's transit through the M. C. (mid-heaven).*

[Margin: Problems 17, 18, 19, 20, 21, 22, 23.]

I have already given all these problems, in the same order, in Book 6, chapter 11, from number 4 to 11, with examples added on fixed stars. They can also be applied to the planets, provided that their observed and apparent distances are converted into true ones by applying parallax and refraction, according to what is to be said in the Section on parallaxes and refractions. There is therefore no need to repeat them here.

24. Probl. Aſcenſionis Rectæ, ac Declinationis Siderum præſertim Fixorum Incrementa ac Decrementa, creſcente Longitudine eorum, diſcernere ac Determinare. *Problem 24. To distinguish and determine the increments and decrements of the right ascension and declination of the stars, especially the fixed stars, as their longitude increases.*

[Margin: Problem 24.]

This whole business, likewise, I dealt with in Book 6, chapters 13 and 19, where I showed the new finding we had detected: namely, that there are some fixed stars whose right ascension decreases continuously for many years, although their longitude increases; and which stars of this kind there are, and how long the time of this decrease lasts, etc.

Probl. Declinationem Sideris extra Meridianum poſiti Obſeruare 25. Per Altitudinem, Azimuthumq. Sideris, cum Altitud. Poli 26. Per Altitudinem Azimuthumq. Sider. & Tempus 27. Per Altitudinem Sider. Tempus & Altitud Poli 28. Per Azimuthum Sideris, Tempus, & Altitud. Poli *Problem. To observe the declination of a star placed outside the meridian: 25. by the altitude and azimuth of the star, with the altitude of the pole; 26. by the altitude and azimuth of the star, and the time; 27. by the altitude of the star, the time, and the altitude of the pole; 28. by the azimuth of the star, the time, and the altitude of the pole.*

[Margin: Problem 25.]

We have indeed given these very problems in Book 6, chapter 11, numbers 3 and 4. But because of other, related problems to be drawn shortly from the same diagram, it seemed good to repeat them here somewhat more distinctly. Here, however, let us presuppose the method of finding or observing the azimuth of a star, which is to be set out a little below, that is, from problem 34 on. For these problems, then, in the following figure, let the horizon be HR, and the meridian HZRQ, in which the vertex, or zenith, is Z, and the pole of the equator EOQ is P; and let ZA be the quadrant of a vertical circle, or circle of altitude, on which the star is either at B, on this side of the equator, or at G, a point of the equator, or at I, beyond the equator (which you will soon tell from the size of the declination). And from the pole of the world let arcs of circles of declination be drawn through the star as far as the equator or beyond, namely PBN, PG and PCI. The azimuth of the star will then be the arc HA, which the angle AZH measures; and the altitude of the pole will be PR, whose complement to 90° will be the distance of the pole from the vertex, PZ.

[Margin: In this figure the point G ought to be on the vertical ZA.]

Diagram. A woodcut in the right column beside the setting-out of problems 25–28: a circle (the meridian HZRQ) with the horizontal diameter HR (the horizon); the equator EOQ drawn as an arc from E at the upper left through O below the centre to Q at the lower right; the pole P at the upper right; arcs of circles of declination drawn from P through B, G and C; and the vertical quadrant from Z towards A. Labels:

- Z (top): zenith

- E (upper left): the equator's end on the meridian
- B (below the top): the star on this side of the equator
- P (upper right): pole of the equator
- N (left, below E): where the arc PBN meets the equator
- G (centre left): the star at a point of the equator
- C (centre left, beside G): on the arc PCI
- I (lower left): the star beyond the equator
- H (left): horizon
- A (inside, near H): foot of the vertical quadrant ZA on the horizon
- O (below the centre): on the equator
- R (right): horizon
- Q (lower right): the equator's end on the meridian

First, then, let the star be at B. In the triangle BZP let the distance of the pole from the vertex, PZ, be given from the altitude of the pole; and from the true altitude of the star, AB (the observed altitude, that is, corrected by adding the parallax and subtracting the refraction), let its complement to 90°, BZ, be given; and the angle BZP, comprehended by these sides, which is the supplement to 180° of the azimuthal angle

[Margin: Order of the problems.]

[Margin: Order of the problems.]

that was observed, AZH. Then by Rule 4 of spherical oblique-angled triangles you will find the base BP, which, subtracted from 90°, will leave the true declination of the star, BN — northern if P is the north pole, southern if it is the south. But if the star is at G, the complement of the true altitude will be GZ, and the rest as above; and the base PG will be found to be of 90°, which will be a sign that the star has no declination but lies on the equator itself. If, however, the star is at I, the complement of the true altitude will be IZ, and the rest as above; but the base PI will come out greater than a quadrant, and you must then take 90° from it, so that what remains is the star's declination towards the other pole, IC. For the rest, you will solve the triangles ZGP or ZIP by the same Rule 4.

[Margin: Problem 26.]

Second, let the star be at B, and let its true altitude AB be given, and its complement to 90°, BZ; and also the azimuth AZH, and its supplement to 180°, BZP; and, from the time before or after noon converted into parts of the equator, the angle ZPB. Then by Rule 7 of spherical oblique-angled triangles you will find the side BP, the complement to 90° of the declination BN. But if the star is at G, the complement of the altitude will be GZ, and the rest given as above; but by the same Rule 4 you will find the side GP to be a quadrant, and therefore there will be no declination. If the star is at I, and the complement of the altitude is IZ, the rest being given as above in the triangle ZIP — that is, the azimuthal angle at Z and the angle of the time IPZ — you will find the side PI greater than a quadrant; and when 90° are subtracted from it, the star's declination towards the other pole, IC, will be left.

[Margin: Problem 27.]

Third, let the star be at B; and let its true altitude AB be given, and its complement to 90°, BZ, and PZ, the complement of the altitude of the pole; and the angle BPZ, from the time before or after noon converted into parts of the equator. Then by Rule 2 of spherical oblique-angled triangles you will find the base BP; when this is subtracted from 90°, the declination BN remains. But if the base PG is found to be a quadrant — namely from the angle GPZ, the complement of the altitude GZ and the side ZP — there will be no declination. If, however, the base is found to be greater than a quadrant, as PI — namely in triangle ZIP, from the angle IPZ, the complement of the altitude IZ and the side ZP — its excess over 90° will be the star's declination IC, but towards the other pole.

[Margin: Problem 28.]

Fourth, let the star be at B; and let there be given, as above, the arc ZP, as a base known from the altitude of the pole, and the angles adjacent to it: BZP, known from the azimuth, and BPZ, from the time. Then by Rule 11 or 12 of spherical oblique-angled triangles you will find the side BP, the complement of the declination NB; or by the same rule you will find, from the angle GPZ or IPZ and the rest given as above, the quadrantal arc PG, the sign of no declination, or PI, greater than a quadrant, from which, when 90° are taken away, CI will be known, the declination towards the other pole.

[Margin: Other methods indicated.]

Other problems could indeed arise if the angle B, or G, or I were given; but that angle is not usually known beforehand here — rather, it is derived from the data already mentioned, as I shall teach shortly.

Probl. Angulum in centro Sideris factum à Circulo Verticali & Declinationis Inquirere, Datis 29. Declinatione & Altitudine Sideris ac Poli 30. Declinatione & Altitudine Sideris atque Azimutho 31. Declinatione, & Altitudine Sideris, ac Tempore 32. Altitudine Sideris, ac Poli, & Azimutho 33. Altitudine Sideris, Azimutho, ac Tempore *Problem. To find the angle made at the centre of a star by the vertical circle and the circle of declination, given: 29. the declination and the altitude of the star and of the pole; 30. the declination and the altitude of the star, and the azimuth; 31. the declination and the altitude of the star, and the time; 32. the altitude of the star and of the pole, and the azimuth; 33. the altitude of the star, the azimuth and the time.*

In the preceding figure ZP is the complement of the altitude of the pole, and the angle at Z is known, since it is the supplement to 180° of the azimuth AZH. Now if the star is at B, with the declination BN towards your pole, the complement of the declination is BP, and that of the altitude BZ. But if it is at G, the declination is nil, and its complement is GP, of 90°, while the complement of the altitude is GZ; if, however, it is at I, the complement of the altitude is IZ, and IP is made up of the declination IC and the quadrant CP. So the triangle to be solved will be either BZP, or GZP, or IZP; and the angle at the pole P is

to be known from the time before or after noon, converted into parts of the equator. Therefore, from the solution of one triangle, BZP, you will learn how the other two are to be solved, so that we are not too long.

[Margin: Problem 29.]

First, then, let the complement of the declination, BP, be given, and that of the altitude, BZ, and the base ZP. Then by Rule 14 of spherical oblique-angled triangles you will find the angle ZBP that the vertical ZA makes at the centre of the star B with the circle of declination PN.

[Margin: Problem 30.]

Second, let the complement of the declination, BP, be given, and that of the altitude, BZ, and from the azimuth the angle at Z. Then by Rule 3 of spherical oblique-angled triangles you will learn the angle ZBP.

[Margin: Problem 31.]

Third, let the complement of the declination, BP, be given, and that of the altitude, BZ, and from the time the angle BPZ; for by the same Rule 3 of spherical oblique-angled triangles you find the angle ZBP.

[Margin: Problem 32.]

Fourth, let the complement of the altitude, BZ, be given, and that of the pole, ZP, and from the azimuth the angle BZP; for by Rule 5 or 6 of spherical oblique-angled triangles you will find the angle ZBP.

[Margin: Problem 33.]

Fifth, let the complement of the altitude, BZ, be given, and from the azimuth the angle BZP, and from the time the angle BPZ. Then by Rule 9 of spherical oblique-angled triangles you will learn the angle ZBP. And the same rules will serve you in the other triangles, GZP or IZP, if you use data of the same kind. Five other problems could have been added, from five other combinations of the data already mentioned; but it is enough to have indicated these, for I shall explain the rest from problem 89 on.

Probl. Azimuthum ſideris Inueſtigare, Datis 34. Declinatione, & Altitudine Sideris ac Poli 35. Declinatione, Altitudine Sideris, ac Tẽpore 36. Declinatione Sid. Altitud. Poli, ac Tẽpore 37. Altitud. Poli, & Sideris, ac Tempore *Problem. To find the azimuth of a star, given: 34. the declination, and the altitude of the star and of the pole; 35. the declination, the altitude of the star and the time; 36. the declination of the star, the altitude of the pole and the time; 37. the altitude of the pole and of the star, and the time.*

Let the figure set out at problem 25 be repeated here, in which the azimuth, that is, the angle AZH, is sought. This becomes known if the angle AZP is known, since that is its supplement to 180°. Further, if the declination is less than a quadrant, as BN, its complement will be BP, and that of the altitude BZ; and the angle BPZ will be known from the time after or before noon, converted into parts of the equator; and so the triangle BZP will have to be solved. But if there is no declination, its complement GP will be of 90°, and that of the altitude GZ, and the angle GPZ known from the time; and the

triangle GZP is to be solved. If, however, the declination is towards the other pole, as CI, the side IP will have to be compounded from the declination IC and the quadrant CP, and the complement of the altitude will be IZ, and the angle IPZ known from the time; and the triangle IPZ is to be solved. It is therefore enough to indicate how, by solving the triangle BZP, the angle BZP, the complement of the azimuth AZH, can be found.

[Margin: Problem 34.]

First, then, let the complement of the declination, BP, be given, as the base, and that of the altitude, BZ; and from the altitude of the pole the side ZP. Then by Rule 14 of spherical oblique-angled triangles you will find the angle BZP.

[Margin: Problem 35.]

Second, let the complement of the declination, BP, be given, and that of the altitude, BZ; and from the time the angle BPZ. Then by Rule 1 of spherical oblique-angled triangles you will learn the angle BZP.

[Margin: Problem 36.]

Third, let the complement of the declination, BP, be given, and the complement of the altitude of the pole, ZP; and from the time the angle BPZ. Then by Rule 5 or 6 of spherical oblique-angled triangles you will learn the angle BZP.

[Margin: Problem 37.]

Fourth, let ZP be given from the altitude of the pole; and from the altitude of the star its complement, BZ; and from the time the angle BPZ. Then by Rule 3 of spherical oblique-angled triangles you will obtain the angle BZP, which is to be subtracted from 180° so that the azimuth AZH becomes known.

Probl. Azimuthum Sideris Obſeruatione colligere 38. Immediatè per inſtrumentum 39. Mediante Altitudine, & Declinatione Solis aut Fixi Sideris tranſeuntis per eumdem Verticalem: Eaq. occaſione Declinationem & Aſc. Rectam ſideris Inquirere. *Problem. To gather the azimuth of a star by observation: 38. directly, by an instrument; 39. by means of the altitude and declination of the Sun, or of a fixed star passing through the same vertical; and on that occasion to find the declination and right ascension of the star.*

[Margin: Problem 38.]

The first method of observing the azimuth is by the azimuthal quadrant, above a horizontal plane

[Margin: Order of the problems.]

[Margin: Order of the problems.]

set up perpendicularly and turning about a centre, from which a horizon has been described in the same plane, with the degrees marked out on its circumference. It is better to wait at a predetermined degree for the arrival of the star than to take the azimuth and the altitude of the star together by moving the quadrant. But a still more certain method, surely, is by our thread triangle, already described in Book 5, chapter 15, number 16: placing it at the boundary of the predetermined degree which the star is next going to reach, and, as soon as the star has arrived there, obtaining the star's altitude through

some companion with a separate instrument. But since you may happen to be in some place where no plane marked in degrees together with a horizon is at hand, and yet you need to observe the azimuth of some planet or fixed star, so that its declination and right ascension may be derived from it and its place in the heavens known, take the method used by us and by Father Francesco Maria Grimaldi.

[Margin: Problem 39.]

[Margin: The method of observation.]

The second method, then, is by a thread hung perpendicularly from above and fixed below to the horizontal plane, together with a second thread hung from the same place and stretched downward, not perpendicularly, but so that it makes a triangle with the plane of the floor, and the two threads present two sides of the thread triangle. This second thread must be tied to some heavy body in such a way that it can be moved to the right or to the left and afterwards fixed firmly in place — of which shortly. And the position must be chosen such that, at the hour of the planet's or star's transit suitable for the observation, the two threads lie in the plane of the vertical circle through which the planet, etc., is to pass; or else, by moving the thread stretched obliquely above the floor, you must at once wait for the planet to pass through the plane enclosed between the two threads, the line of sight being directed through both threads together onto the centre of the star. At the same moment the altitude of the planet must be taken by someone else, and by a third companion the altitude of some known fixed star, so that the moment of time can be known. Afterwards, with nothing in the threads changed, one must wait until another fixed star of known declination reaches the same plane enclosed by the two threads already mentioned, and at that moment its altitude must be taken. And so the observation will have been completed, fit for determining the azimuth of the planet, or of the former star, and indeed also its right ascension and declination.

[Margin: Step 1.]

For in the figure just preceding, let the planet have been observed at I, a point of the vertical plane AZ; and from the altitude of the fixed star observed at that time let the time before or after noon have been gathered, by a problem to be given in Section 3; converted into parts of the equator, this will show the angle IPZ. And let the apparent altitude of the planet, AI, be converted into the true one, by adding the parallax to it and subtracting the refraction, if it has any. Afterwards let the fixed star B, whose declination BN is known from the astronomical tables, have reached the plane AZ of the same vertical, and let its altitude AB have been observed at that time. Then in triangle BZP, from the complement of the altitude BZ, the complement of the declination BP, as base, and the complement of the altitude of the pole PZ, you will find by Rule 14 of spherical oblique-angled triangles the angle BZP, the complement of the azimuth AZH.

[Margin: Step 2.]

Next, in triangle IZP, with the vertical angle BZP just found, that is IZP, with the complement of the altitude of the pole ZP, and with the complement of the planet's true altitude IZ, you will find by Rule 4 of spherical oblique-angled triangles the base IP. This will be either a quadrant, and a sign of no declination; or greater than a quadrant, and then its excess over 90° will give the declination CI, towards the other pole; or less than a quadrant, and then its complement to 90° will give the declination towards your own pole.

[Margin: Step 3.]

Third, from the right ascension of mid-heaven, of which we shall speak from problem 108 on, and from the angle at P, taken as above from the observed time — added to the right ascension of mid-heaven if the time was before noon, or subtracted if it was after noon — you will obtain the right ascension of the planet.

Probl. Altitudinem Sideris cuiuſuis Inquirere, Datis 40. Azimutho, & Declinatione ipſius, ac Poli Altitudine 41. Azimutho, Declinatione, & Tempore 42. Azimutho, Altitud. Poli, & Tempore 43. Altitud. Poli, Declinatione, & Tempore. *Problem. To find the altitude of any star, given: 40. its azimuth and declination, and the altitude of the pole; 41. the azimuth, the declination and the time; 42. the azimuth, the altitude of the pole and the time; 43. the altitude of the pole, the declination and the time.*

These problems too are served by the figure explained at problem 25, in which the altitude of the pole RP, subtracted from 90°, gives the arc ZP; the azimuth AZH, subtracted from 180°, makes the angle AZP known; and from the time before or after noon, converted into parts of the equator, the angle at P becomes known — for instance BPZ, if the star is at B; and then BP, the complement of the declination BN, is useful for solving the triangle BZP. But if the star is at G, the angle known from the time is GPZ, and the complement of the nil declination, for solving the triangle GZP, is a quadrant. If, however, the star is at I, the angle known from the time is IPZ; and the side PI, made up of the quadrant PC and the declination CI, is for the solution of the triangle IPZ. But it will be enough to indicate the solution of the triangle BPZ, for finding BZ, the complement of the altitude; for from data of the same kind, by the same rules, the other two can be solved, and either GZ, the complement of the altitude AG, or IZ, etc., can be found.

[Margin: Problem 40.]

First, then, let the angle Z be given from the azimuth, and the side ZP from the altitude of the pole, and the complement of the declination, BP: for by Rule 2 of spherical oblique-angled triangles you will find the base BZ, the complement of the true altitude AB.

[Margin: Problem 41.]

Second, let the angle Z be given from the azimuth, and the angle BPZ from the time, and the complement of the declination, BP: for by Rule 7 of spherical

oblique-angled triangles the side BZ, the complement of the altitude AB, will become known.

[Margin: Problem 42.]

Third, let the angle Z be given from the azimuth, and the angle BPZ from the time, and from the altitude of the pole the base ZP adjacent to them: for by Rule 11 or 12 of spherical oblique-angled triangles you will learn the side BZ, the complement of the altitude AB.

[Margin: Problem 43.]

Fourth, let the side ZP be given from the altitude of the pole, and the complement of the declination, BP, and from the time the included angle BPZ: for by Rule 4 of spherical oblique-angled triangles you obtain the base BZ, which is the complement of the true altitude AB.

[Margin: A note on the apparent altitude.]

And if you wish to convert the true altitude into the apparent one, take the parallax away from it and add the appropriate refraction.

Probl. Altitudinem Solis, vel cuiuſuis Sideris in Verticali Primario Inquirere, Datis 44. Altitudine Poli, & Declinatione Sideris 45. Altitudine Poli, & Tempore 46. Declinatione Sideris, ac Tempore *Problem. To find the altitude of the Sun, or of any star, on the prime vertical, given: 44. the altitude of the pole and the declination of the star; 45. the altitude of the pole and the time; 46. the declination of the star and the time.*

In the figure added here (though it was devised for other uses as well), let the horizon be HOR and the meridian HVRN, in which the zenith is V and the pole P, from which the equator AOQ has been described, with the parallels CD and KN. And let VM be the quadrant of a vertical that is not the prime vertical, but VTO that of the prime vertical — namely of the one that passes through the common section of the equator and the horizon, that is, through the points of equinoctial rising or setting. For a star cannot be on the prime vertical unless it is on some parallel on this side of the equator — in an oblique sphere, that is; for in a right sphere the prime vertical is the equator itself. Let the star, then, be at T, and consider the triangle TVP, right-angled at V, in which TV, the complement of the altitude OT, is sought.

Diagram. A circle representing the meridian HVRN, set in the right column beside the opening of problems 44–46. The horizontal diameter is the horizon, H at its left end and R at its right, with O on it; V, the zenith, stands at the top and N at the bottom. The equator AOQ runs from A at the upper left down to Q at the lower right; parallels to it run from C (top, left of V) and from K (left) down towards D and N on the lower right. Arcs curve down from V to the left (the verticals VM and VTO); two dotted lines descend across the circle. The pole P is on the rim at the upper right.

- C (rim, just left of V): end of the parallel CD
- V (top): the zenith
- A (rim, upper left): end of the equator AOQ

- B (inside, below C): point, not named on this page
- P (rim, upper right): the pole
- K (rim, left): end of the parallel KN
- S (inside, right of K): point, not named on this page
- I (inside, below S): point, not named on this page
- T (near centre): the star on the prime vertical
- H (left end of the horizon)
- M (inside, just below H): end of the vertical VM
- O (on the horizon, right of centre): common section of equator and horizon
- R (right end of the horizon)
- D (rim, lower right): end of the parallel CD
- Q (rim, below D): end of the equator AOQ
- N (bottom): foot of the meridian, end of the parallel KN

[Margin: Problem 44.]

First, if the complement PV is given from the altitude of the pole, and from the star's declination the complement of the declination, or base, TP, you can find by Rule 6 of spherical right-angled triangles the side TV, that is, the complement of the altitude OT.

[Margin: Problem 45.]

Second, if the side PV is given from the altitude of the pole, and from the time before or after noon, converted into parts of the equa-

[Margin: Order of the problems.]

[Margin: Order of the problems.]

tor, the angle TPV, then by Rule 7 of spherical right-angled triangles you will be able to obtain the side TV, the complement of the altitude OT.

[Margin: Problem 46.]

Third, if the complement of the declination is given, that is, the base TP, and from the time the angle TPV, then by Rule 1 of spherical right-angled triangles you will learn the side TP [?], which is the complement of the altitude OT — the true altitude, that is; and if you add the refraction to it and take away the parallax, you will have the visible, or apparent, altitude of the star on the prime vertical.

47. Probl. Diſtantiam Solis, vel Sideris cuiuſuis à Verticali Primario Inuenire. *47. Problem. To find the distance of the Sun, or of any star, from the prime vertical.*

[Margin: Problem 47.]

Find the azimuth of the Sun or of any star by problems 34 to 39, and subtract it from 90°: the distance of the star from the prime vertical will remain. As in the figure just preceding: if the star was on the vertical VM, say at B, or S, or I, and the azimuthal angle MVH has been found, this angle, subtracted from 90°, will leave the angle MVO, which measures the arc of the horizon MO, that is, the distance of the star from the prime vertical VTO.

Probl. Longitudinem Sideris Inuenire, Datis 48. Diſtantia Polorum, Declinatione, & Aſcenſione Recta Sideris 49. Diſtantia Polorum, Declinatione, & Latitudine Sideris 50. Diſtantia Polorum, Latitudine, & Aſcenſione Recta Sideris 51. Declinatione, Latitudine, & Aſcenſione Recta Sideris. *Problem. To find the longitude of a star, given: 48. the distance of the poles, and the declination and right ascension of the star; 49. the distance of the poles, and the declination and latitude of the star; 50. the distance of the poles, and the latitude and right ascension of the star; 51. the declination, latitude and right ascension of the star.*

In the following diagram let ABCD be the solstitial colure, drawn through the beginning of Cancer, E, and of Capricorn, F. In it the north pole of the equator AVC is B, but that of the ecliptic ETF is G; and the south pole of the former is D, of the latter H. Through the poles of the equator let the circle of declination BλDθ be drawn. Now a star can have a northern declination as well as a northern latitude, as when it is at P or at Z: for when the quadrant of latitude GPQ or GZβ is drawn through it, the latitude of the star P will be PQ and its declination Pλ, while the latitude of the star Z will be Zβ and its declination Zθ, both northern. Conversely, it can have both southern, and then the circles or quadrants of latitude must be drawn through the star from the southern pole of the ecliptic, H: as, if the star is at Y, when the quadrant HYX is drawn, its latitude will be YX and its declination Yλ, both southern. Likewise the declination can be something and the latitude nil, as when the star is at R, to which the quadrant of latitude GR belongs, and its declination is Rλ. Conversely, the latitude can be something and the declination nil, as when the star is at λ and its latitude is λT. Finally, the latitude can be of one kind and the declination of the other: as when the star is at S, for its declination Sλ is northern but its latitude ST southern; and vice versa if the star is at ε, its declination εθ will be southern and

Diagram. A circle, the solstitial colure ABCD, filling the lower half of the left column. The equator runs from A on the left to C on the right; the ecliptic runs from E, beside the sign of Cancer, on the upper left, down through the centre, where the sign of Aries stands, to F, beside the sign of Capricorn, on the lower right. B and G stand at the top, H and D at the bottom. Stars, each marked with a small asterisk, are set at K, P, M, Z, I, ε, N, L, Y and O. R, S, T and X are clustered left of centre, with λ below them and V on the equator below T; θ, ε and β stand right of centre. A dotted line runs from G down towards R and T. Which drawn line carries which letter is not certain from the woodcut as seen.

- B (top): north pole of the equator
- G (top, right of B): north pole of the ecliptic
- K (rim, upper left, star)
- P (inside, below K, star)
- E (rim, left): beginning of Cancer, with the sign ♋ beside it
- M (rim, right, star)

- Z (inside, right of centre, star)
- I (rim, left, below E, star), with a small sign beside it [?]
- R, S, T, X (clustered left of centre)
- A (left end of the equator)
- λ (below S)
- V (on the equator, below T)
- ♈ (centre, on the equator): Aries
- ♎ (below ♈): Libra
- a sign right of centre [?], with θ beside it
- C (right end of the equator)
- N (rim, right, below C, star)
- ε (below θ, star)
- β (below ε, to the left), with a further letter beside it [?]
- L (rim, lower left, star)
- Y (inside, lower centre, star)
- F (rim, lower right): beginning of Capricorn, with the sign ♑ beside it
- O (rim, below F, star)
- H (bottom): south pole of the ecliptic
- D (bottom): south pole of the equator

its latitude εμ northern. We have thought these things worth pointing out so that beginners may know how they ought to draw, through a star placed in various positions on the sphere, the arcs of declination and of latitude from the poles already mentioned, and how to tell them apart, and how to apply to other cases what we shall teach in one case or another. Now when the right ascension of a star is nil, or 360°, it will be at the beginning of Aries; when 180°, at the beginning of Libra; when 90°, at the beginning of Cancer; and when 270°, at the beginning of Capricorn.

[Margin: Problem 48.]

[Margin: Case 1.]

First, let the star be at P; and let there be given the distance of the poles, BG (which is always as great as the obliquity of the ecliptic), and PB, the complement of the declination Pλ, and the right ascension, not greater than 180°. If it is less than 90°, add it to 90°; but if greater, subtract the excess from 180°; and either way you will have the angle PBG, enclosed by the given sides BG and BP. Therefore by Rule 5 or 6 of spherical oblique-angled triangles you will find the angle PGB, namely the argument of the longitude of the star, which always lies in the quadrant of the ecliptic of the same kind as the one to which its right ascension belongs on the equator. So if the right ascension was less than 90°, the angle PGB itself will be the longitude of the star, counted from the beginning of Aries in the order of the signs; but if the right ascension was greater than 90°, the angle PGB, added to 90°, will make up the longitude of the star that is sought.

[Margin: Case 2.]

But if a northern star is at Z — that is, when the right ascension is greater than 180° — then, if it is less than 270°, its complement to 270°, but if greater, its excess over 270°, will be the angle ZBG in the triangle BZG, in which there are given BG, the distance of the poles, and BZ, the complement of the declination Zθ. Therefore by the same Rule 5 or 6 of spherical oblique-angled triangles you will find the angle ZGB, which is to be added to 90°, if the right ascension is less than 270°, to give the longitude of the star; but if the right ascension was greater than 270°, the supplement of the angle ZGB to 180°, added to 270°, will produce the longitude of the star that is sought. And one must operate in the same way in the other cases, if the data are the same, whether the star is northern or southern.

[Margin: Problem 49.]

Second, let the star be at P, and let there be given the distance of the poles, BG, and PB, the complement of the declination Pλ, and PG, the complement of the latitude PQ. For with the three sides of the triangle BPG given, the angle PGB will become known by Rule 14 of spherical oblique-angled triangles. It is to be subtracted from 90°, so that the longitude sought remains, if it is known from elsewhere that the star belongs to the first quadrant of the ecliptic; or added to 90°, to give the longitude of a star belonging to the second quadrant. By the same Rule 14 you will solve the triangle BZG if the star is at Z, since BG is given, as above, together with the complements of the declination, BZ, and of the latitude, GZ: for the angle BGZ, once found and added to 90°, will make up the longitude of a star belonging to the third quadrant of the ecliptic; but if the star belongs to the fourth quadrant, the supplement of the angle BGZ to 180°, added to 270°, will produce its longitude.

[Margin: Problem 50.]

Third, let the star be at P, and let there be given the distance of the poles, BG, and the complement of the latitude, PG, and, from the right ascension, the angle PBG, as I said in problem 48. Then by Rule 3 of spherical oblique-angled triangles you will find the angle PGB, which, subtracted from or added to 90°, makes the longitude of the star, according as the right ascension was either less or greater than 90°, but less than 180°. But if the right ascension is greater than 180° and the star is at Z, you will solve by the same Rule 3 the triangle BGZ, in which there are given BG, as above, and the complement of the latitude, GZ, and, from the right ascension, the angle ZBG. Therefore the angle BGZ, once found and added to 90° if the right ascension is less than 270° — or, if it is greater, the supplement of the angle found to 180°, added to 270° — will produce the longitude of the star.

[Margin: Problem 51.]

Fourth, let the star be at P, but let there be given, from the right ascension, the angle PBG, as above, and the complement of the declination, BP, and the complement of the latitude, GP; for then by the first rule of spherical oblique-angled triangles you obtain the angle PGB, which is the argument of the longitude, as above. In the same way, if the star is at Z, and from the right

ascension the angle ZBG is given, with the complement of the declination, BZ, and the complement of the latitude, GZ, you will find by the same first rule of spherical oblique-angled triangles the angle BGZ, the argument of the longitude, according to the condition of the right ascension, as above.

[Margin: Order of the problems.]

[Margin: Order of the problems.]

Probl. Latitudinem Sideris inquirere, Datis 52. Diſtantia Polorum, Declinatione & Aſc. Recta ſideris 53. Diſtantia Polorum, Declinatione, & Longitudine ſideris 54. Diſtantia Polorum, Aſc. Recta, & Longitudine Sideris 55. Declinatione, Aſc. Recta, & Longitud. Sid. *Problem. To find the latitude of a star, given: 52. the distance of the poles, and the declination and right ascension of the star; 53. the distance of the poles, and the declination and longitude of the star; 54. the distance of the poles, and the right ascension and longitude of the star; 55. the declination, right ascension and longitude of the star.*

[Margin: Problem 52.]

Look at the figure set out at problem 48. First, let the star be at P, and let there be given the distance of the poles, BG, and the complement of the declination, BP, and, from the right ascension, the angle PBG, according to what was said at problem 48. Then in triangle PBG, by Rule 4 of spherical oblique-angled triangles, you will find the base PG, namely the complement of the northern latitude PQ. If this base were a quadrant, like GR, there would be no latitude; but if it were greater than a quadrant, like GS, the excess over 90° would be the southern latitude ST. So in triangle BZG, if the star is at Z, from BG, and the complement of the declination, BZ, and the angle ZBG, known from the right ascension, the base GZ — namely the complement of the northern latitude Zβ — can be known by Rule 4 of the same triangles.

[Margin: Problem 53.]

Second, in triangle PBG, let there be given PB, the complement of the declination of the star P, and BG, the distance of the poles, and the angle PGB, known from the longitude: for if the star belongs to the first quadrant of the ecliptic, that angle is the complement of the longitude to 90°; if to the second quadrant, it is the excess of the longitude over 90°. Therefore by Rule 2 of spherical oblique-angled triangles you will find the base PG, which is the complement of the latitude PQ. Likewise, if the star is at Z, and BG is given, as above, and BZ, the complement of the declination, and, from the longitude, the angle ZGB — which becomes known by taking 90° from a longitude belonging to the third quadrant, or, if it belongs to the fourth quadrant, by adding to 90° the complement of the longitude to 360° — then by the same Rule 2 you will learn the base GZ, which, subtracted from 90°, will give the northern latitude Zβ.

[Margin: Problem 54.]

Third, let the star be at P, and let there be given the distance of the poles, BG, and the adjacent angles, namely PBG, from the right ascension, in the way

stated at problem 48, and PGB, from the longitude, according to what was said at problem 53: for by Rule 11 or 12 of spherical oblique-angled triangles the side PG, the complement of the latitude PQ, will become known, etc.

[Margin: Problem 55.]

Fourth, let the star be at P, but let there be given the angles PBG, from the right ascension, and PGB, from the longitude, and the complement of the declination, BP: for by Rule 7 of spherical oblique-angled triangles the side PG can be found, which is the complement of the latitude PQ. And so for the rest.

Probl. Aſcenſ. Rectam Sideris Inquirere, Datis 56. Diſtantia Polorum, Declinatione, & Longitudine Sideris 57. Diſtantia Polorum, Declinatione, & Latitudine Sideris 58. Diſtantia Polorum, Longitudine ac Latitudine Sideris 59. Declinatione, Longitud. & Latitud. Sideris *Problem. To find the right ascension of a star, given: 56. the distance of the poles, and the declination and longitude of the star; 57. the distance of the poles, and the declination and latitude of the star; 58. the distance of the poles, and the longitude and latitude of the star; 59. the declination, longitude and latitude of the star.*

[Margin: Problem 56.]

Here too use the figure already set out at problem 48, in which let the star be imagined at P; and let there be given the distance of the poles, BG, and the complement of the declination, BP, and, from the longitude, the angle PGB, according to what was said at problem 53. Then by Rule 3 of spherical oblique-angled triangles you will learn the angle PBG. If you take 90° from it (when the longitude belongs to the first quadrant of the ecliptic), you will have the right ascension of the star; but if the longitude belongs to the second quadrant, add to 90° the supplement of that angle to 180°, and the right ascension will result. Now if the star is at Z, and the distance BG is given, and the complement of the declination, BZ, and, from the longitude, the angle ZGB, as above, find by Rule 3 of spherical oblique-angled triangles the angle ZBG; add to 90° its supplement to 180°, if that longitude belongs to the third quadrant of the ecliptic; or, if to the fourth, add the angle ZBG to 270°; and the right ascension of the star will result.

[Margin: Problem 57.]

Second, let the star be at P; and let there be given the distance of the poles, BG, the complement of the declination, BP, and the complement of the latitude, PG: for by Rule 14 of spherical oblique-angled triangles the angle PBG will become known, which is the argument of the right ascension; but the quadrant of the equator to which it belongs must be known beforehand, etc.

[Margin: Problem 58.]

Third, let the star be at P; and let there be given, as above, BG, and the complement of the latitude, GP, and, from the longitude, the angle PGB, according to what was said at problem 56: for then by Rule 5 or 6 of spherical oblique-angled triangles the angle PBG will become evident, which is the

argument of the right ascension, likewise according to what was said at problem 56.

[Margin: Problem 59.]

Fourth, let the star be at P; and let there be given the complements of the declination, BP, and of the latitude, GP, and, from the longitude, the angle PGB, as above: for by Rule 1 of spherical oblique-angled triangles you will obtain the angle PBG, namely the argument of the right ascension.

60. Probl. Aſcenſionum Rectarum Tabulam pro Planetis aut Stellis alijs Latitudinem habentibus Conſtruere. *60. Problem. To construct a table of right ascensions for the planets, or for other stars that have latitude.*

[Margin: Problem 60.]

Use problem 58, and construct the tables in this way. Further, Regiomontanus in his *Directions* gives two tables of the mediations of the heavens: one from page 16, for stars whose latitude does not exceed 8°; the other, at page 40, a general one for any latitude. He assumes an obliquity of the ecliptic of 23° 30′, and teaches their use in problems 3 and 4. Likewise Maginus gives a general table, according to a threefold obliquity of the ecliptic, at page 55 of his *Directions of the Primum Mobile*, and at page 56 one for a latitude not exceeding 7° only; he teaches their use in canon 8. Finally Argolus [Andrea Argoli], in volume 1 of his *Ephemerides*, from page 259, gives the same for latitudes up to 9°, assuming an obliquity of the ecliptic of 23° 31′ 30″. Now they call mediations of the heavens what others call right ascensions.

Probl. Declinationem Sideris inquirere, Datis 61. Diſtantia Polorum, Aſc. Recta, & Longitud. Sideris 62. Diſtantia Polorum, Aſcenſione Recta & Latitud. Sideris 63. Diſtantia Polorum, Longitud. & Latit. Sid. 64. Aſc. Recta, Longitud. & Latitud. Sideris *Problem. To find the declination of a star, given: 61. the distance of the poles, and the right ascension and longitude of the star; 62. the distance of the poles, and the right ascension and latitude of the star; 63. the distance of the poles, and the longitude and latitude of the star; 64. the right ascension, longitude and latitude of the star.*

[Margin: Problem 61.]

Let the figure set out at problem 48 be repeated here, in which, first, let the star be at P, and let there be given the distance of the poles, BG, and, from the right ascension, the angle PBG, according to what was said at problem 48, and, from the longitude, the angle PGB, according to what was said at problem 53. Then in triangle PBG, by Rule 11 or 12 of spherical oblique-angled triangles, you will learn the side BP; when this is subtracted from 90°, the declination Pλ will be left. So in triangle BZG, if the star is at Z, with BG given, and the angles ZBG, from the right ascension, and ZGB, from the longitude, you will obtain the side BZ; when this is taken from 90°, the northern declination Zθ will remain. But if the side obtained were a quadrant, there would be no declination; if it exceeded a quadrant, the excess would be a southern declination.

[Margin: Problem 62.]

Second, let the star be at P; and let there be given the distance of the poles, BG, and, from the right ascension, the angle PBG, and PG, the complement of the latitude PQ: for by Rule 2 of spherical oblique-angled triangles you will find the base BP, the complement of the declination Pλ.

[Margin: Problem 63.]

Third, let the star be at P; and let there be given the distance of the poles, BG, and, from the longitude, the angle PGB, according to what was said at problem 53, and the complement of the latitude, PG: for by Rule 4 of spherical oblique-angled triangles you obtain the base BP, which is the complement of the northern declination Pλ. Similarly in triangle ZBG, if the star is at Z — that is, when the latitude is northern and the longitude belongs to the third or fourth quadrant of the ecliptic — with PG [?] given, as above, and, from the longitude, the angle ZGB, and the complement of the latitude, GZ, you will learn the base BZ, the complement of the northern declination Zθ; and so for the rest.

[Margin: Problem 64.]

Fourth, let the star be at P; and let there be given, from the right ascension, the angle PBG, and, from the longitude, the angle PGB, and the complement of the latitude, PG: for by Rule 7 of spherical oblique-angled triangles you will obtain the side BP, the complement of the declination Pλ.

[Margin: Order of the problems.]

[Margin: Order of the problems.]

65. Probl. Declinationum Tabulam pro Planetis, alijſq. Sideribus Latitudinem habentibus, Conſtruere. *65. Problem. To construct a table of declinations for the planets and other stars that have latitude.*

[Margin: Problem 65.]

Consult problem 63 and, following it, construct a table for each degree of longitude and of latitude for one quadrant of the ecliptic; for the same declination will hold for any degree of longitude equally distant from the nearer equinox, the same latitude being given.

[Margin: The authors of this table.]

Such a table was indeed published by Io. Antonius Maginus in the Tables of the *Directions of the primum mobile*, from page 36; it extends up to 83 degrees of latitude. But it is founded on the distance of the poles, that is, the Tychonic obliquity of the ecliptic, 23° 31′ 30″, as Maginus himself admits in the same place, in Canon 4. So if anyone uses another obliquity, that table will need some correction. The same author, in his new Tables of Directions, page 3 of the tables, gave a table of the equation of declinations for the planets, but extended only up to 8 degrees of latitude, and likewise founded on the Tychonic obliquity. Argoli, for his part, gives the same table in volume 1, before the Ephemerides, at page 246, up to a latitude of 9 degrees. Regiomontanus, for his part, in the Tables of Directions, pages 2 and 14 of the tables, gives one table

for latitude up to 8°, and another, general one; he teaches the use of both there in problems 1 and 2, assuming an obliquity of the ecliptic of 23° 30′.

Probl. Angulum Circuli Declin. & Latitud. in centro Sideris factum indagare, Datis 66. Polorum diſt. Declin ac Latitud. Sideris 67. Polorum diſt. Declin. & Longitud. Sideris 68. Polorum diſt. Decl. & Aſc. Recta Sideris 69. Polorum diſt. Latitud. & Longitud. Sid. 70. Polorum dſt. Lat. & Aſcenſ. Recta Sider. 71. Polor. diſt Longitud. & Aſc. Recta Sideris 72. Longitud. Latitud. & Declinat. Sideris 73. Longit. Latitud. & Aſc. Recta Sideris 74. Longitud. Decl. & Aſc. Recta Sideris 75. Latitud. Declin. & Aſc. Recta Sideris *Problem. To find the angle made at the centre of a star by the circle of declination and the circle of latitude, given: 66. the distance of the poles, and the declination and latitude of the star; 67. the distance of the poles, and the declination and longitude of the star; 68. the distance of the poles, and the declination and right ascension of the star; 69. the distance of the poles, and the latitude and longitude of the star; 70. the distance of the poles, and the latitude and right ascension of the star; 71. the distance of the poles, and the longitude and right ascension of the star; 72. the longitude, latitude and declination of the star; 73. the longitude, latitude and right ascension of the star; 74. the longitude, declination and right ascension of the star; 75. the latitude, declination and right ascension of the star.*

You will solve all these problems by taking as your example the single triangle BPG of the figure set out at problem 48. But since these problems are very rarely used, it will be enough to give the principal and easier one, which is 66.

[Margin: Problem 66.]

Let the star, then, be at P, and let the three sides be given: namely the base BG, the distance of the poles; BP, the complement of the declination; and GP, the complement of the latitude. For by Rule 14 of spherical oblique-angled triangles you will find the angle BPG, which the arcs Bλ, of declination, and GQ, of latitude, make at the centre of the star P. For the other data it is enough to have indicated the angles and sides corresponding to the problems, numbered in order, and the rules of spherical oblique-angled triangles given in Section 1, chapter 5, by which the angle P can be found — as you see done in the following small table.

[Margin: Problems 67, 68, 69, 70, 71, 72, 73, 74, 75.]

Probl. Angulum circuli Declinationis cum Ecliptica inueſtigare, Datis 76. Declinatione ac Longitudine Sideris 77. Declinatione, & Aſc. Recta Sid. 78. Declinatione Sid. & Obliquitate Ecliptica 79. Longitud. & Aſc. Recta Sid. 80. Longitud. Sid. & Obliquitate Ecliptica 81. Aſc. Recta Sid & Obliquit. Eclip. 82. Latitud. complem. & Angulo circuli Declin. ac Latit. in centro Sideris 83. Ijſdem Datis, ſed alio modo. *Problem. To find the angle of the circle of declination with the ecliptic, given: 76. the declination and longitude of the star; 77. the declination and right ascension of the star; 78. the declination of the star and the obliquity of the ecliptic; 79. the longitude and right ascension of the star; 80. the longitude of the star and the obliquity of the ecliptic; 81. the right ascension of the star and the obliquity of the ecliptic; 82. the complement of the latitude, and the angle of the circle of declination and of latitude at the centre of the star; 83. the same data, but in another way.*

The problem can indeed be solved from the data assigned to problem 80, in the way in which we taught in problem 14 how to find the angle of the ecliptic and the meridian, since the meridian is one of the circles of declination, and every circle of declination is, with respect to some horizon, a meridian. So this business could be settled by the table of the angle of the ecliptic and the meridian. Nevertheless, taking the occasion of the figure set out at problem 48, which is to be recalled here, we have decided to complete this practice by a more fruitful inquiry. For it we shall consider the triangle R♈λ, or θ♈μ, right-angled at λ, or at θ.

Diagram. A circle set in the right column, the figure recalled from problem 48: a near-horizontal diameter A–C, a line from E through the centre point ♈ to F, curved arcs descending from B and G to H and D, and a dotted line from G down towards X. Small stars mark K, P, M, I, Z, L, Y, N, O, T and ε. A Capricorn sign ♑ stands beside F; three other small sorts could not be identified on the scan.

- B (top of the rim)
- G (rim, upper right of B)
- K (rim, upper left)
- P (inside, below K)
- M (rim, right)
- E (rim, left), with the sign ♋ just inside it
- [?] (a small sign inside, right of I)
- I (rim, left, below E)

- Z (inside, right, below M)
- R, X, S, T (clustered left of centre)
- [?] (a small sign left of θ)
- θ (right of centre)
- A (left end of the diameter), C (right end)
- ♈ (centre)
- λ (below S), V (right of λ)
- ♎ (below ♈)
- N (rim, right, below C)
- ε (inside, below θ)
- β (below ε, to the left)
- [?] (a sort right of β, with a long descending stroke)
- L (rim, lower left)
- [?] (a small sign touching F)
- F (rim, lower right)
- Y (inside, lower left)
- O (rim, lower right, below F)
- H (bottom left), D (bottom)

In the first triangle the declination of the point of the ecliptic is the arc Rλ, which becomes known from the longitude of the star through the table of declinations treated in problem 15; the obliquity of the ecliptic is the angle at ♈; and the base R♈ is the longitude of the star if it is less than 90°, or the supplement of the longitude to 180° if it is greater than 90° but less than 180°. The side λ♈, in turn, is the right ascension if that is less than 90°, or its supplement to 180° if it is greater than 90° and less than 180°. But if either the longitude or the right ascension exceeds 180°, the triangle θ♈μ must be used. In it the declination is θμ; the obliquity of the ecliptic is the angle θ♈μ; and the base ♈μ is the excess of the longitude over 180° if the longitude is less than 270°, or the complement of the longitude to 360° if it is greater than 270°. Likewise the side ♈θ is the excess of the right ascension over 180°, or its complement to 360°, according as the right ascension is less or greater than 270°. We shall, however, give examples of the problems only in the triangle R♈λ, indicating the data and the rules of spherical right-angled triangles given in Section 1, chapter 4, by which the angle λR♈ can be found. I add, however, that if in the triangle PQR, right-angled at Q, the complement of the latitude PQ is given, together with the angle P from problems 66 and following, the angle R can be obtained by Rule 8 of spherical right-angled triangles; or the base PR by Rule 9, and with it the angle R by Rule 3.

[Margin: Problems 76, 77, 78, 79, 80, 81, 82, 83.]

Probl. Angulum Circuli Latitudinis & Aequatoris inquirere, Datis 84. Declinat Sid. & Angulo Declinat. ac Latitud. in centro Sideris 85. Longitud. & Asc. Recta Sideris 86. Longitud Sid. & Obliquit. Eclipt. 87 Asc. Recta Sid. & Obliquit. Eclipt. *Problem. To find the angle of the circle of latitude and the equator, given: 84. the declination of the star, and the angle of the circles of declination and of latitude at the centre of the star; 85. the longitude and right ascension of the star; 86. the longitude of the star and the obliquity of the ecliptic; 87. the right ascension of the star and the obliquity of the ecliptic.*

Look at the figure immediately preceding, and in it at the triangle VXϒ, right-angled at X, in which the angle V is sought; or at the triangle βδ♋, right-angled at β, in which the angle δ is sought. The angle of the obliquity of the ecliptic is ♋; the base is V♋ in the first triangle and δ♋ in the second, known from the right ascension; and the side X♋, or β♋, is known from the longitude of the star, according as either of them is greater or less than 90° or 270°, following the precepts just given for problem 76 and the rest. We shall give the worked example in the triangle X♋V, for finding the angle XV♋, according to the data corresponding to the problems set out in order, indicating the rules of spherical right-angled triangles given in chapter 4 of Section 1, by which the acute angle at V, which the circle of latitude makes with the equator, can be found. The same angle, however, can also be found in the triangle λYV, if the angle Y is given (on which see from problem 66 on) together with the complement of the declination, λY.

[Margin: Table of this angle.]

Maginus gives a table of this angle in the *Directions of the primum mobile*, page 36, and teaches its use in Canon 3.

[Margin: Problems 84, 85, 86, 87.]

Order of the problems	Data for the angle XV♋	Rules

88. Probl. Angulum Eclipticæ ac Verticalis circuli factum in centro fideris Latitudinem habentis inquirere. *88. Problem. To find the angle of the ecliptic and the vertical circle made at the centre of a star that has latitude.*

[Margin: Problem 88.]

This problem serves hardly any other use than that of eliciting the parallaxes of the luminaries or of comets, and so we solved it in various ways in Book 5, chapter 10, from problem 3 to 5 — besides the mechanical methods, by means of the analemma or the astrolabe, which our Scheiner teaches in the *Rosa Ursina*, from page 144 to 149.

Probl. Angulum Eclipticæ & Verticalis. in centro Solis aut Sid. Latitud. carentis factum, Per angulum Verticalis ac circuli Declinationis ibidem factum, explorare Datis præter Locum eius in Ecliptica 89. Altitudine Poli, Tempore ac Declinat. Sid. 90. Altitud. poli, Tempore, & Altitud. Sid. 91. Altitud. Poli, Tempore, & Azimutho Sid. 92. Altit. Poli Declinat & Altitud Sideris 93. Altitud. Poli, Declinat. & Azimutho Sid. 94. Alt. Poli, Altitud. & Azimutho Sideris 95. Tempore, Declinat & Altitudine Sideris 96. Tempore, Declinat. & Azimutho Sideris 97. Tempore, Altitud. & Azimutho Sideris 98. Declinatione, Altitud. & Azimutho Sid. *Problem. To explore the angle of the ecliptic and the vertical made at the centre of the Sun, or of a star lacking latitude, by way of the angle of the vertical and the circle of declination made at the same place, given, besides its place in the ecliptic: 89. the altitude of the pole, the time and the declination of the star; 90. the altitude of the pole, the time and the altitude of the star; 91. the altitude of the pole, the time and the azimuth of the star; 92. the altitude of the pole, the declination and the altitude of the star; 93. the altitude of the pole, the declination and the azimuth of the star; 94. the altitude of the pole, and the altitude and azimuth of the star; 95. the time, and the declination and altitude of the star; 96. the time, and the declination and azimuth of the star; 97. the time, and the altitude and azimuth of the star; 98. the declination, altitude and azimuth of the star.*

[Margin: Explanation of the diagram.]

For all these, describe the horizon HCR and the meridian HVRA, in which let V be the zenith and P the north pole of the world; and the ecliptic BSA, at a given point of which let the star S stand. Through S let a quadrant of a vertical circle, VC, be drawn, so that on it the true altitude of the star is CS, and its complement SV; and let the altitude of the pole be PH, whose complement to 90° is PV. Now when an arc of a great circle is drawn from the pole P to the centre of the star, that is PS, it will be either the complement of a northern declination; or, if the star is on the equator, a quadrant; or, if it declines to the south, the sum of a quadrant and the southern declination.

Diagram. A circle set at the right of the short-measure lines in the right column: a curve from H across to R (the horizon), a curve from A rising to B

(the ecliptic), a curve from P across to S, and a line from V down through S to C.

- V (top of the rim)
- P (rim, upper left)
- B (rim, right, above R)
- H (rim, left)
- S (inside, right; small italic)
- R (outside the rim, right, at the end of a line)
- A (rim, lower left)
- C (inside, right, below S)
- M (below the bottom of the rim)

Moreover the angle CVR is the measure of the given azimuth CR, and its supplement to 180° is the angle SVP. And when the time before or after noon is given and converted into parts of the equator, the angle SPV is given. Therefore in the triangle VSP, from any three of the five quantities already mentioned, the angle VSP, which the vertical makes with the circle of declination, can be gathered. Further, when the point S of the ecliptic is given, the angle PSA is also given, which the meridian, or circle of declination, makes with the ecliptic, by problem 14 or by problems 76 to 81. So by adding the angle VSP to it, the angle VSA will result; and when this is subtracted from 180°, there will remain the angle VSB, which the vertical makes with the ecliptic. The whole business, therefore, now consists in finding the angle VSP by solving the spherical oblique-angled triangle VSP. This will be done by the following rules, already set out in chapter 5 of Section 1, applied in order to the data of the problems proposed, as the following small table indicates.

[Margin: Problems 89, 90, 91, 92, 93, 94, 95, 96, 97, 98.]

99. Probl. Differentiam Aſcenſionis Rectæ ſeu Diſtantiam Æquatoriam inter duo Sidera Inuenire, Datis Diſtantia eorum inter ſe, & vtriuſq. Declinatione. *99. Problem. To find the difference of right ascension, or the equatorial*

distance, between two stars, given their distance from each other and the declination of each.

[Margin: Problem 99.]

In the following figure, through the south pole of the equator, A, and the north pole, B, let two semicircles of declination, AEB and AQB, be drawn, intercepting the portion EQ of the equator.

[Margin: Case 1.]

First, let both stars be northern, one at C, the other at D, their distance being CD. Then in the triangle CBD the remaining two sides will be given — CB, as being the complement of the declination EC, and BD, the complement of the declination QD — and the base CD will be given. Therefore by Rule 14 of spherical oblique-angled triangles the angle B will be known, which measures the difference of right ascension, namely the arc EQ.

[Margin: Case 2.]

Second, let both stars be southern, one at F, the other at G, with the distance given, that is the base FG, and the sides AF, the complement of the declination FQ, and AG, the complement of the declination GE; for by the same Rule 14 you will find the angle A,

[Margin: Order of the problems.]

[Margin: Order of the problems.]

which measures the arc EQ, that is, the difference of right ascension.

[Margin: Case 3.]

Third [?], let one star be with declination, as at F, the other without declination, as at E, and let their distance, that is the given base, be EF. For in the triangle EAF, from that base, the quadrant AE, and the side AF, the complement of the declination FQ, you will obtain by the same Rule 14 the angle A, which measures the arc EQ.

[Margin: Case 4.]

Fourth, let one star be northern, as C, the other southern, as F. For in the triangle CBF, given the base, that is their distance CF; the side CB, which is the complement of the northern declination EC; and the side BQF, which is the sum of the quadrant BQ and the southern declination FQ, you will find by the same Rule 14 the angle B, which measures the equatorial distance, or difference of right ascension, that is the arc EF. We are speaking here of the true distance: how an apparent, or observed, distance should be converted into the true one, when parallax and refraction intervene, or at least refraction, has been explained in Book 6, chapter 11, problem 8.

Diagram. A lens-shaped figure set in the left column beside the short-measure lines: two semicircles of declination meeting at B above and A below, with the straight line E–Q across the middle and arcs drawn from C to D, from C to F, from E to F and from G to F, and a further arc from the upper left down to F.

- B (top point)
- D (right arc, below B)

- C (left arc, below the level of D)
- E (middle of the left arc)
- Q (middle of the right arc)
- F (right arc, below Q)
- G (left arc, below E)
- A (bottom point)

100. Probl. Aſcenſionem Rectam Sideris notæ Declinationis inueſtigare per Diſtantiam ab alio ſidere notæ Declinationis & Aſc. Rectæ. *100. Problem. To find the right ascension of a star of known declination through its distance from another star of known declination and right ascension.*

[Margin: Problem 100.]

Find by problem 99 the difference of right ascension, and add it to the known right ascension if the star in question is more easterly, as when it is at D; subtract it if it is more westerly, as when it is at C; and the right ascension of the star sought will result, or remain. But if the sum from the addition exceeds 360°, discard them; and if the subtraction has to be of a larger number from a smaller, because the difference of right ascension is greater than the right ascension of the known star, add 360 to the smaller number and subtract the difference from the sum.

101. Probl. Declinationem Sideris inueſtigare, Datis Declinatione alterius ſideris, & Diſtantia eorum inter ſe, cum Differentia Aſc. Rectæ. *101. Problem. To find the declination of a star, given the declination of another star and their distance from each other, with the difference of right ascension.*

[Margin: Problem 101.]

The four cases of problem 99 can arise here, but all of them by Rule 2 of spherical oblique-angled triangles. First, let the star be C, whose declination EC is known, and so also its complement CB; let the other be D; and let their distance CD be given, with the angle B, which measures the difference of right ascension between them. For by the said Rule 2 the base BD will be found, which is the complement of the declination DQ. Conversely, if the declination DQ is known, and its complement BD, you will find the base BC, the complement of the declination EC. Likewise in the triangle CBF: if CB is known, and the distance CF and the angle B are given, and the base found turns out greater than a quadrant, as BQF, then once the quadrant BQ is subtracted the declination FQ, towards the other pole, will be known; but if the base found were the quadrant AE, in the triangle EAF, there would be no declination. If you do not understand the rest, you are too dull.

102. Probl. Differentiam Longitudinis, ſeu Diſtantiam Eclipticam inter duo ſidera inuenire, Data diſtantia eorum inter ſe, & Latitudine vtriuſq. *102. Problem. To find the difference of longitude, or the ecliptic distance, between two stars, given their distance from each other and the latitude of each.*

[Margin: Problem 102.]

Consult problem 99, changing the names, and taking A and B to be the poles of the ecliptic, EQ an arc of the ecliptic, and AEB and AQB the semicircles of latitude. Carry out the rest as there.

103. Probl. Longitudinem ſideris notæ Latitudinis inueſtigare, Per Diſtantiam ab alio ſidere notæ Latitudinis ac Longitudinis. *103. Problem. To find the longitude of a star of known latitude through its distance from another star of known latitude and longitude.*

[Margin: Problem 103.]

Find the difference of longitude by problem 102, and add it to the known longitude if the star in question is more easterly; subtract it if more westerly. If in the first case the sum exceeds 360°, discard them, keeping the remainder; but if in the second case the subtraction cannot be made, add 360° to the given longitude, and then subtract the difference of longitude from the sum. In this way you will have the longitude of the other star.

104. Probl. Latitudinem Sideris inueſtigare, Datis Latitudine alterius ſideris eorumq. tum Diſtantia, tum Differentia Longitudinis. *104. Problem. To find the latitude of a star, given the latitude of another star, together with both their distance and their difference of longitude.*

[Margin: Problem 104.]

Do everything as in problem 101, changing the names of declination into latitude and of right ascension into longitude.

105. Probl. Diſtantiam duorum Siderum inter ſe inquirere, Datis vtriuſq. Latitudine, ac Differentia Longitudinis, vel vtriuſq. Declinatione ac Differentia Aſcenſionis rectæ. *105. Problem. To find the distance of two stars from each other, given the latitude of each and the difference of longitude, or the declination of each and the difference of right ascension.*

[Margin: Problem 105.]

Use the figure of problem 99, in which, by Rule 4 of spherical oblique-angled triangles, you will find the base — that is, the distance of the stars sought — from the given sides, namely the complements of the two latitudes, and the vertical angle, that is, the difference of longitude; or from the complements of the two declinations and the vertical angle, namely the difference of right ascension. For example, in the triangle CBD, given CB, the complement of the latitude EC, and BD, the complement of the latitude DQ, and the angle B, which measures the difference of longitude, find the distance CD. It can happen, however, that one of the sides already mentioned is a quadrant, say EF, in the triangle EAF, because one star, E, has no latitude or declination; or that it is greater than a quadrant, as BQF in the triangle CBF, because the latitude or declination of one star is northern and that of the other southern. Nevertheless, by the same Rule 4 you will find the base, or distance, EF or CF, and so on.

How an apparent distance is converted into the true one has been explained in Book 6, chapter 11, problem 8, and it belongs to the section on parallaxes and refractions.

106. Probl. Longitudinem ac Latitudinem Stellæ inquirere, Data eius Diſtantia à duabus ſtellis notæ Longitudinis ac Latitudinis. *106. Problem. To find the longitude and latitude of a star, given its distance from two stars of known longitude and latitude.*

107. Probl. Aſcenſionem Rectam, & Declinationem Stellæ inquirere, Data eius Diſtantia à duabus ſtellis notæ Aſcenſionis Rectæ, & Declinationis. *107. Problem. To find the right ascension and declination of a star, given its distance from two stars of known right ascension and declination.*

[Margin: Problem 106.]

[Margin: Problem 107.]

I have already taught these problems sufficiently in Book 6, chapter 12, problem 2. But for problem 107 one must change the names and functions of longitude into right ascension, of latitude into declination, of the ecliptic into the equator, and of the poles A, B of the ecliptic into the poles of the equator; for everything else is to be done exactly as there. And from the operations to be carried out there it will be clear how great a saving of labour results if the distance between those stars which are used to learn the conditions of the third has been known beforehand. To this end we have presented, in the same Book 6, chapter 10, the distances of so many fixed stars, observed with care partly by Tycho and partly by ourselves.

[Margin: Notice about a double problem to be inserted here.]

Insert here problems 131 and 132, which for good reasons I have put off to that place.

[Margin: Order of the problems.]

[Margin: Order of the problems.]

Probl. Aſcenſionem Rectam Medij Cæli, ſeu Punctum Aequatoris Culminans Indagare, Datis præter Aſc. Rect. Sideris aut Puncti Eclipt. 108. Tempore ante vel poſt meridiem 109. Tempore ante vel poſt tranſitum Stellæ per Meridianum 110. Altitudine Poli, Altitudine, & Declinatione Sideris 111. Altitud. Poli Altitud. & Azimutho Sid. 112. Altit. Poli. Declinat. & Azimutho Sid. 113. Azimutho, Altitudine, & Declinat. Sid. *Problem. To find the right ascension of mid-heaven, that is, the culminating point of the equator, given, besides the right ascension of the star or of the point of the ecliptic: 108. the time before or after noon; 109. the time before or after the transit of a star across the meridian; 110. the altitude of the pole, the altitude, and the declination of the star; 111. the altitude of the pole, the altitude, and the azimuth of the star; 112. the altitude of the pole, the declination, and the azimuth of the star; 113. the azimuth, the altitude, and the declination of the star.*

Let the figure set out at problem 25 be taken up again here. Its meridian is HZR, its horizon HR, its equator EQ, and AZ is a quadrant of a vertical circle. In it the star is either at B, with BP the complement of its declination; or at G, with no declination, so that GP is a quadrant; or at I, so that IP is the sum of the declination IC, toward the other pole, and the quadrant CP. The visible pole is P.

Diagram. A circle set in the left column beside the text of problem 108, recalling the figure of problem 25: the horizon H–R runs across it, with arcs drawn from the pole P on the right-hand rim. Labels read:

- Z (above the rim at the top, right of centre): one end of the vertical quadrant AZ
- E (rim, upper left): the culminating point of the equator
- B (inside, near the top): a star with declination, BP its complement
- P (rim, upper right): the visible pole
- N (inside, below E)
- G (inside, left of centre): a star with no declination
- C (immediately right of G)
- I (below G): a star whose declination IC lies toward the other pole
- H (outside the rim, left) and R (outside the rim, right): the horizon HR; the meridian HZR
- A (inside, lower left): the foot of the vertical quadrant AZ
- O (inside, below centre)
- Q (rim, lower right): the equator EQ

[Margin: Problem 108.]

First, then, let the star be at B, and from the time before or after noon, converted into parts of the equator, let the angle ZPB be given, which measures the arc of the equator corresponding to it. For this angle, added to the given right ascension of a western star, or subtracted from it if the star is eastern, will make up or leave the point E culminating, that is, passing through the meridian, or the right ascension of mid-heaven. Thus, if the star were at G, the angle known from the time would be GPE, measuring the arc EG of the equator; but if the star were at I, that angle would be IPE, measuring the arc EC of the equator, to be added to the right ascension of a western star or subtracted from that of an eastern one.

[Margin: Problem 109.]

Second, let a star of known right ascension cross the meridian, and let the time from its transit, or before its transit, be counted with the help of the pendulum, on which see Book 2, chapter 20. That time, converted into parts of the equator and added to the star's right ascension if the time is after the transit, or subtracted from it if before, will give the right ascension of mid-heaven for the moment at which you began counting the time before the transit, or finished counting it after the star's transit across mid-heaven. The same could, however, also be obtained with the equatorial armillae, with which the angle

already mentioned, or the culminating point of the equator itself, would be observed.

[Margin: Problem 110.]

Third, let the star be at B, and in the triangle BZP let there be given PZ, the complement of the altitude of the pole; BZ, the complement of the true altitude of the star; and BP, the complement of the declination — or, if there is no declination, a quadrant, or else the sum of the declination toward the other pole and the quadrant. For by Rule 14 of spherical oblique-angled triangles you will find the angle at P, which is to be added to the given right ascension of a western star, or subtracted from it if the star is eastern, so as to obtain the right ascension of mid-heaven.

[Margin: Problem 111.]

Fourth, in the same triangle let PZ and BZ be given as above, and the angle BZP, the supplement of the azimuth AZH to 180°. For by Rule 5 or 6 of spherical oblique-angled triangles you will find the angle at P; use it as above.

[Margin: Problem 112.]

Fifth, in the same triangle let PZ and BP be given, and the angle BZP, as above. For by Rule 3 of spherical oblique-angled triangles you will find the angle at P; use it as above.

[Margin: Problem 113.]

Sixth, in the same triangle let there be given, as above [?], the angle BZP and the sides BZ and BP. For then by Rule 1 of spherical oblique-angled triangles the angle at P will be given; use it as above in problem 110.

Probl. Aſcenſionalem Differentiam; ipſiuſq. 114. Tabulam, & Amplitudinem Ortiuam & 115. Occiduam Puncti Eclipticæ aut Sideris Determinare, Data eius Declinatione, & Altitudine Poli. *Problems 114 and 115. To determine the ascensional difference and its table, and the rising and setting amplitude of a point of the ecliptic or of a star, given its declination and the altitude of the pole.*

[Margin: Explanation of the figure.]

Consider the figure below, in which the meridian is HCQ, the horizon HMR and the equator AMQ, while its southern parallel is KBN and its northern parallel CDT. To the points where these parallels cut the horizon, B and D, let the arcs of declination PIB and PDL be drawn from P, the northern pole of the equator, as far as the equator or through it. Then DL will be the northern declination of the point D, or of a star rising or setting there; ML will be the ascensional difference; and MD the rising or setting amplitude of the Sun, or of another planet, or even of a fixed star. BI, on the other hand, will be the southern declination of a point of the ecliptic, or of a star, rising or setting at B; its ascensional difference will be the arc IM of the equator, and its rising or setting amplitude the arc BM of the horizon. Finally, when the altitude of the pole PR is subtracted from 90°, the depression of the equator RQ is given,

to which the elevation HA is equal; and either of the two measures the acute angle at M.

[Margin: Problems 114, 115.]

First, then [?], let the northern declination DL be given, and the acute angle M, already known from the altitude of the pole. For in the triangle MDL, right-angled at L, you will find by Rule 10 of spherical right-angled triangles the side LM, which is the ascensional difference, and by Rule 11 the base MD, that is, the rising or setting amplitude.

Diagram. A circle set in the right column beside the text of problems 114–115: the horizon H–R runs across it, crossed by the equator and two parallels, with arcs of declination drawn from the pole P on the upper right rim. Labels read:

- C (rim, top) and Q (rim, lower right): the meridian HCQ
- A (rim, upper left) and M (centre, on the horizon): the equator AMQ
- K (rim, left, below A), B (on the horizon, left of centre) and N (rim, bottom): the southern parallel KBN
- D (on the horizon, right of M) and T (outside the rim, lower right): the northern parallel CDT
- P (rim, upper right): the northern pole of the equator
- I (inside, left of centre): the foot on the equator of the arc PIB
- L (inside, below D): the foot on the equator of the arc PDL
- H (outside the rim, left) and R (outside the rim, right): the horizon HMR

Second, if the southern declination BI of a point or star B is given, and the acute angle M, known from the altitude of the pole, then in the triangle BIM, right-angled at I, look for the side IM, that is, the ascensional difference, by Rule 10 of spherical right-angled triangles, and by Rule 11 of the same, the base BM, that is, the rising or setting amplitude. Further, if the declination of the Sun or of a star were the greatest possible for it, it would produce the rising or setting amplitude so called without qualification.

[Margin: Authors of the table.]

Tables of the ascensional difference are given by Regiomontanus in the *Directions*, page 44; by Reinhold in the same work, page 102; by Copernicus, Book 2, chapter 7; by Clavius in the *Sphere*, page 340; by Maginus in the *Small Directions*, page 670, and in the *Tables of Directions*, table 4 of the Analogy, whose use he teaches in canon 10; by the *Rudolphine Tables*, folio 24; and by Argoli in the *Ephemerides*, volume 1, page 223. A particular way of constructing this table is taught in the same place by Reinhold, in precept 23. Maginus, for his part, adds in canon 10 that the difference of the semidiurnal arc from 90° is itself the ascensional difference, and that it can thus be had from the tables of the semidiurnal arc.

Probl. Angulum Horizontis & Circuli Declinationis in centro Sid. aut puncto Eclipticæ Oriente vel Occidente factum inuenire, Datis 116. Altitud. Poli & Declinatione Sideris 117. Altitud. Poli, & Aſcenſionali differentia 118. Altitud. Poli, & Amplitudine Ortiua 119. Declinatione;

& Aſcenſ. Differentia 120. Declinatione, & Amplitudine Ortiua 121. Aſcenſionali differ. & Amplitud. Ortiua *Problem. To find the angle made by the horizon and the circle of declination at the centre of a star, or of a point of the ecliptic, as it rises or sets, given: 116. the altitude of the pole and the declination of the star; 117. the altitude of the pole and the ascensional difference; 118. the altitude of the pole and the rising amplitude; 119. the declination and the ascensional difference; 120. the declination and the rising amplitude; 121. the ascensional difference and the rising amplitude.*

On this angle, however, when the star or point is off the horizon, I shall speak from problem 188 onward.

In the figure immediately preceding, consider the triangle MLD, right-angled at L, in which what is sought is the angle

[Margin: Order of the problems.]

[Margin: Order of the problems.]

MDL, which the horizon HR makes with the circle of declination PL at the centre of the star D as it rises or sets, or at some given point of the ecliptic. The acute angle at M, for its part, is known from the altitude of the equator, which is the complement of the altitude of the pole. Similarly, in the triangle BIM, right-angled at I, the angle IBM is sought. Either angle can be found by the following rules of spherical right-angled triangles set out in Section 1, chapter 4, as the small table below shows, arranged in order, according to the data, for the problems proposed.

[Margin: Problems 116, 117, 118, 119, 120, 121.]

Order of the problems	Data for the angle MDL	For the angle IBM	Rules
116	Angle M and side DL	Angle M; side BI	12
117	Angle M; side ML	Angle M; side MI	8
118	Angle M; base MD	Angle M; base BM	3
119	Side DL; side LM	Side BI; side IM	14
120	Side DL; base MD	Side BI; base BM	5
121	Side LM; base MD	Side IM; base BM	4

I pass over two less convenient methods: by the distance of the rising or setting point from the meridian, or by the angle of the ecliptic and the meridian together with the meridian altitude.

122. Probl. Arcum Semidiurnum ac Seminocturnum Puncti Eclipticæ vel Sideris cuiuſuis, inquirere, Datis Aſcenſionali Differentia, vel Altitudine Poli ac Declinatione Puncti aut Sideris: & Tabulam conſtruere pro huiuſmodi arcu. *122. Problem. To find the semidiurnal and seminocturnal arc of a point of the ecliptic or of any star, given the ascensional difference, or the altitude of the pole and the declination of the point or star; and to construct a table for an arc of this kind.*

[Margin: Problem 122.]

If the ascensional difference is not given, find it by problem 114 or 115 from the given altitude of the pole and declination of the point of the ecliptic or of the star. Then look at the figure set out at problem 114. If the declination is toward the visible pole P, namely LD, add the ascensional difference ML to the arc AM of the equator, which is 90°, and the result will be the semidiurnal arc AML, through which the point or star D must revolve until, from its true rising, appearing at D, it reaches the meridian. The same difference ML, subtracted from 90°, will give the seminocturnal arc. But if the point or star is at B, declining toward the other pole, subtract the ascensional difference IM from 90° for the semidiurnal arc, and add it for the seminocturnal.

I said "from the true rising" because refraction visibly raises the star, so that it rises somewhat earlier at B or D, and sets later. Therefore, if the true rising and setting have to be converted into the apparent, or the apparent into the true — and the semidiurnal arc with them — the refraction of the star, or even its parallax, must be known beforehand, and this problem must be corrected, as we shall say in Section 3.

[Margin: Authors of the table.]

Further, a table of the semidiurnal arc for every degree of the ecliptic, from 34° to 55° of the altitude of the pole, is given by Maginus in the *Directions*, folio 134, and in the *New Tables*, page 315. But it can also be had from the tables of semidiurnal time, to be reviewed in the next section, if the time is converted into parts of the equator.

123. Probl. Aſcenſionem ac Deſcenſionem Obliquam Puncti Eclipticæ, vel Sideris cuiuſuis determinare, Datis aut Aſcenſionali Differentia, aut Alt. Poli ac Declinat. & Tabulam Aſcenſionum Obliquarum conſtruere.
123. Problem. To determine the oblique ascension and descension of a point of the ecliptic or of any star, given either the ascensional difference or the altitude of the pole and the declination; and to construct a table of oblique ascensions.

[Margin: Problem 123.]

If the ascensional difference is not given, find it by problem 114 or 115, or by the tables listed there. Then find the right ascension of the point of the ecliptic by problems 8 to 16, or by the tables listed at problem 16; or the right ascension of the star by problems 25 to 28, or 56 to 60, or by the tables listed at problem 60. With these obtained, look at the figure set out at problem 114. In it, if the declination of the point or star is toward the pole visible to you — as when the star or point is at D — the ascensional difference, that is, the arc LM, added to the right ascension will make the oblique descension, and subtracted from it will make the oblique ascension at the given altitude of the pole. But if the point or star declines toward the opposite pole — as when it is at B — the ascensional difference MI, added to the right ascension, will make up the oblique ascension, and subtracted from it will leave the oblique descension.

It is by this device, then, that the tables of oblique ascensions for the degrees of the ecliptic have been made, for many if not all degrees of altitude of the

northern pole. These can nevertheless also serve for the degrees of altitude of the southern pole, if the descension is exchanged for the ascension, or the ascension for the descension, according to the rules of Book 1, chapter 23, rules 7 to 12. There I also taught how the oblique ascensions of the remaining quadrants are very easily gathered from the oblique ascensions of one quadrant of the ecliptic.

[Margin: Authors of the tables of oblique ascensions.]

Tables of oblique ascensions, further, are given by Ptolemy, Book 2, chapter 8 — but for every ten degrees of the ecliptic, and from the first clime up to an altitude of the pole of 54½°, where the longest day is of 17 hours; by Regiomontanus in the *Directions*, from page 54, from 1° to 60° of polar altitude; by Copernicus, Book 2, chapter 10 — but only for every six degrees of the ecliptic, and from 39° to 57° of altitude of the pole; by Erasmus Reinhold in the *Directions*, page 133, who extends Regiomontanus's table from 61° of polar altitude up to 89°, and at page 174, where he gives tables of oblique ascensions from 16° to 66° of altitude of the pole — but assuming the greatest obliquity of the ecliptic, the Ptolemaic one of 23° 52′, whereas in the rest, just like Regiomontanus, he had assumed an obliquity of 23° 30′, and Copernicus, for his part, 23° 28′; by Clavius in the *Sphere* [?], page 341, from 36° to 60° of altitude of the pole, assuming an obliquity of the ecliptic of 23° 30′; and by Maginus in the *Directions of the primum mobile*, from page 59, from 1° to 66° of altitude of the pole, assuming an obliquity of the ecliptic now the greatest, 23° 52′, now the least, 23° 28′. From page 93, however, Maginus constructs another table for an obliquity of the ecliptic of 23° 31′ 30″, from 1° to 79° of altitude of the pole, and he teaches the use of these tables in canons 11 and 12. This later table he carried over into the *New Tables of Directions*, from page 7, and teaches its use in canon 7 — but only up to 55° of altitude of the pole. Longomontanus gives one in Book 2 of the *Spherics*, page 70, but only for an elevation of the pole of 56°; Argoli, in volume 1 of the *Ephemerides*, page 282, but only for altitudes of the pole of 41° 50′ and 45°; Boulliau in the *Philolaic Tables*, from page 144, beginning from 1° of altitude of the pole and running up to 67°, and for the degrees of four signs, since for the remaining altitudes he gives the ascensional difference. It is worth while, however, to consult Reinhold, precept 25 of the *Directions*, or Clavius above, on the construction of these tables.

124. Probl. Data Poli Altitudine & Aſcenſione aut Deſcenſione Obliqua; Inuenire Punctum Eclipticæ ipſi congruens. *124. Problem. Given the altitude of the pole and the oblique ascension or descension, to find the point of the ecliptic corresponding to it.*

[Margin: Problem 124.]

Look up, in the body of the tables named in the preceding problem, the given oblique ascension or descension under the given altitude of the pole. At the head of the table you will have the sign of the ecliptic, and in the left margin the corresponding degree of the sign.

[Margin: Order of the problems.]
[Margin: Order of the problems.]

125. Probl. Eclipticæ punctum, cum quo Stella Oritur, aut Occidit, inuenire, Datis eius Aſcenſ. ac Deſcenſ. Obliqua, & Altitud. Aequatoris. *125. Problem. To find the point of the ecliptic with which a star rises or sets, given its oblique ascension and descension and the altitude of the equator.*

[Margin: Problem 125.]

Look up, by problem 124, the point of the ecliptic corresponding to the oblique ascension or descension. That is precisely the point with which the star rises, if you have used the ascension, or sets, if you have used the descension. Or else have recourse to problem 5, which I gave in Book 6, chapter 20, in which, however, the obliquity of the ecliptic is also assumed to be known. For stars whose latitude is not greater than 7°, canon 10 of Maginus's *New Directions* can also serve this purpose, together with the table of the difference of rising that he gives in the same place, from page 124 to 312, for altitudes of the pole from 1° to 50°.

126. Probl. Eclipticæ punctum, cum quo Stella oritur aut occidit inquirere, Data Latitudine Longitudine & Declinatione ipſius, atq. Altitudine Poli cum Obliq. Eclipt. *126. Problem. To find the point of the ecliptic with which a star rises or sets, given its latitude, longitude and declination, and the altitude of the pole with the obliquity of the ecliptic.*

[Margin: Problem 126.]

Let the meridian be ALG, the horizon GHL, and the equator FHI, whose northern pole is B and southern pole Z; and let the ecliptic be EKO, whose northern pole is C and southern V. Let the star rise or set at D or at Q, and through it let there be drawn from their poles the quadrants of declination BN and ZR, and of latitude CM and VT. Finally, let BC and ZV be the distance of the poles, that is, as great as the obliquity of the ecliptic. What is now sought is the point K of the ecliptic with which the star D or Q rises or sets.

Diagram. A circle set in the left column beside the text of problem 126, with two small circles on its rim, at upper right and lower left, drawn about the poles of the equator; a horizontal line G–L crosses it, with oblique lines for the equator and ecliptic and quadrants drawn from the poles. Labels read:

- A (above the rim, top), G (outside the rim, left) and L (outside the rim, right): the meridian ALG; G and L also end the horizon GHL
- E (rim, upper left), K (right of centre, on the horizontal line) and O (outside the rim, lower right): the ecliptic EKO
- F (rim, left, below E), H (left of centre, on the horizontal line) and I (rim, lower right): the equator FHI
- B (inside the upper-right small circle): the northern pole of the equator
- Z (inside the lower-left small circle): the southern pole of the equator
- C (right of the upper small circle): the northern pole of the ecliptic

- V (rim, lower left): the southern pole of the ecliptic
- D (on the horizontal line, right of K) and Q (left of centre, on the horizontal line): the star rising or setting
- N (lower right, right of P) and R (inside, left, below T): ends of the quadrants of declination BN and ZR
- M (lower right, below P) and T (inside, upper centre): ends of the quadrants of latitude CM and VT
- S (below H) and P (inside, lower right)

With these laid down: first, in the triangle BDL, right-angled at L, there is given, as a side, the altitude of the pole BL, and, as the base, the complement of the declination BD. Therefore by Rule 4 of spherical right-angled triangles you will find the angle BDL. Second, by problem 66, find the angle BDC — since in this triangle the three sides are given: BC, the distance of the poles; BD, the complement of the declination; and CD, the complement of the latitude — and subtract it from the angle BDL; for there will remain the angle CDL, to which the angle MDK is equal. Third, in the triangle MDK, right-angled at M, the angle already mentioned is given, and the side MD, namely the latitude of the star. Therefore by Rule 7 of spherical right-angled triangles the side MK will become known. Added to the longitude of the star, determined at M by the arc CM, it will give the point K with which the northern star D sets; subtracted, the point with which it rises. But if the star is southern, at Q, the arc TK must be sought in the same way; this, however, subtracted from the longitude T, will give the point of co-setting, and added to it, the point of co-rising. The rest concerning the risings and settings of the stars we shall give in Section 3.

Probl. Punctum Eclipticæ, cum quo Sidus tranſit per Medium cæli, ſeu Mediationem cæli inueſtigare, Data Recta Aſcenſione Sideris: ſeu Arcum Eclipticæ coaſcendentem in Sph. Recta Dato Arcui Aequatoris inuenire, & Tabulas Mediationum condere. 127. 128. 129. 130. *Problems 127, 128, 129, 130. To find the point of the ecliptic with which a star passes through mid-heaven, that is, the mediation of the heavens, given the right ascension of the star; or to find the arc of the ecliptic that rises together with a given arc of the equator in the right sphere; and to construct tables of mediations.*

[Margin: Problem 127.]

This can be obtained in four principal ways. The first and quicker way is by the tables of right ascensions, which some call the mediations of the heavens, of which I spoke at problem 60. For if you look up the given right ascension in the body of those tables, you will find at the head of the table the sign, and at the left side the degree of the sign, with which the star culminates, that is, passes through mid-heaven, even in the oblique sphere; or else the arc of the ecliptic that rises together with the given arc of the equator in the right sphere.

[Margin: Problem 128.]

The second way is by trigonometry. For it, bring back here the figure set out at problems 48 and 76, in which, for the sake of one example, let the star

be at P, and let its right ascension be given, and from it the arc λ♎, which is either the right ascension itself, if this does not exceed 90°, or its argument, if it does, according to the rules given at those same problems. Therefore in the triangle R λ ♎, right-angled at λ, the side λ♎ is given, and moreover the angle ♎, which is the obliquity of the ecliptic. Hence by Rule 9 of spherical right-angled triangles the base R♎ will not remain hidden; it will be either the arc of the ecliptic sought, if the right ascension did not exceed 90°, or, if it did, its argument, belonging to a similar quadrant.

[Margin: Problem 129.]

The third way is likewise by trigonometry, if the angle of the circle of declination with the ecliptic is given, by problems 76 and following, together with the obliquity of the ecliptic. For in the triangle R♎λ of the same figure the angles at R and at ♎ will be given; therefore by Rule 15 of spherical right-angled triangles the base R♎ will become known.

[Margin: Problem 130.]

The fourth way is also trigonometric, if the right ascension of the star is given, and the angle of the ecliptic and the circle of declination, treated from problem 76 onward. For in the triangle already mentioned the side λ♎ will be given, and the opposite angle R; and so by Rule 11 of spherical right-angled triangles the base R♎ will become known. From these a skilled geometer will understand how to proceed in the remaining cases.

[Margin: Authors of the tables.]

For transit of this kind through mid-heaven, that is, for mediation, tables had been given by Maginus, in the *Introduction to the Ephemerides*, page 145 of the Latin and 166 of the Italian, but for the year 1581, and relying on the Copernican places of the stars; by Longomontanus, Book 2 of the *Spherics*, chapter 4, at the end of problem 2, but for the year 1630, relying on the Tychonic places of the stars; by Argoli as well, volume 1, chapter 29, for the year 1640, likewise relying on the Tychonic places; and finally by Franciscus Montebrunus, at the end of volume 2 of the *Ephemerides*, for the year 1650, but using Lansbergen's places of the stars.

131. Problema. Longitudinem ac Latitudinem Stellæ inuenire, aut Aſcenſionem Rectam & Declinationem, per Duas Stellas notæ Longitud. ac Latitud. vel Aſc. Rectæ ac Declinationis, in eadem recta linea cum ſtella ignoti loci exiſtentes, & Diſtantiam ignotæ ab vna notarum. *131. Problem. To find the longitude and latitude of a star, or its right ascension and declination, by means of two stars of known longitude and latitude, or of known right ascension and declination, which stand in the same straight line with the star of unknown place, and by means of the distance of the unknown star from one of the known ones.*

[Margin: Problem 131.]

Let the poles of the ecliptic be V and R, and let GH be a portion of the ecliptic. Let the observed star be I, in a straight line with two known fixed stars,

A and B, or C and O, through which let the semicircles of latitude VBR, VOR, VIR, VCR and VAR be drawn.

Diagram. A lens-shaped figure of semicircles of latitude set in the right column beside the text of problem 131, all meeting at V at the top and R at the bottom, crossed by a horizontal line G–H; stars are drawn at A, O, I, C and B. Labels read:

- V (top point) and R (bottom point): the poles of the ecliptic
- G (outside, left end of the horizontal line) and H (outside, right end): the portion GH of the ecliptic
- I (left of centre, with a star): the observed star
- A (left, with a star) and B (lower right of centre, with a star): one pair of known fixed stars
- C (lower left, with a star) and O (upper centre, below a star): the other pair of known fixed stars
- P (right of centre, above the line): with VP a quadrant and PB the latitude of B
- M (left, just above the line), N and S (small, on the line right of M), L (below the line, right of C)

[Margin: Step 1.]

Now, if the star I is in a straight line with the stars A and B, consider the triangle VAB, in which the sides are given: AV, the complement of the latitude AG of the star A; and VB, which in our case is the sum of the quadrant VP and the latitude PB. The angle AVB is known from the difference of the longitudes of the stars A and B. Therefore, by Rule 4 of

[Margin: Order of the problems.]

spherical oblique-angled triangles, find the base AB, that is, the distance of the stars, unless it is already known from the observations, ours or others', adduced in Book 6, chapter 10. Then, by Rule 5 or 6 of the same triangles, find the angles VAB and VBA.

[Margin: Step 2.]

Second, subtract the distance of the unknown star I from either A or B, and AI or IB will remain. Therefore, in the triangle VAI, from the givens VA, the complement of the latitude of the star A, the distance AI, and the included angle VAI, you will find by Rule 4 of oblique spherical triangles the base VI, which is the complement of the latitude IS of the star I; and by Rule 5 or 6 the angle AVI, which measures the difference of longitude, to be added to the longitude of the star A, the more westerly, so that the longitude of the star I may become known. Similarly, in the triangle VIB, from the given distance IB, the side VB, and the angle VBI already found, you will find by Rule 4 the base VI, that is, the complement of the latitude of the star I, and the angle BVI, which measures the difference of longitude, to be subtracted from the longitude of the star B, the more easterly, so that the longitude of the star I may become known. From these you will gather how to proceed in other similar cases.

[Margin: On right ascension and declination.]

Moreover, whatever has been said so far of longitude and latitude holds entirely of right ascension and declination, if the names and functions of the poles, and of the arcs or angles, of longitude are exchanged for those of right ascension, and those of latitude for those of declination.

132, Longitudinem ac Latitudinem Stellæ inuenire, aut Aſc. Rectam & Declinat. ope 4. Fixarum notæ Longitud ac Latitud. vel Aſc. Rectæ & Declinat. Quarum binæ ſint in eadem recta Linea cum Stella ignoti loci, & alteræ binæ in altera recta linea cum eadem Stella. *132. To find the longitude and latitude of a star, or its right ascension and declination, by means of four fixed stars of known longitude and latitude, or of known right ascension and declination, two of which are in the same straight line with the star of unknown place, and the other two in another straight line with the same star.*

[Margin: Problem 132.]

In the preceding problem the distance of the star from one of the fixed stars was required; here it is not required, and the business can be completed by means of two threads stretched crosswise before the eye, and a straight line in which, together with the star of unknown place, there are two stars on one side and two on the other. This is easier still if the distances of the fixed stars from one another are already known from Book 6, chapter 10. Otherwise an analysis of 7 triangles must be swallowed; but the tedium of the calculation is relieved by the ease of the observation, which needs no instruments. So, in the figure of the preceding problem, let everything be set out as it is there, and let the star be at I, standing in the straight line AIB with the stars A and B, and in the straight line CIO with the stars C and O.

[Margin: Step 1.]

First, then, find by the preceding problem the distance AB, unless you already know it, and the angle VBA.

[Margin: Step 2.]

Second, in the triangle CRO, find by the same problem 131 the distance CO, unless it is known, and the angle RCO, whose supplement to a semicircle is the angle VCO.

[Margin: Step 3.]

Third, in the triangle BLP, right-angled at P, in which there are given the angle B already found and the side BP, namely the latitude of the star B, find the angle PLB by Rule 8 of spherical right-angled triangles, and the side PL by Rule 7.

[Margin: Step 4.]

Fourth, in the triangle CMN, right-angled at M, in which there are given the angle found at C and the side CM, known from the latitude of the star C, find by the same Rule 8 the angle MNC, and by Rule 7 the side MN.

[Margin: Step 5.]

Fifth, when the sides PL and MN have been joined, let their sum be subtracted from the whole MP, that is, from the difference of longitude of the stars C and B, and the portion NL will be known.

[Margin: Step 6.]

Sixth, in the triangle NIL there are given the portion NL, from step 5, and the angles at N and L, from steps 3 and 4; therefore find the side NI by Rule 10 of oblique-angled spherical triangles.

[Margin: Step 7.]

Seventh, in the triangle NIS, right-angled at S, there are given the angle N, by step 4, and the base NI, by step 6. Therefore find by Rule 1 of spherical right-angled triangles the side IS, which is the latitude of the star I, and by Rule 2 of the same the side NS. If you add to it the side MN, known from step 4, the arc MS will result, to be added to the longitude of the star C, the more westerly, so that the longitude of the star I may become known. From this you will learn the method to be kept in other cases,

[Margin: On right ascension and declination.]

and how the right ascension and declination are to be gathered, if the names and functions of longitude are exchanged for those of right ascension, and those of latitude for those of declination. And let V and R be the poles of the equator, and GH a portion of it, cut at G, M, S, L and P by the circles of declination drawn through all the stars, and so on. Since these things are easy, and the reader is supposed to be already well practised in what precedes, there is no reason to set them out more fully here.

Probl. Punctum Eclipticæ Culminans, eiuſque Altitudinem meridianam inuenire, Datis 133. Aſcenſione Recta Medij Cæli 134. Solis loco; Azimutho, & Altitudine, cum Angulo Eclipticæ & Verticalis per Solem ducti. 135. Solis loco, Declinatione, ac Tempore 136. Puncto Eclipticæ Oriente aut Occidente, Anguloque ipſius cum Horizonte, & Amplitudine Ortiua, aut Occidua. *Problems. To find the culminating point of the ecliptic and its meridian altitude, given: 133. the right ascension of mid-heaven; 134. the place of the Sun, its azimuth and altitude, with the angle of the ecliptic and of the vertical drawn through the Sun; 135. the place of the Sun, its declination, and the time; 136. a point of the ecliptic rising or setting, with its angle with the horizon, and its rising or setting amplitude.*

[Margin: Problem 133.]

First, if the right ascension of mid-heaven is given, by one of the methods of problems 108 to 113, or is known in some other way, look it up in the body of the tables of right ascensions: for at the head you will have the sign, and in the left margin the degree of the sign, that is, the culminating point, the one passing through the meridian.

[Margin: Problem 134.]

Second, for problem 134. In the following figure [?] let the meridian be HVRC, the horizon HBR, and the ecliptic EBC, on which let the Sun be at S.

Through the Sun's centre let there pass the quadrant VSA of the vertical circle, and from the northern pole of the world P the portion PS of a great circle, which will be either the complement of the northern declination, if the Sun is in the northern signs; or the sum of a quadrant and the southern declination, if it is in the southern signs; or a quadrant, if it is on the equator. Therefore, in the triangle ESV, the portion ES of the ecliptic must be obtained; added to the place of the Sun S, if the Sun is in the western quadrant, or subtracted, if in the eastern, it will give the culminating point [?] of the ecliptic.

Diagram. A circle set in the right column beside the text of problem 134, crossed by a near-horizontal line from H to R, with arcs for the ecliptic, the vertical through the Sun, and a great circle from the pole P. Labels read:

- H (outside the rim, left), V (rim, top), R (outside the rim, right) and C (outside the rim, lower right): the meridian HVRC
- H, B (below the line, right of centre) and R: the horizon HBR
- E (outside the rim, upper left), B and C: the ecliptic EBC; E is also the culminating point, with HE its meridian altitude
- S (inside, upper left): the Sun
- V, S and A (inside, left, on the line): the quadrant VSA of the vertical circle
- P (rim, upper right): the northern pole of the world, with PS a portion of a great circle
- M (above the rim, left of V), O (outside the rim, left, below E), K (inside, right, just above the line) and I (below B, near the rim)

You will obtain ES because there are given SV, the complement of the Sun's altitude; SVE, the Sun's azimuth; and ESV, the angle of the ecliptic and the vertical (or else found from problems 89 to 98). Therefore by Rule 11 or 12 of oblique spherical triangles the side ES will become known, and EV, the complement of the meridian altitude HE of the point E.

[Margin: Problem 135.]

Third, for problem 135, consider the triangle SPE, in which the angle PSE is given: for from the place of the Sun on the ecliptic the angles of the ecliptic and the meridian, that is, the circle of declination, are given by problem 14, or 76 to 83. And from the time before or after noon, converted into degrees of the equator, the angle SPE is given; finally, from the declination of the Sun, SP is given. Therefore by Rule 11 or 12 of oblique-angled spherical triangles the side ES will become known; added to the place of the Sun when it is western, or subtracted from the place of the Sun when it is eastern, it will give the culminating point of the ecliptic. And when VP, the complement of the altitude of the pole, is taken from the arc EP, there will remain EV, the complement of the meridian altitude HE of the culminating point E.

[Margin: Problem 136.]

Fourth, for problem 136, look at the triangle HBE, right-angled at H, in which, from the rising or setting point B, the angle HBE, which the ecliptic makes with the horizon, is given by the tables or by the problems that follow.

Moreover, from the rising or setting amplitude the arc HB is given. This arc either is, according to some, the rising or setting amplitude itself; or it is made up of that amplitude and a quadrant, if the point B is on this side of the equator; or it is the remainder of a quadrant from which the rising or setting amplitude of the point B, situated beyond the equator, has been taken. With these given, find by Rule 9 of spherical right-angled triangles the base BE, and by Rule 7 the side HE, which is the meridian altitude of the culminating point E. This point is known if you add the base BE to the place of the point B when it is setting, or subtract it from the place of the point B when it is rising. It will help, however, to use a globe, so that you may see more quickly how to proceed.

[Margin: Order of the problems.]

137. Probl. Punctum Eclipticæ imum Cæli obtinens, eiuſque Depreſſionem inuenire. *137. Problem. To find the point of the ecliptic that occupies the lowest point of the heavens [imum caeli], and its depression.*

[Margin: Problem 137.]

Find by problems 133 to 136 the culminating point and its meridian altitude. For the point of the ecliptic diametrically opposite to it, that is, 180° distant from the culminating point, will be the one found in the hidden part of the meridian; and its depression will be as great as the meridian altitude of the culminating point.

138. Probl. Puncti Eclipticæ Culminantis Altitudinem Meridianam inuenire, Data eius Declinatione, & Altitudine Poli. *138. Problem. To find the meridian altitude of the culminating point of the ecliptic, given its declination and the altitude of the pole.*

[Margin: Problem 138.]

In the figure of problem 134, let the given declination of the culminating point E of the ecliptic be either northern, EO, or southern, EM; and let the point of the equator passing through the meridian be either M, whose altitude is HM (which, of course, is known if you subtract the altitude of the pole from 90°), or O, whose altitude is HO, known in the same way. Therefore subtract the southern declination EM from the altitude HM of the equator, or add the northern declination EO to the altitude HO of the equator, and you will have the meridian altitude HE of the point E.

139. Probl. Punctum Eclipticæ Oriens vel Occidens inuenire, Datis Solis aut puncti noti Eclipticæ Culminantis Altitud. meridiana, cum angulo Eclipticæ & Meridiani. *139. Problem. To find the rising or setting point of the ecliptic, given the meridian altitude of the Sun, or of a known culminating point of the ecliptic, with the angle of the ecliptic and the meridian.*

[Margin: Problem 139.]

In the figure immediately preceding, the triangle HBE is right-angled at H, and in it there are given the altitude HE of the Sun or of the point E, and

also the angle HEB, of the ecliptic and the meridian. Therefore by Rule 9 of spherical right-angled triangles obtain the base BE; add it to the place of the Sun or of the point E, and you will have the rising point B of the ecliptic; subtract it, and you will have the setting point. If the rising amplitude of the point B were given, and from it the arc HB, this could be done another way; but that amplitude is not usually given unless the point B is known first.

140. Probl. Punctum Eclipt. Oriens vel Occidens inuenire, Datis Tempore à Meridie, & loco Solis, cum Altitudine Poli. *140. Problem. To find the rising or setting point of the ecliptic, given the time from noon and the place of the Sun, with the altitude of the pole.*

[Margin: Problem 140.]

Under the given altitude of the pole, look up the semidiurnal arc in its own tables, and also the oblique ascension corresponding to the place of the Sun in the tables of oblique ascensions, which are treated at problem 123. Finally, convert the given time from noon into degrees of the equator, and combine these three into one sum, casting off 360° if the sum exceeds them. Then enter the body of the tables of oblique ascensions with the sum already mentioned, or with its remainder, under the given altitude of the pole: for at the head you will have the sign, and in the left margin the degree, that is, the rising point of the ecliptic, from which the setting point is 180° distant.

141. Probl. Punctum Eclipticæ Oriens & Occidens inuenire, Datis Altitudine Aequatoris, Obliquitate Eclipticæ, & Tempore ante vel poſt meridiem ex Sidere notæ Aſcenſ. Rectæ. *141. Problem. To find the rising and setting point of the ecliptic, given the altitude of the equator, the obliquity of the ecliptic, and the time before or after noon taken from a star of known right ascension.*

[Margin: Problem 141.]

If the star from which the time is known is eastern, you will look for the rising point of the ecliptic; if western, the setting point; for the one is 180° from the other along the ecliptic. Now in the accompanying diagram let the meridian be HARK, the horizon GFR, and the equator AGQ; and first let the intersection with the equator of the portion ZO or TF of the ecliptic standing above the horizon be at C, whether vernal or autumnal. Through the star from which the time was taken, whether it is on the ecliptic or off it, as at L, let there be drawn the circle of declination PLD, through the poles of the equator P and D, which will determine the right ascension of that same star at G.

[Margin: Step 1.]

First, then, the arc GC of the equator will be known, namely the distance of the point G from the nearer equinox; and from the time before or after noon, converted into degrees of the equator, the arc GA is known, whose complement to 90° is the arc GB. Add to it the arc GC, and the arc CB becomes known.

[Margin: Step 2.]

Second, if the star is eastern and the intersection C vernal, or western and the intersection C autumnal, use the triangle CBO, in which, besides the side or base CB, there are given the angle BCO, the angle of the obliquity of the ecliptic, and the angle CBO, the supplement to two right angles of the angle ABH, which measures the altitude of the equator. Therefore by Rule 11 or 12 of oblique-angled spherical triangles the side CO will become known, that is, the distance of the point O, rising or setting, from the nearer equinox.

Diagram. A circle set in the right column beside the text of problem 141, crossed by a near-horizontal line from H to R, with arcs for the equator, the ecliptic and the circle of declination, and a small star drawn below L. Labels read:

- H (outside the rim, left end of the line), A (top), R (outside the rim, right end of the line) and K (below the rim, bottom): the meridian HARK
- G (just above the line, left of centre), F (just below the line, left of centre) and R: the horizon GFR, as printed
- A, G and Q (bottom, right of K): the equator AGQ; G is also where the circle of declination meets the equator
- Z (above the rim, top left), O (below the line, right of B), T (top, right of A) and F: the portions ZO and TF of the ecliptic
- C (inside, upper half, left of centre): the intersection of the ecliptic and the equator above the horizon
- L (inside, right of C, with a star): the star off the ecliptic
- P (rim, upper right) and D (rim, lower left): the poles of the equator, on the circle of declination PLD
- B (below the line, right of F): the point of the arcs GB and CB and of the angles CBO, ABH and FBC
- M (inside, lower half, below O): the intersection below the horizon
- S (bottom, right of Q)

But if the star is eastern but the intersection C autumnal, or western and the intersection vernal, use the triangle CBF, in which, besides CB, there are given the obliquity of the ecliptic BCF and the angle FBC, from the altitude of the equator. Therefore by Rule 11 or 12 of the same triangles find FC, the distance of the point F, rising or setting, from the nearer equinox.

But if the intersection of the ecliptic and the equator is below the horizon, as at M, the right ascension will give the arc GM, namely the distance of the point G from the nearer equinox, and the time, as above, will give the arc AG, and from it GB. When GB is subtracted from the arc GM, the arc BM will be known. With it, in the triangle BMO or BMF, and with the angles set up — that of the obliquity at M, and that of the altitude of the equator, or its complement, at B — you will find by the same Rule 11 or 12 the arc MO or MF, that is, the distance along the ecliptic of the rising or setting point from the nearer equinox M.

Probl. Punctum Eclipticæ Oriens aut Occidens inuenire duobus modis, Datis Loco Solis, & Tempore apparenti poſt meridiem, cum Altitudine Poli. 142. 143. *Problems 142 and 143. To find the rising or setting point of the ecliptic in two ways, given the place of the Sun and the apparent time after noon, with the altitude of the pole.*

[Margin: Problems 142 and 143.]

I taught the first of these ways in Book 5, chapter 10, number 5, and the second in the same place, number 6, by the tables of houses. And opposite the rising point lies the setting point, 180° distant from it.

Probl. Punctum Aequatoris Oriens & Occidens inuenire, Datis 144. Aſc. Recta Medij Cæli 145. Aſc. Recta ſideris, eiuſq. Diſtãtia Aequatoria à Meridiano. *Problems. To find the rising and setting point of the equator, given: 144. the right ascension of mid-heaven; 145. the right ascension of a star and its equatorial distance from the meridian.*

[Margin: Problem 144.]

Add 90° to the right ascension of mid-heaven, and you will have the rising point of the equator; subtract 90° from the same right ascension of mid-heaven, and you will have the setting point of the equator.

[Margin: Problem 145.]

If the equatorial distance of a star from the meridian, known either from the time before or after noon (as happens with the Sun) or from some other source, is a quadrant, that is, 90°, the right ascension of the star itself will give the rising point of the equator if the star is eastern, and the setting point if it is western. But if the distance is less than a quadrant, its complement to 90°, added to the right ascension of an eastern star, will give the rising point of the equator; subtracted from the right ascension of a western star, it will give the setting point. But if the distance of the star from the meridian exceeds a quadrant of the circle, its excess over 90°, subtracted from the right ascension of an eastern star, will give the rising point of the equator; added to the right ascension of a western star, it will give the setting point.

[Margin: Order of the problems.]

146.Probl. Aſcenſionem Obliquam Horoſcopi, ſeu Puncti Eclipticæ Aſcendentis inuenire, Dato Loco Solis, & Tempore à meridie. *146. Problem. To find the oblique ascension of the horoscope, that is, of the ascending point of the ecliptic, given the place of the Sun and the time from noon.*

[Margin: Problem 146.]

Find the right ascension of the given place of the Sun by the tables reviewed at problem 16, and add to it the hours from noon converted into degrees of the equator; the result will be the right ascension of mid-heaven, casting off, however, 360° if it exceeds them. Add to this ascension a quadrant, that is, 90°, and the result will be the oblique ascension of the horoscope.

Probl. Angulum Eclipticæ & Horizontis inueſtigare, Datis 147. Puncti Eclipticæ Culminantis Altitudine meridiana, & Angulo Eclipt. ac Meridiani 148. Puncti Eclipt. Culminantis angulo Eclipt. ac Meridiani & Puncti Eclipt. in Horizõte poſiti Amplitudine ortiua vel occidua 149. Puncti Eclipt. Culminantis angulo Eclip. ac Merid. & Puncto Eclipticæ Oriente aut Occidente. 150. Puncti Eclipticæ Culminantis Altitudine meridiana, & puncti Eclipt. Orientis, vel Occidentis Amplitud. ortiua, vel occid. 151. Puncti Eclipticæ Culminãtis Altitud. meridiana, & Pũcto Eclipticæ Oriente vel Occidente 152. Puncti Eclipticæ Orientis vel Occidentis Amplitud. ortiua vel occidua, & Puncto Eclipt. Culminante. *Problems. To investigate the angle of the ecliptic and the horizon, given: 147. the meridian altitude of the culminating point of the ecliptic, and the angle of the ecliptic and the meridian; 148. the angle of the ecliptic and the meridian at the culminating point of the ecliptic, and the rising or setting amplitude of the point of the ecliptic standing on the horizon; 149. the angle of the ecliptic and the meridian at the culminating point of the ecliptic, and the rising or setting point of the ecliptic; 150. the meridian altitude of the culminating point of the ecliptic, and the rising or setting amplitude of the rising or setting point of the ecliptic; 151. the meridian altitude of the culminating point of the ecliptic, and the rising or setting point of the ecliptic; 152. the rising or setting amplitude of the rising or setting point of the ecliptic, and the culminating point of the ecliptic.*

Let the figure set out at problem 134 be repeated here, in which the culminating point of the ecliptic is E, its meridian altitude HE, and the angle of the ecliptic and the meridian HEB, while the rising or setting point of the ecliptic is B. When B is given together with the point E, the difference along the ecliptic shows the base EB in the triangle EHB, right-angled at H; in this triangle, from the given point B, the rising amplitude is known, and from it, in turn, the side HB. Now the angle HBE is sought, which can be had by the rules of spherical right-angled triangles written below, according to the order of the givens.

Diagram. The woodcut of problem 134 set again in the left column beside the text of problems 147–152: a circle crossed by a near-horizontal line from H to R, with arcs for the ecliptic, the vertical, and a great circle from the pole P. Labels read:

- E (outside the rim, upper left): the culminating point, with HE its meridian altitude and HEB the angle of the ecliptic and the meridian
- B (below the line, right of centre): the rising or setting point, with EHB the triangle right-angled at H and HB its side on the horizon
- H (outside the rim, left end of the line) and R (outside the rim, right end): with PR the altitude of the pole and BPR the triangle right-angled at R (problem 153)
- P (rim, upper right): with PB the complement of the declination of B (problem 153)
- C (outside the rim, lower right): in the angles PBC and RBC (problem 153)

- S (inside, upper left): the nonagesimal degree, with BS a quadrant (problems 154–155)
- A (inside, left, on the line) and V (rim, top): with ASB the triangle right-angled at A, AS the altitude of the nonagesimal, SV its distance from the vertex, and VA the circle of altitude (problems 154–155)
- M (above the rim, left of V), O (outside the rim, left, below E), K (inside, right, just above the line) and I (below B, near the rim)

Order of the problems	Data for the angle EBH	Rules
147	Angle HEB, side HE	8
148	Angle HEB, side HB	12
149	Angle HEB, base EB	3
150	Side HE, side HB	14
151	Side HE, base EB	4
152	Side HB, base EB	5

[Margin: Problems 147, 148, 149, 150, 151, 152.]

153.Probl. Angulum Eclipticæ & Horizontis inuenire, Datis Puncto Eclipticæ Oriente vel Occidente, ipſiuſq. Declinatione & Alt. Poli. Et Tabulas huius Anguli cõſtruere. *153. Problem. To find the angle of the ecliptic and the horizon, given the rising or setting point of the ecliptic, its declination, and the altitude of the pole; and to construct tables of this angle.*

[Margin: Problem 153.]

In the preceding figure let B be the rising or setting point of the ecliptic. The complement of its given declination is the base PB in the triangle BPR, right-angled at R, in which the side PR is given, which is the altitude of the pole. Therefore by Rule 4 of spherical right-angled triangles find the angle PBR, and add it to the angle PBE, known from the point B (for it is as great as the angle of the ecliptic and the meridian, treated at problem 14, or the angle of the ecliptic and the circle of declination, treated from problem 76 onward); and the angle EBR will result, whose supplement to two right angles is the angle sought, EBH. Or, if from the angle PBC, known from the angle of the ecliptic and the meridian, that is, the circle of declination, you subtract the angle PBR, there remains RBC, equal to the angle sought, EBH.

It is chiefly by this device that the table of the angle of the orient is constructed for each altitude of the pole — that is, of the angle of the ecliptic and the horizon made in the east. The angle made in the west by the ecliptic and the horizon is always equal to it, speaking of angles of the same kind and comparing acute with acute, as Regiomontanus shows in the *Epitome of the Almagest*, Book 2, proposition 35. And in the same place, proposition 36, he demonstrates that the external eastern angle taken together with the internal western, or the internal eastern together with the external western, are equal to two right angles.

[Margin: Authors of the table [?] of this angle.]

Furthermore, a table of such angles is given by Copernicus, Book 2, chapter 10, from a polar altitude of 39° to 57°, for every sixth degree of the signs; by Maginus, in the *Tables of Directions of the primum mobile*, from folio 200 on, for each degree of the rising signs, and from an altitude of the pole of 30° to 51°; and by Kepler, in the *Rudolphine Tables*, folio 26, for each altitude of the pole and for every third degree of the rising signs. This last table was reproduced by Reinerus [Vincenzo Renieri] in the new *Medicean Tables*, page 324, and by Boulliau in the *Philolaic Tables*, page 158. On their use see what I said in Book 5, chapter 10, number 8.

154. Probl. Angulum Eclipticæ & Horizontis inuenire, Data Nonageſimi Eclipticæ gradus ab Horizonte computati Altitud. aut Diſtantia à vertice. *154. Problem. To find the angle of the ecliptic and the horizon, given the altitude, or the distance from the vertex, of the nonagesimal degree of the ecliptic reckoned from the horizon.*

[Margin: Problem 154.]

In the figure immediately preceding, let S be the nonagesimal degree reckoned from the horizon point B, so that the base BS is 90°. Therefore in the triangle ASB, right-angled at A, if the altitude AS of the nonagesimal is given, known either by itself or through its complement SV, which is the distance of the nonagesimal from the vertex, the angle sought, ABS, will also be given by Rule 4 of spherical right-angled triangles.

155. Probl. Diſtantiam Nonageſimi Eclipticæ gradus à Vertice vel eius Altitudinem inuenire Modis 7. & de Tabula Diſtantiæ huius vel Altitud. *155. Problem. To find the distance of the nonagesimal degree of the ecliptic from the vertex, or its altitude, in 7 ways; and on the table of this distance or altitude.*

[Margin: Problem 155.]

The altitude of the nonagesimal degree of the ecliptic, reckoned from the horizon, subtracted from 90°, gives its distance from the vertex. The altitude of the nonagesimal itself can be found in as many ways as the angle of the ecliptic and the horizon can be found — not, however, by the ways that presuppose the altitude of the nonagesimal — namely by problems 147, 148, 149, 150, 151, 152 and 153. The reason is that in the preceding figure the distance of the nonagesimal S along the ecliptic from the horizon, namely the arc BS, is a quadrant, since it amounts to 90°; while the circle of altitude VA makes a right angle with the other arc of the horizon, AB, just as it does with BS. Therefore the angles at A and S are right, and so, by the properties of spherical triangles, AB is a quadrant, and the angle ABS is the measure of the altitude AS. Hence the tables of the angle of the ecliptic and the horizon, treated at the end of problem 153, serve as they stand for the altitude of the nonagesimal. Besides these, Nicolaus Mulerius, in the *Frisian Tables*, page 448, gives a table of the distance of the nonagesimal both from the vertex and from the meridian; so, by subtracting the distance from the vertex from 90°, the altitude of the nonagesimal remains. But he

gives the table from an altitude of the pole of 42° to 56°, whereas our own Petavius [Denis Pétau], in Book 8 of *De doctrina temporum*, page 735, extends it from an altitude of 31° to 51°.

[Margin: Order of the problems.]

Probl. Angulum Meridiani & Verticalis per Nonageſimum Eclipt. gradum ducti inueſtigare, ideſt Azimuthum Nonageſimi; Datis 156. Altitudine puncti Eclipticæ Culminantis, & Arcu Eclipticæ inter Meridianum ac Nonageſimum 157. Diſtantia Nonageſimi à Vertice, & Arcu Eclipt. inter Meridianũ ac Nonageſimum 158. Diſtantia Nonageſimi à Vertice, & Altitudine puncti Eclipt. Culminantis 159. Angulo Eclipticæ & Meridiani noto ex puncto Eclip.. culminante, & Diſtantia Nonageſimi à Vertice 160. Angulo eodem, & Arcu Eclipticæ inter Meridianum ac Nonageſimum 161. Angulo eodem, & Altitudine puncti Eclipticæ Culminantis. *Problems. To investigate the angle of the meridian and the vertical drawn through the nonagesimal degree of the ecliptic, that is, the azimuth of the nonagesimal, given: 156. the altitude of the culminating point of the ecliptic, and the arc of the ecliptic between the meridian and the nonagesimal; 157. the distance of the nonagesimal from the vertex, and the arc of the ecliptic between the meridian and the nonagesimal; 158. the distance of the nonagesimal from the vertex, and the altitude of the culminating point of the ecliptic; 159. the angle of the ecliptic and the meridian, known from the culminating point of the ecliptic, and the distance of the nonagesimal from the vertex; 160. the same angle, and the arc of the ecliptic between the meridian and the nonagesimal; 161. the same angle, and the altitude of the culminating point of the ecliptic.*

Taking up again the figure we set out at problem 153, consider the triangle EVS, right-angled at S. It is right-angled because the vertical circle AV, drawn through the nonagesimal S, makes a right angle at S with the ecliptic EC, since it is the same as the circle of latitude, as is clear from what was said in Book 5, chapter 10, Theorem 1. In this triangle the angle EVS is sought, from any two of the four remaining parts of the triangle. These are: the base EV, which is the complement to 90° of the altitude HE of the culminating point E; the side ES, that is, the arc of the ecliptic lying between the meridian and the nonagesimal S; the side SV, namely the distance of the nonagesimal from the vertex, which is the complement of the altitude AS, known from problem 155; and finally the angle SEV, which the ecliptic makes with the meridian, and which is known by problem 14 if the point E of the ecliptic is known. Which of the angles at E serves, an inspection of the astronomical globe will show. With this laid down, we shall indicate in our usual way the rules of spherical right-angled triangles by which the angle EVS can be found, according to the givens that serve the problems set out in order.

Amplitud. Ortiua vel Occidua 171. Angulo Eclipticæ, & Horizontis; & Altitud. puncti Eclipt Culmin. 172. Angulo Eclipticæ & Horizontis; & puncti Aſcend vel Deſcendentis Amplitudine Ortiua, vel Occidua 173. Altitudine puncti Eclipticæ Culminantis; & puncti Aſcendentis, aut Deſcendentis Amplitudine Ortiua vel Occidua. *Problems. To find the arc of the ecliptic between the meridian and the nonagesimal, and also between the meridian and the horizon, given: 162. the angle of the ecliptic and the meridian, from the culminating point, and the altitude of the culminating point of the ecliptic; 163. the same angle, and the altitude of the nonagesimal; 164. the same angle, and the angle of the meridian and the vertical drawn through the nonagesimal; 165. the altitude of the culminating point of the ecliptic, and that of the nonagesimal; 166. the altitude of the culminating point of the ecliptic, and the angle of the meridian and the vertical drawn through the nonagesimal; 167. the altitude of the nonagesimal, and the angle of the meridian and the vertical drawn through the nonagesimal; 168. the angle of the ecliptic and the meridian, and the angle of the ecliptic and the horizon; 169. the angle of the ecliptic and the meridian, and the altitude of the culminating point of the ecliptic; 170. the angle of the ecliptic and the meridian, and the rising or setting amplitude of the ascending or descending point; 171. the angle of the ecliptic and the horizon, and the altitude of the culminating point of the ecliptic; 172. the angle of the ecliptic and the horizon, and the rising or setting amplitude of the ascending or descending point; 173. the altitude of the culminating point of the ecliptic, and the rising or setting amplitude of the ascending or descending point.*

Let the figure set out at problem 153 be called back here. In it, if the arc ES is obtained, which lies between the meridian HVR and the nonagesimal S, that arc, added to the quadrant SB, will make up the arc EB of the ecliptic

between the meridian and the horizon. Conversely, if the arc EB of the ecliptic intercepted between the meridian and the horizon is obtained, then, when the quadrant SB, that is, 90°, is taken away, the arc ES between the meridian and the nonagesimal will remain.

[Margin: For the arc ES.]

Furthermore, the arc ES can be obtained in the triangle [?] ESV, right-angled at S, from pairs of the four givens — EV, the complement of the altitude HE of the culminating point; VS, the complement of the altitude of the nonagesimal; the angle SEV of the ecliptic and the meridian, known from the culminating point E; and the angle EVS of the meridian and the vertical VA drawn through the nonagesimal S — if the rules of spherical right-angled triangles written below are applied.

Diagram. The woodcut of problems 134 and 147–155 set again in the right column beside the text for problems 162–173: a circle crossed by a near-horizontal line from H to R, with arcs for the ecliptic, the vertical, and great circles from the pole P. Labels read:

- E (outside the rim, upper left): the culminating point, with HE its altitude, SEV the angle of the ecliptic and the meridian, and HEB the same angle in the triangle EBH
- V (rim, top): the vertex, with EV the complement of the altitude of E, VS the complement of the altitude of the nonagesimal, and VA the vertical through S
- S (inside, upper left): the nonagesimal, with ES the arc of the ecliptic from the meridian to the nonagesimal, SB a quadrant, and EVS the triangle right-angled at S
- H (outside the rim, left end of the line) and R (outside the rim, right end): with HVR the meridian, EBH the triangle right-angled at H, and HB the rising or setting amplitude of B
- B (below the line, right of centre): the rising or setting point, with EB the arc of the ecliptic between the meridian and the horizon, and HBE the angle of the ecliptic and the horizon
- A (inside, left, below the line): with AS the altitude of the nonagesimal
- C (outside the rim, lower right): with EC the ecliptic
- M (above the rim, left of V), P (rim, upper right), O (outside the rim, left, below E), K (inside, right, just above the line) and I (below B, near the rim)

The arc EB, on the other hand, is obtained in the triangle EBH, right-angled at H, from pairs of the four givens: HE, the altitude of the culminating point E; HEB, the angle of the ecliptic and the meridian, known from the culminating point E; the angle HBE, of the ecliptic and the horizon; and HB, the rising amplitude of the point B when it is rising, or the setting amplitude when it is setting; or let the rules of spherical right-angled triangles written below be followed. Remember, however, that if the rising amplitude is less than a

quadrant, the nonagesimal is in the western quadrant; if greater, in the eastern. The contrary of these happens with the setting amplitude.

[Margin: For the arc EB.]

[Margin: 168, 169, 170, 171, 172, 173.]

A table for this arc ES, however, constructed from a polar altitude of 51° to 55°, is given by Mulerius in the *Frisian Tables*, page 448.

[Margin: Table of this arc.]

[Margin: Order of the problems.]

Probl. Amplitudinem Ortiuam Horoſcopi, vel Occiduam puncti Eclipticæ occidentis Inuenire, Datis 174. Azimutho Nonageſimi, de quo Prob. 156. 175. Angulo Eclipt. & Horizontis, & Altitud. puncti Eclipticæ Culminantis 176. Angulo Ecl. & Horiz. & Arcu Eclipticæ inter Meridianum & Horizontem 177. Angulo Ecl. & Horiz. & Angulo Eclip. ac Meridiani 178. Angulo Eclipt. & Meridiani, & Altitud. puncti Eclipticæ Culminantis 179. Angulo Eclipticæ & Meridiani, & Arcu Eclipt. inter Merid. & Horizontem. 180. Altitudine puncti Eclipticæ Culminantis, & Arcu Eclipt. inter Merid. & Horiz. *Problems. To find the rising amplitude of the horoscope, or the setting amplitude of the setting point of the ecliptic, given: 174. the azimuth of the nonagesimal, treated at problem 156; 175. the angle of the ecliptic and the horizon, and the altitude of the culminating point of the ecliptic; 176. the angle of the ecliptic and the horizon, and the arc of the ecliptic between the meridian and the horizon; 177. the angle of the ecliptic and the horizon, and the angle of the ecliptic and the meridian; 178. the angle of the ecliptic and the meridian, and the altitude of the culminating point of the ecliptic; 179. the angle of the ecliptic and the meridian, and the arc of the ecliptic between the meridian and the horizon; 180. the altitude of the culminating point of the ecliptic, and the arc of the ecliptic between the meridian and the horizon.*

[Margin: Problem 174.]

Look at the figure immediately preceding, and at the explanation given for the arc EB. If, then, the azimuth AVH is given, by problems 156 to 161, since it measures the arc HA, add that arc to 90°, that is, to the quadrant AB; and the result will be the rising amplitude of the point B when it is rising, if the nonagesimal is in the eastern quadrant, or when it is setting, if it is in the western. Conversely, subtract the arc HA from 90°, and you will have the rising amplitude of the point B when it is rising, if the nonagesimal is in the western quadrant, or when it is setting, if it is in the eastern. For the other problems use the triangle EHB, right-angled at H, and the givens and rules of spherical right-angled triangles that follow.

181. Probl. Nonageſimum Eclipticæ gradum aut Punctum ab Horizonte numeratum Inuenire. *181. Problem. To find the nonagesimal degree or point of the ecliptic, reckoned from the horizon.*

[Margin: Problem 181.]

Find, by one of problems 139 to 143, the rising or setting point of the ecliptic; then subtract 90° from the longitude of the rising point, or add 90° to that of the setting point. For what remains, or results, will be the nonagesimal degree of the ecliptic reckoned from the horizon. As in the preceding figure: if from the ecliptic place, that is, the longitude, of the rising point B you subtract the quadrant BS, the longitude of the nonagesimal point S will be known; but if B is the setting point, add the quadrant BS to it.

Probl. Nonageſimi Situm Inuenire, hoc eſt, ſitne in Meridiano, an in Quadrante Orientali, vel Occid. Eclipticæ, Datis 182. Nonageſimo ipſo puncto Eclipticæ; 183. Puncto Eclipticæ Oriente 184. Puncto Eclipt. Oriente, & Culminante 185. Puncto Eclipticæ Culminante 186. Puncti Eclipticæ Orientis Amplitudine Ortiua. *Problems. To find the situation of the nonagesimal, that is, whether it is on the meridian, or in the eastern or the western quadrant of the ecliptic, given: 182. the nonagesimal itself, as a point of the ecliptic; 183. the rising point of the ecliptic; 184. the rising and the culminating point of the ecliptic; 185. the culminating point of the ecliptic; 186. the rising amplitude of the rising point of the ecliptic.*

[Margin: Problem 182.]

First: if the given nonagesimal is the beginning of ♋ or ♑, the nonagesimal will be on the meridian, as it will be whenever it passes through the vertex. But if the nonagesimal is neither of the beginnings mentioned, and the inhabitant is outside the Torrid Zone: from the beginning of ♋ to the beginning of ♑, that is, in the descending signs, it will be in the western quadrant for northerners, and in the eastern for southerners. But if the nonagesimal is in the ascending signs, namely from the beginning of ♑ to the beginning of ♋, it will be in the eastern quadrant for northerners, and in the western for southerners.

Within the Torrid Zone, however: if the nonagesimal is from the beginning of ♋ to the beginning of ♑, it will be in the eastern quadrant with respect to northerners and in the western with respect to southerners, if its declination is greater than the geographical latitude of the inhabitant and of the same kind; but if it is less, or of a different kind, it will be in the western with respect to northerners and in the eastern with respect to southerners. If, on the other hand, the nonagesimal is from the beginning of ♑ to the beginning of ♋, it will be in the western quadrant with respect to northerners and in the eastern with respect to southerners, if its declination is greater than the geographical latitude and of the same kind; but if it is less, or of a different kind, it will be in the eastern with respect to northerners and in the western with respect to southerners.

Finally, with respect to those who live under the equator, the nonagesimal of the first or third quadrant of the ecliptic is in the western quadrant, while that of the second or fourth is in the eastern.

[Margin: Problem 183.]

Second: if the rising point of the ecliptic is the beginning of ♈ or ♎, the nonagesimal will be on the meridian, and it will be the beginning of ♋ or ♑. But if the rising point is neither of the beginnings mentioned, and the inhabitant is outside the Torrid Zone: if the rising point of the ecliptic is within the northern semicircle, the nonagesimal will be in the eastern quadrant with respect to northerners, and in the western with respect to southerners. On the contrary, if the rising point is within the southern semicircle [?], the nonagesimal will be in the western quadrant with respect to northerners [?], and in the eastern with respect to southerners.

Within the Torrid Zone, however, subtract 90° from the rising point, and you will have the nonagesimal. With this, then, proceed as in the part of the preceding problem that concerns the Torrid Zone.

[Margin: Problem 184.]

Third: if the rising point and the culminating point of the ecliptic are exactly 90° apart, the nonagesimal will be on the meridian, and will culminate. But if they are more than 90° apart, the nonagesimal will be in the eastern quadrant; if less than 90°, in the western.

[Margin: Problem 185.]

Fourth: if the culminating point of the ecliptic is the beginning of Cancer or Capricorn, the nonagesimal will be on the meridian. But if it is neither of these, and the inhabitant is outside the Torrid Zone: from the beginning of ♋ to the beginning of ♎, that is, in the descending signs, the nonagesimal will be in the western quadrant with respect to northerners, and in the eastern with respect to southerners; but from the beginning of ♎ to the beginning of ♋, the nonagesimal will be in the eastern with respect to northerners, and in the western with respect to southerners.

Within the Torrid Zone, however: if the culminating point is in the descending signs, that is, from the beginning of ♋ to the beginning of ♎, the nonagesimal will be in the eastern quadrant with respect to northerners and in the western with respect to southerners, if the declination of the culminating point is greater than the geographical latitude of the inhabitant and of the same character; but if it is less, or of a different character, it will be in the western with respect to northerners and in the eastern with respect to southerners. But if the culminating point is within the ascending signs, the nonagesimal will be in the western quadrant with respect to northerners and in the eastern with respect to southerners, if the declination of the culminating point is greater than the geographical latitude and of the same kind; but if it is less, or of a different kind, it will be in the eastern with respect to northerners and in the western with respect to southerners.

Finally, with respect to those who are in the right sphere: if the culminating point is in the 1st or 3rd quadrant of the ecliptic, the nonagesimal is in the western quadrant; but if in the 2nd or 4th quadrant, the nonagesimal is in the eastern quadrant.

[Margin: Problem 186.]

Fifth: if the rising amplitude of the rising point of the ecliptic is a quadrant, the nonagesimal will be on the meridian; and it will be the beginning of Cancer when the beginning of Libra is rising, or of Capricorn when the beginning of Aries is rising — and this, indeed, for anyone whatever. For an inhabitant outside the Torrid Zone, however: if the amplitude just mentioned is greater than a quadrant, the nonagesimal will be in the eastern quadrant with respect to northerners, and in the western with respect to southerners; on the contrary, if it is less than a quadrant, the nonagesimal will be in the western quadrant with respect to northerners, and in the eastern with respect to southerners. Within the Torrid Zone, however, since the rising point of the ecliptic is given, use the second part of problem 183.

What has been said about the problems concerning the nonagesimal, or related to it, from problem 133 to this one, 186, [Margin: Order of the problems.]

taken together with what was said in Book 5, chapter 10, contains a complete and very clear doctrine for eclipses of the Sun and other astronomical matters. Besides these, some matters still remain for Section 3, concerning the time at which a star is in the nonagesimal. But first we must complete Section 2.

[Margin: Note on [?] the use of the nonagesimal [?] for [?] eclipses of the Sun, etc.]

187. Probl. Arcum Meridiani inter Sidus culminans & Eclipticæ punctum culminans inuenire, Data vtriuſq. Declinatione. *187. Problem. To find the arc of the meridian between a culminating star and the culminating point of the ecliptic, given the declination of each.*

[Margin: Problem 187.]

If the declination of the star and that of the culminating point of the ecliptic are of the same kind, that is, both northern or both southern, the difference of the declinations will be the arc sought; but if they are of different kinds, the sum of the declinations will be. Another method, by the analysis of triangles, will be given below at problem 216. For the present problem, however, the figure set out at problem 162 serves after a fashion, in which the culminating point of the ecliptic is E. For let us imagine that the equator passes through H and that the star is in O: then the arc sought, OE, will be the difference between the northern declination HE of the point E and the northern declination HO of the star O. Likewise, if the equator passes through V and the star is in M, the arc sought, EM, will be the amount by which the southern declinations EV and MV differ from each other. Conversely, if, with the equator drawn through O, the star is in H, the arc sought will be HE, made up of the southern declination HO of the star and the northern declination OE of the culminating point, and so on.

Probl. Angulum Horizontis, & Circuli Declinationis, per Sidus aut punctum Eclipt. extra Horizontem poſitum ducti inuenire, Datis 188. Altitudine Poli, & Diſtantia Aequatoria Sideris aut puncti à Meridiano. 189. Altitudine Sideris aut Puncti, eiuſque Azimutho & Declinatione 190. Altit. & Azimutho Sideris aut puncti, & Altit. Poli 191. Altitudine, Azimutho, & diſtantia Sid. aut puncti à Meridiano 192. Altitudine, ac Declinat. Sid. vel Puncti, cum Alt. Poli 193. Altitud. ac Declinat Sid. vel Puncti, eiuſque diſtantia à Meridiano. *Problems. To find the angle of the horizon and the circle of declination drawn through a star or a point of the ecliptic placed outside the horizon, given: 188. the altitude of the pole, and the equatorial distance of the star or point from the meridian; 189. the altitude of the star or point, and its azimuth and declination; 190. the altitude and azimuth of the star or point, and the altitude of the pole; 191. the altitude, the azimuth, and the distance of the star or point from the meridian; 192. the altitude and declination of the star or point, with the altitude of the pole; 193. the altitude and declination of the star or point, and its distance from the meridian.*

Above, at problems 116 to 121, we sought this angle, but with the star, or any point, standing on the horizon; now we seek the same angle with the star or point of the ecliptic placed outside the horizon. For this, in the following figure, let the meridian be HVRQ, in which the vertex is V, and let the visible

pole of the world, say [?] the northern, be P, from which the equator EBQ is described. Let the star be in M, or in S, or in C, above the horizon, or below it, in I or in T; and from the pole P let arcs of declination be drawn through the centre of the star as far as the equator and the horizon, such as PMCKI TSP; and through the centre of the star let quadrants of the circle of altitude be drawn from V, namely ACV and FMV.

[Margin: What I say of a star holds for a point of the ecliptic.]

Diagram. A circle set in the left column beside the text of problems 188–193: the meridian HVRQ crossed by a horizontal line from H to R (the horizon), with the equator EBQ, arcs of declination from the pole P, and quadrants of altitude from the vertex V. Labels read:

- H (outside the rim, left end of the line), V (rim, top), R (outside the rim, right end of the line) and Q (outside the rim, lower right): the meridian HVRQ
- V (rim, top): the vertex, from which the quadrants of altitude ACV and FMV are drawn
- P (rim, upper right): the visible pole, with PR the altitude of the pole and VP its complement
- E (outside the rim, top, left of V), B (centre, below the line) and Q: the equator EBQ
- M (inside, upper right) and L (inside, upper centre): the star M with its declination LM and its altitude FM
- S (inside, right, above the line) and G (inside, lower centre): the star S with its declination GS and its altitude FS
- C (inside, left, above the line) and A (below the line, right of D): the star C with its southern declination CL and its altitude AC
- I (inside, lower left of centre) and T (below the line, right of centre): the star below the horizon, with IG, AI, TZ and VZ
- Z (inside, right, below S; a z-shaped sort): with the depression TZ and the quadrant VZ
- D (inside, just right of H, below the line), O (inside, right, on the line) and F (right of O, below the line): the angles at D and O and the right angles at F
- K (outside the rim, lower left) and N (rim, bottom): the other pole K and the nadir N, with the triangle KIN

With this laid down, the altitude of the pole will be PR, and its complement to 90° will be VP. The declination of the star M will be LM, whose complement is MP; that of the star S will be GS, and its complement SP; while the southern declination CL of the star C, added to a quadrant, will make up the arc PC. The equatorial distance from the meridian (which, for the Sun, is known from the time before or after noon, converted into degrees of the equator) will be the angle DPE for a star placed in M or C, and its supplement to 180° will be the angle DPR; but for the star S the distance will be GPE, and its supplement to 180° will be the angle OPR. Finally, the altitude of the star M will be FM,

and its complement MV; while the altitude of the star S is FS, its complement SV; and the azimuth of both is the angle HVF, whose supplement to 180° gives the angle FVR. But for a star placed in C the altitude is AC, its complement CV, and its azimuth HVA, whose supplement to 180° is AVR.

[Margin: Problem 188.]

Now, if the star is in C or in M, the acute angle at D is sought, which can be found from the givens of problem 188. For in the triangle DPR, right-angled at R, the side PR, the altitude of the pole, is given, and the angle DPR, the complement of the star's distance from the meridian; therefore by Rule 8 of spherical right-angled triangles you will find the angle D. So too, if the star is in S, or in T, or in I, the acute angle O is sought in the triangle OPR, in which PR, the altitude of the pole, is given, and the angle OPR, the complement of the star's distance from the meridian; therefore by Rule 8 of the same, find the angle O.

[Margin: Problem 189.]

[Margin: 190, 191, 192, 193.]

For the other problems, however, the angle made by the circle of declination and the vertical at the centre of the star C, M or S must be found by problems 29 to 33. Then, if the star is in C, use the triangle DAC, right-angled at A; and with the angle C found and the altitude AC, find the angle D by the same Rule 8. But if the star is in M, use the triangle DMF, right-angled at F, and by the angle M, found as before, and the altitude FM, find the angle D by the same Rule 8. Finally, if the star is in S, use the triangle OSF, right-angled at F, in which the angle S, found as above, is given, and the altitude FS; therefore by the same Rule 8 you will obtain the acute angle O.

Probl. Diſtantiam Stellæ aut Puncti Ecliptici à Meridiano inquirere, Datis 194. Aſc. Recta Stellæ & Aſc. Recta Medij cæli 195. Altitud. Poli; & Stellæ Altitudine vel Profunditate, ac Declinatione 196. Altit. Poli, Azimuth & Altitudine Stellæ, aut Profunditate 197. Alt. Poli Azimuth ac Declinatione ſtellæ 198. Azimutho, Altitudine vel Profundit. ac Declinatione Stellæ.
Problems. To find the distance of a star or of a point of the ecliptic from the meridian, given: 194. the right ascension of the star and the right ascension of mid-heaven; 195. the altitude of the pole, and the altitude or depression [profunditas] of the star, and its declination; 196. the altitude of the pole, the azimuth, and the altitude or depression of the star; 197. the altitude of the pole, the azimuth, and the declination of the star; 198. the azimuth, the altitude or depression, and the declination of the star.

[Margin: Problem 194.]

For problem 194: if the star is in the eastern hemisphere, subtract the right ascension of mid-heaven from its right ascension; but if it is in the western hemisphere, subtract the right ascension of the star from the right ascension of mid-heaven, taking 360° in addition where the subtraction cannot otherwise be made; and what remains will be the distance of the star from the meridian. Understand the same of a point of the ecliptic.

[Margin: Problem 195.]

For problem 195, look at the figure immediately preceding, and in it the star in four places, two above and two below the horizon. For if the star is in M, use the triangle VMP, and seek the distance from the meridian, that is, the angle MPV, from the givens VP, the complement of the altitude of the pole; VM, the complement of the altitude of the star, as the base; and MP, the complement of the declination; and do this by Rule 14 of spherical oblique-angled triangles. But if the star is in C, use the triangle VCP, and by the same Rule 14 seek the angle CPV from the givens VP, as above; VC, the complement of the altitude of the star; and CP, made up of the quadrant LP and the declination LC towards the other pole. But if the star is below, as in T, use the triangle VTP, seeking the angle of distance TPV by the same Rule 14 from the givens VP, as above; TP, the complement of the declination; and VT, made up of the depression TZ of the star and the quadrant VZ. But if it is in I, use the triangle KIN, in which KN is as great as VP, the complement of the altitude of the pole, since K is the other pole and N the nadir; and KI is the complement of the declination IG, while IN is the complement of the depression AI. Therefore by the same Rule 14 you will find the angle IKN, the supplement to 180° of the angle IKE, which measures the distance of the star from the meridian.

[Margin: Problem 196.]

For problem 196: the supplement of the azimuth to 180° is the vertical angle contained by the complement of the al- [Margin: Order of the problems.]

titude of the pole and by the complement of the altitude or depression of the star, or by the aggregate of the quadrant and the depression. Therefore by Rule 5 or 6 of spherical oblique-angled triangles you will find the angle opposite the altitude or depression, which measures the distance sought if the star is in M, C or T; or it is the supplement to 180° of the distance sought if the star is in I.

[Margin: Problem 197.]

For problem 197, the vertical angle is sought that measures the distance sought if the star is in M, C or T, or its supplement to 180° if the star is in I. This angle is contained by the complement of the altitude of the pole and by the complement of the given declination; and the angle opposite the complement of the declination is given, namely the complement of the azimuth. Therefore, by Rule 3 of spherical oblique-angled triangles, seek the vertical angle already mentioned.

[Margin: Problem 198.]

For problem 198, the angle opposite the complement of the declination is given from the complement of the azimuth; the complement of the altitude or depression is given, or the aggregate of the depression and the quadrant; and the angle opposite this complement or aggregate is sought by Rule 1 of spherical oblique-angled triangles. This angle measures the distance of the star from the meridian if the star is in C, M or T; or it is the supplement of the distance to 180° if the star is in I.

199. Probl. Angulum in Centro Sideris Orientis vel Occidentis, factum à Circulo Latitudinis & Horizontis inuenire, Datis Latitudine, ac Declinatione Sideris cum Altitudine Poli, & Diſtantia Polorum Eclipticæ ac Aequatoris. *199. Problem. To find the angle at the centre of a rising or setting star made by the circle of latitude and the horizon, given the latitude and declination of the star, with the altitude of the pole and the distance between the poles of the ecliptic and of the equator.*

[Margin: Problem 199.]

First, by problem 66, seek the angle at the centre of the star made by the circles of latitude and of declination. Second, by problem 116, seek the angle at the centre of the star made by the circle of declination and the horizon, and let it be called the second angle. Third, inspect the astronomical globe: if the arc of declination falls within the angle sought, you will add the first angle to the second; but if it falls outside, you will subtract it, and the angle sought will result, or remain.

200. Probl. Angulum ad Polum Aequatoris factum à Coluro Solſtitiorum, & à Circulo Declinationis Stellæ aut puncti cæleſtis inuenire, Data Stellæ aut puncti prædicti Aſcenſione Recta. *200. Problem. To find the angle at the pole of the equator made by the solstitial colure and by the circle of declination of a star or celestial point, given the right ascension of the star or point already mentioned.*

[Margin: Problem 200.]

If the right ascension is less than 90°, subtract it from 90°. But if it is greater than 90° but less than 270°, subtract 90° from the ascension. Finally, if it is greater than 270°, subtract 270° from the ascension; and the angle sought will remain. This angle is nil if the right ascension is exactly 90° or 270°, and right if the right ascension is nil or 180°. When the angle found is obtuse, if you are seeking an acute one, subtract it from 180°.

201. Probl. Angulum ad Polum Eclipticæ factum à Coluro Solſtitiorum, & circulo Latitudinis Stellæ aut puncti Cæleſtis inueſtigare, Data Lõgitudine Stellę aut pũcti. *201. Problem. To find the angle at the pole of the ecliptic made by the solstitial colure and by the circle of latitude of a star or celestial point, given the longitude of the star or point.*

[Margin: Problem 201.]

Do everything as in problem 200, exchanging the names and roles of the right ascension for the names and roles of the longitude; or see the explicit rules given in Book 6, chapter 13, from number 4 to the end of the chapter.

202. Probl. Angulum ad Polum Mundi factum à Coluro Aequinoctiorum, & circulo Declinationis ducto per Stellam aut punctum cæleſte inuenire, Data Aſc. Recta ſtellę aut puncti. *202. Problem. To find the angle at the pole of the world made by the equinoctial colure and by the circle of declination drawn through a star or celestial point, given the right ascension of the star or point.*

[Margin: Problem 202.]

This angle is as great as the right ascension, if the ascension is less than 180°; but if it is greater, subtract 180° from it, and what remains will be the angle sought. The angle will, however, be nil if the right ascension is nil or 180°.

203. Probl. Angulum ad Polum Eclipticæ factum à Coluro Aequinoctiorum, & circulo Latitudinis ducto per Stellam vel punctum cæleſte, inuenire, Data Longitudine puncti aut Stellæ. *203. Problem. To find the angle at the pole of the ecliptic made by the equinoctial colure and by the circle of latitude drawn through a star or celestial point, given the longitude of the point or star.*

[Margin: Problem 203.]

This angle is nil if the longitude is nil or 180°; but it is as great as the longitude when the longitude is less than 180°. For if it is greater, subtract 180° from the longitude, and the remainder will be the angle sought.

204. Angulum qui fit ad Polum Mundi, à Meridiano & à Coluro Solſtitiorum, quando hi circuli non coincidunt; Dato Temporis momento, aut reliquis ad Aſc. Rectam Medij cæli requiſitis; inueſtigare. *204. To find the angle formed at the pole of the world by the meridian and by the solstitial colure, when these circles do not coincide, given the moment of time, or the other things required for the right ascension of mid-heaven.*

[Margin: Problem 204.]

Let the right ascension of mid-heaven be given, or found by problems 108 to 113. If it is 90° or 270°, there will be no such angle, but the meridian will coincide with the solstitial colure; if it is nil, or 180°, the angle already mentioned will be 90°, that is, right. But if the right ascension of mid-heaven is less than 90°, subtract it from 90°; if it is greater than 90° but less than 180°, subtract 90° from it; if greater than 180° but less than 270°, subtract it from 270°; finally, if it is greater than 270°, subtract 270° from it, and you will obtain the acute angle sought.

205. Probl. Angulum qui fit ad Polum Mundi, à Meridiano & Coluro Aequinoctiorum, inuenire, Datis quæ in Probl. 204. *205. Problem. To find the angle formed at the pole of the world by the meridian and the equinoctial colure, given what is given in problem 204.*

[Margin: Problem 205.]

Seek the right ascension of mid-heaven by the problems set out from 108 to 113. If it is nil, or 180°, there will be no such angle, but the meridian will coincide with the equinoctial colure; if it is 90° or 270°, that angle will be 90°, that is, right. But if it belongs to the 1st quadrant of the equator, the angle will be as great as the right ascension of mid-heaven; if to the 2nd, subtract it from 180°; if to the 3rd, subtract 180° from it; if to the 4th, subtract it from 360°; and so the acute angle sought will be known.

Probl. Diſtantiam Poli Eclipticæ à Vertice inuenire, Datis. 206. Altitudine Nonageſimi 207. Altitud. Poli; Diſtantia Polorum, & Angulo ad Polum Mundi facto à Coluro Solſtitiorum, & Meridiano. *Problems. To find the distance of the pole of the ecliptic from the vertex, given: 206. the altitude of the nonagesimal; 207. the altitude of the pole, the distance between the poles, and the angle made at the pole of the world by the solstitial colure and the meridian.*

[Margin: Problem 206.]

In the adjoining diagram the meridian is HVRM, the horizon HBR, and the pole of the world P, from which the small polar circle CZ is described; and on its circumference lies the pole of the ecliptic, now at C, now at I, now at Z, now at L. A portion of the ecliptic is EBM; and the portion ZVNA of the great circle drawn from the pole Z through the vertex V makes a right angle with the ecliptic at N. Since this circle passes from the vertex to the horizon, it becomes at once the circle of latitude and the circle of altitude, and it marks at N the nonagesimal degree of the ecliptic, counted from the point B of the horizon. Therefore, since the arc of latitude ZN from the pole of the ecliptic Z to the ecliptic

Diagram. A circle set in the right column beside the text of problems 206–207: the meridian HVRM, crossed by the horizon HBR and by the ecliptic EBM, with a small circle about the pole of the world P carrying the positions C, I, Z and L of the pole of the ecliptic, and the arc ZVNA from Z through the vertex. Labels read:

- E (outside the rim, upper left, at the end of a line): the ecliptic EBM
- V (rim, top): the vertex
- O (inside, upper left): not named in the text of this page
- N (inside, left): the nonagesimal, where ZVNA meets the ecliptic at right angles
- D (inside, left of centre): not named in the text of this page
- C (inside, on the small circle), I (inside the small circle, top), Z (outside the rim, upper right; a z-shaped sort) and L (rim, right, below P): positions of the pole of the ecliptic on the small polar circle
- P (on the small circle, right): the pole of the world
- H (outside the rim, left) and R (rim, right): the horizon HBR and the meridian HVRM
- A (inside, lower left, below the horizon): the end of the arc ZVNA
- B (inside, lower centre): the point of the horizon from which the nonagesimal is counted
- M (outside the rim, lower right): the meridian HVRM and the ecliptic EBM

[Margin: Order of the problems.]

is a quadrant, and VA is likewise a quadrant, then if the complement NV of the altitude AN of the nonagesimal, which is the arc common to both quadrants, is taken away, there will remain the distance of the pole Z from the vertex, that is, the arc ZV, as great as the altitude AN of the nonagesimal.

[Margin: Problem 207.]

Second, if in the triangle VPZ the complement PV of the altitude PR of the pole is given, and the distance between the poles PZ, and, by problem 204, the angle VPZ, which is formed by the meridian and the solstitial colure (of which colure PZ is a portion), then by Rule 4 of spherical oblique-angled triangles the base ZV will certainly become known, namely the distance of the pole of the ecliptic from the vertex. In the same way, if the pole of the ecliptic were at C, from the givens VP and PC and the angle VPC, as above, you will gather the distance of C. But if the pole of the ecliptic is on the meridian itself, say at I, that is, when the beginning of Capricorn culminates, then the distance between the poles IP, less the complement VP of the altitude of the pole, will leave the distance VI; but if it is at L, that is, when the beginning of Cancer culminates, the distance between the poles PL, added to the complement PV, will make up the distance VL.

Probl. Angulum in centro Sideris culminantis, factum à Circulo Latitudinis & Meridiano, inuenire, Datis 208. Diſtantia Polorum; Declinatione, & Latitudine Sideris 209. Diſtantia Polor. Declinat. & Angulo ad Mundi Polum Meridiani & Coluri Solſtit. 210. Diſtantia Polor. Declinat. & Angulo ad Eclipt. Polum facto à Circulo Latitud. & Coluro Solſtitiorum 211. Diſtantia Polorum, Latitudine, & Angulo ad Mundi Polum ſupradicto. 212. Diſtantia Polorum, Latitudine, & Angulo ad Eclipt. Polum ſupradicto 213. Diſtantia Polorum, & Angulis ad Polos Mundi & Eclipticæ ſupradictis 214. Declinat. & Angulis ad Polos prædictis. 215. Latitudine, & Angulis ad Polos prædictis. *Problems. To find the angle at the centre of a culminating star made by the circle of latitude and the meridian, given: 208. the distance between the poles, and the declination and latitude of the star; 209. the distance between the poles, the declination, and the angle at the pole of the world of the meridian and the solstitial colure; 210. the distance between the poles, the declination, and the angle at the pole of the ecliptic made by the circle of latitude and the solstitial colure; 211. the distance between the poles, the latitude, and the angle at the pole of the world mentioned above; 212. the distance between the poles, the latitude, and the angle at the pole of the ecliptic mentioned above; 213. the distance between the poles, and the angles at the poles of the world and of the ecliptic mentioned above; 214. the declination, and the angles at the poles already mentioned; 215. the latitude, and the angles at the poles already mentioned.*

Look at the figure immediately preceding, in which the culminating star is at V, whether at the vertex or away from the vertex. Let the portion PV of the meridian be the complement of the given declination, VZ the complement of the given latitude, and PZ the given distance between the poles. Let the angle at the pole of the world made by the meridian and the solstitial colure, known from problem 204, be VPZ, since PZ is a portion of the solstitial colure; and finally let the angle at the pole of the ecliptic made by the circle of latitude and the solstitial colure, known by problem 201, be VPZ. Now in the triangle PVZ

the angle at V is sought; and it will be found by the following rules of spherical oblique-angled triangles, which correspond in order to the problems proposed.

[Margin: Problem: 208, 209, 210, 211, 212, 213, 214, 215.]

Section 1, chapter 5.

216. Probl. Pũctum Eclipticæ Culminans cum Sidere notæ Longitudinis ac Latitudinis; Arcumq. Meridiani inter Sidus & punctũ Eclipticæ Culminans, & inde Declinationem Sideris inuenire, Dato Angulo in centro Sideris Culminantis facto à Meridiano, & circulo Latitudinis. *216. Problem. To find the culminating point of the ecliptic together with a star of known longitude and latitude, and the arc of the meridian between the star and the culminating point of the ecliptic, and hence the declination of the star, given the angle at the centre of the culminating star made by the meridian and the circle of latitude.*

[Margin: Problem 216.]

We devised this problem, and the others from problem 201 that serve it, both for other purposes and especially for the sake of the lunar parallaxes, which are the foundations of the distance both of the Moon and of the other planets from the Earth. Let there be, then, in the preceding diagram the Moon, or any star whatever, culminating at V; let its latitude VN be given, and from its longitude let the point N of the ecliptic be known. In the triangle ONV, right-angled at N, besides the side VN, let the angle NVO be given, from the angle PVZ, which is equal to it and has been found by problems 209 to 215 (for in problem 208 the declination is presupposed known, which is what we are seeking here). With these given, then, gather by Rule 7 of spherical right-angled triangles the side NO, and by Rule 9 the base OV. Then, if the point N, which is known, is eastern, as it lies in the figure, subtract the side NO from it; but if it is western, add it; and the culminating point O of the ecliptic will be known, and its declination from the table of problem 15. Comparing this declination with the base OV that has been found, you will easily gather the true declination of the star V. For if the point O is the beginning of Aries or of Libra, the arc OV itself will be the declination of the star V; but if the point O is in the northern semicircle of the ecliptic, and the star is more northern than it, the aggregate of the declination of the point O and the base OV will make up the declination of

the star V; if, however, the point O is in the southern semicircle, and the star is more northern than it, the difference between the declination of the point O and the base OV will give the declination of the star V. From these you will understand the remaining cases.

[Margin: Note for the observation of the parallaxes of the Moon.]

Although this declination can be obtained by means of the tables indicated at problem 65, yet if anyone lacks them, or if they are not constructed for so great a latitude as would be needed, this problem will be very useful. Once the true declination is known, and the altitude of the equator, the true meridian altitude of the star is known; compared with the meridian altitude observed exactly with some instrument, it yields the parallax of the star belonging to that altitude, if the star has any, provided that the star is beyond the hazard of sensible refractions, as I showed by many examples in Book 4, chapter 14.

217. Probl. Eclipticæ Arcum ſemper Apparentem determinare, Datis Obliquitate Eclipticæ, & Altitudine Poli, excedente tamen complementum Obliquitatis Eclipticę. *217. Problem. To determine the arc of the ecliptic that is always visible, given the obliquity of the ecliptic and the altitude of the pole, the altitude, however, exceeding the complement of the obliquity of the ecliptic.*

[Margin: Problem 217.]

First consider the figures of the following diagram, in which the meridian is HVPD and the horizon HBR, and the equator AQ is described from the northern pole of the world P, whose altitude is PR and the complement of whose altitude is PV, since the zenith or vertex is V. Let the ecliptic be CBD; the remaining semicircles signify parallels of the equator, among which are the tropics: that of Cancer, CN, and that of Capricorn, KD. The greatest declination of the Sun, or the measure of the obliquity of the ecliptic, is the arc AC, or QN; and its complement to 90° is the arc CVP.

[Margin: Case 1.]

First, then, if, as in the 1st of the figures, the altitude of the pole PR is less than the complement CVP of the obliquity of the ecliptic, every parallel that the Sun describes is cut by the horizon, and therefore all the points of the ecliptic rise and set every day in such a horizon.

[Margin: Case 2.]

Second, if, as in the 2nd of the figures, the altitude of the pole PR is equal to the complement CVP of the obliquity of the ecliptic, the tropics graze the horizon and are not cut by it. Thus the tropic of Cancer CN, standing wholly above the horizon, touches the horizon at R with a single point of itself, N; the tropic of Capricorn KD, wholly hidden, touches the horizon at H; and the remaining solar parallels are cut by the horizon. The result is that, when the Sun is at the beginning of Cancer and is describing its tropic, the day among the northern peoples is exactly 24 hours long and there is no night, because the Sun does not wholly set, but only half of it, the centre of the solar disc being at R (I say this, abstracting for now from refraction and parallax). Conversely,

there is a night of 24 hours among the southern peoples who have an altitude of the south pole as great as the complement of the obliquity of the ecliptic, for the whole parallel of Cancer is hidden from them. On the same day, moreover, the circles, the Ar- [Margin: Order of the problems.]

ctic and the Antarctic, pass, the former through the vertex, the latter through the nadir.

Diagram. Three circles set side by side across the left column: "the figures of the following diagram" for the three cases of problem 217, numbered 1, 2 and 3 in the text from left to right by their order on the page. Each circle is crossed by a horizontal line (the horizon HBR or its like) and by oblique parallels of the equator. Labels read:

- First figure (case 1): K (rim, upper left); A, C and V (along the rim at the top); P (outside the rim, right, above the line); H (left end of the line); B (centre, on the line); R (right end of the line); D (below the rim, bottom); Q (rim, lower right, beside D); N (outside the rim, lower right)
- Second figure (case 2): C (outside the rim, upper left); V (top); P (outside the rim, upper right); A (outside the rim, left, above the line); H (left end of the line); K (inside, left); B (centre, below the line); N (outside the rim, right, above the line); R (right end of the line), where the tropic of Cancer CN touches the horizon; Q (outside the rim, right, below the line); D (rim, lower right)
- Third figure (case 3): C, V and P (top); O (outside the rim, upper left); A (outside the rim, left, above the line); H (left end of the line); S (inside, upper centre); G (inside, left, on the line; a small sort); B (centre), the beginning of Aries; I (inside, right of B; a slanting sort); T (inside, below B); N (outside the rim, right, upper); R (right end of the line); O (outside the rim, right, below R); M (outside the rim, lower right); D (rim, lower right)

[Margin: Case 3.]

The third case, the one our problem requires, is represented in the 3rd of the figures; for in it the altitude of the pole PR is greater than the arc CVP, that is, than the complement of the obliquity of the ecliptic. Therefore the horizon cuts only those parallels that lie within the parallel OR and HM; and the tropic of Cancer CN stands so far above the horizon that it does not touch it. Now look at the ecliptic CBD and its two arcs: one before the beginning of Cancer, let it be SC; the other following the beginning of Cancer and equal to the former, let it be CS. For when the Sun has reached the point S, for the whole time it spends in the arc SC and in the arc CS it will never set for such a horizon, because the parallels within CN and OR are not cut by the horizon. We must therefore find the arc of the ecliptic that is always visible, which consists of the arcs SC and CS. It will be found if the points S of the ecliptic are known, one preceding and the other following the beginning of Cancer, through which passes the parallel OSR, touching the horizon. These points will become known from the declination of the parallel OSR; and this declination

is AO, or QR, as great, that is, as the complement PQ of the altitude PR of the pole to the quadrant. Now of the points S one lies in the first quadrant of the ecliptic and the other in the second, and they are equally distant from the beginning of Cancer; therefore, once the former is known, the other is known at once.

Go back, then, to problem 15; and with the given declination of the parallel OSR, that is, with the complement of the altitude of the pole, namely SG, and with the angle GBS of the obliquity of the ecliptic opposite it, seek in the spherical triangle GBS, right-angled at G, the base BS, by Rule 11 of spherical right-angled triangles. For that will be the elongation of the point S from the beginning of Aries, B, and it will accordingly give the point S that precedes the beginning of Cancer. But if you subtract the base BS from 180°, you will have the elongation of the later point S from the same beginning of Aries. You have an example below, in Section 3, problem 14, in the first step; although this can be completed without trigonometry, by seeking in the body of the table of the Sun's declinations the declination already mentioned, that is, the complement of the altitude of the pole. For at the head and foot of the table you will have the sign, and in the margin the degrees sought, which enclose on either side the arc of the ecliptic that is always visible. How much time the Sun spends in traversing this arc you will learn from astronomical tables or from ephemerides; but on this time, which must in every case be corrected on account of refraction, since refraction increases it greatly, I shall speak in the following section, problems 13 and 14. Further, the arc always hidden, namely TD taken twice, is as great as the arc always visible, SC taken twice.

In another way, not very different, though without demonstration and figure, Reinhold accomplishes this in his *Tabulae directionum*, precept 41. "Multiply," he says, "the sine of the complement of the altitude of the pole by the radius, and divide the sum by the sine of the obliquity of the ecliptic; for the quotient will be the sine of the base BS, whose complement to the quadrant is the arc SC."

218. Probl. Stellæ aut Puncti Eclipticæ ſitum reſpectù hemiſphærij Orientalis aut Occidentalis diſcernere, ſeu vtrùm ſit in parte Orientali, an Occidentali, Datis Aſc. Recta ipſius, & Aſcenſ. Recta Medij Cæli ad Tempus datum. *218. Problem. To determine the position of a star or of a point of the ecliptic with respect to the eastern or the western hemisphere, that is, whether it is in the eastern or the western part, given its right ascension and the right ascension of mid-heaven at a given time.*

[Margin: Problem 218.]

Subtract the right ascension of the given star or point from the right ascension of mid-heaven (taking 360° in addition if the subtraction requires it), and the elongation of the star or point from the meridian will remain. If this is less than 180°, the star or point will be in the western hemisphere; if greater, in the

eastern; if nil, it will be in mid-heaven; if 180°, it will be in the angle of the earth, that is, at the lowest mid-heaven.

219. Probl. Vtrùm Stella vel Punctum Eclipticæ, ſit ſupra an infra Horizontem, diſcernere, Datis Aſc. Recta ipſius & Arcu Semidiurno, & Aſc. Recta Medij Cæli. *219. Problem. To determine whether a star or a point of the ecliptic is above or below the horizon, given its right ascension and semidiurnal arc, and the right ascension of mid-heaven.*

[Margin: Problem 219.]

With the right ascension of the star and the right ascension of mid-heaven, gather by problem 218 the elongation of the star or point from the meridian, and its position. Then, if the star is in the western hemisphere and its elongation from the meridian is less than the semidiurnal arc (known by problem 122), the star will be above the horizon; if greater, it will be below; if equal, it will be on the western horizon. But if the star or point is in the eastern hemisphere, then when 180° is subtracted from its elongation from the meridian (taking in the circle of 360° if need be), the elongation from the angle of the earth will remain; and if this is less than the seminocturnal arc, it will be below the horizon; if equal, it will be on the eastern horizon.

You will determine this in another and quicker way if you know the rising point of the ecliptic, by problems 140 to 143, and the point of the ecliptic with which the star rises and with which it sets, by problem 125; for in this way you will know which half of the ecliptic is below the horizon and which above. And if the point with which the star rises is in the eastern part but has not yet risen, the star will be below; but if the point with which it sets is in the western part and has not yet set, the star will be above the horizon, and so on.

220. Probl. Altitudinem vel Profunditatem Solis, aut ſtellæ cuiuſuis inueſtigare, Datis Altitud. Poli; loco Solis aut Stellæ, cum eius Declinatione & arcu Semidiurno, ſiue Parallelus Sideris ſecet, ſiue non Horizontem. *220. Problem. To find the altitude or depression of the Sun or of any star, given the altitude of the pole, and the place of the Sun or star, with its declination and semidiurnal arc, whether the parallel of the star cuts the horizon or not.*

[Margin: Problem 220.]

I have chosen to transcribe this problem here, without a figure, from Cavalieri's *Centuria*, problems 3 and 17.

[Margin: Step 1.]

First, then, with the altitude of the pole and the declination of the star, seek by the table, or by problem 122, the semidiurnal arc of the star, and from the moment of time the distance of the star from the meridian, by problems 194 to 198.

[Margin: Step 2.]

Second, if the parallel of the star cuts the horizon (which you will learn from its declination and the altitude of the pole), join together these five: namely,

the logarithm of the binary, that is, of the number 2; the second logarithm of the altitude of the pole; the second logarithm of the declination of the star; the logarithm of the half-sum made from the semidiurnal arc and the distance of the star from the meridian; and finally the logarithm of the half-difference between the semidiurnal arc and the distance of the star from the meridian. For the sum of these 5, the superfluous units being discarded (according to what was said in Section 1, chapter 1, precept 2), will be the logarithm of the altitude or depression sought. If the arc found by this logarithm exceeds 90°, its excess over 90° will be the depression; but if it does not exceed it, it will be either the altitude or the position on the horizon itself.

[Margin: Step 3.]

Third, if the parallel of the star does not cut the horizon (which happens when the declination of the star exceeds the complement of the altitude of the pole), or even if it does cut it (for this rule is universal), the second mesologarithm of the declination of the star, joined with the second logarithm of the distance from the meridian, will make the mesologarithm of an arc, which is to be called the first arc. Next, the logarithm of the declination; the residue of the second logarithm of the first arc found; and the logarithm either of the sum made from the first arc and the altitude of the pole (if the distance of the star from the meridian is less than a quadrant in a northern parallel, or greater in a southern one), or of the difference between the first arc and the altitude of the pole (if the distance of the star from the meridian is greater than a quadrant in a northern parallel, or less in a southern one): these three, I say, joined together, make the logarithm of the second arc. If this arc is greater than 90°, its excess is the depression of the star; if it is less, the arc is that of the altitude.

[Margin: Order of the problems.]

221. Probl. Altitudinem aut Profunditatem Solis inquirere, Datis Loco Solis Ecliptico, puncto Eclipticæ Oriente, cum Angulo Eclipticæ & Horizontis. *221. Problem. To find the altitude or depression of the Sun, given the Sun's place in the ecliptic and the rising point of the ecliptic, with the angle of the ecliptic and the horizon.*

[Margin: Problem 221.]

Let the figure set out earlier for problem 162 be repeated here. First, let the Sun's place in the ecliptic be at S, and the rising point of the ecliptic at B. Their difference gives the base BS in the triangle ASB, right-angled at A, in which the angle ABS of the ecliptic and the horizon is given. Therefore by the first rule of spherical right-angled triangles you will find the Sun's altitude AS. Second, let the Sun be at I, below the horizon. The difference, namely, between its place I and the rising point B will give the base BI in the triangle BKI, right-angled at K, in which the angle KBI of the ecliptic and the horizon is given. Therefore by the same first rule you will find the Sun's depression KI; for VKI is a portion of a vertical circle.

Diagram. A circle set at the right of the left column, beside the text of problem 221: the figure "set out earlier for problem 162", here repeated and used for problems 221 to 223. It is crossed by a near-horizontal line from H to R (the horizon) and by arcs and straight lines drawn from P and from V. Labels read:

- M (outside the rim, top, left of V)
- V (top of the rim)
- E (outside the rim, upper left)
- O (outside the rim, left, below E)
- S (inside, upper left)
- P (rim, upper right)
- H (left end of the line)
- K (inside, right, above the line)
- R (right end of the line)
- A (inside, left, below the line)
- B (inside, below the line, centre)
- I (inside, near the rim, lower right)
- G (outside the rim, lower right)

222. Probl. Altitud. aut Profunditatem Solis inquirere, Datis Loco Solis in Ecliptica, pũcto Eclipticæ Culminante, ipſiuſq. Diſtantia à Vertice, & Angulo Eclipticæ ac Meridiani. *222. Problem. To find the altitude or depression of the Sun, given the Sun's place in the ecliptic, the culminating point of the ecliptic and its distance from the vertex, and the angle of the ecliptic and the meridian.*

[Margin: Problem 222.]

In the preceding figure, if the Sun is at S, use the triangle SEV. In it the side ES is given from the Sun's place S and the culminating point E; the distance EV of the point E from the vertex is given; and, from the angle of the ecliptic and the meridian that belongs to the point E, the angle contained by the given sides, that is, SEV, is given. Therefore by the 4th rule of spherical oblique-angled triangles seek the base SV; when it is subtracted from 90°, the Sun's altitude AS becomes known. But if the Sun is below, as at I, use the triangle IEV. In it the difference between the Sun's place I and the point E gives the side EI; the side EV is given, as above; and so is the contained angle IEV. Therefore by the same 4th rule you will find the base VI, which will be greater than the quadrant VK; when the quadrant is taken away, then, the Sun's depression IK will remain.

223. Probl. Solis Altit. aut Profunditatem inueſtigare, Datis Altitudine Poli Declinatione ac Diſtantia Solis à Meridiano. *223. Problem. To find the altitude or depression of the Sun, given the altitude of the pole, the declination, and the distance of the Sun from the meridian.*

[Margin: Problem 223.]

If the Sun is at S, above the horizon, use the triangle SVP. In it the side PS is given from the declination: it is either a quadrant, if the Sun is on the equator; or the complement of the declination, if the Sun is northern; or the aggregate of the declination and a quadrant, if the Sun is southern. VP is also given, the complement of the altitude of the pole; and so is the contained angle SPV, known from the Sun's equatorial distance from noon, that is, from the time before or after noon converted into parts of the equator. Therefore by the 4th rule of spherical oblique triangles the base SV will be found [?], which is the complement of the altitude sought, AS.

But if the Sun is below, at I, use the triangle IPV, in which the side IP is given from the declination, as above; VP, the complement of the altitude of the pole; and the angle IPV, from the distance from the meridian. Therefore by the same 4th rule seek the base VI, which is of course greater than the quadrant VK; when the quadrant is taken away, the remainder will be the Sun's depression KI.

224. Probl. Angulum Horarij circuli & Eclipticæ, inueſtigare, Datis puncto Eclipticæ per quod tranſit Horarius, eiuſq. puncti Declinatione. *224. Problem. To find the angle of an hour circle and the ecliptic, given the point of the ecliptic through which the hour circle passes, and the declination of that point.*

[Margin: Problem 224.]

Since an hour circle is one of the circles of declination, and a circle of declination is the meridian of some people, seek the angle of the ecliptic and the meridian by problem 14, or by problems 76 to 83. See also, if you like, the practical instrument for this in Scheiner, *Rosa Ursina*, page 363.

225. Probl. Arcum Horizontis reſectum à circulo Horario inuenire, Datis Alt. Poli, & ipſo Horario. *225. Problem. To find the arc of the horizon cut off by an hour circle, given the altitude of the pole and the hour circle itself.*

[Margin: What the hour arc is.]

[Margin: Problem 225.]

In the following scheme let the meridian be HVRN, the horizon HBR, and the equator ABQ, described from the poles of the world P and O. Let the quadrant of the equator AB, and BQ, be divided into 6 parts, each containing 15 degrees, that is, one hour, so that a circle drawn through the poles of the world and such divisions is a circle of declination in such a way that it is also an hour circle. Thus the circle OBP is the circle of the sixth hour after or before noon; and the circle OLP, for example, if AL is equal to LB, is the circle of the 3rd hour after or before noon; and the circle OIP is that of the 9th hour before or after noon, in accordance with what was said more fully in Book 1, chapter 21, number 7.

Diagram. A circle set at the right of the right column, beside the text of problem 225, the "following scheme" used for problems 225 and 226. The rim is the meridian HVRN. It is crossed by a vertical diameter from V to N (the

vertical VBN of problem 226), a horizontal diameter from H to R (the horizon HBR), and the diameter from A to Q (the equator ABQ), with arcs and lines drawn from the poles P and O. Labels read:

- V (top)
- A (outside the rim, upper left)
- P (rim, upper right)
- L (inside, upper left)
- G (inside, right of L, by the vertical)
- H (left end of the horizontal)
- R (right end of the horizontal)
- K (inside, left, below the horizontal)
- B (inside, centre, below the horizontal)
- M (inside, right, below the horizontal)
- I (inside, lower right)
- O (rim, lower left)
- S (inside, below B, by the vertical)
- Q (rim, lower right)
- N (bottom)

Now the arc HK, or MR, cut off by such a circle is sought. Consider, then, the triangle HOK, right-angled at H. In it HO is given, the depression of the south pole, as great as the given altitude PR of the north pole. There is given besides the angle HOK, as great as OPA, determined by the hours before or after noon converted into parts of the equator, that is, by the arc AL; and these hours the hour circle itself, which is named from them, displays. Therefore by the 7th rule of spherical right-angled triangles seek the arc HK of the horizon, cut off by such an hour circle.

[Margin: Another way to conclude the same.]

But if you seek MR, use the triangle MPR, right-angled at R, in which the altitude of the pole RP is given, and the angle MPR, the supplement to two right angles of the angle IPA, which is known from the kind of hour circle, that is, from the hours before or after noon converted into parts of the equator. Accordingly, by the same 7th rule seek the side MR. The arc BK or BM, however, can also be found by problem 227, and when it is subtracted from 90°, the arc HK or MR is obtained.

226. Probl. Arcum Verticalis circuli cuiuſuis, reſectum ab Horario circulo inuenire, Datis præter Horarij ſpeciem, Azimutho, ſeu Declinatione Verticalis à Meridiano, & Altit. Poli. *226. Problem. To find the arc of any vertical circle cut off by an hour circle, given, besides the kind of hour circle, the azimuth, that is, the declination of the vertical from the meridian, and the altitude of the pole.*

[Margin: Problem 226.]

In the preceding figure let the vertical be VBN. What is sought, then, is the arc GV, cut by the hour circle OGP, or the arc NS, cut by the hour circle OIP. Use, therefore, the triangle VGP or ONS, in which the angle at V or at N is

right if the vertical is the prime vertical; otherwise it is known, because it is the complement of the given azimuth. There is given besides the complement of the altitude of the pole, which is PV, or of the depression of the other pole, which is ON; and from the kind of hour circle, that is, from the hours before or after noon converted into parts of the equator, the angle GPV is known, or SON, the supplement of the angle SOA to two right angles. Therefore, either by the 7th rule of spherical right-angled triangles, or by the 11th or 12th of the oblique-angled, you will learn the arc sought, GV or SN.

Probl. 227. 228. Arcum Horarium, ſeu Horizontis interceptum à Circulo Horario & puncto veri ortus occaſuſue Solis inueſtigare, Data Hora Aſtronomica, Italica, aut Babylonica & Altitudine Poli. *Problems 227 and 228. To find the hour arc, that is, the arc of the horizon intercepted by an hour circle and the point of the true rising or setting of the Sun, given the astronomical, Italian or Babylonian hour, and the altitude of the pole.*

[Margin: Problem 227.]

First, if the astronomical hour is given, the hour circle is also given, and from it the portion of the equator between the hour cir- [Margin: Order of the problems.]

cle and the meridian or the horizon.

Therefore, in the figure of problem 225, let the Sun be at L, and let the hour be the 3rd before or after noon. For the circle OLP will be given, answering to this hour and intercepting the arc AL of the equator, of 3 hours, that is, of 45 degrees. The complement of this arc to 90 degrees is the arc LB, in the triangle KBL, right-angled at L, in which the angle KBL is given, which the altitude of the equator measures, that is, the complement of the altitude of the pole. Therefore by the 9th rule of spherical triangles you will seek the base BK, which is called the hour arc; for the point of the true, that is, the equinoctial, rising or setting is B.

[Margin: Problem 228.]

Or seek the arc HK by problem 225; when it is subtracted from the quadrant HB, the arc KB will remain. Likewise in the triangle BIM, right-angled at I: when the hour before or after noon is given and converted into parts of the equator, and 90 degrees, that is, the quadrant AB, are subtracted, the side BI will be given, and the angle IBM, namely the altitude of the equator. Therefore by the same 9th rule you will obtain the desired arc BM; or certainly by problem 225, if you take the arc MR from the quadrant BR.

Second, if the hour is Italian or Babylonian, convert it into an astronomical hour by means of the semidiurnal arc, and do the rest as above. Or certainly, let the Italian or Babylonian hour be halved, that is, let half of it be taken, and let it be turned into parts of the equator. For in this way you will have the distance from the meridian of the hour arc answering to such an hour, namely the arc AL or AI. From these the arc BL or BI will also be known; and with these, as above, in the triangle KBL or BIM, and with the angle at B, you will find by

the 9th rule already mentioned the desired arcs BK or BM. The reason why the Italian or Babylonian hour is to be divided in two is given by our Clavius [Christoph Clavius], proposition 17 of his *Gnomonica*.

229. Probl. Poſitionis Arcum inuenire, ideſt Altitudinem Poli cõſpicui ſupra Circulum poſitionis ſtellæ aut puncti, Datis Altitudine poli, Declinatione ſtellæ ſeu puncti, & Diſtantia ipſius Aequatoria à Meridiano. & de Tabulis Poſitionum. *229. Problem. To find the arc of position, that is, the altitude of the visible pole above the circle of position of a star or point, given the altitude of the pole, the declination of the star or point, and its equatorial distance from the meridian. And on the tables of positions.*

[Margin: Problem 229.]

The circle of position, according to Regiomontanus's *Directions*, problem 20, and the common notion of the astrologers, as I also taught in Book 1, chapter 21, number 10, is a great circle drawn through the two common sections of the meridian and the horizon, and through a star or point of the celestial, or even of the terrestrial, spherical surface.

[Margin: The circle of position and the arc of position are not the same.]

But the arc of position is an arc of a great circle drawn from the visible pole of the world to the circle of position orthogonally, that is, at right angles. This arc is called the elevation of the visible pole of the world above the circle of position, and among the astrologers it is the foundation of directions. For it most of them usually hand down various rules and tables; but you would scarcely find anyone who knows how, or is willing, to dispatch this problem by a geometrical figure without tables, or to explain the foundation of the tables thoroughly. Indeed, Magini and some others confuse their readers when they confuse circles of position with arcs of position.

Let there be, then, in the adjoining figure the meridian HAPR, the horizon HBR, and the equator ABQ. And first let the star be at S, through which the semicircle of position HSR is to be drawn; and from the visible pole of the world P let the quadrant PSD of a circle of declination be drawn through the star; and from the same pole P the arc PC, falling perpendicularly on the semicircle of position HSR. For this arc will be the measure of the altitude of the pole P above the circle of position.

Diagram. A circle set at the right of the left column, beside the text of problem 229: the "adjoining figure", with the meridian HAPR as its rim, the horizon HBR as the horizontal line, the equator ABQ as the oblique line from A to Q, and arcs through H and R (semicircles of position) and lines from the pole P. A small star marks the point S. Labels read:

- A (outside the rim, upper left)
- S (inside, upper left, above the star)
- P (rim, upper right)
- C (inside, right of centre, above the line)
- D (inside, left, above the line)

- H (left end of the line)
- B (inside, centre, below the line)
- I (small, beside B at the right)
- R (right end of the line)
- O (inside, lower right)
- M (inside, lower left of centre)
- Q (rim, lower right)

[Margin: Step 1.]

To find this arc, then: first, in the triangle SPR seek the angle PRS by the 5th or 6th rule of spherical oblique-angled triangles. For in it the sides are given: PR, the altitude of the pole; and PS, which is either the complement of the declination DS, as in the figure, or a quadrant, or the aggregate of the quadrant and the declination of the star or point toward the other pole. There is given besides the vertical angle, that is, the angle contained by the given sides, namely SPR, since it is the supplement to 180 degrees of the angle SPA, which is known from the equatorial distance DA of the star S from the meridian.

[Margin: Step 2.]

Second, in the triangle PCR, right-angled at C, seek by the first rule of spherical right-angled triangles the arc of position CP, since in it the base PR is given, which is the altitude of the pole, and the angle CRP adjacent to it, found by the 1st step. But if the star or point is at M, first, in the triangle PMR, seek the angle MRP by the 5th or 6th rule of the oblique-angled, since PM is given, the aggregate of the quadrant PI and the southern declination MI; and PR, the altitude of the pole; and the angle MPR, the supplement to two right angles of the angle MPA, which is known from the distance from the meridian. Then, in the triangle POR, with the base PR and the angle MRP found, that is, ORP, seek the arc of position PO; and so for the rest.

[Margin: The authors of these tables.]

But if anyone unskilled in trigonometry, or weary of it, wants to find the arc of positions by means of tables, let him consult the tables of positions that Regiomontanus constructed: either the particular ones for altitudes of the pole of 42°, 45°, 48° and 51°, from page 176, up to the 32nd degree of declination, which is about the greatest declination of the planets; or the general one from page 224. Their use and construction he teaches, though very obscurely, in problems 20 and 29. Or consult Giovanni Antonio Magini, in his older *Tables of Directions*, from folio 137, where the general table of positions begins; or from folio 148, where the particular tables of positions begin, from a degree of the altitude of the pole up to 46°, for declination up to 31°, which hardly any planet exceeds. He teaches the use of these tables in the same place, canons 30 and 33. In his more recent *Tables of Directions*, published on Tychonic principles, he gives two general tables of positions from page 341, and two particular ones, which he calls "directorial", for altitudes of the pole of 42° and 45°, from page 379; their construction and use he teaches in the same place, canons 16, 17 and 18. From these Argoli and some others put together their own.

230. Probl. Horarium Stellæ aut Puncti circulum, ſeu ſitum inquirere, hoc eſt quot Horis Temporalibus diſtet à Meridiano, Datis Diſtantia eius à Meridiano & Arcu Semidiurno, aut Seminocturno. *230. Problem. To find the hour circle, that is, the position, of a star or point, that is, by how many temporal hours it is distant from the meridian, given its distance from the meridian and its semidiurnal or seminocturnal arc.*

[Margin: Problem 230.]

Gather the distance of the star or point from the meridian, if it is above the earth, or from the lowest heaven, if it is below the earth, and do so by problem 194; and gather the semidiurnal arc, if it is above, or the seminocturnal, if it is below the earth, by problem 122. Then multiply the distance of the star or point from the meridian by 6, and divide the sum by the semidiurnal or the seminocturnal arc; for the quotient will give the temporal hours by which the star is distant from the meridian or from the lowest heaven. Unless you prefer to use the general Ptolemaic table that Magini sets out in his *Tables of Directions*, folio 162, teaching its use in canon 35.

231. Probl. Aſcenſionem, aut Deſcenſionem Horariam Stellæ, aut Puncti Eclipticæ, ſeu Circulum Poſitionis Horarium inuenire. *231. Problem. To find the horary ascension or descension of a star or of a point of the ecliptic, that is, the horary circle of position.*

[Margin: Problem 231.]

Every point of the ecliptic and every star passes through the angle of the east with the oblique ascensions, through the angle of the west with the oblique descensions, and through the meridian with the right ascensions. Since this is so, that point or star, by the motion of the primum mobile, while it is moved from one angle to another, that is, from the beginning of one house to the beginning of another, produces a variation in ascension or descension as great as the ascensional difference at such an altitude of the pole. Again, since six temporal hours are assigned to a quadrant of the primum mobile, the ascensional difference turns out different for the individual hours, that is, less or greater according to the greater or lesser distance of the star from the meridian. Therefore, if the ascensional difference is distributed into six equal parts, and if from the right ascension of the star, in the first half of the ecliptic, the sixth part of the ascensional difference is taken away six times in succession, while in the remaining half it is added, the horary ascensions will result, for six whole

[Margin: Order of the problems.]

hours before noon. For the descensions and the hours after noon the contrary must be done; that is, subtraction in place of addition, and addition in place of subtraction. Or certainly use the table of horary ascension that Magini gives in his *Directions*, page 190, teaching its use in canons [?] 36 and 37.

The remaining problems, which serve judicial astrology, I have decided, for just reasons, to suppress.

232. Probl. Angulum Verticalis & Circuli Latitudinis in centro Sideris factum, inuenire. *232. Problem. To find the angle made at the centre of a star by the vertical and the circle of latitude.*

See the Appendix to Book 3, chapter 7, rule 3, problem 1.

SECTIO TERTIA IN QVA PROBLEMATA TEMPORIS.

Section Three, in which are the problems of time.

1. Problema. Diem Primi Mobilis à Die Sidereo & Solari diſcernere, ipſiuſq. Horas ac Minutias in partes Aequatoris, & has viciſſim in Tempora conuertere, ac Tabulas pro vtriſque exactas conſtruere. *Problem 1. To distinguish the day of the primum mobile from the sidereal and the solar day; to convert its hours and minutes into parts of the equator, and these in turn into times; and to construct exact tables for both.*

[Margin: Problem 1.]

What the primum mobile is, and how it is given, we discussed sufficiently in Book 9, Section 2, chapter 3. How great the difference is between one day of the primum mobile, one sidereal day, or day of the fixed stars, and one solar day, we examined most minutely in Book 3, chapter 31; and there we brought forward the cause of the difference, and the method of constructing 4 tables, of which two suit the day of the primum mobile and two the solar day. For one sidereal day is not longer than a day of the primum mobile by a hundred-and-twentieth part of a second of time, that is, of a beat of the human artery; and therefore this small addition escapes every subtlety of the senses, so that in practice, for a single day at least, it is to be disregarded.

[Margin: The root of the 1st table.]

The first table, then, is for converting degrees and minutes of the equator into hours and minutes of hours of the primum mobile. In it 4 minutes of time are given for each degree, 4 seconds for each minute of the equator, 4 thirds of time for each second, and so on.

[Margin: The root of the 2nd table.]

The second table is for converting hours and minutes of the primum mobile into degrees, or parts, and minutes of the equator. In it 15 degrees are given for each hour; 15 minutes of the equator for each minute of time; 15 seconds of the equator for each second of time; 15 thirds of the equator for each third of time; and so on.

[Margin: The root of the 3rd table.]

The third table is for converting degrees and minutes of the equator into hours and minutes of time of the mean solar day. In it there must be attributed to each degree $3^{m}\ 59^{s}\ 20½'''$ of time; to each minute of the equator, $3^{s}\ 59'''\ 20½''''$ of time; to each second of the equator, $3'''\ 59''''\ 20½'''''$ of time; and to each third of the equator, $3''''\ 59'''''\ 20½''''''$ of time.

[Margin: The root of the 4th table.]

The fourth table, finally, is for converting hours and minutes of the solar day into degrees and minutes of the equator. In it one must assign to each hour 15° 2′ 27″ 51‴, or 15° 2′ 28″ (granted that Reinhold, choosing a round number, gives 15° 2′ 30″); to each minute of time, 15′ 2″ 28‴ of the equator; to each second of time, 15″ 2‴ 28⁗; and finally to each third of time, 15‴ 2⁗ 28⁗′. See the form of these tables in the small tables that follow.

[Margin: Order of the problems.]

Auctores Tabularum præmiſſarum. *The authors of the tables set out above.*

The first table, complete, is found everywhere in the books on the sphere: the Alphonsine Tables, page 32; the Prutenic Tables, page 3; Orontius [Oronce Finé], Book 4 of the *Sphere*, chapter 5; Clavius in the *Sphere*, page 231; Blancanus [Giuseppe Biancani] in the *Sphere*, Book 1, part 1, chapter 5; Magini in the *Directions*, canon 16, and in the *Second Movables*, canon 9.

The second table, complete, is given by the Alphonsine Tables, page 32; Clavius in the *Sphere*, page 231; Lansbergen in the *Tables*, page 4; and Orontius, cited above.

The third table is given by Magini in the *Directions*, canon 16, and in the *Second Movables*, canon 9.

The fourth table is given by Reinhold in the *Directions*, precept 51.

2. Probl. Diſcernere Vſum temporis Primi Mobilis & Diei Solaris. *Problem 2. To distinguish the uses of the time of the primum mobile and of the solar day.*

[Margin: Problem 2.]

It matters greatly to know this difference, so that we do not confuse one time with another. The general rule is this: whenever we consider a time measured by the revolution of the equator viewed in itself — whether it is the measure of one revolution of the equator or of its parts — we should use the first or the second of the tables already mentioned. The same must be done when we consider arcs of the equator intercepted between two fixed points of the equator. But if the time is referred to the solar day and its parts, the third and fourth tables are to be used; and if the uses of both times are mixed, tables 1 and 2 must be used in part, and 3 and 4 in part.

[Margin: Case 1. Example.]

For example, suppose that from the difference of right ascension you are seeking the difference in time between the arrival of one fixed star and of another at the meridian, just as if the Sun did not exist in nature, or moved with no other motion than the fixed stars. Then the first table is to be used, because sidereal time differs insensibly from the time of the primum mobile. Conversely, suppose that from the time of the primum mobile between the transit of one fixed star and of another through the same meridian (known beforehand from the whole revolution of one fixed star to the same meridian) you wish to know the difference of right ascension: then Table 2 will have to be used.

[Margin: Case 2. Example.]

But if, from the Sun's distance from the meridian, you wish to know the solar time, or the hours of the Sun before or after noon, or the semidiurnal time, the 3rd table must be employed. Conversely, if from solar time, or the hours of the solar day, you want to know the arc of the equator, or the semidiurnal arc, use Table 4.

[Margin: Case 3. Example.]

When, finally, both kinds of time are mixed in practice, or an arc of the equator is to be gathered from both times, tables 1 and 2 must be employed in part, and 3 and 4 in part. Suppose, for instance, that from the distance of a fixed star from the meridian, and from its right ascension, the right ascension of the midheaven — that is, the point of the equator passing through the middle of the heavens — is to be gathered; and that then, from the right ascension

that the Sun has at that time of day (known in whatever way), compared with the right ascension of the midheaven, you wish to know the time in common use, namely the hour of the solar day reckoned from noon. You must then convert by the 3rd table into time the parts of the equator that correspond to the difference found between the right ascension of the midheaven and the right ascension of the Sun — granted that, to find the right ascension of the midheaven, you used an arc of the equator that abstracts from the Sun's motion. And conversely, suppose the time is counted up to the transit of a star through the meridian, and the time before or after the transit of the Sun through the meridian, so that from the difference or the sum of the two, together with the right ascension of the Sun, you may gather the right ascension of the fixed star. The time of the star's transit is then to be converted into parts of the equator by the 2nd table, but the time of the Sun's transit into parts of the equator by the 4th table.

I do not yet see these rules noticed by any of the astronomers. Magini and Reinhold, in the places cited under problem 1, were content only to acknowledge that the operation is more precise if we use table 3 in place of 1, and table 4 in place of 2. And yet, if this is neglected, there is a danger of erring at times by a whole half degree in the arc of the equator, and by two minutes in the time, when a semicircle is under consideration, as mostly happens; for in a whole circle the error committed could be one degree in the one case and 4 minutes in the other.

3. Probl. Minutias Diei in Horas ac Minutias Horarias, Parteſq. Aequatoris; & has viciſſim in Diei Minutias conuertere; ac Tabulas pro his condere. *Problem 3. To convert minutes of the day into hours and minutes of time, and into parts of the equator; and these in turn into minutes of the day; and to construct tables for them.*

[Margin: Problem 3.]

Since the Arabs, imitating Ptolemy, divide the day itself into 60 minutes, we shall make the first table if we multiply the given minutes of the day by 24 hours and divide the total by 60. For if no fraction remains, we shall have hours; otherwise we should divide the quotient again by 60, so that the second quotient gives the minutes of time.

[Margin: Table 1.]

From these, by the 2nd or the 4th table of problem 1, we shall then easily find the corresponding parts of the equator, and so make the second table. Alternatively, we shall obtain the same thing by multiplying the minutes of the day by 360 and dividing the total by 60.

[Margin: Table 2.]

Conversely, we shall multiply the given hours and minutes by 60 and divide the total by 24, for the quotient will show the minutes of the day that correspond to the hours and minutes of time; and in this way the third table can be made.

[Margin: Table 3.]

[Margin: Table 4.]

Lastly, the fourth table will be made if the parts of the equator are multiplied by 60 and the total is divided by 360 degrees.

[Margin: The authors of these tables.]

Tables 1 and 3, complete, are given by the Prutenic Tables, page 9½, and by Lansbergen, page 7 of the *Tables*. Table 2 is given by the Alphonsine Tables, page 32. Table 4, moreover, is given by the Prutenic Tables, page 3½; the Alphonsine Tables, page 32½; and Magini in the *Second Movables*, canon 9.

4. Probl. Tempus Aequale in Apparens, aut Apparens in Aequale conuertere, iuxta inæqualitatem Dierum Naturalium. *Problem 4. To convert equal time into apparent, or apparent into equal, according to the inequality of the natural days.*

[Margin: Problem 4.]

This was treated at length in Book 3, chapters 31 and 32, to which we refer the reader.

5. Probl. Horas Aſtronomicas, Babylonicas, Italicas & Europæas inuicem commutare. Nec non Aequales Horas in Temporales ſeu Inæquales. *Problem 5. To exchange astronomical, Babylonian, Italian and European hours for one another; and also equal hours for temporal, or unequal, hours.*

[Margin: Problem 5.]

The first conversion is treated sufficiently in Book 1, chapter 28; the second exchange in Book 1, chapter 29.

6. Probl. Horas quibus Luna noctu lucet, determinare. *Problem 6. To determine the hours during which the Moon shines by night.*

[Margin: Problem 6.]

This too we have treated thoroughly in Book 4, chapter 4, problem 2.

7. Probl. Semidiurnum ac Seminocturnum Tēpus Verum ſiue Solis ſiue cuiuſuis ſideris, inuenire Modis 4. Datis Declinatione ſideris, & Altitudine Poli vbi Sideris parallelus Horizontem ſecat; & Tabulas Condere. 8. 9. 10. Vel datis Aſcenſione Recta & Aſcenſ Differentia, aut Aſc. Obliqua ſideris ac Tabulas condere vel examinare. *Problem 7 [with 8, 9, 10]. To find the true semidiurnal and seminocturnal time, whether of the Sun or of any star, in 4 ways. Given the declination of the star and the altitude of the pole where the star's parallel cuts the horizon; and to construct tables. Or, given the right ascension and the ascensional difference, or the oblique ascension of the star, both to construct tables and to examine them.*

[Margin: Problem 7.]

The first way is mechanical, and uses an astronomical or a geographical globe, as I taught in Book 1, chapter 27, number 3; but it is not so exact. The second is carried out most exactly by problem 122, given in section 2.

[Margin: Problem 8.]

For the semidiurnal arc, once found, is to be converted into hours and minutes of time of the solar day by table 4, indicated in problem 1 of this section, rather than by table 2; but if the star is a fixed one, table 2 is to be employed. This time, subtracted from 12 hours, will leave the seminocturnal time. Furthermore, as great as the semidiurnal time is among the northern peoples, so great on the same day is the seminocturnal time among the southern peoples who have an equal alti- [Margin: Order of the problems.]

tude of their own pole; and as great as the seminocturnal time is for the northern peoples, so great is the semidiurnal for the southern peoples just mentioned.

[Margin: Problem 9.]

The third way is completed without trigonometry, by tables of the right ascensions of the Sun or of any star, together with tables of right ascensions. For when the ascensional difference corresponding to the place of the Sun, or of another star, in the ecliptic has been found for the given altitude of the pole, it is added to the right ascension if the star is on this side of the equator, and subtracted if it is beyond; and the result, or what remains, is the semidiurnal arc among the northern peoples, which is converted into hours, and so on, as was stated above for the 2nd way.

[Margin: Problem 10.]

The fourth way is carried out with the help of tables of oblique ascensions. For, for the given altitude of the pole, one looks up the oblique ascension of the star corresponding to its place in the ecliptic, and also the oblique ascension corresponding to the diametrically opposite place, that is, the one 180 degrees away from it in the ecliptic; and the former is subtracted from the latter (adding 360 degrees if need be). What remains is the diurnal arc, and this, cut in two, gives the semidiurnal arc, to be converted into hours as above. See the example in Book 1, chapter 27, number 4.

[Margin: The authors of this table.]

Tables of the semidiurnal time, moreover, are given by the Alphonsines, page 30, from a polar altitude of 36° to 45°, and for every third degree of the signs. Clavius in the *Sphere*, page 409, from an altitude of 36° to a polar altitude of 56°, and for every third degree of the signs. Magini in the Latin *Introduction to the Ephemerides*, page 25, and in the Italian, 32, for polar altitudes from 35° to 58°, but for each single degree of the signs; he adds as well a table of the rising and setting of the Sun, and of noon, in Italian hours. Franciscus Iunctinus [Francesco Giuntini], at the end of the *Speculum Astrologicum* and in its resolved tables, page 4, for polar altitudes of 36° to 55°, and for every third degree of the signs. Iosephus Moletius [Giuseppe Moletti] in Book 1 of Ptolemy's *Geography*, page 78, exactly as Iunctinus. Origanus in volume 1 of the *Ephemerides*, page 91, where he gives two tables for the single polar altitude of Frankfurt, 52° 20′, one according to the Prutenic obliquity of the ecliptic, the other according to the Tychonic; then, on page 91, he gives a table for polar altitudes from 6° to 89°,

and for every third degree of the signs, constructed according to an obliquity of the ecliptic of 23° 28′. And finally Argoli, in volume 1 of the *Ephemerides*, page 97, gives one like Magini's.

11. Probl. Semidiurnum Tempus Verum Solis determinare, vbi Parallelus Solis Horizontem non Secat, Seu Tempus continuatorum dierum abſq nocte, Datis Declinatione Sideris, & Altitudine Poli, & Obliquit. Eclipticæ. *Problem 11. To determine the true semidiurnal time of the Sun where the Sun's parallel does not cut the horizon, or the time of continuous days without night; given the declination of the star, the altitude of the pole, and the obliquity of the ecliptic.*

[Margin: Problem 11.]

Seek, by problem 217 of section 2, the arc of the ecliptic that is always visible. For as many degrees as such an arc contains, so many natural days, very nearly, will the Sun spend above the given horizon, making a continuous day. But if you wish to work more accurately, consult astronomical tables or ephemerides, and see how many days are needed for the Sun to pass from the degree in which the always-visible arc of the ecliptic begins to the degree in which it ends, taking one of those limits inclusively and the other exclusively. For instance, if that arc is of 20 degrees, of which the first is the 22nd degree of Gemini and the last the 11th degree of Cancer, seek the time in which the Sun runs from the 22nd degree of Gemini inclusive to the 11th degree of Cancer exclusive. This time, divided in two, can be called semidiurnal in the sense already given, and so on.

12. Probl. Semidiurnum Tempus Solis Apparens, aut cuiuſuis Sideris, Computatis Refractionibus & Parallaxibus inuenire Datis horizontali Refractione, Parallaxi & Declinatione Solis, vnà cum Alt. Poli: vbi Parallelus Sideris Horizōtem ſecat. *Problem 12. To find the apparent semidiurnal time of the Sun, or of any star, taking account of refractions and parallaxes; given the horizontal refraction, the parallax and the declination of the Sun, together with the altitude of the pole, where the parallel of the star cuts the horizon.*

[Margin: Problem 12.]

How great the force of refraction is in raising a star in appearance has been stated sufficiently in Book 1, chapter 36, and more fully in Book 3, chapter 9, in the scholia. It follows, then, that the Sun seems to rise somewhat sooner than it really rises, and to set somewhat later; and so, since the semidiurnal arc is increased at both ends, the apparent day is lengthened and the night shortened. The semidiurnal arc must therefore be corrected. To do this exactly, consider the following figure, in which, as usual, HVR is the meridian, HBR the horizon, ABQ the equator, CE its northern parallel and KD its southern.

Diagram. A circle set at the right of the right column, beside the opening of the construction of problem 12: the "following figure". V stands at the top of the rim, with C and A at the upper left, K at the left above H, H at the left, P at the upper right, R at the right, E and Q at the lower right and D at the

bottom. A near-horizontal line runs from H to R (the horizon HBR), with O, B, a small unread mark, and G standing along it from left to right. T stands below and left of O; L and F below G; N and M below the line; Z lower down, near the rim between M and Q. Straight lines run from V and from P to points on and below the line HR. Labels read:

- V (top of rim): the zenith end of the vertical; on the meridian HVR
- C (upper left of rim): end of the northern parallel CE
- A (upper left of rim): end of the equator ABQ
- K (left of rim, above H): end of the southern parallel KD
- P (upper right of rim): the pole of the world
- H (left): meridian and horizon
- R (right): meridian and horizon
- O (on the horizon, left of B): apparent rising of the star N
- B (on the horizon): point of the horizon and the equator
- [?] (on the horizon, immediately right of B): a very small mark that does not resolve on the scan; the text names a point I on the horizon, where the star M rises in appearance
- G (on the horizon, right of B): apparent rising of the star F
- T (below the horizon, left): where the star N would rise
- L (below G): where the star F would rise
- F (below G, right of L): the star on the northern parallel
- N (below the horizon, left): the star on the southern parallel
- M (below the horizon, centre): the star on the equator
- Z (near the rim, lower right): end of the quadrant of declination PFZ
- E (lower right of rim): end of the northern parallel CE
- Q (lower right of rim): end of the equator ABQ
- D (bottom of rim): end of the southern parallel KD

Now let the star be at the point F of the northern parallel, so that it would rise at L if refraction and parallax did not prevent it; but by the force of the corrected refraction let it rise apparently at G, when it is really at F, because refraction raises it visibly in the vertical VF by as much as the arc FG. And from the pole of the world P, through the star F, let the quadrant of declination PFZ be drawn. For in the triangle VFP three sides will be given: namely VP, the complement of the altitude of the pole; FP, the complement of the northern declination FZ; and VGF, made up of the quadrant VG and GF, the horizontal refraction of the star, first corrected by subtracting the star's parallax. Therefore, by [proposition] 14 of the oblique-angled spherical triangles, seek the angle VPF, which measures the arc ABZ of the equator, and so the semidiurnal arc as made apparent by the force of refraction. Further, the difference between the true semidiurnal arc AM and the apparent AZ will be the arc MZ, which the angle MPZ measures.

Similarly, if the star is at the point M of the equator, which would otherwise rise when it reached B, but by the force of the corrected refraction MI rises apparently at I, use the triangle VMP. In it VP is given, as above; PM is

a quadrant; and VM is made up of the quadrant VI and MI, the horizontal refraction of the star, corrected by subtracting the horizontal parallax. Therefore by the same [proposition] 14 you will seek the angle VPM, which is the measure of the semidiurnal arc AM; on account of refraction this is greater than the true semidiurnal arc AB by as much as the arc BM of the equator. Finally, if the star is at the point N of the southern parallel, which would rise on its arrival at T but rises apparently at O by the force of the horizontal refraction NO, employ the triangle VPN. In it the side VP is known, as above; PN consists of the quadrant PB and the southern declination BN; and VN consists of the quadrant VO of the vertical and the corrected horizontal refraction NO. Then by [proposition] 14 of the same triangles investigate the angle VPN, which measures the arc AB of the equator, that is, the apparent semidiurnal arc.

If the Sun is the star you are using, you will convert the semidiurnal arc into solar hours; if a fixed star, into hours of the day of the primum mobile. Further, from the time counted from the altitude of the fixed stars to the physical rising of the Sun, or from this to noon, compared with the semidiurnal quantity, we find that around the equinoxes the Sun usually rises sooner by two and sometimes by three minutes; but the variety of the refractions produces a remarkable diversity in this.

13. Probl. Semidiurnum Tempus Solis Apparens, computatis Refractione & Parallaxi Inuenire, vbi Parallelus Solis Horizontem non ſecat, ſeu diem continuam plurium dierum naturalium apparentem; Datis horizontali Refractione, & Parallaxi; ac Declinatione Solis; vnà cum Alt. Poli. *Problem 13. To find the apparent semidiurnal time of the Sun, taking account of refraction and parallax, where the Sun's parallel does not cut the horizon, or the apparent continuous day of several natural days; given the horizontal refraction and the parallax, and the declination of the Sun, together with the altitude of the pole.*

[Margin: Problem 13.]

Let the figure set out in section 2, problem 217, case 3, be taken up again. In it the parallel grazing the horizon is OR, and its true declination is AO, or GS, or QR — as great, that is, as the complement of the altitude of the pole to a quadrant. But if the Sun's horizontal refraction and parallax are known, subtract the parallax from the refraction, and there will remain the corrected refraction, which is to be subtracted from the declina- [Margin: Order of the problems.]

tion QR, since refraction, by raising the star, increases its declination — or, to speak more precisely, it makes the Sun, although it is on a parallel nearer the equator and having a smaller declination (say, below the parallel OSR), nevertheless seem to be on the parallel OSR. It follows that the arc BS of the ecliptic is smaller, and SC larger; and SC doubled makes the arc of the ecliptic that is always visible. Therefore, by problem 217 of section 3 [?], but using the declination, or the complement of the altitude of the pole, corrected by subtracting the horizontal parallax, seek the arc BS. You will then have the

apparent distance of the Sun S from the beginning of Aries, and so the point of the ecliptic that begins the always-visible arc; and the point S that ends the same arc is the same distance from the beginning of Libra. So the arc of the ecliptic enclosed within these points will not be hidden — namely, the arc of the ecliptic that is always visible by the force of the corrected refraction. From the ephemeris, moreover, the time will be known during which the Sun stays in that arc, which comes to nearly as many days as there are degrees in that arc.

Diagram. Three small circles set side by side across the left column, within the text of problem 13; each is crossed by a horizontal line from H to R (the horizon) and by oblique lines. The letters are very small. Labels read:

- First circle: K, A, C, V (along the upper left of the rim); P (right, above the line); H (left); B (centre); R (right); N (lower right); D, Q (together at the bottom)
- Second circle: C (upper left); V (top); P (upper right); A, K (left, above the line); H (left); B (below the centre); N, R (right); Q (right, below R); D (bottom)
- Third circle: V, P (together at the top); C (upper left); O (inside, below C); A (left); S (inside); H (left); G (a small letter just right of H, on the line); B, I, T (inside, below the centre); N, R (right); O (right, below R); M (right); D (bottom)

The contrary happens with the arc of the ecliptic that is always hidden, namely the arc TD taken twice: for it is made shorter than the true arc by as much as the true arc SC, taken twice, is made longer by the force of refraction.

14. Probl. Refractionem Horizontalem Solis, conuenientem ei in Altitudine Poli tanta, vt parallelus eius Horizontem non ſecet, inuenire, Datis Altitudine Poli, Declinatione Solis vera, & Arcu Eclipticæ ſemper apparente, aut ſemper latente ex obſeruatione cognito vel Die primæ aut vltimæ apparitionis Solis &c. *Problem 14. To find the horizontal refraction of the Sun that corresponds to it at an altitude of the pole so great that its parallel does not cut the horizon; given the altitude of the pole, the true declination of the Sun, and the arc of the ecliptic always visible or always hidden, known from observation, or the day of the Sun's first or last appearance, etc.*

[Margin: Problem 14.]

I have decided to insert this problem here, although it otherwise belongs to refractions, because of its affinity with the preceding one, and to illustrate it with a famous example reported by the observers themselves, the Dutch sailors, in the voyage to Nova Zembla [Novaya Zemlya] undertaken in 1596.

[Margin: The Dutch observation of the Sun always hidden.]

In qno [?] year, when they were at a northern polar altitude of 76 degrees, they saw the Sun on 2 November, new style, almost whole for the whole day, but not quite whole; on the 3rd they barely saw the upper edge of the Sun; and on the 4th they saw nothing of it at all, until 24 January 1597, when they began to see the upper limb of the Sun; and on the 25th they saw the whole

Sun standing clear — although, by problem 12, they did not expect the Sun until 11 February. They add, too, that from 30 April 1597 the Sun was always visible. Not knowing, then, the cause of so great a portent, they recorded it in writing as a wonderful thing in part 3 of the *Dutch Navigation*. From there Magini took it, in Book 6 of the *Primum Mobile*, problem 16, and so did Kepler in the *Astronomiae Pars Optica*, page 138, both rightly ascribing it to a very great refraction caused by the thickness of the vapours on that horizon.

For neither — as Kepler rightly argues — could those Palinuruses, who repeated the altitude of the pole so often, have committed so great an error as would be needed to defend this difference, which, as we shall soon see, exceeds 2 degrees; nor, as the disciples of Bodinus [Jean Bodin] imagined, was the place or shore where they were held fast in the bonds of the ice floating in the ocean, so that during that night of nearly three months it migrated sixty German miles towards the south. For they testify that they were then likewise at the same polar altitude of 76°, on 4 November of the year 1576[53] and on 24 January of the year 1579[54].

[Margin: Step 1: for the arc always visible, and the continuous day.]

In order, then, to investigate the enormous quantity of this refraction: first, by problem 217 of section 2, we shall investigate the true arc of the ecliptic that is always hidden, and always visible, at the given polar altitude of 76°, whose complement to 90° is 14°; and the declination GS, or TI, is as great. With this, and with the obliquity of the ecliptic — that is, the acute angle B — of 23° 30′, I find each of the arcs BS and BT to be 37° 21′. The first point of the ecliptic, S, distant from the beginning of Aries, B, and beginning the always-visible arc of the ecliptic, is therefore Taurus 7° 21′; and the point ending that arc is Leo 22° 39′. Now in the year 1597 the Sun was at Taurus 7° 21′ on 27 April, and at Leo 22° 39′ on 15 August; therefore from 27 April to 15 August the Sun ought always to have been visible above the horizon in question.

[Margin: For the arc always hidden, and the continuous night.]

Conversely, since from the arc BT of 37° 21′, reckoned from the beginning of Libra, one finds Scorpio 7° 21′, where the Sun was in the year 1596 on 30 October; and since, taking 37° 21′ before the beginning of Aries, one finds Aquarius 22° 39′, where the Sun was on 11 February 1597: it follows that the Sun ought to have been hidden on that horizon, with perpetual night, from 30 October inclusive to 11 February of the following year exclusive. And yet it was hidden only from 4 November to 25 January.

[Margin: Step 2: for the refraction.]

Second, converting the problem: the Dutch observation gives the time of the first occultation, which fell between 3 and 4 November, with the Sun placed at Scorpio 11° 44′ for the western shore of Nova Zembla; to this place of the Sun a declination of 15° 24′ corresponds. If you subtract from this the declination TI, corresponding to the parallel that grazes the horizon — that

[53] so printed; the passage's own dates are 1596–97, see 24 January 1597 above
[54] so printed; the passage's own date for this day is 24 January 1597

is, the complement of the altitude of the pole, which is 14° — there remains a refraction of 1° 24′. But between 24 and 25 January following, the Sun was at Aquarius 5° 5′, to which a declination of 19° 2′ corresponds; if you subtract 14° from this, there remains a refraction of 5° 2′. Magini, granted, in the place cited, gathers this second refraction as 4° 58′, because he uses the place of the Sun for day 25, without reducing it to the meridian of the western shore of Nova Zembla; while Kepler, using another and more obscure method, gathers the refraction now as 4° 3′, now as 4° 14′. Finally, on 30 April 1597 the Sun was at Taurus 9° 51′ for the western shore of Nova Zembla, and its declination is 14° 49′; subtract, then, 14 degrees, and a refraction of 49′ remains. Magini, granted, gathers 40′, because he uses a place of the Sun at Taurus 9° 25′. But since the Sun ought always to have been visible before 27 April, as is clear from the 1st step, I suspect that there is an error in the number of days, or that clouds stood in the way for several preceding days, or that they had sailed towards the south.

[Margin: Summary of the rule.]

Accordingly this problem 14 is solved by finding the declination of the Sun at the time of its first or last appearance at the given polar altitude, and comparing that declination with the complement of the altitude of the pole; for the difference between the complement and that declination is the horizontal refraction, which must, however, be corrected by subtracting the Sun's horizontal parallax.

Probl. Temporis momentum ex Obſeruatione Solis inquirere, Datis 15. Altitudine poli 16. Alt. Poli, Soliſq. Altitud. ac Loco in Eclipt. 17. Alt. Poli, Declinatione, & Altitudine Solis 18. Alt. Poli Azimutho, & Declinatione Solis 19. Alt. Poli, Altitud. ac Azimutho Solis 20. Azimutho, Altitud. ac Declinatione Solis *Problem. To find the moment of time from an observation of the Sun, given: 15. the altitude of the pole; 16. the altitude of the pole, and the Sun's altitude and place in the ecliptic; 17. the altitude of the pole, and the declination and altitude of the Sun; 18. the altitude of the pole, and the azimuth and declination of the Sun; 19. the altitude of the pole, and the altitude and azimuth of the Sun; 20. the azimuth, altitude and declination of the Sun.*

In the following scheme the meridian is HZRQ, the horizon HR, the equator EQ, and the north pole P, whose altitude PR, subtracted from 90 degrees, gives PZ, the distance of the pole from the zenith. The quadrant of the vertical circle, or circle of altitude, is AZ. The Sun's place is either at B, a point of the northern parallel — and then its northern declination is BN, and the complement of this to 90 degrees is BP — or at G, a point of the equator, and then no declina-

Diagram. A circle set at the right of the right column, beside the opening of the joint problems 15–20: the "following scheme". The horizon runs across it from H to R, and lines run from P and from Z across the circle. Labels read:

- Z (above the rim at the top): the zenith
- E (upper left of rim): end of the equator EQ
- N (just below E): end of the declination BN

- B (on an arc near the top): the Sun's place on the northern parallel
- P (right of rim): the north pole
- G (inside, left of centre): the Sun's place on the equator
- C (inside, right of G): not named in the text on this page
- I (below G): not named in the text on this page
- H (left): meridian and horizon
- A (on the horizon, below H): end of the vertical quadrant AZ
- R (right): meridian and horizon
- O (below the centre): not named in the text on this page
- Q (lower right of rim): meridian and equator

[Margin: Order of the problems.]

tion exists, but GP is a quadrant of the circle of declination; or at I, a point of the southern parallel, and then its southern declination is CI, which together with the quadrant CP makes up the arc ICP. Finally, the azimuth of the Sun — that is, the distance from the meridian of the vertical circle drawn through the Sun's centre — is the arc HA of the horizon, which the angle HZA measures; when that angle is subtracted from 180°, the angle AZP becomes known.

[Margin: Problem 15.]

First, then, if only the altitude of the pole is given, and you have equatorial armillae, set them so that the meridian of the armillae, which is HZRQ, coincides with the meridian line, and the equator of the armillae, ECQ, stands as far from the vertex or zenith as the altitude of the pole, PR; for in this way they will be set up analogously to the heavens. Then turn the circle of declination until one pinnule shades the other, or until the circle of declination itself, with its convex side, exactly shades the concave side opposite it. Note the arc of the equator between the meridian and the circle of declination, and convert the intercepted degrees into solar hours: in this way you will have the hours and minutes of hours before noon or after noon, according as the Sun was observed in the eastern or the western hemisphere.

[Margin: Problem 16.]

Second: if you lack armillae, use an astronomical globe. Raise the pole to the altitude due to it, and raise the point of the ecliptic in which the Sun then stands above the horizon by as much as the altitude of the Sun given by the observation requires. Through that point of the ecliptic draw, from the pole of the world, the semicircle of declination, fixed to the poles of the world so that it can be turned round; for the arc of the equator intercepted between this semicircle and the meridian, converted into solar hours, will give the time before or after noon. But if you wish to work more accurately, have recourse to the analysis of triangles by the following methods.

[Margin: Problem 17. The principal one.]

Third: let the Sun be at B, on this side of the equator. For in the triangle BZP the distance PZ of the pole from the vertex is given; and BP, the complement of the Sun's declination, which is known from the table of declinations if the Sun's place in the ecliptic is known from the ephemeris for the approximately

known hour; and finally the base BZ is given, since it is the complement to 90° of the observed altitude, corrected by adding the parallax and subtracting the solar refraction. Therefore, by [proposition] 14 of the oblique-angled spherical triangles, the angle BPZ will become known. It measures the arc NE of the equator, which is to be converted into solar hours so that you have the time before or after noon, according as the Sun was observed in the eastern or the western quadrant.

But if the Sun is in the equinoctial points, G, use the triangle GZP and seek the angle GPZ by the same 14; for the sides PZ, as above, and GP, which is a quadrant, are given, and GZ, the complement of the corrected solar altitude. But if the Sun is at I, beyond the equator, employ the triangle IZP, seeking the angle IPZ, which measures the arc CE; for the side PZ is given, and IP, made up of the declination and a quadrant, and the base IZ, the complement of the corrected altitude of the Sun. Then the arc of the equator, known from the angle P and converted into solar hours, gives the time before or after noon.

This problem is the most important of all those of this order, because it is enough to observe the altitude of the Sun and to correct it as has been said: the altitude of the pole is already given, and from the Sun's place, known in the ephemeris, the Sun's declination is given by the table, on which see section 2, problem 15. One must, however, know the hour beforehand roughly, so that from the two places of the Sun at noon — of the present day and of the preceding day if the Sun is in the eastern quarter, or of the following day if it is in the western — you may have a more exact place of the Sun for the said hour, and from it the corrected declination.

[Margin: Problem 18.]

Fourth: if, besides the side PZ, there are given the angle at Z, the supplement of the azimuth to 180°, and the side opposite it — namely BP, the complement of the declination, or GP, a quadrant, or IP, made up of the declination and a quadrant, according as the Sun was at B, at G or at I — seek, by [proposition] 3 of the oblique spherical triangles, the angle at P; convert it into solar hours before or after noon, according as the Sun was observed in the eastern or in the western hemisphere.

[Margin: Problem 19.]

Fifth: if, besides PZ, known as above, there is given the corrected altitude of the Sun, and from it its complement BZ, or GZ, or IZ, according as the Sun was at B, or G, or I; and the angle at Z, contained by the given sides and known from the azimuth, of which it is the supplement to 180°: seek by [proposition] 5 or 6 of the oblique spherical triangles the angle at P, and

[Margin: Order of the problems.]

convert it into hours before or after noon, and so on.

[Margin: Problem 20.]

Sixth: if there are given, from the azimuth, the angle at Z, and the complement of the corrected altitude, BZ, or GZ, or IZ; and either BP, the complement of the declination, or GP, a quadrant, or IP, the aggregate of the quadrant and

the declination: seek by [proposition] 1 of the oblique spherical triangles the angle at P, to be converted into hours before or after noon. Therefore in the four problems set out above, the triangle BZP, or GZP, or IZP must be solved, according as the Sun was at B, or at G, or at I.

[Margin: Other methods indicated.]

I pass over the remaining methods, which depend on a given angle at B, or G, or I, because this angle is not usually known except from the data already mentioned; and once these are in hand, the moment of time is found more readily through them. Since, however, these problems are in frequent use in astronomy, I will give an example in the one that is the easiest and most certain of all, namely in 17.

EXEMPLVM Probl. 17. *Example of problem 17.*

Let the altitude of the Sun be observed on 1645 April 10, at a polar altitude of 45°, in the morning, with an astronomical quadrant or otherwise, and let it be 10° 20′, at about the 6th hour before noon. First, then, I find from the ephemeris that the Sun's place at noon of April 10 is Aries 20° 54′, and on the preceding day 19° 56′; so the Sun's daily motion was 59′ [?]. Of these, about 15′ belong to 6 hours, to be subtracted from the place of the 10th day, so that the Sun's place at the 6th hour before noon is Aries 20° 39′. With this, from the table of the Sun's declinations, I find a northern declination of 8° 5′.

Next, since the Sun is at about its mean distance from the Earth, I find in my own tables that the Sun's parallax for the observed altitude of 10° 20′ is, by my reckoning, 24⅓″ (for Tycho's is 2′ 56″), and the refraction 9′ 40″. So, adding my parallax and subtracting the refraction from the apparent altitude, the corrected altitude of the Sun comes out at 10° 10′ 44″, that is, very nearly 10° 10′.

Therefore in the triangle BZP the side PZ is given, 45°, and the side BP, 81° 55′, as the complement of the declination BH, 8° 5′; finally the base BZ is given (much larger than the scheme shows), 79° 50′, as the complement of the corrected altitude AB, 10° 10′. With these, by [proposition] 14 of the oblique-angled spherical triangles, I find the angle BPZ, 82° 22′; to which, by Table 3 given in problem 1 of this section, correspond $5^{h}\ 28^{m}\ 34^{s}$ of solar time before noon. Working by logarithms, the example stands as follows.

Quantity	Arc	Logarithm	Value
PZ	45° 0′	Residual log.	015051
PB	81° 55′	Residual log.	000434
Aggregate	126° 55′		
BZ	79° 50′		
Sum	206° 45′		
Difference	47° 5′		
Half-sum	103° 22′	Log.	999925
Half-difference	23° 32½′	Log.	960143

Quantity	Arc	Logarithm	Value
Sum		Doubled log.	1975553
Half of the logarithm		Second log.	987776

To this second logarithm corresponds the angle 41° 11″ [?]. Therefore the vertical angle BPE is, as I said, 82° 22′.

SCHOLIA. *Scholia.*

[Margin: For observing the altitude.]

I. Although the more usual and more certain way of observing the altitude of the Sun uses a quadrant, or a square, or an astronomical ring, it can nevertheless also be observed by means of a gnomon casting a right or a versed shadow, or both. For these, look at the figure in

[Margin: Order of the problems.]

which there is a ruler AB parallel to the horizon, from which a style or ruler AC is raised perpendicularly, a little less high than a Roman foot, so that it casts a rather long shadow, but still a distinctly bounded one. And with the Sun at S, let the outermost ray DE fall from the upper limb D through the tip C of the ruler; then AE will be the right shadow.

[Margin: First method: by the right shadow.]

The ruler AB, however, must be divided into equal parts as small as possible, just like the ruler AC, so that you know exactly the parts of the right shadow AE in the parts in which AC is known. For in this way, in the triangle CAE, right-angled at A, the two sides about the right angle will be given; from them, by [proposition] 5 of the right-angled plane triangles, seek the angle AEC, which measures the altitude of the Sun's upper limb. If you subtract from it the Sun's apparent semidiameter SD, which is very nearly 16′, you will have the apparent altitude of the Sun's centre S.

Diagram. A figure set at the right of the left column beside the opening lines of the page, serving the three ways of observing the Sun's altitude by shadows. A small circle (the Sun) stands at the upper left, with lines running down from two points of its rim; below, a horizontal base line, an upright rising from its left end, a short horizontal at the top of the upright joined to a second upright, a long oblique line to the right end of the base, and an arc rising from the base. Labels read:

- S (centre of the small circle): the Sun's centre
- D (rim of the circle, right): the Sun's upper limb
- M (rim of the circle, left): the Sun's lower limb
- H (top of the left upright): end of the ruler FH; edge of the window CH
- F (top of the right upright): top of the wall FG
- C (on the left upright, below H): tip of the ruler AC; edge of the window CH
- V (on the oblique line, right of the upright through F): end of the versed shadow FV

- A [?] (lower left, the foot of the upright; printed without a visible crossbar): foot of the ruler AC
- E (on the base, right of A): end of the right shadow AE
- G (on the base, beside E): foot of the wall FG
- B (right end of the base): end of the line MB

[Margin: Second method: by the versed shadow.]

II. Now, for the versed shadow, let there be a wall or small beam FG, erected perpendicular to the horizontal plane AB and divided into very small equal parts; to its top F let another, shorter ruler FH be fixed, about a foot long or at most two feet, so that it makes a perfectly right angle F with FG, and divided into parts of the same kind as those in FG. With the Sun placed at S, the outermost ray MV will fall from the lower edge M through the end H, bounding the versed shadow FV. So, by counting the parts it takes up, the sides FV and FH about the right angle will be known; therefore by the same 5 you will find the angle H, which measures the altitude of the Sun's lower limb M. If you add to it the Sun's apparent semidiameter MS, you will have the apparent altitude of the Sun's centre.

[Margin: Third method: by both shadows.]

III. Finally, let there be a wall ACH erected perpendicular to the horizontal plane AB, in which there is a small window CH, with a plate on either side ending in sharp edges C and H; and let the length of the window, or the distance between the plates, CH, be known in the parts in which the height AC is known. For when the Sun shines directly on the window and sends its rays into the room (which ought to be thoroughly dark), the ray DE, grazing the lower edge of the window, will make or bound the right shadow AE; with it and with the side AC you will find, as above, the angle AEC, that is, the altitude of the Sun's upper limb. The ray MB, grazing the upper edge of the window, will bound the versed shadow, but a hidden one; in its place use the side AB and the whole height ACH, and seek by the same rule 5 of triangles the angle ABH, that is, the altitude of the Sun's lower limb. The difference between the altitudes of the upper and the lower limb will be the measure of the Sun's apparent diameter; and half that difference, added to the altitude of the lower limb, will give the apparent altitude of the Sun's centre.

Probl. Temporis momentum ex Obſeruatione Stellarum Fixarum, abſq. Trigonometria 21. deducere, Datis 22. Aſc. Recta Stellæ ac Solis 23. Aſc. Recta Stellæ ac Solis & Altitudine Stellæ ac Poli 24. Aſc. Recta Stellæ ac Solis, & Altitud. Poli. *Problem. To deduce the moment of time from an observation of the fixed stars, without trigonometry, given: 21. — 22. the right ascension of the star and of the Sun; 23. the right ascension of the star and of the Sun, and the altitude of the star and of the pole; 24. the right ascension of the star and of the Sun, and the altitude of the pole.*

[Margin: Preparation for the problems.]

The right ascension of the Sun, which is required here, becomes known from astronomical tables, or from an ephemeris constructed for your meridian or reduced to it: take the Sun's place in the ecliptic, and with it consult the tables of right ascensions given in problem 16 of section 2. Moreover, if you want to know the moment of time as it is a part of the day of the primum mobile, it is enough to gather the right ascension from the place of the Sun that it held at the preceding noon. But if, as is commonly done, you want the time and the hour of the solar day, you must know approximately, or roughly, the hour after noon of the preceding day; this is to be multiplied by 60 and the result divided by 24, for the quotient will give the minutes to be added to the place that the Sun had in the ecliptic at the preceding noon. With this place of the Sun, the Sun's right ascension is to be sought.

[Margin: Order of the problems.]

[Margin: Problem 21.]

First: if a fixed star crosses the meridian — shown by threads hanging perpendicular over the meridian line, or otherwise — the right ascension of the star will likewise be the right ascension of the midheaven. From it subtract the right ascension of the Sun (adding 360° if need be), and convert the remainder into solar hours and minutes, so that you have the time counted from the preceding noon. Therefore, if some astronomical observation can conveniently be made, by waiting for the moment of transit of a known fixed star through the midheaven, the moment of time can be gathered at once.

[Margin: Problem 22.]

Second: if a fixed star of known right ascension is distant from the meridian, let the time that elapses between the observation made and the transit of the fixed star through the meridian be counted by means of the pendulum (on which see Book 2, chapter 20, at the end of proposition 11), and let that time be converted into parts of the equator by Table 2, given in problem 1 of this section. These parts subtract from the right ascension of the fixed star itself if the star was eastern, or add if it was western, and you will have the right ascension of the midheaven; from this subtract the right ascension of the Sun, and convert the remainder into solar hours and minutes of hours, so that you have the time from noon.

[Margin: Problem 23.]

Third: use a very large astronomical globe, raising the pole to the given altitude of the pole and turning the globe until the fixed star whose altitude is given reaches that given altitude above the horizon, measuring it with a special pair of compasses or with a quadrant arc fitted to the globe. For if you draw the semicircle of declination from the pole of the world through the star, it will cut off the arc of the equator lying between this semicircle and the meridian. Subtract this arc from the right ascension of the star if it is eastern, or add it if it is western, and the right ascension of the midheaven will result; subtracting from it the right ascension of the Sun, and turning the remainder into solar hours and minutes, you will have the time from noon.

[Margin: Problem 24.]

Fourth: employ equatorial armillae set up astronomically, as the altitude of the pole requires. For the circle of declination, turned so that the star's rays pass through the dioptric pinnules, will cut off the arc of the equator between itself and the meridian; use this arc as in problem 23.

Probl. Temporis momentum ex Stellæ Fixæ obſeruatione Deducere Trigonometricè, Datis præter Aſcenſionem Rectam Solis & Stellæ Fixæ 25. Alt. Poli, Declinatione ac Altitudine Stellæ 26. Alt. Poli, Azimutho, & Declinat. Stellæ. 27. Alt. Poli, Azimutho, & Alt. ſtellæ. 28. Azimutho, Altitudine ac Declinat. Stellæ. *Problem. To deduce the moment of time trigonometrically from an observation of a fixed star, given, besides the right ascension of the Sun and of the fixed star: 25. the altitude of the pole, and the declination and altitude of the star; 26. the altitude of the pole, and the azimuth and declination of the star; 27. the altitude of the pole, and the azimuth and altitude of the star; 28. the azimuth, altitude and declination of the star.*

How the right ascension of the Sun is to be gathered, I taught in the preparation for problem 21. Once it is known, use the figure set out in problem 15, and carry out for the fixed star everything I said there about the Sun, so as to have the angle at P, the pole of the world; for this angle measures the arc of the equator intercepted between the meridian and the circle of declination drawn through the star. This arc, then, you will subtract from the right ascension of the fixed star itself if the star is in the eastern hemisphere, and add it if in the western, and you will obtain the right ascension of the midheaven. From this subtract the right ascension of the Sun (adding 360°, if the subtraction requires it), and convert the remainder into solar hours and minutes of hours; in this way you will have the exact time from the preceding noon.

[Margin: Problems 25, 26, 27, 28.]

Therefore you will solve problem 25 as problem 17, problem 26 as problem 18, problem 27 as problem 19, and problem 28 as problem 20. Yet of them all the easiest and most certain is 25, for it is enough to observe the altitude of the star without the azimuth; the rest are given easily, namely the distance of the pole from the vertex, since it is the complement

[Margin: Order of the problems.]

of the altitude of the pole; and the other side is given from the declination of the fixed star, since it is either the complement of the declination, if the star is on this side of the equator; or a quadrant, if the star is on the equator; or the aggregate of the quadrant and the declination of a fixed star placed beyond the equator. These two sides contain the required angle at the pole of the world. The base, moreover, is the complement of the observed altitude, corrected by subtracting the refraction; although it is advisable to use stars raised beyond the hazard of sensible refractions, namely those having an altitude of not less than 20°. With these given, then, the angle at the pole is obtained by [proposition] 14 of the oblique spherical triangles. Since, however, this problem 25 is the

most used in most of the astronomical observations made at night, I am glad to add an example of it.

EXEMPLVM Problematis 25. *Example of problem 25.*

Let the altitude of Arcturus in the east be observed on 1645 April 10, at a polar altitude of 45°, as 44° 20′, at about the 9th hour after noon. First, the ephemeris gives the Sun's place at noon as Aries 20° 54′. The 9 hours multiplied by 60 make 540; divided by 24 hours, these yield 22½′[55], the minutes to be added to the Sun's place; and so at the 9th hour the Sun's place in the ecliptic is Aries 21° 16′. To this place, from the table of right ascension constructed for an obliquity of the ecliptic of 23° 30′, there corresponds a right ascension of the Sun of 19° 39′. From the corrected tables of the fixed stars, moreover, the right ascension of Arcturus for this time is found to be 209° 57′ 11″, and its northern declination 21° 5′ 27″, whose complement is 68° 54′ 33″. With these prepared, the triangle BPZ will be solved as follows, in the figure of problem 17, which is set on page 578.

Quantity	Arc	Logarithm	Value
PZ	45° 0′ 0″	Residual log.	015051
BP	68° 54′ 33″	Residual log.	003011
Aggregate	113° 54′ 33″		
Base BZ	45° 40′ 0″		
Sum	159° 34′ 33″		
Difference	68° 14′ 33″		
Half-sum	79° 47′ 16″	Log.	999306
Half-difference	34° 7′ 16″	Log.	974892
		Doubled second log.	1992260
Half vertical angle	23° 50′ 0″	Second log.	996130
Angle BPZ	47° 40′ 0″		

Since, then, half of the doubled second logarithm is the second logarithm of the half-angle BPZ, 23° 50′, the whole vertical angle BPZ, or NPE, is in any case 47° 40′. When these are subtracted from the right ascension of Arcturus in the east, 209° 57′, there remains the right ascension of the midheaven, 162° 17′. Subtracting from this the right ascension of the Sun, which is 19° 39′, there is left an arc of 142° 38′, which, converted into solar hours, gives 9^h 29^m after noon on April 10.

29. Probl. Temporis momentum deducere, Datis Alt. Poli Aſc. Recta Solis, & duabus Stellis in eodem ſimul Verticali obſeruatis, quarum nota ſit Aſc. Rec. & Declinatio, eaq. occaſione, ſi lubeat, Altitudinem Fixarum inuenire. *Problem 29. To deduce the moment of time, given the altitude of the pole, the right ascension of the Sun, and two stars observed at the same time on the*

[55] so printed; 540 divided by 24 gives 22½

same vertical circle, whose right ascension and declination are known; and on that occasion, if one wishes, to find the altitude of the fixed stars.

In the following figure the meridian is HVRQ, the horizon HOR, the equator AOQ, and the altitude of the pole PR, whose complement to 90° is PV. The quadrant of the vertical circle is VT, on which stand the two stars F and G together; through them let the quadrants of declination PFK and PGM be drawn.

[Margin: Problem 29.]

First, in the triangle FPG, seek by [proposition] 4 of the oblique spherical triangles the base FG, and by 5 or 6 the angle PGF; for in it are given the side FP, the complement of the declination of the star F, the side GP, the complement of the declination of the star G, and the contained angle GPF, since it is the difference of the right ascensions of the two stars.

[Margin: Order of the problems.]

Second, in the triangle VGP, seek by 3 of the same triangles the angle GPV, that is, MPA, and by 2 the base VG; for there are given the sides VP, the distance of the pole from the vertex, and GP, the complement of the declination of the star G, and the angle VGP, already found.

Third: subtract the angle MPA, that is, the arc MA, from the right ascension of the star G if it is eastern, or add it if western, and the right ascension of the midheaven will become known; subtract from this the right ascension of the Sun, and the remainder, converted into solar hours, will give the desired time from the preceding noon. Fourth: subtract the base VG from 90°, and there will remain the true altitude TG of the star G; if you add to it the base FG, found in the first step, the altitude TF of the star F will result.

Diagram. A circle set at the right of the right column, beside the solution of problem 29: the "following figure" of that problem. The horizon runs across it from H to R, the equator from A through O to Q, an arc of the vertical circle from V down through F and G, and lines run from P to K and from P through G to M. Labels read:

- V (top of the rim): the vertex
- A (upper left of the rim, a short dash before it): end of the equator AOQ
- F (inside, below V): the star F
- P (upper right of the rim): the pole
- K (inside, left): end of the declination quadrant PFK
- G (inside, below F): the star G
- H (left of the rim): meridian and horizon
- M (inside, left of centre): end of the declination quadrant PGM
- R (right of the rim): meridian and horizon
- O (below the centre): intersection of horizon and equator
- T (inside, right of O): foot of the vertical quadrant VT
- Q (lower right of the rim): meridian and equator

30. Probl. Temporis momentum Data Aſc. Recta Solis ac Medij Cæli aut Obliqua Horoſcopi, ſeu puncti Eclipt. Aſcendentis. *Problem 30. The moment of time, given the right ascension of the Sun and of the midheaven, or the oblique ascension of the ascendant, that is, of the rising point of the ecliptic.*

[Margin: Problem 30.]

If the right ascension of the midheaven is not given, subtract 90° from the oblique ascension of the ascendant; there will remain the right ascension of the midheaven. From this subtract the right ascension of the Sun, and convert the remainder into solar hours and minutes, so that you have the time from noon.

31. Probl. Temporis momentum definire, Dato Temporis momento in alio loco Terræ, cuius nota ſit differentia longit. à tuo loco. *Problem 31. To determine the moment of time, given the moment of time at another place on the Earth whose difference of longitude from your place is known.*

[Margin: Problem 31.]

Suppose the beginning of an eclipse was observed at Paris at $10^h\ 30^m$ after noon. Then, since Bologna in Italy differs in longitude by 11°, to which correspond 44 minutes of time, and Bologna is more easterly, you will conclude that the beginning took place at Bologna at $11^h\ 14^m$; but if Bologna were more westerly, those 44^m would have to be subtracted.

32. Probl. Tempus Ortus, Occaſuſue Solis veri aut Apparentis inueſtigare. *Problem 32. To investigate the time of the rising or setting of the Sun, true or apparent.*

[Margin: Problem 32.]

Seek the true semidiurnal time by problems 7 or 8, etc., or the apparent one by problem 12; and that very time will be the time before noon at which the Sun's centre will rise, and after noon at which it will set, truly or apparently.

33. Probl. Tempus Apparens Ortus & Occaſus Limborum Solis definire. *Problem 33. To determine the apparent time of the rising and setting of the Sun's limbs.*

[Margin: Problem 33.]

Consult problem 12: subtract the Sun's apparent semidiameter from the Sun's horizontal refraction, and carry out the rest as there; for you will have the semidiurnal time at which the upper limb of the Sun will apparently both rise before noon and set after noon. Again, add the Sun's apparent semidiameter to the Sun's horizontal refraction and do the rest as there; for you will obtain the semidiurnal time at which the lower limb of the Sun will apparently rise before noon, and at which it will set after noon.

34. Probl. Tempus requiſitum vt totus Solis diſcus oriatur ſupra Horizontem definire. *Problem 34. To determine the time required for the whole disc of the Sun to rise above the horizon.*

[Margin: Problem 34.]

Find the time of the apparent rising of each edge of the Sun by problem 33; for the difference between the risings of the two limbs will be the required time. Or at least observe it, [Margin: Order of the problems.]

by counting the time with the help of the pendulum explained in Book 2, chapter 20. We have done this very often, as we shall relate, God willing, in volume 3 among the solar observations, and we found it to be 186^s or 184^s of time on the equinoctial days, but 320^s at the time of the summer solstice and 380^s at the time of the winter solstice. See also, if you please, the small table set out for this in the Appendix to Book 3, chapter 10, towards the end.

[Margin: Our observation concerning the rising of the Sun's disc.]

35. Probl. Tempus, quo Sol aut Luna oritur priùs habitanti in Montis aut Turris cacumine, quàm habitanti ad pedem Montis aut Turris, Datis Semidiametro Terræ, Altitudine Montis aut Turris, Altitudine Poli, ac Declinatione Solis, Methodo Petri Nonij ſed fallaci. *Problem 35. The time by which the Sun or the Moon rises earlier for someone living on the summit of a mountain or tower than for someone living at the foot of the mountain or tower, given the Earth's semidiameter, the height of the mountain or tower, the altitude of the pole and the declination of the Sun: by the method of Petrus Nonius, but a fallacious one.*

[Margin: Problem 35.]

Let ANCQ be a vertical circle passing through the centre [?] of the rising Sun, and under this circle let TKR be a great circle of the Earth, with a tower or mountain TD standing on it, whose summit is D and foot T. Let the rational horizon of the inhabitant at T be ABC, and his sensible horizon ETG; for the inhabitant at K, let the rational horizon be PBQ and the sensible horizon HKM, touching the Earth at K. Let the lines NB and BL be perpendicular, NB to the horizon AC and BL to the horizon PQ. Now it is evident that at the moment when the Sun M rises physically for the inhabitant at K, it also rises for the inhabitant at D; and when it rises at G, it rises sensibly for the inhabitant at T.

With these premises, the first thing sought is the arc MG, that is, the difference between the sensible horizons, or the depth of the Sun M below the horizon ETG when the Sun rises at M. You will find this arc as follows. In the triangle BKD, right-angled at the point of contact K by [proposition] 18 of the third book of Euclid, there are given BK, the Earth's semidiameter, known in paces, and BTD, consisting of the Earth's semidiameter BT and the height TD. Therefore by [proposition] 11 of the plane right-angled triangles find the angle DBK, or NBL. This angle is equal to the angle CBQ: for each of them together with the angle LBC makes up a right angle, the first the angle NBC, the second the angle LBQ; hence, when the common angle LBC is taken away, there remains NBL equal to CBQ, which measures the arc QC, that is, the distance of the rational horizon PQ from the horizon AC. But the distance of the sensible horizon HM from the sensible horizon EG is just as great, because the arc MQ, by which PQ is distant from HM, is equal to the arc CG, by which

AC is distant from EG, since the parallels of each pair are distant from each other by the same terrestrial semidiameter, BK and BT. Therefore MG is given, the depth of the Sun M below the horizon, which we were seeking.

Secondly, then, with this depth, the declination of the Sun and the altitude of the pole, find the semidiurnal arc and time by problem 12, using the arc MG just found in place of the horizontal refraction, adding it to the vertical quadrant, and carrying out the rest as there. Compare this time with the semidiurnal time for the given day (for if the declination is given, one or other of the days on which that declination belongs to the Sun, before or after the nearer solstice, is also given) and for the given altitude of the pole: the difference of this time from the former will be the time by which the Sun rises earlier for the inhabitant at D than for the inhabitant at T. But that holds if the Sun's rays are supposed unrefracted, as Nonius supposes them in his book *De crepusculis*. Since in reality they are refracted in the denser air around the Earth, by their force the Sun will rise much sooner for the summit of the mountain; and so this problem is liable to an optical fallacy, which we shall correct in the following Section, problem 36.

[Margin: The error of Petrus Nonius.]

Diagram. A large circle set at the right of the left column, with a small circle (the Earth) drawn about T inside it. A vertical runs from N at the top through D, T and B; two horizontals run from E to G and from A to C; lines run from P through T and K to M, from H down towards Q, and from K up to L.

- P, H (upper left of the rim): ends of the lines through the Earth
- N (top): the zenith end of the vertical NB
- L (upper right): end of the perpendicular BL
- G, C (right of the rim, G above C): ends of the horizons ETG and ABC
- E, A (left of the rim, E above A): the other ends of those horizons
- D (inside, above the small circle): the summit of the tower or mountain
- T (centre of the small circle): its foot
- K (right edge of the small circle): the second inhabitant's station
- B (below T): the Earth's centre in the construction
- R (inside, below the small circle): on the Earth's great circle TKR
- M (lower right of the rim): the Sun rising for the inhabitant at K
- Q (below M): end of the rational horizon PBQ

[Margin: Order of the problems.]

36. Probl. Crepuſculi apparentis Quantitatem inquirere, Data Profunditate Solis ſub Horizonte ad initium matutini, aut finem veſpertini Crepuſculi cum Altit. Poli & Declinatione Solis. *Problem 36. To find the length of the apparent twilight, given the Sun's depth below the horizon at the beginning of morning twilight or the end of evening twilight, together with the altitude of the pole and the declination of the Sun.*

[Margin: Problem 36.]

How the Sun's depth at the beginning or end of an observed twilight is gathered, and how great it is, was stated in Book 1, chapter 31, and in its Scholium 2. With that depth given, therefore, and added to the quadrant of the vertical circle, use problem 12 and its figure, in which let FG be the depth, added to the quadrant VG, so that the side VF is known; let the side FP be the complement of the Sun's declination, and VP the complement of the altitude of the pole. Therefore, in the triangle VFP, find by [proposition] 14 of the oblique spherical triangles the angle FPV, which measures the arc ABZ of the equator. From this subtract the semidiurnal arc; the remainder, converted into solar hours or minutes of time, will give the length of the twilight. I know that others investigate this with the help of the analemma, as Biancani does in the *Sphaera*, Book 10, or "On the Sun", chapter 16, or else by plane triangles. But the method I have proposed here is the most exact of all.

37. & 38. Probl. Tempus inuenire, quo Sol aut Sidus quoduis venit ad Verticalem Primarium, aut ad quemuis Verticalem, Datis Altitud. Poli, Declinatione Sideris, & Azimutho ipſius Verticalis. *Problems 37 and 38. To find the time at which the Sun or any star comes to the prime vertical, or to any vertical, given the altitude of the pole, the declination of the star, and the azimuth of the vertical itself.*

[Margin: Problem 37.]

In the next figure the meridian is HVRN, the horizon HR, the equator AOQ, and the prime vertical quadrant VO, in which the Sun is at T. Now in the triangle TVP, right-angled at V, there are given PV, the complement of the altitude of the pole PR, and TP, the complement of the declination. Therefore by [proposition] 5 of the right-angled spherical triangles seek the angle TPV; converted into hours and minutes, either solar or of the primum mobile according as the star is the Sun or a fixed star, it will give the time both before and after noon at which the star comes to the prime vertical.

[Margin: Problem 38.]

Now let the star be at the point B of another vertical. In the triangle BPV find the angle BPV, to be converted into time, so that you have the time before and after noon at which the star will arrive at the vertical VM. Seek it, I say, by [proposition] 3 of the oblique-angled spherical triangles: for in that triangle there are given VP, the complement of the altitude of the pole; BP, the complement of the star's declination; and the angle BVP, because it is the supplement of the given azimuth to two right angles. But if the star is beyond the equator, at I, use the triangle IPV, seeking the angle IPV, since there are given VP, the angle at V as above, and IP, consisting of a quadrant and the star's declination.

Diagram. A circle (the sphere) set at the right of the right column. HR runs across it; dotted lines descend from V through T and O and from M towards Q; straight lines run from P to K, from P to A, and from P through T towards I and M; an arc runs from C down through B and S to I.

- V (top of the rim): the zenith, on the meridian HVRN
- C (upper left, outside the rim)
- A (upper left of the rim): end of the equator AOQ
- B (inside, below C): the star on another vertical
- P (right of the rim, high): the pole
- K (left of the rim, below A)
- S (inside, right of K; italic)
- T (inside, above O): the Sun on the prime vertical
- I (inside, at the left; small): the star beyond the equator
- H, R (left and right of the rim): ends of the horizon HR
- M (inside, below H): on the vertical VM
- O (centre)
- D (lower right of the rim)
- Q (lower right, below D): end of the equator AOQ
- N (foot): on the meridian

39. Probl. Tempus inuenire, quo Sidus veniet ad datam altitudinem in Verticali, Datis Alt. Poli, & Declinat. Sideris. *Problem 39. To find the time at which a star will come to a given altitude in a vertical, given the altitude of the pole and the declination of the star.*

[Margin: Problem 39.]

In the figure immediately preceding, let the star be at B, and consider the triangle BPV, in which there are given PV, the complement of the altitude of the pole; BV, the complement of the star's given altitude; and BP, the complement of the declination. Therefore by [proposition] 14 of the oblique-angled spherical triangles you will find the angle BPV, which, converted into time, will give the desired time before or after noon at which the star will arrive at the given altitude.

[Margin: Order of the problems.]

40. & 41. Probl. Tempus inuenire, quo Sol, aut quoduis Sidus perueniet ad Nonageſimum Eclipticæ gra[?]um, dato die & in data Altitudine Poli. *Problems 40 and 41. To find the time at which the Sun, or any star, will arrive at the nonagesimal degree [?] of the ecliptic, on a given day and at a given altitude of the pole.*

[Margin: Problem 40.]

If the star is not the Sun, consult Book 4, chapter 4, problem 8, and take what was said there of the Moon as said of any other planet or fixed star. If it is the Sun, seek the semidiurnal time by problem 12. Then seek the oblique ascension of the point of the ecliptic in which the Sun is, and of the point of the ecliptic 90 degrees distant from it in the order of the signs; and take the arc of the equator intercepted between the two oblique ascensions, converted into solar time, away from the semidiurnal time, if the semidiurnal time is the greater: the remainder will be the time before noon at which the Sun will be in

the nonagesimal degree of the ecliptic, counted from the rising horizon. But if the semidiurnal time is the smaller, subtract it from the arc already mentioned, converted into time; the remainder will be the time after noon at which the Sun will come to the nonagesimal. Finally, if the arc already mentioned were equal to the semidiurnal arc, the Sun will be in the nonagesimal at the very moment of noon.

[Margin: Problem 41.]

You will obtain the same result another way, by the doctrine of triangles, from the figure already set out in Section 2, problem 206, in which N is the nonagesimal degree of the ecliptic and the Sun is in it. *First*, then, in the triangle NPZ, find by [proposition] 14 of the oblique spherical triangles the angle PNZ. For there are readily given the base PZ, which is the distance between the poles of the ecliptic and of the equator, as great as the obliquity of the ecliptic; and the sides N VZ [?], which is a quadrant of the circle of latitude, and NP, which is the complement of the Sun's declination if the Sun is on this side of the equator, or a quadrant if it is on the equator, or the sum of a quadrant and the declination if it is beyond the equator.

[Margin: Step 1.]

Secondly, in the triangle NVP, seek by [proposition] 3 of the oblique spherical triangles the angle NPV: for there are given the angle VNP, already found, and the side PN, from the Sun's declination; and VP, which is the complement of the altitude of the pole, is supposed known. Lastly, convert the angle NPV into solar hours and minutes of hours, for you will have the time before or after noon at which the Sun is in the nonagesimal: before noon if the nonagesimal (namely the given place of the Sun) is in the eastern quadrant, but after noon if it is in the western quadrant. For the situation of the nonagesimal in this respect consult problem 182 of Section 2; or, if you please, gather it easily by looking at a globe and turning it.

[Margin: Step 2.]

Diagram. A circle set at the right of the left column, with a small circle drawn about P at the right of the rim; a curve runs from E at the upper left over V to the small circle. HR runs across; a line runs from N through D and C to P; another from H through A and B towards M; lines descend from V.

- E (outside, upper left): end of the curve
- V (top of the rim): the zenith
- Z (outside, upper right; small): the pole of the ecliptic, per the text
- O (upper left of the rim)
- N (inside, below O): the nonagesimal degree, with the Sun in it
- D (inside, right of N)
- C (inside, right of centre)
- I (inside, upper right)
- P (inside the small circle at the right): the pole of the world
- L (right of the rim, below P)
- H, R (left and right of the rim)

- A (inside, lower left)
- B (on the rim, below)
- M (outside, lower right)

42. Probl. Tempus inuenire, quo arcus Eclipticæ datus, tranſit per Verticalem Primarium aut quemuis alium, Datis Declinatione, & Aſcenſ. recta extremorum Eclipticæ arcum concludentium & Alt. Poli, & quandoq. Azimutho Verticalis. *Problems 42 and 43. To find the time in which a given arc of the ecliptic passes through the prime vertical or through any other vertical, given the declination and right ascension of the endpoints of the ecliptic that enclose the arc, the altitude of the pole, and sometimes the azimuth of the vertical.*

[Margin: Problem 42.]

If the given arc of the ecliptic has one or both of its endpoints in the southern semicircle of the ecliptic, it never passes whole through the prime vertical for an inhabitant of the north. If the arc is the whole northern semicircle, it passes through the prime vertical in 12 equal hours. If it is less than the northern semicircle, but each of its endpoints is equally distant from the beginning of Cancer — as if the arc lay between 20° of Taurus and 10° of Leo — the arc of the equator enclosed between the right ascensions of the two endpoints, converted into hours of the solar day, will give the desired time. But if it is less than the northern semicircle and its endpoints are not equally distant from the beginning of Cancer, look at the following figure, in which the meridian is HVRN; the horizon HMR; the equator AOQ; the ecliptic GOE; the prime vertical VMN, making right angles with the meridian at V and N; and let P be the north pole of the world.

[Margin: Order of the problems.]

Now let the arc FK of the ecliptic be given, whose beginning F has a greater declination than its end K: it will pass through a higher point of the vertical, say through B, than the end, which passes through the point K. The contrary would happen if the beginning of the arc had a smaller declination than the end, for it would pass through a less high point. Now let quadrants of declination be drawn through the points B and K, and let them be PBI and PKL. With this set up, *first*, in the triangle BVP, right-angled at V, investigate by [proposition] 5 of the right-angled spherical triangles the angle BPV; for there are given the base BP, which is the complement of the greater declination, and the side VP, the complement of the altitude of the pole.

[Margin: Step 1.]

Secondly, in the triangle KVP, right-angled at V, seek the angle KPV by the same [proposition] 5; for there are given the base KP, the complement of the smaller declination, and VP, as above. Then subtract the smaller of the angles found from the greater; there will remain the angle BPK, measuring the arc IL of the equator, which is called the equation or prosthaphaeresis.

[Margin: Step 2.]

Thirdly, subtract the smaller of the right ascensions of the given endpoints of the ecliptic from the greater, and the remainder will be an arc of the equator, to be held in mind here for the time being. From this arc, then, subtract the prosthaphaeresis already mentioned if the beginning of the arc is more northerly, that is, has the greater declination; but add it if the beginning has a smaller declination than the end. What remains or results, converted into hours and minutes of the solar day, will give the time required for the arc already mentioned to pass through the prime vertical.

[Margin: Step 3.]

But if the vertical is not the prime vertical, there must be given, besides what has been said, the azimuth HVM, and from it the angle MVP, which is the supplement of the azimuth to two right angles. With this angle, with VP, the complement of the altitude of the pole, and with BP, the complement of the greater declination, find in the triangle BVP the angle BPV; and in the triangle KVP seek, with KP, the complement of the smaller declination, the angle KPV, by [proposition] 3 of the oblique-angled spherical triangles. Having subtracted the smaller of the angles found from the greater, complete the rest as in the third step of problem 42.

[Margin: Problem 43.]

Diagram. A circle set at the right of the right column, at its head. HR runs across and a vertical runs from V to N; lines run from A through O to Q, from G through F, L and M towards E, from P through B to I, and from P through K towards L.

- V (top of the rim), N (foot): on the meridian HVRN and the prime vertical VMN
- G (upper left of the rim), E (lower right of the rim): the ecliptic GOE
- A (left of the rim, high), Q (outside, lower right): the equator AOQ
- H, R (left and right of the rim): the horizon
- P (right of the rim, high): the north pole of the world
- F (inside, below G): the beginning of the given arc FK
- K (inside, right of L): its end
- B (inside, right of F): where F crosses the vertical
- I, L (inside, left): ends of the quadrants of declination PBI and PKL
- M (inside, below L): on the prime vertical VMN
- O (inside, right of M): the intersection in GOE and AOQ

44. Probl. Tempus inter tranſitus duorum Siderum aut Punctorum Eclipticæ per Medium cæli determinare, Datis eorum Aſc. Rectis. *Problem 44. To determine the time between the transits of two stars or of two points of the ecliptic through the midheaven, given their right ascensions.*

[Margin: Problem 44.]

The difference of the right ascensions, converted into time by the tables indicated in problem 1, will give the required time; although this very interval can be discerned in the stars by observation, if the time elapsing between their

transits is counted with the help of the pendulum described in Book 2, chapter 20.

45. Probl. Temporis momentum inuenire, quo Eclipticæ punctum datum, aut Sidus quoduis à Sole diſtinctum, tranſit per Medium cæli, dato die, Datis Altitudine poli, Aſcenſione recta Puncti aut Sideris, & Solis, & Semidiurno tempore Solis. *Problem 45. To find the moment of time at which a given point of the ecliptic, or any star other than the Sun, passes through the midheaven on a given day, given the altitude of the pole, the right ascension of the point or star and of the Sun, and the semidiurnal time of the Sun.*

[Margin: Problem 45.]

Subtract the right ascension of the Sun from the right ascension of the point or star (taking 360 degrees for the subtraction, if need be), and the remainder, converted into time, will give the time of the transit already mentioned, counted from the preceding noon. Now if this time is less

[Margin: Order of the problems.]

than the semidiurnal time, or greater than its complement to 24 hours, the point or star will arrive at the midheaven by day; but if the time already mentioned is greater than the semidiurnal time, or less than its complement to 24 hours, it will arrive by night.

46. Probl. Diem, quo Stella cum Sol[?] Cælum Mediat, ſeu tranſit cum illo Meridianum, inuenire. *Problem 46. To find the day on which a star mediates the heavens with the Sun [?], that is, passes through the meridian with it.*

[Margin: Problem 46.]

Seek, by problems 126 to 130 of Section 2, or by the tables indicated there, the mediation of the heavens, that is, the point of the ecliptic with which the star culminates. Then from astronomical tables or an ephemeris find the day on which the Sun will be in that degree of the ecliptic; for on that day the star will pass through the meridian with the Sun.

47. Probl. Temporis momentum datæ diei inuenire, quo Stella aliqua vel punctum Eclipticæ abſolutè oritur aut occidit; Datis Aſcenſione Recta Solis & Aſcenſione Obliqua puncti aut ſtellæ, & Semidiurno tempore Solis. *Problem 47. To find the moment of time on a given day at which a star or a point of the ecliptic rises or sets absolutely, given the right ascension of the Sun, the oblique ascension of the point or star, and the semidiurnal time of the Sun.*

[Margin: Problem 47.]

We call absolute rising the ascension above the horizon, and absolute setting the descension, without any regard to the moment of the Sun rising or setting together with the star, according to what was said in Book 6, chapter 21. From the oblique ascension of the point or star, then — given, or found by problem 123 of Section 2 — subtract the sum of 90 degrees and the right ascension of the Sun; and the remainder, converted into solar time, will give the time,

reckoned from the preceding noon, at which the point or star will rise within the given day. For the setting, seek the oblique ascension of the point of the ecliptic diametrically opposite the given point in which the star is, or in which its longitude is determined, and from it subtract the sum of 90 degrees and the right ascension of the Sun: the remainder, converted into hours, will give the moment of the rising of the opposite point, that is, of the setting of the proposed point or star. Further, if the remainder already mentioned is less than the Sun's semidiurnal time, or greater than the complement of the semidiurnal time to 24 hours, the rising or setting will be by day; but if it is greater than the Sun's semidiurnal time, but not greater than the complement of the semidiurnal time to 24 hours, the rising or setting will be by night — according as you have solved the problem for the rising or for the setting.

48. & 49. Probl. Idem inueſtigare duobus alijs modis. *Problems 48 and 49. To investigate the same in two other ways.*

[Margin: Problems 48 and 49.]

I set out these two methods earlier, in Book 6, chapter 20, problem 7, and we illustrated it with an example; so turn there.

50. Probl. Tempus inuenire, quod intercedit inter duorum Siderum aut punctorum Ortus Occaſuſue abſolutos. *Problem 50. To find the time that elapses between the absolute risings or settings of two stars or points.*

[Margin: Problem 50.]

For the time between two risings of points or stars within the same natural day, gather their oblique ascensions by problem 123 of Section 2; for [?] the time between settings, their oblique descensions. Now subtract the smaller from the greater, or the earlier from the later, of the oblique ascensions; the remainder, converted into time, will be the time from the rising of the point or star whose oblique ascension is smaller to the rising of the point or star whose oblique ascension is greater. But if you subtract that same time from 24 hours, there will remain the time from the rising of the point or star whose oblique ascension is greater to the rising of the one whose oblique ascension is smaller. What I have said of risings holds for settings, if you use oblique descensions. And if you use an oblique ascension on the one side and an oblique descension on the other, you will have the time between the rising of one and the setting of the other; for which see also the rules given in Book 6, chapter 21, page 467.

[Margin: Order of the problems.]

51. Probl. Diem Ortus & Occaſus reſpectiui, ſed Veri ſiue Matutini ſiue Veſpertini, cuiuſuis ſtellæ inuenire. *Problem 51. To find the day of the respective rising and setting of any star — but the true one, whether morning or evening.*

[Margin: Problem 51.]

See Book 6, chapter 20, problem 6, where there are also examples; for the definitions of these risings and settings, see chapter 21 in the same place.

52. Probl. Tempus inuenire, quo Stella aliqua olim verè Oriebatur vel Occidebat. *Problem 52. To find the time at which some star formerly truly rose or set.*

[Margin: Problem 52.]

Seek the sense of the problem, and its solution, in Book 6, chapter 20, problem 8.

53. Probl. Arcum Viſionis ſeu Fulſionis & interuallum Eclipticæ pro Ortu & Occaſu Heliaco ſiderum determinare. *Problem 53. To determine the arc of vision, or of shining, and the interval of the ecliptic, for the heliacal rising and setting of the stars.*

[Margin: Problem 53.]

See Book 6, chapter 20, problem 9, and the first part of that problem.

54. Probl. Diem Ortus & Occaſus Heliaci ſeu apparentis, cuiuſuis Sideris determinare. *Problem 54. To determine the day of the heliacal, or apparent, rising and setting of any star.*

[Margin: Problem 54.]

See Book 6, chapter 20, the whole of problem 9, where I gave an example in Sirius and in Procyon; for an understanding of the definitions, consult chapter 21 in the same place. And you have examples of the risings and settings in the ancient poets or historians explained in the same place, in the whole of chapter 22.

55. Probl. Tempus inuenire quo ſtella perueniet ad Aequatorem, aut Tropicum, aut etiam illum tranſgre[?]ietur, ſi ſit capax talis aduentus. *Problem 55. To find the time at which a star will reach the equator or a tropic, or even pass beyond [?] it, if it is capable of such an arrival.*

[Margin: Problem 55.]

See Book 6, chapter 19, problem 1, where it is also taught which star is capable of the arrival already mentioned.

56. Probl. Tempus inuenire, quo ſtella capax tranſitus per Verticem dati loci, tranſitura ſit per illum. *Problem 56. To find the time at which a star capable of a transit through the zenith of a given place will pass through it.*

[Margin: Problem 56.]

In Book 6, chapter 19, problems 2 and 3, it is taught which stars are capable of a transit through the zenith of a given place, and in problem 4 the time at which it has passed or will pass through the zenith.

57. Probl. Tempus inuenire, quo ſtella oriens & occidens, euaſura ſit inter Semper Apparentes, aut Latentes, & inter eas duratura. *Problem 57. To find*

the time at which a star that rises and sets will pass among the stars that are always visible, or always hidden, and will remain among them.

[Margin: Problem 57.]

See Book 1, chapter 17, and then Book 6, chapter 19, problems 6 and 7; for from these you will gather a sufficient way of solving this problem.

58. Probl. Tempus inuenire, quo ſtella capax perueniendi ad Mundi Polum ſit illuc peruentura, aut iam peruenerit. *Problem 58. To find the time at which a star capable of reaching the pole of the world will reach it, or has already reached it.*

[Margin: Problem 58.]

Consult Book 6, chapter 19, problem 5, where we also teach which star is capable of such an arrival.

59. Probl. Tempus indagare, quo ſtella idonea peruentura ſit ad circulum Polarem, ſiue intra illum ſit, ſiue extra. *Problem 59. To find out the time at which a suitable star will reach the polar circle, whether it is inside it or outside.*

[Margin: Order of the problems.]

[Margin: Problem 59.]

In Book 6, chapter 19, problem 11, we solved this problem on the occasion of the following one.

60. Probl. Tempus inuenire, quo Stellæ ad id idoneæ Aſcenſio Recta creſcet, & quo decreſcet; quamuis ſemper Longitudo creſcat: aut creuit decreuitq. olim. *Problem 60. To find the time at which the right ascension of a star suited to this will increase, and at which it will decrease, although its longitude always increases; or at which it increased and decreased in the past.*

[Margin: Order of the problems.]

[Margin: Problem 60.]

We have already taught this new problem in Book 6, chapter 19, problem 11, with examples given.

SECTIO QVARTA IN QVA PROBLEMATA GEOGRAPHICA.

Section Four, in which are the geographical problems.

1. Probl. Proportionem Paralleli ad Maximum ſphæræ circulum inuenire, & Tabulam ipſius condere, Data Paralleli Declinatione. *Problem 1. To find the proportion of a parallel to a great circle of the sphere, and to construct a table of it, given the declination of the parallel.*

[Margin: Problem 1.]

Look at the following figure. In it let ABC be the terrestrial meridian, described about the Earth's centre D; let AEC be the semicircle of the equator, whose pole is B; and let AD be the sine of the left-hand quadrant AE of the equator, falling perpendicularly on the axis BD of the equator. Further, let TGH

be a parallel to the equator, whose quadrant is TG and whose semidiameter is TI. Now since the axis DB passes through the centre D of the great circle AEC and through the centre I of the parallel TGH, and stands on the plane of the parallel at right angles, making the angles TIB and TID right angles, TI will be the right sine of the arc TB; and TB is the complement of the arc AT, which is known from the declination of the parallel. Moreover, the circumferences of circles are to one another as their semidiameters are to one another, by theorem 5 of book 11 of the *Mathematical Collections* of Pappus of Alexandria. Therefore the semicircumference AEC of the equator will be to the semicircumference TGH of the parallel as the semidiameter AD is to the semidiameter TI. But AD is the radius, or whole sine, of the quadrant AE; and TI is the right sine of the arc TB, and also the whole sine of the quadrant TG. Let it be done, therefore: as the whole sine AD, of 100,000 parts, is to the sine of the arc TB, so is the quadrant AE of the great circle, of 90 degrees, to the arc TG, in parts of which AE is 90.

Diagram. A half-ellipse set in the left column beside the text: the meridian runs from A at the left over T, B and H to C at the right, and the lower curve runs back under the base through E. A vertical runs down from B through I and G to D; the horizontal AD forms the base line; TI runs across from T to the vertical; a shaded arc runs from I to H.

- B (top): pole of the equator
- T (upper left): end of the parallel's semidiameter TI
- I (on the vertical, under B): centre of the parallel
- H (upper right): point of the parallel
- G (on the vertical, below I)
- A (left end of the base)
- D (right end of the base, under G): the Earth's centre
- C (right)
- E (bottom, below the base)

EXEMPLVM. *Example.*

Let the parallel TGH decline from the equator AEC by the arc AT, of 63 degrees; its complement TB will then be 27 degrees, whose sine TI is 45,399 parts. Let it be done, then: as AD, of 100,000 parts, is to TI, of 45,399 parts, so is the quadrant AE, of 90 degrees, to another; and there will come out the arc TG, that is, the quadrant TH of the parallel, of 40° 51′ 33″. Therefore, although TG is of 90 degrees with respect to the parallel, yet with respect to the equator it contains only 40° 51′ 33″ of degrees as large as the degrees of the equator are. In other words, if TG were transferred to AE, it would not equal AE, but of the 90 equal parts of AE it would equal only 40° 51′ 33″ parts. Granted that Moletius and Vernerus reckon 40° 53′ 3″.

By this device a table is constructed for the single degrees of declination by which the parallels stand off from the equator, showing the proportion of the quadrant of a parallel to the quadrant of a great circle — such a table as Iosephus

Moletius [Giuseppe Moletti] and Io. Vernerus [Johannes Werner] have left us on chapter 23 of Ptolemy's *Geography*, page 64, and Orontius Finaeus in Book 5 of his *Cosmography*, chapter 1.

[Margin: The authors of these tables.]

To this table it is usual to append a second, containing the proportion of one degree and minute included in any parallel to the degree and minute of a great circle. It is made by multiplying the degrees of the great circle found in the quadrant of the parallel by 60 and dividing the sum by 90. As in the preceding example: if one makes, as 90 is to 40° 51′ 33″, so 60 to another, one will find that one degree of the parallel already mentioned contains 27′ 15″ 24‴ of a degree of the great circle. Such a table is given by Vernerus, Moletius and Orontius in the places cited a little earlier, and also by Egnatius Dantes [Egnazio Danti] in the *Astrolabe*, part 2, chapter 37, and by Io. Schonerus [Johannes Schöner] in his booklet *On the Distances of Places*.

A third table, finally, ought to be attached to these, containing the miles included in one degree or one minute of a parallel, of the kind of which one degree of a great circle, or one minute of it, consists, according to the opinion or view chosen on the size of the terrestrial globe that we indicated in Book 2, chapter 7.

[Margin: 3. Table.]

Præambulum ad Problemata de Magnitudine Orbis Terræ. *Preamble to the problems on the size of the globe of the Earth.*

The size of the globe of the Earth — that is, of the globe compacted of water and earth, which it has been thought fit to call the Terraqueous globe — is investigated in two general ways. The first is through the investigation of the diameter. For once the quantity of the terrestrial diameter has been found in stades, leagues or known miles, if one makes, as 7 to 22, or (which is better) as 100 to 314, so the diameter found to another, there will come out the number of stades, leagues or miles comprised in the circumference of a great circle of the Earth, such as the meridian, the equator, and any vertical circle, or any circle drawn through the poles of the world and described on the surface of the Earth. The second way proceeds from the investigation of the stades, leagues or miles comprised in one or a few degrees of a great circle of the Earth to the quantity of the whole circumference. Once that is known, if one makes, as 22 to 7, or rather as 314 to 100, so the stades, leagues or miles comprised in the circumference to another, the stades, leagues or miles included in the diameter of the terrestrial globe will be known. And once the diameter and circumference are known, how the area of a great circle, the whole surface and the solidity of the terrestrial globe are found is clear from what was said in Book 1, chapters 4 and 6, and from the example given in Book 2, chapter 7, number 8.

2. Probl. Diametri Terreſtris Quantitatem Inueſtigare Methodo Maurolyci, non tamen omnino exacta. *Problem 2. To investigate the quantity of the terrestrial diameter by the method of Maurolycus — not, however, an entirely exact one.*

[Margin: Problem 2.]

Franciscus Maurolycus, Abbot of Messina, in dialogue 3 of his *Cosmography*, proposes roughly this method, [Margin: Order of the problems.]

[Margin: Order of the problems.]

and from him Silvius Bellus, in *De Distantiis*, part 3, proposition 12, though somewhat differently. In the accompanying diagram, let BCD be a great circle of the terrestrial globe — say, a vertical — and on it a very high mountain AB, such as he takes Etna to be, from which there is a view out over the sea along the visual ray AC, touching the terraqueous globe at C. Then let the perpendicular height AB of the mountain above the level of the sea be found by hypsometry [Greek: ὑψομετρίαν (hypsometrian, "measurement of heights")], that is, the measurement of heights; and by embadometry [Greek: ἐμβαδομετρίαν (embadometrian, "measurement of ground")], or the measurement of the ground, the length BC as far as the limit of vision. This length cannot be so great that it could not be taken, without danger of notable error, for the straight line CE, perpendicular to AG. Given, then, in the triangle AEC, right-angled at E, the sides CE and AB (that is, approximately AE), if each is multiplied by itself, the squares of the sides CE and AE will result; their sum, by proposition 47 of the first book of Euclid, is equal to the square of the subtending side AC, and its square root will give the quantity of AC itself. But by the penultimate proposition of the third book of Euclid's *Elements*, the square of the line AC is equal to the rectangle made by the whole DA and the external straight line AB; hence this rectangle will be known. And AB, the height of the mountain, is known; therefore the whole AD will be known, and if you subtract AB from it, the diameter BD of the Earth becomes known.

Diagram. A circle set at the right of the left column. A vertical runs from A above the circle through B, E and G to D; a line runs from A down to C, where it touches the circle; EC runs across from the vertical to C.

- A (top, above the circle): summit of the mountain
- B (top of the circle): foot of the mountain
- E (on the vertical, just below B)
- C (right): the point of tangency
- G (centre)
- D (foot of the vertical)

Willebrord Snel disapproves of this method in book 2 of the *Eratosthenes Batavus*, chapter 17, because refraction visibly raises the limit C for the observer at A. Nor can this evil be met if sailors, on coming to C, begin to see the summit A of the mountain and note the limit and the distance CB, as Biancani advises in book 4 of the *Sphaera*, treatise 3, chapter 5. I, rather, do not altogether approve the method: both because it is very difficult to know the height of the

mountain exactly without prior knowledge of the Earth's semidiameter; and because, with BC, a curve, assumed for CE, and AB for AE, the problem limps on both feet in geometry and is liable to an error not to be despised, as I have shown by an example in my Geographical book — especially in investigating the height of mountains, and in the slope of the mountain and of the plain lying below it down to the sea. Nor is it approved by Clavius himself, in book 8 of the *Geometria Practica*, proposition 34. Silvius Bellus, moreover, is mistaken in thinking that Maurolycus orders AC to be measured; for Maurolycus plainly wants the curve BC to be measured, which he then orders to be taken for a straight line, just as if it were EC.

[Margin: The error of Silvius Bellus.]

3. Piobl. Diametrum Terræ inueſtigare methodo P. Chiſtophori Griembergeri Societatis IESV. *Problem 3. To investigate the diameter of the Earth by the method of Father Chistophorus [?] Griembergerus, of the Society of Jesus.*

[Margin: Problem 3.]

Father Griembergerus, with German candour, communicated this invention of his to Father Mario Bettini, who published it in *Apiarium* 2, *Progymnasma* 3, proposition 7, scholium 2. Reduced to a few words, it runs as follows.

[Margin: Step 1. A suitable construction of a wall on the shore.]

First, on a shore of the sea running straight for up to 40 or 50 miles, let a wall ABMN be built, proceeding in the plane of the same vertical circle; this can be done by skilful architects and builders.

Diagram. A long masonry wall standing on the waves, with a water-line ruled beneath. At each end stands a gabled level, each lettered E, with a plumb-line hanging inside. Hatched rules lie along the top of the wall: the lower course lettered A, C, D, I, K and M from left to right, and a raised course above it lettered G at the left, F and H in the middle, and L at the right. B stands at the lower left corner of the wall and N at the lower right.

- E (left gable): the level
- G (left, raised course): end of the rule GF
- F (middle, raised course): end of the rule GF
- H (middle, raised course): end of the rule HL
- L (right, raised course): end of the rule HL
- E (right gable): the level
- A (upper left corner of the wall)
- C (top course, left)
- D (top course)
- I (top course)
- K (top course, right)
- M (upper right corner of the wall)
- B (lower left corner, at the water)
- N (lower right corner, at the water)

Let this wall stand above the shore, when the sea is at its calmest, so that AB is one or two palms. On the wall let a rule AC be laid which, by means of the level E, is exactly balanced to the horizon, and along its upper side let a line AD be marked to serve as the fiducial line. Then lay on it a rule GF which over a large part of itself fits against and touches AC itself, and let the wall go on being built in such a way that between the rule GF and the wall there can be inserted, without any gap, a rule DI of the same thickness as AC. On this in turn let a rule HL be laid, fitting against and touching DI itself over a large part of itself, and let the wall proceed so that between DI and the rule HL there can be inserted, without a gap, a rule KM equal in thickness to DI. And so, by means of three or four rules with a perfectly straight edge, the same straight line will be continued through the whole length AM of the wall. Let this length be measured exactly with ten-foot rods, and the measure reduced to thousandths, or at least hundredths, of one palm. Further, if this wall runs on for about 50 miles over the shore, equally high with respect to the surface of the calm sea, it will be found higher at its end MN, etc., than at its beginning AB; and the level E, placed on the last rule KM, will incline its plumb-line somewhat to the left, so that it tends towards the centre of the Earth.

[Margin: Step 2.]

With the wall built, now use, *secondly*, the following figure. In it let BOPG be the vertical circle on the surface of the Earth in whose plane the wall lies, representing a great circle of the Earth, and let the centre of the Earth be C. Through C let the diameter BP be drawn, continued with the initial and perpendicular height AB of the wall. Let the wall be ABMN, whose length AM is known; and in it let BN be understood to be drawn from B, parallel and equal to AM, touching the globe of the Earth at B and making there, with the surface of the sea, the right angle ABN. Now from M let the straight line MN be drawn, equal to AB and making, by means of an exact square, the right angle AMN; and let the point N be marked on the wall. Through N and through the centre C let the diameter GCL be drawn, continued through N to Q, the point that terminates AM continued as far as Q. And from N, letting down a plumb-line, let the straight line LN be measured.

Diagram. A circle set at the right of the right column. Above it A, M and Q stand on a horizontal; BN is a horizontal touching the circle at B; a vertical runs from A through B and C to P at the foot of the circle; a diameter runs from G at the lower left through the centre C and L, past O on the circle, through N to Q; MN joins M to N.

- A (upper left): top of the wall's height AB
- M (top): end of the wall AM
- Q (upper right): where GN continued meets AM continued
- B (top of the circle): point of tangency of BN
- N (right of B): end of the tangent BN
- L (near the circle, upper right): point of the diameter GCL
- O (on the circle, upper right)

- C (centre)
- G (lower left, on the circle)
- P (foot of the circle)

[Margin: Step 3.]

Thirdly, multiply the parts of the tangent BN, which is known from AM, by themselves, and you will have its square. By proposition 36 of the third book of Euclid, the rectangle under the whole GN and the external segment LN, terminated by the tangent, is equal to that square. Therefore, the square of BN being known, the rectangle already mentioned will be known; and since its side LN is known in parts of the same kind, and so is the square of LN, if you divide the square of the tangent BN by the square of LN, the quotient will show how many times LN is contained in the whole GN. Or, if you divide the square of BN by the line LN, the whole GN will become known; and with LN taken from it, the diameter GL of the Earth will be known.

So, most ingeniously, Griembergerus. But it is extremely difficult for the thickness of the rules to be so equal that one of them does not fall short by as much as a hundredth of an inch. So if any rule is 10 feet long, and at each application falls short of straightness by one hundredth of an inch, then after 1200 applications, that is, after 2400 paces, it will fall short by one foot; and after 50,000 paces, by 20 feet and more. But grant that the workmen have the eyes of a lynx in making and applying the rules: this wall will be so costly that it is not worth undertaking. For LN will be only about 250 ancient Roman paces, or 1250 feet, if we suppose BN to be 50 miles, or 50,000 such paces — paces of which, from what was said in Book 2, chapter 7, there are 5,174,000 in the semidiameter CB and 10,348,000 in the diameter GL. But let there be 5,000,000 in CB, in round figures. Then from BN and CB, in the triangle CBN, right-angled at B, the angle BCN is found, by [proposition] 5 of plane right-angled triangles, to be 34′ 20″, whose secant is 100,005. Therefore by [proposition] 3 of the same triangles you will find the base CN to be 5,000,250 paces. With CL, of 5,000,000 paces, taken away, there remains, as I said, LN, of 250 paces, that is, 1250 ancient Roman feet — a height that no tower in Europe is found to have. For the measures of the taller towers, as I have collected them with great diligence, are those set down below.

[Margin: The difficulty of this practice, and the insane height of the wall at its end.]

[Margin: Order of the problems.]

[Margin: Order of the problems.]

[Margin: The height of some notable towers.]

Height of the towers	Feet	Ancient Roman
Modena	Feet of Modena 175	262
Bologna, the Asinelli	Feet of Bologna 234	312
Cremona	Feet of Cremona 332	362
Genoa, the lantern with its rock	Palms of Genoa 440	480

Height of the towers	Feet	Ancient Roman
Strasbourg	Feet of Strasbourg 765	705

Who, though, could safely raise so great a height of wall over the shore of the sea without its tottering? Or at what expense, I ask, would so insane a substructure stand? It would be better to build a single tower at least 500 feet high, which could serve both this very purpose and other uses.

4. Probl. Diametrum Terræ indagare Methodo P. Marij Bettini S. I. sed fallaci. *Problem 4. To find the diameter of the Earth by the method of Father Mario Bettini, S.J. — but a fallacious one.*

[Margin: Problem 4.]

Father Bettini, in *Apiarium* 2, *Progymnasma* 3, proposition 7, proposes his own method, which he prefers to the way of Maurolycus and Eratosthenes. "In the following diagram," he says, "let there be the globe of the Earth and its great circle BMEK, and its diameter BE, on which let a tower, or a rock, or a mountain AB, of known height, stand perpendicularly. From its foot B let the visual line BC be stretched out by a dioptra to the edge C of the sensible horizon, so that by means of a square it makes with AB the angle ABC a right angle. Now the moderate reach of vision over the plane of the horizon, namely BC, is 35 Italian miles" (he says). Now about the centre Q, through the end-point C, let the semicircle ACF be described, and let AE be continued as far as F, so that AF is the diameter of this semicircle; and let C be joined to its extremities by the straight lines AC and FC. For by proposition 31 of the third book of Euclid the angle ACF will be a right angle, and the perpendicular BC let fall from C will, by proposition 13 and by the corollary of proposition 8 of the sixth book of the *Elements*, be a mean proportional between AB, which is known, and BF. Let BC, then, which is 35,000 paces, be multiplied by itself, and the sum will be 1,225,000,000. When this is divided by the paces contained in AB, the quantity of the straight line BF will come out. From this, finally, let EF, which is equal to AB, be subtracted, and the diameter BE of the Earth will remain.

Diagram. Two concentric circles set at the right of the left column, the inner one drawn as a globe with outlines of land. A vertical runs from A at the top of the outer circle through B at the top of the inner circle, the centre Q, and E at the foot of the inner circle, to F at the foot of the outer circle. C stands on the outer circle at the right; lines run from A to C, from B to C and from F up to C. P lies on a line inside, running towards C; K stands at the left of the inner circle and M at its right.

- A (top of the outer circle)
- B (top of the inner circle): foot of the tower AB
- C (right, on the outer circle): edge of the sensible horizon
- P (inside, towards C)

- K (left of the inner circle)
- Q (centre)
- M (right of the inner circle)
- E (foot of the inner circle)
- F (foot of the outer circle)

[Margin: The fallacy of this method.]

But it is false that the common and middling distance of vision BC is 35 Italian miles. For if the height of the eye B is nothing above the convexity of the Earth, which is concentric with the sea, there is hardly any such distance; and if there is some height, the distance of vision varies with the varying height of the eye, as we have already shown in Book 2, chapter 10. There you will also see Father Bettini excused, who erred in this along with some great men — especially since he himself, in scholium 1, suggests a way, difficult indeed but not impossible, of measuring the line BC. This would be if C were the top of a rock PC, or of a ship's mast, from which the visual line BC were directed to B; and from there the angle BCQ were taken with a quadrant, whose complement to a right angle is the angle BQC, the secant of which is QC. For, the height PC being known, one would make: as the excess PC of the secant QC is to the paces included in PC, so is the tangent BC of the same angle BQC to the paces included in BC. But the tower would have to be on the shore of the sea, like the Lantern of Genoa, and one would have to sail towards it until, from C, the top of the ship's mast, its foot B came into view, and then take the angle PCB with a most exact instrument.

5. 6. & 7. Probl. Diametrum Terræ inueſtigare triplici Methodo P. Chriſtophori Clauij Soc. IESV. *Problems 5, 6 and 7. To investigate the diameter of the Earth by a threefold method of Father Christoph Clavius, of the Society of Jesus.*

Father Clavius, in Book 8 of the *Geometria Practica*, proposition 34, intending to correct the method of Maurolycus, teaches three ways of measuring the Earth's diameter; Kepler touches on two of them, from Clavius, in Book 1 of the *Epitome of Copernican Astronomy*, page 29.

[Margin: Problem 5.]

The *first* is as follows. In the following figure let ADG be a great circle of the Earth, whose diameter is AG and centre C; and let AB be a tower or mountain of known height, from whose top B the surface of the calm sea is viewed. Let the angle B be taken with an instrument by means of the visual line BD, touching the surface of the sea at D; Clavius thinks this is done most surely at the moment when the centre of the Sun, or a star, rises apparently from the horizon, or sets. For, the angle B being known, and AF drawn perpendicular to AB, there will arise the triangle ABF, right-angled at A, in which the angle BFA will be known, as the complement of the angle B to a right angle. Hence, AB being given, you will find by [proposition] 6 of plane right-angled triangles the base BF, and by [proposition] 7 the side AF, which is equal to the side FD

by the corollaries of proposition 36 of the third book of Euclid. Hence, FD being added to the base BF, the whole tangent BD will be known; and its square is equal to the rectangle comprised under the whole GB and the segment AB, by proposition 36 of the third book of Euclid. Therefore, when that square is divided by the height AB, the quotient will give the length of the whole BG; subtract AB from it, and there will remain the diameter AG of the Earth, known in parts of which AB was known.

Diagram. A circle set at the right of the right column. A vertical runs from B above the circle through A at its top and the centre C to G at its foot. A horizontal runs from A through F to E at the right; a line runs from B through F to D, where it touches the circle; a dotted line runs from C up towards F, and a line joins C to D.

- B (above the circle): top of the tower or mountain AB
- A (top of the circle): its foot
- F (on the horizontal AE, where BD crosses it)
- E (right end of the horizontal)
- D (on the circle): point of contact of BD
- C (centre)
- G (foot of the circle)

[Margin: Problem 6.]

Secondly, another way. With the height AB known, and the angle B known by the dioptra, and a straight line CD drawn from the Earth's centre through the point of contact D, there will arise the triangle BCD, right-angled at the contact D, by proposition 18 of the third book of Euclid; in it the angle BCD will be known, as the complement of the angle B to the other right angle, by proposition 32 of the first book of the *Elements*. Now let there be another line AE, touching the Earth at A, equal to BD and cutting BD at F; and from C let a straight line be understood to be drawn to F. Then AF will be equal to FD by the corollaries of proposition 36 of the third book of Euclid. Hence in the triangles ACF and DCF, right-angled at the contacts A and D, the sides containing the right angles — namely AC and CD, and AF and DF — will be equal; and therefore, by proposition 4 of the first book of the *Elements*, the angle ACF will be equal to the angle DCF, and known, as being half of the angle BCD already found above. With these known beforehand: *first*, in the triangle ABF, right-angled at A, the height AB is given, and the acute angle F, namely the complement of the angle B; therefore by [proposition] 7 of plane right-angled triangles, seek [?] the side AF. *Secondly*, in the triangle ACF, right-angled at A, AF is given and the opposite angle ACF; therefore by the same [proposition] 7 seek the side AC, that is, the semidiameter of the Earth, whose double gives the diameter AG.

[Margin: Step 1.]

[Margin: Step 2.]

[Margin: Problem 7.]

Thirdly, another way. With the height AB of the mountain or tower known, and the angle B as above, the angle BCD will be known, as being the complement of the angle B to a right angle. Then for the angle BCD find the secant CB (since its tangent is BD); from this secant cut off the whole sine AC, and there will remain the excess AB of the secant over the whole sine. Let it be done, therefore: as this excess is to the paces or feet of the known height AB, so is the whole sine, or radius, AC to another; and there will come out the semidiameter AC of the Earth, known in paces or feet.

8. Probl. Diametrum Terræ inuenire Methodo P. Pauli Cafati Soc. IESV. *Problem 8. To find the diameter of the Earth by the method of Father Paulus Casatus [Paolo Casati], of the Society of Jesus.*

[Margin: Problem 8.]

Father Paulus Casatus, while reading through our studies on the size of the Earth, at once found this method, with the skill in geometrical matters that he possesses. I have already reported it in Book 2, chapter 7, number 4, and, drawn together into fewer words, it is as follows. In the figure set immediately before, and already explained, the height AB of a tower situated at the sea is supposed known; and it is supposed that, a ship at sea or some other visible sign having been viewed from B at its base D, the angle B has been taken, from which its complement to a right angle, that is, the angle BFA, is known. In the triangle right-angled at A, therefore, let AF and BF be found, in parts of which AB is known; and since AF is equal to FD, as the same man demonstrated in the same place, if AF, that is FD, is added to BF, there will be known

[Margin: Order of the problems.]

[Margin: Order of the problems.]

the tangent BD, in the triangle CDB, right-angled at the contact D; and since the angle B is given in this triangle, the side CD — that is, the semidiameter of the Earth — can at once be found by [proposition] 4 of plane right-angled triangles. One could also seek the tangent of the acute angle C, which is the complement of the angle B to a right angle, and make: as BD, the tangent, is to the same BD known in paces or feet, so is the whole sine AC to the semidiameter of the Earth in paces or feet.

9. Probl. Diametrum Terræ inquirere Methodo Kepleriana. *Problem 9. To investigate the diameter of the Earth by Kepler's method.*

[Margin: Problem 9.]

Johannes Kepler, in Book 1 of the *Epitome of Copernican Astronomy*, page 28: "Since the Earth," he says, "is round, plumb-lines hung in distant places must nod towards each other, and towers built to the perpendicular must nod away from each other at their tops and stand farther apart from each other than at the bottom." In the following figure, then, above the surface of the Earth DFBE, let there be two mountains AB and MF, or towers, or citadels, very distant from each other, yet such that the summit of one can be seen from

the other. From A, along the visual line AM, let M be sighted and the angle MAB observed; again, from M let A be sighted and the angle FMA taken. For when AB and MF are produced to C, the centre of the Earth, the angle C will be known, as the supplement of the angles A and M, taken together, to two right angles. Now let the distance between the places, namely FB, be measured in paces or miles, if it is not known from elsewhere. For in this way, in the isosceles triangle FCB, the base FB will be given, and the angle C, and either of the angles at the base, as half of the supplement of the angle C to two right angles. Therefore, given the two angles C and CFB, with the opposite side FB, you will find by [proposition] 2 of plane oblique-angled triangles the side CB, opposite the angle F, that is, the semidiameter of the Earth; and when it is doubled, the whole diameter of the Earth will be known.

Diagram. A small figure set at the right of the left column. M at the upper left and A at the upper right are joined by a straight line, and a second line runs from A down towards G. An arc, the surface of the Earth, runs from D at the left through F and B to E at the right. Lines from M through G and F, and from A through B, converge below on C.

- M (upper left): summit of the mountain MF
- A (upper right): summit of the mountain AB
- G (below M, on the line MF)
- D (left end of the arc)
- F (on the arc): foot of MF
- B (on the arc): foot of AB
- E (right end of the arc)
- C (foot of the figure): centre of the Earth

10. Probl. Diametrum Terræ inquirere Methodo P. Nicolai Cabæi Soc. IESV, & D. Alphonſi Iſæi. *Problem 10. To investigate the diameter of the Earth by the method of Father Nicolaus Cabaeus [Niccolò Cabeo], of the Society of Jesus, and of D. Alphonsus Isaeus.*

[Margin: Problem 10.]

Each of these two (which is nothing new), unaware of the other's discovery, once pointed out to me the method I shall set out below; and Father Cabeo later presented it in Book 1 on the *Meteorologica*, text 7, question 1. Let there be a hemisphere of the Earth, with its great semicircle ABH and its diameter AH; and let there be a tower on the seashore, or a ship's mast, MP, whose perpendicular line is produced to the Earth as far as C, so that the whole is PMC. From another place on the sea, or on a seashore raised hardly at all above the sea — say from the place F — let the point G of the tower or mast be marked along a line parallel to the horizon, or lying most exactly at the level of the horizon, namely FG. This will be done more surely by means of a lamp placed at G and moved up or down by another person until it can be observed from F along the horizontal line FG. Then at F let a pole or small beam, or another ship's mast, BK, be erected perpendicularly from B; and, with the eye moved

to G, let another point or sign K be marked along another horizontal GK, which makes a right angle at G with CP. Let its distance FK be measured most exactly in equal small parts, going down to inches, or even to small parts of an inch (although neither Cabeo nor Isaeus states this); and let FB likewise be measured, if F is raised above the shore or the surface of the sea; and then the straight line FG, either with stretched cords or by trigonometry, taking the angle K and using the side KF in the triangle KFG, right-angled at F. Finally, when KB is produced to C, there will arise the triangle KGC, right-angled at G; from which FG, the perpendicular let fall and now known, will be a mean proportional between KF and FC. Let it be done, therefore: as KF is to FG, so FG is to FC; and let that small height FB, which will be at least as great as the observer's stature, be subtracted from FC; and BC will remain, that is, the semidiameter of the Earth, known in the parts already mentioned.

Diagram. A figure set at the right of the left column. A semicircle stands on the base AH, with C, its centre, on the base. A vertical runs from C up through B, the top of the semicircle, and F to K. A horizontal runs from F to G, and a line runs from K down to G. A line runs from C through M on the semicircle and through G to P at the upper right.

- K (top of the vertical): the sign on the pole BK
- P (upper right): top of the mast MP
- F (on the vertical above B): the observer's place
- G (on the line CP): the point marked on the tower or mast
- B (top of the semicircle)
- M (on the semicircle): foot of the mast MP
- A (left end of the base)
- C (centre, on the base): centre of the Earth
- H (right end of the base)

[Margin: The fallaciousness or slipperiness of this method and of the preceding ones.]

But if, because of the distance FG, the sign K is not a certain point, and an error of one inch of a foot is committed which cannot be discerned, an error of more than 300 Italian miles could be committed in the semidiameter of the Earth, as I demonstrated in my book on geography. And I say the same of all the preceding problems, from 2 to this 10, if the angles taken deviate from the truth by even half a minute. It therefore seems better to take refuge in those problems by which the arc of the Earth is investigated, and from it the circumference and the diameter.

11. Probl. Terræ Ambitum, Eratoſthenis modo Inueſtigare, & ipſius Errores corrigere. *Problem 11. To investigate the circumference of the Earth by the method of Eratosthenes, and to correct his errors.*

[Margin: Problem 11.]

Eratosthenes of Cyrene — the man famous for the duplication of the cube, the measurer of the pyramids of Egypt, prefect of the royal library of Alexandria,

and, to use the words of Pliny the Elder, Book 2, chapter 108, "subtle in every branch of letters, and in this one surely skilled beyond the rest," namely in the measurement of the Earth — seemed to have accomplished it in such a way that Pliny, in the same place, calls it a presumptuous venture, but one grasped by reasoning so subtle "that one would be ashamed not to believe it." For he noticed, or learned by report, that at Syene at noon on the summer solstice the Sun lit up the bottoms of wells, and that no upright shadows were then cast by gnomons set up above the horizon; from this he concluded that the Sun was then vertical to that place. He believed, moreover, the surveyors' report that 5000 stadia lay between Syene and Alexandria in Egypt (which he thought were situated under the same meridian). He therefore inquired how many degrees and minutes the arc of the meridian between Alexandria and Syene contained, by means of a gnomon set in a scaphe at Alexandria and the observation of its solstitial shadow at noon; from this he concluded that the arc was the fiftieth part of the whole circle, namely 7° 12′. Multiplying 5000 by 50, therefore, he concluded that there were 250 000 stadia in the whole circumference of the Earth, and 694⅗ in one degree. But if 700 are given to one degree, the whole circle comes to 252 000 stadia. From this two opinions have flowed concerning Eratosthenes' numbers, which I have already reported in Book 2, chapter 7, scholium 2, indicating errors committed by Eratosthenes, some of which I set out in Book 3, chapter 27, number 7, where I also examined Eratosthenes' method.

[Margin: The fallacy of this method is fourfold.]

It is not necessary, therefore, to repeat these things here again; it is enough to indicate that of the four things assumed by Eratosthenes, two are doubtful and two false. For it is false that Alexandria and Syene are under the same meridian, since according to Ptolemy's *Geography* Syene is farther east by 1½ degrees. From this difference, and the difference of the polar altitudes, a greater arc between those places is gathered than Eratosthenes gathers, so that he should have assigned to one degree of a great circle only 649 21/46 stadia, as I showed in the book on geography. It is false, moreover, that two rays of the Sun, one issuing from its centre and the other from its edge, reach the Earth sensibly parallel, as I have already shown in Book 3, chapter 27, number 7; and so he should have added to the arc of 7° 12′ the apparent semidiameter of the Sun, namely 15′ or 16′. It is doubtful, however, whether Syene lies exactly under the Tropic of Cancer, and whether the Sun at the solstitial noon stands over its zenith, since the space of the Earth within which there are then no shadows and the bottoms of wells are lit up occupies 300 stadia, on the testimony of Cleomedes, Book 1, and Strabo, Book 17. It is doubtful, moreover, whether there are 5000 stadia between Syene and Alexandria, as Cleomedes, Book 1, Strabo, Book 2, and Pliny, Book 2, chapter 73, report, adding as many stadia found between Meroë and Syene. For the same Pliny, Book 6, chapter 29, says that explorers sent by Nero found 874 miles between Syene and Meroë, that is, 6992 Roman stadia; and Pliny and Censorinus use these stadia in Eratosthenes'

measurement — although it may be more probable that Eratosthenes, or the royal surveyors, used the Alexandrian stadium. This ambiguity is confirmed by Hipparchus, who, as Pliny says, thought that 25,000 stadia should be added to Eratosthenes' circumference of the Earth, and 69 stadia to one degree.

[Margin: Eratosthenes' measurement emended by Hipparchus.]

[Margin: Order of the problems.]

[Margin: Order of the problems.]

12. Probl. Terræ Ambitum inquire modo Poſſidonij, eiuſq. Errores corrigere. *Problem 12. Investigate the circumference of the Earth by the method of Posidonius, and correct his errors.*

[Margin: Problem 12.]

Posidonius of Apamea, who flourished about the year 40 before Christ, and who is praised for his manifold learning by Cicero in the book *De natura deorum*, by Strabo, Book 16, and by Pliny, Book 7, chapter 30, believed that Rhodes and Alexandria are under the same meridian and are 5000 stadia apart; and that Canopus, the star set on the rudder of Argo, was raised in his time above the horizon of Alexandria at its meridian altitude by 7° 30′. Climbing, therefore, a certain lookout on the island of Rhodes in order to measure the arc between Rhodes and Alexandria from the meridian altitude of Canopus, he saw Canopus graze the horizon and rise not at all. He therefore concluded that that arc was 7° 30′, and so that the whole great circle of the Earth contains 240,000 stadia, and one degree 666⅔ stadia, as Cleomedes reports in Book 1 of *De mundo*, chapter 10, and Proclus at the end of the *Sphere*. In this reasoning some things are doubtful and some false. It is false that at that time the true meridian altitude of Canopus at Alexandria was 7° 30′, although Geminus also reports this in the *Elements of Astronomy*, and Pliny, Book 2, chapter 70. This is so, first, because the horizontal refraction, which the ancients left out, had to be subtracted from this altitude — a refraction which Kepler, in the *Astronomia optica*, page 149, suspects was about 3 degrees, because of the vapours of the Nile and the rains towards the Mountains of the Moon. It is so, secondly, because the difference in the altitude of the pole between Rhodes and Alexandria is only 5° 2′, if one compares what Ptolemy states in Book 2 of the *Almagest*, chapter 6, and Book 5, chapter 12, and in Book 1 of the *Geography*, chapter 11, and Book 4, chapter 5; or it is a little greater, if the altitude of the pole at Rhodes is corrected from the observation of the equinoctial shadow made there and reported by Vitruvius, Book 9, chapter 8. It is false, secondly, that Alexandria and Rhodes are under the same meridian, since Rhodes is farther west by 2°, or by 1° 45′, as is clear from ancient and recent geographical maps — although Ptolemy, in Book 5 of the *Almagest*, chapter 3, says that they lie almost under the same meridian. It is doubtful, however, whether there are 5000 stadia between these two places; for I suspect this equality and roundness of the numbers between Rhodes and Alexandria, between Alexandria and Syene, and between Syene and Meroë. Besides, if we listen to the differing opinions on the interval between Rhodes

and Alexandria reported by Strabo, Book 2, and by Pliny, Book 5, chapter 31, it is very uncertain. Finally, it is doubtful whether Posidonius observed Canopus in the city of Rhodes, or rather at a place 400 stadia away from it; or at Cnidus, where it had been observed by Eudoxus, as Strabo says in the same place; or near Lindus, with mountains lying between, as Snel suspects in Book 1 of the *Eratosthenes Batavus*, chapter 14; and whether, as often happens, that star, with the vapours of the horizon standing in the way, could not be seen before it was one or two degrees from the horizon.

13. Probl. Terræ Ambitum metiri artificio Marini Tyrij & Ptolemæi. *Problem 13. To measure the circumference of the Earth by the device of Marinus of Tyre and of Ptolemy.*

[Margin: Problem 13.]

This is done by means of the meteoroscope — that is, the instrument by which high things are observed from a low place, or lower things from a high one — indicated by Ptolemy in Book 1 of the *Geography*, chapter 3: by taking the angle of position between two places of known polar altitude, and measuring the distance between them in the same vertical. Let one place be D and the other E, and through them from the pole of the Earth, C, let the quadrants of declination, or of geographical latitude, CDA and CEB be drawn as far as the arc AB of the equator; and let the parallel of the place D be DF, and that of the place E, GE. Let the observer be at D, and let him, sighting E, take the angle of position CDE. It is now proposed to find the arc DE in the triangle CDE, in which there are given the observed angle CDE; the side CD, which is the complement of the altitude of the pole at the place D; and the side CH, the complement of the altitude of the pole at the place E. Therefore by [proposition] 2 of spherical oblique-angled triangles the arc DE can be found in degrees and minutes. Hence, if the stadia or miles contained in DE are known, and these are multiplied by 360 and the sum is divided by the degrees and minutes of the arc DE, the size of the Earth's circumference will be known. Similarly, if the place D is sighted from E, then from the angle CED so taken, and from the complements CE and CD already mentioned, DE will be found. Although Ptolemy adduces no observation of his own or of Marinus, he nevertheless hints at this method in Book 1 of the *Geography*, chapters 7 and 11, and Book 7, chapter 5, where 500 stadia were found by Marinus and by himself in one degree of a great circle of the Earth, and 180,000 in the whole circumference — figures to which not a few have subscribed, as I reported in Book 2, chapter 7, scholium 3.

Diagram. A figure set at the right of the left column: a spherical triangle. Two arcs descend from C at the apex, the left one through G and D to A, the right one through E and F to B, and an arc AB joins their feet. Parallels run across from G to E and from D to F, and a straight line joins D to E.

- C (apex): the pole of the Earth
- G (on the left arc): end of the parallel GE of the place E

- E (on the right arc): the second place
- D (on the left arc): the first place, where the observer stands
- F (on the right arc): end of the parallel DF of the place D
- A (foot of the left arc): on the equator
- B (foot of the right arc): on the equator

14. Probl. Terræ Ambitum venari, modo Almæonis, & multorum Arabum atque Coſmographorum. *Problem 14. To hunt down the circumference of the Earth by the method of Almaeon and of many Arabs and cosmographers.*

[Margin: Problem 14.]

One must explore the altitude of the pole at two places situated under the same meridian, or take at both places the meridian altitude of a fixed star on the same nights, or at any rate within a space of three months, provided that the star is high enough not to be subject to refractions. In this way the arc of the meridian lying between the two places will be established from the difference of the altitudes of the pole, or of the star. Then one must survey the distance between the places in stadiasms or miles, proceeding by a straight route, multiply the distance found by 360, and divide the sum by the degrees found in the arc already mentioned, so that the size of the Earth's circumference becomes known. This method was used by Ismael Abilfedea and other most skilled geometers at the command of Almaeon — or rather Alammon [al-Maʾmūn], king of the Arabs — proceeding along the same meridian in the plains of Zinar, or Fingar, along the straight route of the Red Sea; and they found that one degree of the terrestrial meridian contained 56⅔ miles — but miles each of which consists of 4000 cubits, as Alfraganus [al-Farghānī] relates in the *Rudiments of Astronomy*, difference 8. Why these Arabian miles make 68 ancient Italian miles, as Fernel and Maurolycus also teach, and Kepler, and who subscribed to this opinion, I have said in Book 2, chapter 7, scholium 4 — although our Clavius, in chapter 1 on the *Sphere*, page 211, and Barocius [Francesco Barozzi], in Book 1 of the *Cosmographia*, page 38, took those 56⅔ as Latin miles.

[Margin: The opinion of Adriaan Metius and of al-Battānī.]

Using this method, Adrianus Metius [Adriaan Metius], in his book on the use of the globe, says that Franeker in Friesland and Deventer are situated under the same meridian and differ in the altitude of the pole by exactly one degree, and that between them there are 15 common German miles. Another similar example, but of doubtful reliability because of the huge interval, you have in Kepler, precept 57 of the *Rudolphine Tables*; and Albategnius [al-Battānī], in chapter 6, says that 85 miles were found in one degree of a great circle of the Earth, or the journey of two days for a man travelling light.

15. Probl. Terræ Ambitum conquirere artificio Io. Fernelij. *Problem 15. To seek out the circumference of the Earth by the device of Io. Fernelius [Jean Fernel].*

[Margin: Problem 15.]

Jean Fernel, no less skilled in measuring than in healing, relates in Book 1 of the *Cosmotheoria*, chapter 1, in the scholia, that on August 25 he observed the meridian altitude of the Sun at Paris, and from it found the altitude of the pole to be 48° 38′. Then from the table of declinations of the ecliptic he gathered how great the meridian altitude of the Sun would be at a place one degree distant from Paris towards the north, and found that it would be as follows:

August, day	Altitude of the ☉
27	47° 26′
28	47° 5′
29	46° 41′

Then, having prepared a carriage with a certain wheel whose single revolutions, counted by single strokes of a drum, would show the route straight north from Paris, he arrived on the 29th at a place where the meridian altitude of the Sun was observed by him to be 46° 41′. He therefore deduced that this place was one degree distant from Paris; and, having counted the revolutions of the wheel already mentioned, he found that 68 96/1000 miles were contained in that degree. For the circumference of the wheel was 4 paces, or 20 feet, and its diameter 6 feet and 6 common digits across, and the revolutions came to 17024.

[Margin: Order of the problems.]

[Margin: Order of the problems.]

16. Probl. Terræ Ambitum ingenio Nonij & Iacobi Mazzonij concludere. *Problem 16. To determine the circumference of the Earth by the ingenuity of Nonius and of Jacopo Mazzoni.*

[Margin: Problem 16.]

Petrus Nonius, in Book 2 of *De observatione*, chapter 18, pointed out this method, hidden from many, after rejecting Eratosthenes' method because of the paralogism indicated above; but Jacopo Mazzoni of Cesena, a man most learned in every field, set it in a better light in Book 1 of his Italian *Defence of Dante*, chapter 77, on the occasion of the passage which the poet Dante had imagined from the surface of the Earth to its centre — an example of which fiction and Greek vanity I pointed out in Dionysiodorus, in Book 2, chapter 7, scholium 9. But Mazzoni illustrated this device with no figure or demonstration. Let ABOD, then, be the terrestrial meridian, whose centre is C; and let ERF be the visible hemisphere of the Sun, with its diameter ESF and its centre S, from which at noon on the day of the solstice the ray SL descends straight onto the style AL of a gnomon; and let it be produced to C. At either end of the terrestrial space IK, within which there is then no shadow of gnomons, let there be the gnomons GI and HK, along whose length the rays from the extreme edges of the Sun pass to the centre of the Earth, namely the ray TGIC and the ray VHKC. Through the tips of the same gnomons let two other rays be drawn from the opposite edge of the Sun, striking the Earth at M and N, namely the

ray XHN and the ray ZGM. Again, let two further rays be drawn touching the Sun and the Earth, namely EB and FD; and to these let there be drawn from C through M the straight line CMP, and through N the straight line CNQ. For the arc IAK of the Earth will be the one that both lacks all shadow and is measured by the angle ICK, which at the same time measures the apparent diameter EF of the Sun, since that diameter is comprehended by the same angle TCV: for because of the huge distance of the Sun from the Earth, the points E and T, no less than F and V, can be taken as the same. Now the arc AK will be irradiated by all the points of the solar portion RV, and the arc AI by all the points of the portion RT, by the axioms of optics. So although the arc AK is not wholly lit by the points of the portion RT, the gnomon AL preventing it, nor the arc AI wholly illuminated by the points of the portion RV, and AL therefore casts a certain penumbra, it will nevertheless hardly be sensible, since the brightness of the points of the other portion overcomes it. Outside that arc, however, there will be some pure shadow cast by the gnomons GI and HK, since they are supposed to stand at the extremes and to bound the space that lacks shadow simply so called.

Diagram. A tall figure set at the right of the left column. At the top is a horizontal frame line with S at its centre, and beneath it a semicircle, the Sun's hemisphere, hangs from the upper left to the upper right, with R at its lowest point. At the upper left three letters stand one below another — E, T, and a third that is not certainly legible — and at the upper right likewise F, V, and a third not certainly legible. A vertical runs from S through R and L down to the circle. Long lines run down from the upper corners and cross before reaching two small dark gnomons, G at the left and H at the right, beside L. At the foot is a circle, the Earth, with B at the left, D at the right, C at its centre and O at its foot; on its upper arc stand I, A and K, with M at the left and N at the right; lines run from C through M to P at the left and through N to Q at the right.

- S (top centre): centre of the Sun's hemisphere
- E (upper left): end of the Sun's diameter
- T (upper left, below E): edge of the Sun
- X (upper left, below T)
- F (upper right): end of the Sun's diameter
- V (upper right, below F): edge of the Sun
- Z (upper right, below V)
- R (lowest point of the semicircle)
- G (left gnomon)
- L (between the gnomons): top of the style AL
- H (right gnomon)
- P (left, on the line CMP)
- Q (right, on the line CNQ)
- I (on the Earth's arc, left of A)
- A (top of the Earth's circle): foot of the style AL
- K (on the Earth's arc, right of A)

- M (left, on the circle)
- N (right, on the circle)
- B (left of the circle)
- C (centre of the circle): centre of the Earth
- D (right of the circle)
- O (foot of the circle)

Now let that space IAK be measured, and let the angle TCV be known from the apparent diameter of the Sun at the summer solstice; for in this way it will be known how many stadia or miles are in the minutes enclosed in the arc IAK, and accordingly how many in 60 minutes, or in one degree, and finally how many in 360°. Mazzoni, moreover, supposes that 300 stadia were found in the arc IAK around Syene and Cyrene — as Cleomedes, Book 1 of *De mundo*, chapter 10, Pausanias, and Pliny, Book 2, chapter 73, and Book 6, chapter 29, report from Eratosthenes; and from Posidonius he takes the diameter of the Sun at apogee to be the seven-hundred-and-fiftieth part of the whole circumference of the solar heaven, that is, 28′ 48″. And so he concludes that there are 625 stadia in one degree, and 225,000 in the whole circumference of the Earth. But the diameter of the Sun at apogee is somewhat larger.

17. Probl. Terræ Ambitum inueſtigare Geometriſmo Villebrordi Snellij. *Problem 17. To investigate the circumference of the Earth by the geometrism of Willebrord Snel.*

[Margin: Problem 17.]

Willebrord Snel, many years ago, published two books on the measurement of the Earth, to which he gave the title *Eratosthenes Batavus*. In them he first investigated with much diligence the measure of the ancient Roman foot, which he contends is equal to the present-day Leiden or Rhineland foot, contained twelve times in the Leiden perch. Then, as in the following figure, he chose two towers, that of Leiden, L, and that of Zoeterwoude, S, because between them there is a field spread out into a large and convenient plain. In it he drew, by staking out, the straight line LS, and another, AB, cutting it at right angles; and, having marked the stations A and B, he measured the interval AB and found it to be 87 Leiden perches, 0 [?] feet and 5 digits.

[Margin: Step 1.]

Diagram. A figure set at the right of the right column: a rhombus with B at the top, L at the left, S at the right and A at the foot; its diagonals LS and BA cross at D.

- B (top): station B
- L (left): the tower of Leiden
- D (centre): crossing of LS and AB
- S (right): the tower of Zoeterwoude
- A (foot): station A

Then, using a quadrant that showed every two minutes of each degree, from A he sighted the station B along the side of the quadrant, and through

the movable dioptra the tower now L, now S, and observed the angles BAL and BAS, which make up the angle LAS. Again from B, sighting the station A, and from there the towers L and S, he obtained the angles LBA and SBA, which make up the angle LBS. Since, then, in the triangle ABL the angles LAB and LBA were known, their sum subtracted from 180 degrees showed the angle ALB, by [proposition] 32 of the first book of the *Elements*; likewise in the triangle ABS the sum of the angles BAS and ABS, taken from 180 degrees, showed the angle ASB. Therefore in the triangle ABL, with all the angles known, and the side AB, he found the sides AL and BL by [proposition] 2 of plane oblique-angled triangles; likewise in the triangle ABS, with all the angles also known, and the side AB, he found the sides AS and BS. Afterwards in the triangle LAS, with the sides AL and AS known, and the included angle, he investigated the distance LS by [proposition] 5 of plane oblique triangles; and he confirmed it by exploring the same distance in the triangle LBS, in which the sides LB and SB were known, and the included angle LBS. Although, since LS was drawn perpendicular to AB, the same interval could have been rendered more surely by [proposition] 1 of right-angled triangles, in ADL and ADS — by finding, from the bases AS and AL already found and the angles DAS and DAL, the opposite sides DS and DL, and compounding the interval LS from them. This he finally found to be 1029 Leiden perches, 3 feet and 3 digits, and such, he found, was the distance between the tower of Leiden and the town of Zoeterwoude. This distance, acquired as a great side, he used in investigating the distances of other neighbouring towns, as we shall shortly say in the second step.

[Margin: Step 2.]

Secondly, then, having similarly taken the angles of position of Leiden and Zoeterwoude with The Hague and the neighbouring villages, and so, with three angles known as above, and the side LS, he obtained the distance between Leiden and The Hague; and by this method, with manifold geometry, he obtained the intervals between the places of Holland written below, which I have used to correct the differences of longitude in my book on geography.

Ends of the distances	Leiden perches	Leiden feet
Leiden and Zoeterwoude	1029	3 3/12
Leiden, The Hague	4103	3
The Hague, Gouda	7594	3
Leiden, Gouda	5897	8
Gouda, Dordrecht	5897	8
The Hague, Dordrecht	10112	7
Leiden, Dordrecht	10633	1
or	10634	7

[Margin: Order of the problems.]

[Margin: Order of the problems.]

Ends of the distances	Leiden perches	Leiden feet
Remainder of the preceding table		
Gouda, Utrecht	7847	5
Leiden, Utrecht	11628	8
or	11631	8
The Hague, Rotterdam	5616	8
Leiden, Rotterdam	6972	3
Leiden, Oudewater	7975	1
or	7981	8
Oudewater, Montfoort	1566	1
The Hague, Haarlem	10725	1
Leiden, Haarlem	7040	4
Amsterdam, Utrecht	9201	0
Leiden, Amsterdam	9725	8
Amsterdam, Alkmaar	8193	0
Leiden, Alkmaar	14750	0

Thirdly, and finally, having observed with a large quadrant the altitudes of the pole of many of the places already mentioned, and also the angles of position, he investigated by the analysis of spherical triangles the arc of the vertical circle lying between pairs of places, and especially between Leiden and Alkmaar, whose very great distance he had obtained. Let the figure set out in Problem 13 be repeated here, and let Leiden be D, whose latitude, known from the altitude of the pole, is AD, 52° 10′ 30″, and its complement DC 37° 49′ 30″. Let Alkmaar be E, whose altitude of the pole is 52° 40′ 30″, as Snel gives it, and its complement 37° 19′ 30″; and let the angle of position CDE be 14° 58′. The arc DE of the vertical circle will then come out at 0° 31′ 4″. Since, then, by the second step, this arc contains 14,750 Leiden perches, that is, 177,000 ancient Roman feet, or 35,400 paces, it follows that one degree of a great circle of the Earth contains 68 400/1000 ancient Roman miles, and the whole circle 24,624, as I reported in Book 2, chapter 7. I have shown, however, in my book on geography that the Roman foot which Snel compared with the Leiden foot was more recent, and larger, than Vespasian's. But because of the over-complicated operation into which Snel was forced, in order at last to find a great distance corresponding to about half a degree, it is no wonder if he fell short of that truer measure which we have reached by a simpler and surer way, as we shall explain in the following problem.

18. Probl. Ambitum Terræ Methodo Noſtra & P. Franciſci Mariæ Grimaldi. *Problem 18. The circumference of the Earth by our own method and that of Father Francesco Maria Grimaldi.*

[Margin: Problem 18.]

Although I have already given this problem in Book 2, chapter 7, from number 6 on, with a notable example added, I think it should be repeated here, condensed into a few words, for the completeness of the doctrine and its unity

with what precedes. We carried it out, moreover, in four steps. *First*, with great diligence I sought out the measure of the Roman foot in use under Vespasian, or even under Augustus, and compared it with the Bologna foot and with the feet or palms of many notable cities, as appears in the table of measures placed at the beginning of our book on geography — which I shall perhaps transcribe at the end of this Section. I found that 1495 ancient Roman feet make 1200 present-day Bologna feet, and so that the Bologna foot is to the Roman as 5 to 4, with an insensible difference, and likewise the pace to the pace and the mile to the mile. We set down a measure of this kind in Book 2, chapter 7, number 2.

[Margin: Step 1.]

Secondly, along the bank of the Reno, where there is an open and great plain, *Father Grimaldi*, with several companions and helpers, measured the interval from the small tower of the gate of San Felice as far as a certain quadrilateral column standing near the gate, on the bank of the river; it came to 1088 2/5 Bologna paces, a cord being stretched in a straight line and held up at intervals, and ten-foot rods being used. Having acquired this great side, and having observed the angles of four other stations — namely, of the Asinelli Tower; of the church of the Most Holy Virgin painted by St Luke, standing on the Mount of the Guard, commonly *della Guardia*, a definite part of it being chosen; of our country house, situated on Monte Paderno; and finally of the tower of Modena, which is plainly seen from that house, as it is also from part of the church already mentioned and from the summit of the Asinelli tower — by an accurate analysis of only five rectilinear triangles we determined that between the tower of Modena and our country house there are 21,176 Bologna paces, 26,470 Roman; and between the tower of Modena and the Asinelli of Bologna 20,404 Bologna paces, that is, 25,505 ancient Roman. This agrees very closely with the 25 miles which the *Antonine Itinerary* puts between Modena and Bologna — whether the Roman surveyors neglected the 505 paces, content with a round number, or rather used other termini, since the towers already mentioned did not then exist. You have the angles already mentioned, and the scheme of the stations used, in Book 2, chapter 7, number 7.

[Margin: Step 2.]

Thirdly, in a window of the country house of our College of Bologna, which stands in the Serra, or Monte Paderno, a thread triangle was erected perpendicularly, such as we described in Book 5, chapter 15, number 16, and turned towards the tower of Modena, which could conveniently be seen from there by day; and it was kept in the same plane of the vertical circle passing through that window and the tower already mentioned. When the Fidicula of the heavenly Lyre reached that plane, its altitude was taken, and it was 20° 17′. The northern declination of the Fidicula was then 38° 30′; and on the same mountain the altitude of the pole had already been examined earlier and found to be 44° 27′.

[Margin: Step 3.]

Fourthly, Father Grimaldi went to Modena and observed most diligently the altitude of the pole in our College at Modena, which is very near the tower of that city, and found it to be 44° 37′. Therefore, from the complements of the polar altitudes and of the declination of the Fidicula, according to the scheme shown in Book 2, chapter 7, number 6, the arc of the vertical circle drawn through the tower of Modena and the window already mentioned was found to be 0° 17′ 35″. Since, then, by the second step, there are between these two places 21 176/1000 Bologna miles, and 26 470/1000 ancient Roman miles, there are accordingly in one degree 72 256/1000, or 72 1/4, Bologna miles, but 90 8/25 Roman; and in the whole circumference of the Earth 26,010 Bologna miles, 32,512 Roman, as we said in the same place.

[Margin: Step 4.]

19. Probl. Terræ Ambitum Noſtra alia methodo tentare. *Problem 19. To attempt the circumference of the Earth by another method of our own.*

[Margin: Problem 19.]

Let two places on the Earth be chosen, very distant indeed, but such that the interval between them in miles or stadia can be known, either by proceeding along a straight route with ten-foot rods, or by geometry, in the way that Snel did in Problem 17 and we in Problem 18. Let the altitude of the pole be observed exactly in each place, and the beginning of some total eclipse of the Moon — or rather of the total obscuration — but with the diligence which we required in Book 5, chapter 15; and let each observer obtain the moment of the beginning from the altitude of a fixed star, using Problem 25 of Section 3. For when the smaller time is subtracted from the greater, and the difference converted into parts of the equator, the difference of geographical longitude will be known. With these obtained, let the figure of Problem 13 be taken up again, and in it let one place be D and the other E. For in the triangle DCE the sides CD and CE will be known, since they are the complements of the polar altitudes, and the angle C, since it measures the arc AB of the equator, that is, the difference of the longitudes. Therefore, by [proposition] 4 of spherical oblique-angled triangles, the vertical arc DE drawn through both places will be found — that is, how many degrees and minutes it contains. And since the miles or stadia belonging to this arc will be known, those which are in one degree, and in 360 degrees, or the whole circumference of the Earth, will also become known.

20. Probl. Terræ Ambitum ὁλοσχερῶς, ſeu Eminus diſcernere. *Problem 20. To discern the circumference of the Earth in the gross [Greek: ὁλοσχερῶς], or from afar.*

[Margin: Problem 20.]

This can be done by means of a geographical globe, and of a sea voyage from one place to another very distant one, made as straight as possible, and as diligently as possible from

[Margin: Order of the problems.]

[Margin: Order of the problems.]

the measures customary among shipmasters, ascertained. For when the legs of a pair of compasses are spread from the one place to the other, and so transferred onto the equator of the globe, the degrees, and very nearly the minutes, contained in the arc of the vertical circle passing through those two places will be known; and so, from the miles or leagues found on that voyage, how many miles are owed to one degree and to the whole circumference.

[Margin: Example of the problem.]

For example, Ferdinandus Magellanus [Fernão de Magalhães], in the year 1519, on September 20, set sail with favourable winds from the port of Sanlúcar, which lies beyond Seville, and on the 26th reached the island of Tenerife by an almost straight course, having covered 960 present-day Italian miles, as Antonius Pigafetta [Antonio Pigafetta] and Odoardus Barbosa [Duarte Barbosa] attest from the daily observation of the shipmasters; and the globes of the more recent geographers show an arc of 12 degrees between that port and Tenerife. It follows that about 80 miles are contained in one degree of a great circle of the Earth. But if that course is corrected and reduced to a straight path, we are certain that somewhat fewer are contained — especially since he reached another port, 24 degrees distant from Tenerife, after covering 1680 miles counted from Tenerife, from which 70 miles to one degree would follow. But it is better to use Problem 18, if anyone has been granted the opportunity of such places.

Problemata. 21. 22. 23. 24. 25. 26. Altitudinem Turris Sex modis præcipuis Geometricè metiri per Altimetriam. *Problems 21, 22, 23, 24, 25, 26. To measure the height of a tower geometrically, by altimetry, in six principal ways.*

[Margin: Problem 21.]

I said "geometrically", for there is no one who does not know how to measure it mechanically, with a stretched rope or with rods. For these, then, let there be in the following figure a tower AB, lit by the Sun and casting a shadow as long as AD, bounded by the ray BD; and let the straight line AD be measured with ten-foot rods. Let a pole XZ be erected perpendicularly at the place X — that is, at such a position that its tip is bounded by the ray BD, so that a tiny part of it is lit at Z, or rather a small ball fixed on its tip. Let the part DX of the shadow be measured with ten-foot rods, and let the length of the pole be known in the same kind of units in which DX is known. For if AD makes a right angle with AB, or is brought to one by means of a horizontal level, two equiangular triangles will arise, namely BDA and ZDX: for the right angle DXZ will equal the right angle DAB, and the angle ADB will be common to both triangles. Therefore, by [proposition] 32 of the first book of the *Elements*, the complements to the other right angle, that is, the angles DZX and DBA, will be equal to each other. Therefore, by [proposition] 4 of the sixth book of Euclid's *Elements*, let it be done: as DX, known in feet, is to XZ, known in feet, so DA, known in feet, is to AB; and thus the height of the tower AB will be known in feet. Indeed, in place of the pole XZ a man of known stature

could be used, who would walk to and fro until the ray of the Sun grazed the top of his head.

Diagram. A figure set within the width of the left column. At the right stands a tall tower, drawn with two barred windows and a round-headed door at its foot, with A at its foot and B at its top beside a small cross-like finial. A base line runs from D at the left to A, with T, O, V and X lettered below it. At the left a vertical rises from D to Y, and from Y a quadrant hangs to the right, with I on its arc and H below it. Long lines run from B down to D and from Y down towards A, crossing near the middle of the figure. A vertical stands at X, with Z at its top on the line BD. Above T stands E, with a quadrant whose vertical side ends at G, with K on its arc and L at the end of its horizontal side; below E hangs a small quadrant with R at the left and S at the right. A horizontal line runs from E to C on the tower. Dotted lines run from L down to V and from V up towards F. A second quadrant stands at F, with M at the top of its vertical side, P on its arc and Q at the right; lines run from E and from F up to B.

- Y (top left): the station Y, top of the cord DY
- I (on the arc at Y)
- H (below I, left)
- B (top of the tower)
- Z (top of the pole XZ)
- G (top of the vertical side of the quadrant at E)
- K (on the arc of the quadrant at E)
- M (top of the vertical side of the quadrant at F)
- P (on the arc of the quadrant at F)
- E (the observer's eye, the station E)
- L (end of the horizontal side of the quadrant at E)
- F (the station F)
- Q (right of F, below the line)
- C (on the tower, at the end of the line EC)
- R (left end of the hanging quadrant below E)
- S (right end of the hanging quadrant below E)
- D (lower left corner)
- T (on the base line, below E)
- O (on the base line, below L)
- V (on the base line, where the dotted lines meet)
- X (on the base line, foot of the pole XZ)
- A (foot of the tower)

[Margin: Problem 22.]

Secondly, measure the shadow AD as above, provided it is at right angles to AB; and, taking your station at T, turn the dioptra RE of a hanging quadrant onto the extreme ray BD of the Sun — the one, that is, that bounds the shadow — so that the ray passes through the holes of the pinnules, or rather grazes their upper side; and observe on the quadrant the arc TER. For it will be equal

to the angle DBA, because of the parallelism of the perpendicular lines BA and ET; and the angle TES will be equal to the angle ADB, by [propositions] 29 and 32 of the first book of the *Elements*. Therefore, by [proposition] 4 of plane right-angled triangles, given AD and the angle ADB, the height AB will become known.

[Margin: Problem 23.]

Thirdly, let there be in the plane AD a plane mirror TX, parallel to the horizon, on which there falls from the top of the tower, B, a ray, or image, of B itself; let it be BV. You, then, move back from the mirror towards E until, with your eye placed at L, you see the image of the point B at V by the reflected ray VL; and, dropping a plumb line from L, measure the height of the eye OL in parts as small as possible, but equal, and also the distances OV and AV. For here too you will obtain two equiangular triangles, namely VBA and OLV, since the right angles VAB and LOV are equal, and the angle of incidence BVA, by the axioms of catoptrics or anacamptics, is equal to the angle of reflection OVL; and so the remaining angle VBA is equal to the remaining angle OLV. Let it be done, therefore, by [proposition] 4 of the sixth book: as OV is to OL, so VA is to AB; and the height AB will be known.

[Margin: Problem 24.]

Fourthly, stretch yourself out on your back, parallel to the horizon, and let your eye be at D and your feet at T; and let a companion be present who, with the help of a plumb line, fixes a pole of known length upright to the horizon, moving it to and fro in the plane DA, which is at right angles to the tower AB, until Z, the tip of the pole XZ, is in the same straight line BD — the line of sight that runs from the top of the tower, B, to your eye; and let both the distance DX and the distance DA be known. For, from what was said in Problem 21, as DX is to XZ, so DA is to the height of the tower AB.

[Margin: Problem 25.]

Fifthly, since the plane AD is sometimes not parallel to the horizon, place at the height of your eye (while you stand upright) a quadrant EGKL, or a geometrical square, so that the side GE stands perpendicular to the horizon and the other side, EL, is parallel to it; and, turning the dioptra towards the top of the tower, observe the angle KEL, that is, BEC, by the arc KL. You could also obtain it by means of a hanging quadrant ERS, with its centre placed at E and the eye at R; for the angle TER, by [proposition] 15 of the first book of the *Elements*, equals the angle GEK, and so their complements to a right angle, namely TES and KEL, are equal. With these angles noted, measure the height ET and the interval TA, or rather EC. For in the triangle BEC, right-angled at C, given the side EC and the adjacent angle BEC, you will be able to find, by [proposition] 4 of plane right-angled triangles, the height CB; and if to it you add the height ET — or rather AC, if from E you have marked the point C along the line of sight and have measured AC — the whole height AB will be known.

[Margin: Problem 26.]

Sixthly, if you cannot get to the foot of the tower, because water, or an enemy army, or some other obstacle lies between, nor measure the whole distance AD or EC, choose two of the stations available: one at E, where, as above, take the angle BEL by means of a quadrant, or a square, or a ring; the other at F, where take the angle PFQ. Then measure the interval EF between the stations. For in the triangle BEF, besides the side EF, all the angles will be known: BEF is known from the earlier observation; the angle BFE, by [proposition] 13 of the first book of the *Elements*, is the supplement to two right angles of the angle PFQ, known from the later observation; and the third, EBF, is the supplement of these two to two right angles, by [proposition] 32 of the first book of the *Elements*. Therefore, by [proposition] 2 of plane oblique-angled triangles, you will find the side BE; and with it and the angle BEC, in the triangle BEC, right-angled at C, find by [proposition] 1 of right-angled triangles the height BC. This will differ from the height AB by not much more than the height of your eye, ET, if TA is, at least to the senses, a plain of a kind.

But if you can neither get to A nor have an interval EF sufficient for a proper operation, draw from D a cord DY at right angles to the line of sight DA, with the help of a set-square or gnomon, and measure the distance DY with ten-foot rods. Then at the station Y, by means of a quadrant parallel to the horizon, take the angle DYA by the arc HI, sighting, that is, the foot of the tower, A. For in the triangle DYA, right-angled at D, given the side DY and the angle DYA, you will obtain by [proposition] 4 of right-angled triangles the interval AD, with which you may then operate as in the earlier Problems 21, 22 or 24.

[Margin: Order of the problems.]

[Margin: Order of the problems.]

27.Probl. Diſtantiam Inſulæ, aut alterius loci ex littore maris, vel ripa fluminis conſpicui, metiri. *Problem 27. To measure the distance of an island, or of some other place, visible from the shore of the sea or from the bank of a river.*

[Margin: Problem 27.]

You will solve this problem by the latter part of Problem 26. For in the figure set out above, let A be an island or some other place, and suppose you wish to measure the interval AD between it and the shore D. For if on the shore you set up the angle YDA by means of a set-square, and, having measured the distance DY, take at the station Y, on the shore or the bank, the angle HYI, that is, DYA, you will find the interval DA, as was said there.

28.Probl. Montium Altitudinem per partes ope normæ metiri. *Problem 28. To measure the height of mountains by parts, with the help of a set-square.*

[Margin: Problem 28.]

Let there be a mountain APB, whose perpendicular height AP is to be found; but suppose that above the plane AB you have a gnomon, or set-square, MNO, containing a most exact right angle N, whose height NB is as great as your

stature from foot to eye. Starting from the foot of the mountain, B, and setting the side NB of the square upright to the horizon with the help of a plumb line,

Diagram. A figure set within the width of the left column. A frame has A at its lower left and B at its lower right, with P at the top of its left side and G and C below P. The hatched slope of a mountain falls from P at the upper left to B at the lower right, and three set-squares stand on it as steps: at the top one with E and D, whose vertical DF runs down to F, with S beside it; in the middle one with I and H, whose vertical HK runs down to K; and at the right one with M and N, whose vertical runs down through O to B. Horizontal lines run from G through S, and from C through K, to the right side. Each square carries a small quadrant arc in its corner. A small letter stands on the slope under K, partly lost in the hatching and not certainly legible.

- E (top square, left end of its upper side)
- D (top square, corner)
- P (top of the left side): the summit of the mountain
- F (foot of the vertical DF)
- G (left side, below P)
- S (beside F, on the line from G)
- I (middle square, left end of its upper side)
- H (middle square, corner)
- K (foot of the vertical HK)
- [?] (on the slope under K)
- M (lowest square, left end of its upper side)
- N (lowest square, corner)
- C (left side, below G)
- O (on the right side, below N)
- B (lower right corner): the foot of the mountain
- A (lower left corner)

look through the pinnules of the side MN at a sign L on the mountain, placed there by a companion — some ball, or a paper disc coloured red. Then climb to the sign L and set up the square in the same way, so that it has the position IHK, and look through the side HI at a sign placed at S. Afterwards climb to S and set up the square so that it has the position EDF, with the side F upright to the horizon; and through the side ED sight the sign P; and go on in this way, step after step, if P were not the summit of the mountain. Then let the height of the side BN be known: for as many such stations as there have been, so many times will the side BN be contained in the height AP. For BN is equal to AC, by [proposition] 34 of the first book of the *Elements*, since ACNB is a parallelogram, all its angles being right — because AC and NB are perpendicular to AB, and the angle N is right by the construction of the square; and so the straight line NML, continued in imagination to C, is parallel to AB, by [proposition] 28 of the first book of the *Elements*. Similarly HK will equal CG, and FD will equal GP; and so the three NB, HK and DF together will equal the three AC, CG and GP taken together, that is, the whole

perpendicular height of the mountain, AP, above the horizontal AB — not, however, the whole height absolutely above the surface of the Earth concentric with the surface of the sea, unless AP stood on the shore of the sea, or were the height of a cliff, or of a promontory, and so on.

[Margin: Note, for avoiding error in the heights of mountains.]

The problem can also be solved by climbing to L, placing the square there upright to the horizon, and looking back along the other side at a small ball N fixed on a pole BN — provided the pole is upright to the horizon by means of a plumb line — and so on successively: for as many stations of observation as there were up to the summit P, so many times would the length of the pole be contained in the height AP.

[Margin: Another way.]

29. Probl. Montis aut Turris Altitudinem abſolutam metiri, Data ſemidiametro Terræ, & Angulo in vertice ipſius obſeruato, ſi inde liber ſit proſpectus in Mare, aut ſuperficiem Mari concentricam. *Problem 29. To measure the absolute height of a mountain or a tower, given the semidiameter of the Earth and the angle observed at its top, if from there there is a free view onto the sea, or onto a surface concentric with the sea.*

[Margin: Problem 29.]

I call absolute height the perpendicular height, not above a straight and horizontal line, but above that surface of the Earth which is concentric with the surface of the sea and coincides with it — or which is as far from the centre of the Earth as that surface is. In the following scheme, then, let HAR be the hemisphere of the terraqueous globe, HCR its rational horizon, and AC the semidiameter perpendicular to it, in which let AB be the height of the mountain. From its top, by means of a very large quadrant that shows not only the minutes of each degree but at least the tens of seconds, with the pinnules turned down onto the horizon below, which no obstacle obstructs, let the angle B be observed along the line of sight BG, touching the globe of land and sea at G; and, drawing the straight line CG in imagination, let the triangle BCG be considered, right-angled at G, by [proposition] 18 of the third book of Euclid's *Elements*.

[Margin: What the absolute height of mountains is.]

Diagram. A small figure set at the right of the right column. A semicircle stands on the diameter HR, with C at its centre. A vertical rises from C through A on the arc to B above it. A horizontal chord runs from F at the left to G at the right; a line from B touches the arc at G, and a line runs from C to G.

- B (top): the summit of the mountain
- A (top of the arc): the foot of the mountain's perpendicular
- F (left end of the chord)
- G (right end of the chord): the point of contact
- H (left end of the diameter)
- C (centre): the centre of the Earth

• R (right end of the diameter)

For in it the side CG is given, which is the semidiameter of the Earth, known not only in miles but also in paces or feet; and so is the opposite angle, whose complement to a right angle is the other angle, BCG. Therefore, by [proposition] 3 of plane right-angled triangles, find the base CB; and if you subtract from it the Earth's semidiameter AC, the height of the mountain, AB, will remain. From this, moreover, you will gather how exact the knowledge of the Earth's semidiameter must be: for if paces or feet in it are neglected, the measure of the height AB will also be crude, and it will come out differently according to the different opinions about the semidiameter of the Earth. By this device we measured the height of Monte Paderno near Bologna.

[Margin: Corollary.]

30. Probl. Montis Altitudinem abſolutam indagare, Datis Semidiametro Terræ, & Circuli magni Arcu inter Montis perpendiculum, atque oculum primò detegentem Montis apicem. *Problem 30. To find the absolute height of a mountain, given the semidiameter of the Earth and the arc of a great circle between the perpendicular of the mountain and the eye that first discovers the peak of the mountain.*

[Margin: Problem 30.]

In the figure immediately preceding, let AB be the perpendicular height of the mountain, and let someone sailing, or swimming, towards it arrive at G, where he first discovers the summit B, which a little before was hidden, so that the line of sight BG touches the eye G, placed almost on the surface of the sea. For in the triangle CBG, right-angled at the point of contact G by [proposition] 18 of the third book of Euclid, the angle BCG is given, which the given arc AG measures, and the side CG, which is the semidiameter of the Earth. Therefore, by [proposition] 3 of plane right-angled triangles, the base BC will be found; and by subtracting from it the Earth's semidiameter AC, the height sought, AB, will become known. The arc AG, moreover, is observed very easily if one sails towards A in the plane of the meridian, towards the poles of the world, and, when the ship has come within sight of the top B, the altitude of the pole is taken, the altitude of the pole on the mountain AB being known; or else the meridian altitude of the same fixed star is taken in both places in the same year, for the difference of the altitudes will give the arc AG. But if that arc is given in miles, let them be converted into degrees and minutes, and let the rest be completed as above.

EXEMPLVM *Example.*

In Montibus Ætna, Pico, & Caucaſo. *On the mountains Etna, the Peak and the Caucasus.*

Maurolycus, in the third dialogue of the *Cosmographia*, page 75, and certain Knights of Malta have reported to us that the summit of Etna is discerned right

from the island of Malta, and even beyond, from a distance of 216 Italian miles and more; and to these, by what was said in Book 2, chapter 7, correspond 3 degrees of a great circle — where we also showed that CG, the semidiameter of the Earth, is 4139 Bologna miles. Let it be done, then: as the radius CG, of 100,000 parts, is to 4139 miles, so the secant BC of the arc AG, 3°, of 100,138 parts, is to 4144 71/100 miles. For when AC, 4139 miles, is subtracted, there will remain the height of Etna, AB, of 5 7/10 Bologna miles — granted that Snel, in Book 2 of the *Eratosthenes Batavus*, puts only 4, because of refractions, which, as Father Kircher also thinks in a letter sent to me on 1647 February 17, intervene and make either the peak of the mountain visible from the island, or the island from the peak of the mountain, when otherwise they could not be seen. But the height of Mount Athos, of which I shall speak in Problem 35, and which cannot be diminished by refractions, to me very probable makes this height. How this height, and that of the mountains that follow, is to be corrected once the intervention of refraction is granted, I shall say in Section 6, Problem 50.

[Margin: The height of Etna.]

[Margin: Order of the problems.]

[Margin: Order of the problems.]

Aloysius Cadamustus [Alvise Cadamosto], in his voyages, in Ramusius [Giovanni Battista Ramusio], volume 1; Io. Hugonis Lintschotanus[56] [Jan Huyghen van Linschoten], in his; Snel, in Book 2 of the *Eratosthenes Batavus*, chapter 17, and in Book 2 of the *Tiphys Batavus*, near the end; and our Fournier, in Book 19 of the *Hydrographia*, chapter 8 — all report that the Peak, the mountain of the island of Tenerife, one of the Fortunate Islands, is seen by those sailing towards the south pole, and by those sailing back towards the north, from a distance of 4 degrees of a great circle; indeed, that its summit is seen like a temple from the island of Madeira [Materia], that is, from a degree of 4° 10′. Let it be done, then: as AC, 100,000, is to 4139 miles, so the secant BC of 4 degrees, 100 244, is to 4149 1/10 miles. For there remains the height of the Peak, AB, of 10 1/10 Bologna miles — as much as Snel also gathers, disregarding the fractions. But if refraction should diminish it, see Section 6, Problem 50.

[Margin: The height of the Peak.]

Aristotle, in Book 1 of the *Meteorologica*, text 63, or summa 4, chapter 1, among the signs of the height of the Caucasus, sets down this as well: "For it is seen from the so-called Deeps, and by those sailing into the Lake." The Deeps are the parts of the Euxine Sea near the Cimmerian Bosporus, so called because they have no bottom, sailors having sounded for it in vain; the Lake is the Maeotic marsh. He means, then, that those sailing from the Euxine into the Maeotis through the Bosporus see the Caucasus. In Ptolemy the Cimmerian Bosporus lies almost on the same parallel as the Caucasus, and is distant from it in longitude by at least 12 degrees. The altitude of the pole of the Caucasus is 47 degrees; that of the Bosporus, at its mouth, 47 1/2 degrees. From these,

[56] printed "Lintſchoſanus", long s for t

by Problem 102, to be set out below, the distance of the Bosporus from the Caucasus on a vertical circle is deduced as 9° 32′, whose secant is 101,400. Now let it be done: as the radius CA, of 100,000 parts, is to 4139 miles, so the secant BC, of 101 400 parts, is to 4196 97/100 miles. Therefore AB, the height of the Caucasus, would be at least 57 97/100 Bologna miles, or 58 — unless it is to be corrected for refractions, according to what will be said in Section 6, Problem 50. The more recent geographers, however, set the Caucasus less far from the Bosporus, and so on their reckoning the height of the Caucasus would decrease.

[Margin: A passage of Aristotle on the Caucasus explained.]

[Margin: The height of the Caucasus.]

31. Probl. Montium Altitudinem metiri more antiquiorum Geometrarum, duplicem tamen fallaciam continente. *Problem 31. To measure the height of mountains in the manner of the older geometers — a manner, however, that contains a double fallacy.*

[Margin: Problem 31.]

In the following figure, already set out in Book 2, chapter 4, number 8, let CB be a quadrant of the Earth, described from the centre A, and on it the height of the mountain MP. Let the perpendicular PM be continued as far as A, and let the surveyor's eye be at C, the point of contact made by the tangent CK. On this tangent let the side CD of the geometrical quadrant CDF stand perpendicularly; and, with the eye set at C, let the alidade [dioptra] CE be raised and the summit M sighted through it, and let the arc EF, divided in the usual way into degrees and minutes, show the angle ECF. For in the triangle GCK, right-angled at C, if the distance CK is known, you can find the height GK by [proposition] 4 of plane right-angled triangles. But if CK is not known, find it by Problem 26. In this way Dicaearchus and Zenagoras, in Pliny the Elder, Book 2, chapter 65, and in Plutarch's *Aemilius*, seem to have measured the height of Cyllene, Pelion, Olympus, Satabyrium and other mountains; and indeed they find it far too small — namely, for Olympus and Pelion, 1250 paces; for Cyllene, 14 stadia, or 1750 paces; and for Satabyrium, 15 stadia, or 1875 paces. Certainly our Biancani, in the *Sphaera*, part 3, treatise 3, chapter 1, appendix 1, affirms that by this method he found the height of Monte Baldo, which rises out of the territory of Verona, to be 804 paces, supposing the distance CK from the territory of Parma, where he was staying, to be 70 Italian miles, and so the angle GCK to be 39 1/2 minutes.

Diagram. A figure set at the right of the left column. From the centre A at the lower left a straight line rises to M at the upper right; an arc of the Earth's surface runs from C at the upper left down to B at the lower right, crossing the line AM at P, with K on AM above P. At C stands a small quadrant, its side running up to D and its arc through E; lines run from C to G and M at the top and along the tangent to K, with F on that line below E. A vertical line falls to B.

- D (upper left, above C): the upper end of the quadrant's side CD

- E (top, right of D): on the quadrant's arc
- G (top): the top of the height GK
- M (upper right): the summit of the mountain
- C (left): the surveyor's eye, the point of contact
- F (below E): on the quadrant's arc, on the line CK
- K (right, on AM): the foot of the height GK on the tangent
- P (on AM, at the arc): the foot of the mountain on the Earth's surface
- A (lower left): the centre of the Earth
- B (lower right): the end of the quadrant CB

But in this practice a double fallacy lies hidden, and I am surprised that it was not mentioned by Orontius [Oronce Finé] in his *Geometria practica*, Book 2; nor by Clavius, Book 3; nor by Maurolycus in dialogue 3 of the *Cosmographia*; nor by Daniel Santbech in his problems, from proposition 77 to 82; nor by Gemma Frisius in the *Radius Astronomicus*, chapter 10; nor by Io. Taisnerus [Johannes Taisnier] in *De usu annuli*, Book 1; nor by Magini, book 2, *De altitudinibus*; nor by Sylvius Belus [Silvio Belli]; nor by many other geometers; nor, finally, by Biancani himself. First: if the distance of the station C from the mountain PM is considerable, and of many miles, a notable slope of the ground usually intervenes, increasing or diminishing the apparent height of the mountain. Second: the height taken in the manner already mentioned is not the absolute height, but the height above the horizontal CK, which is imagined; and usually — unless the foot of the mountain is on the seashore — there remains a great part belonging to the height of the mountain and lying hidden below the horizontal CK, down to that surface of the Earth which is concentric with the convex surface of the sea. Indeed, the height GK is not perpendicular to such a surface, nor does its line tend to the centre of the Earth. And yet, when the question in cosmography is the perpendicular height of mountains, we commonly seek the height that stands perpendicularly on the convex surface of the terrestrial globe and rises from that same surface, concentric with the surface of the sea — especially when we wish to know their absolute height, and how much it hinders the perfect roundness of the Earth, and how great a space is visible all round from the summit of the mountains, and how great the slope is from there down to the level of the sea. Some years after I had written this, however, I came upon Father Cabeo [P. Cabæi], Book 1 of the *Meteorologica*, text 63, question 1, where he mentions this fallacy; but not even he supplied a sufficient remedy for it, as I shall presently show.

[Margin: Error, or oversight, of some geometers.]

[Margin: First fallacy.]

[Margin: Second fallacy.]

32. Probl. Altitudinem Montium, more antiquo menſuratam corrigere, & ad abſolutam reducere, data Terræ ſemidiametro. *Problem 32. To correct the height of mountains measured in the old way, and to reduce it to the absolute height, given the semidiameter of the Earth.*

[Margin: Problem 32.]

Look at the figure set out and explained just above, in which let ABC be a quadrant of the Earth's globe, with its centre A. Let the observer at C, by means of the quadrant CDF standing perpendicularly on the horizontal plane CK, sight the summit M of the mountain PM through the alidade and along the line of sight CM, and take the angle ECF subtending the arc EF; and with this angle and the distance CK, in the triangle CKG, right-angled by supposition at K, let him gather the height GK, according to what was said in Problem 31. The principal error of the geometers in this measurement, then, is to take the height GK for the absolute height MP, and to suppose that GK falls perpendicularly on the surface CPB. This error must now be corrected, and we shall accomplish it in two steps. First, in the triangle ACK, right-angled at C, CK is supposed known, and the semidiameter of the Earth AC; therefore, by [proposition] 8 of plane right-angled triangles, we shall find the base AK, and by [proposition] 5 of the same, the angle AKC. This, joined to the right angle GKC, will make the angle PKG, and its supplement to two right angles, by [proposition] 13 of the first book of the *Elements*, will show the angle GKM. Second, then, in the triangle GKM we shall find the side KM by [proposition] 2 of plane oblique-angled triangles. For in it are given the side GK, found by Problem 31; the angle GKM, just found; and the angle KGM, because by [proposition] 32 of the first book of Euclid it equals the right angle CKG and the acute angle GCK, already observed, taken together. And so, by the same proposition, the angle M opposite the side GK becomes known, because it is the supplement to two right angles of the sum made of the angles GKM and KGM. Next, we shall add the side KM to the straight line AK, found by the first step, and the whole AM will result; and if we subtract from it the Earth's semidiameter AP, there will remain the absolute height of the mountain, PM, measured along the perpendicular tending to the centre of the Earth. Here, however, the eye C is supposed not to be raised at all above the Earth; for if it were raised, there would have to be added to GK as great a portion as the height of the observing eye is thought to be, so that we may correct the first fallacy.

[Margin: Step 1.]

[Margin: Step 2.]

EXEMPLVM. *Example.*

Thus I showed in the Geographical Book that the hill of Parma, near Forum Naevii, from which Father Biancani was sighting the summit of Monte Baldo, is higher than the ground of Bologna by about 40 paces; and let the ground of Bologna now be set higher than the level of the Adriatic Sea by at least 16 Roman paces. And so that place of Parma will be higher than the already mentioned sea by about 56

[Margin: Example of the correction.]

paces; and these, added to the height GK of 804 paces reckoned by Biancani, make it 860 paces. But since in Magini's *Italia* Monte Baldo is 75 modern miles

distant from the centre of Parma, which make 95 ancient Roman miles, then, if the angle KCG observed by Biancani was 41′, it follows by Problem 31 that the height KG above CK is 1134 Roman paces; and the height of the hill of Parma, added to these, makes KG 1190 paces.

[Margin: Order of the problems.]

[Margin: Order of the problems.]

With these supposed, there is given, first, the side CK, 95 000 Roman paces, and AC, by what was said in Book 2, chapter 7, 5 174 000 Roman paces. Therefore, by [proposition] 5 of right-angled triangles, the angle AKC will come out 88° 57′, and by [proposition] 8 of the same, AK will come out 5 174,879 1/2 paces. The angle GKM comes out 1° 3′; and the sum of the right angle GKC and the observed angle GCK, 41′ — that is, the quantity of the angle KGM — is 90° 41′; and so the angle M is 88° 16′. With these, and with the side GK of 1190 paces, KM is found to be 1190 1/2 paces; and these, added to the paces of AK already found, make 5 176,070 paces. Finally, when AP, 5 174 000 paces, is subtracted from them, there remains the absolute height of Monte Baldo, PM, of 2070 ancient Roman paces, or 1654 of the modern Italian paces of this region of Italy of ours — that is, twice as great as Biancani gathered. So great an error can be committed because of the fallacies already mentioned. But the height comes out greater still if you take the distance between Forum Naevii, where Father Biancani was, and Monte Baldo from Magini's *Italia*, as 85 miles.

[Margin: Biancani's error in measuring Monte Baldo.]

Now Father Cabeo, in Book 1 on Aristotle's *Meteorologica*, text 64, question 1, says that he was present at Biancani's observation, but that PK must be added to the height KG, the secant AK being found first from the given tangent CK and the radius AC. Strictly, however, it is KM that must be added to PK; and at a much greater distance of the eye C from the mountain, KM can come out many paces greater than GK.

[Margin: A small error of Cabeo in the same matter.]

33. Probl. Montis altitudinem abſolutam, ex & Mari aut littore ſpectabilis, inueſtigare, 34. Data Terræ ſemidiametro ſola, aut cum Diſtantia in Milliarib. inter perpendiculum montis & menſorem. *Problems 33 and 34. To find the absolute height of a mountain visible from the sea or the shore, given the semidiameter of the Earth alone, or together with the distance in miles between the perpendicular of the mountain and the surveyor.*

[Margin: Problem 33.]

Let AGB be a terrestrial hemisphere, whose diameter is ACB and whose centre is C; from C let the straight line CGM be raised as far as the summit M of the mountain GM. Let the surveyor be at K, whether he is at sea or on the shore, and let him raise a very long pole, or the mast of a ship, KN, perpendicular to the convexity AGKB, its straightness continued with CK. At its foot let the angle MKN, which the fiducial line KM makes with the pole KN, be observed

with a quadrant; then, from the top N of the pole or of the ship's mast, let the angle MNK be observed with a quadrant. For from the given height of the pole or mast KN, and from the adjacent angles, whose sum taken from 180 degrees shows the angle KMN, the side KM can be known by [proposition] 2 of plane oblique-angled triangles. With it, in the triangle CKM, and with the semidiameter of the Earth CK and the included angle CKM — which is the supplement to two right angles of the observed angle MKN — the base CM is to be found by [proposition] 5 of plane oblique-angled triangles; and if the semidiameter of the Earth CG is subtracted from it, the height of the mountain, GM, will be known.

Diagram. A figure set at the right of the left column. A semicircle stands on the diameter AB, with C at the centre of the base. A hatched mountain rises from G on the arc to its summit M at the upper left; a dotted line runs from M across the top through L to N at the upper right. A line from C rises through G to M, and another from C runs up through K on the arc to N. Lines run from M down to K and across to N; R and P lie on the lines below a small arc near N, which carries O.

- M (upper left): the summit of the mountain
- L (top, between M and N)
- N (upper right): the top of the pole or mast
- O (right, on the small arc near N)
- R (middle, on the line from M)
- P (right of R): with R, the ends of the arc PR
- G (left, on the arc): the foot of the mountain
- K (on the arc, right of centre): the surveyor's station
- A (lower left): end of the diameter
- C (bottom centre): the centre of the Earth
- B (lower right): end of the diameter

But if the distance GK is given in miles, it is to be converted into the degrees and minutes corresponding to it, according to the proportion of the circumference that corresponds to the given semidiameter; and the arc GK will be known, and the angle GCK subtending it. It will suffice, then, to observe the angle MKN by means of the arc PR, so that you have, by [proposition] 13 of the first book of the *Elements*, its supplement to two right angles, that is, the angle CKM; and the sum of this and of the angle C, taken from 180 degrees, will give the angle CMK. Therefore, in the triangle CMK, the angles CMK, opposite the given side CK, and CKM, opposite the side sought, CM, will be given; and so, by [proposition] 2 of plane oblique-angled triangles, CM will be found, and by subtracting from it the Earth's semidiameter CG, the remainder will be the height of the mountain, GM. Or, indeed, in the triangle MGK seek the height GM, since the angle GMK is given, with the side opposite it, GK, and the angle MKG. For when the angle C is taken from two right angles, and the angle MKC is taken from half the remainder, that is, from CKG, MKG remains.

[Margin: Problem 34.]

35. Probl. Montis altitudinem abſolutam metiri Datis Semidiametro Terræ, Montiſque Vmbra in littus aut Mare proiecta, & Momento temporis, quo Mons proijcit tantam Vmbram. Vbi notatu digna de Monte Atho. *Problem 35. To measure the absolute height of a mountain, given the semidiameter of the Earth, the mountain's shadow cast onto the shore or the sea, and the moment of time at which the mountain casts so long a shadow. With points worth noting about Mount Athos.*

[Margin: Problem 35.]

Very famous is the shadow of Mount Athos, which on the day of the solstice it casts as far as the island of Lemnos, commonly called Stalimene, which lies eighty-six thousand paces from it, or 87 000 — that is, onto a bronze heifer set up for the purpose in the forum of the town of Myrene [Myrina], which is on that island, as Solinus reports in chapter 21, Pliny the Elder in Book 4, chapter 12, Plutarch in the book *On the spots in the orb of the Moon*, Statius in Book 5 of the *Thebaid*, from the verse beginning "Lemnos, where fire-bearing…", and Valerius Flaccus in Book 1 of the *Argonautica*, from the verse beginning "At the rising of the Sun…". From this shadow Jacopo Mazzoni, in the *Comparison of Plato and Aristotle*, section 3, chapter 5, and in the *Defence of Dante*, Book 3, chapter 12, elicits a varying and rather inconsistent height for this mountain, and falls into a kind of ageōmetria [Greek: ἀγεομετρίαν [recte: ἀγεωμετρίαν] (ageōmetrian, "want of geometry")], about which I have said more in the Geographical Book. Certainly, from the length of such a shadow alone the height of this or of any mountain cannot be known. But if the moment at which it casts the shadow is known, it certainly can. Look, then, at the figure of Problem 33, in which let GM be the height of the mountain, and let the length of the shadow, GK, be given; according to one's opinion about the circumference of the Earth, let it be converted into the arc GK, which shows the angle GCK. Next, from the given moment of time, and so from the time from noon, and from the declination belonging to the Sun on that day, and from the altitude of the pole at the place where the shadow ends, let the true altitude of the Sun be gathered, by Problem 43 of Section 2. For if the parallax of the Sun is taken from it, and the refraction and the apparent semidiameter of the Sun are added, the visible altitude of the upper limb of the Sun will be given, and its complement to 90 degrees will be the angle MKN — since the line KN tends to the zenith of the place K, where the shadow ends, while the line MK, bounding the shadow, is the ray falling on the upper limb of the Sun, and the arc RP measures the visible distance of that solar limb from the zenith. When, therefore, the angle MKN is known, its supplement to two right angles, CKM, will also be known, in the same triangle in which, as I said, the angle C is known by means of the shadow, and so is the supplement of both to two right angles, namely the angle CMK. The semidiameter of the Earth, CK, is also given; therefore, by [proposition] 2 of plane oblique-angled

triangles, the side CM can be found, and when the semidiameter of the Earth CG is subtracted from it, the height of the mountain, GM, remains, known.

[Margin: The shadow of Mount Athos.]

Would that the ancients had handed down to us the hour at which the shadow of Mount Athos reached that heifer of the town of Myrene! It is certain, however, from the situation of the two places, that this could not have happened at noon, as Mazzoni once suspected; nor near noon, nor at any time before noon, since Myrene lies further east than that mountain, and on very nearly the same parallel; nor yet at the moment of setting itself, almost, when the ends of the shadows fade away and cannot be made out. With these things set down, from the altitude of the pole of Myrene, which is 41° 10′, and from the geographical globe, with the Sun's place at the beginning of Cancer, you will gather that the shadow of Mount Athos could not have fallen on Lemnos except when the Sun was sinking towards its setting, far from noon. We must therefore find this moment of time, since no historians have recorded it for us. This we shall do once we are given the azimuth of the vertical circle passing through the summit of Mount Athos and the town of Myrene, or Myrina; for in the plane of this vertical lies the ray MK, which bounds the shadow cast from M to K. The azimuth we shall find by means of the following Lemma, and afterwards the time, and finally the altitude of the Sun.

[Margin: Order of the problems.]

[Margin: Order of the problems.]

Lemma. Data duorum locorum Altitudine Poli, & Differentia Longitudinis, inuenire Azimuth Verticalis per vtriuſq. verticem ducti, & Poſitionis Angulos. *Lemma. Given the altitude of the pole of two places and the difference of longitude, to find the azimuth of the vertical circle drawn through the zenith of each, and the angles of position.*

I. EXEMPLVM *First Example.*

Pro Angulis poſitionis Montis Atho, & oppidi Myrinæ. *For the angles of position of Mount Athos and of the town of Myrina.*

In the following figure let HMBR be the meridian passing through Myrina, M, and HOR its horizon; let NAP be the meridian passing through Mount Athos, which lies further west, and NOP its horizon; let MAV be the western vertical semicircle, drawn through A and M; let EQ be the equator, KG the tropic of Capricorn, and CF that of Cancer, on which the Sun is at S, near setting, with BS the complement of its declination, 66° 30′; and let B be the north pole of the world. Now, by Ptolemy, Book 3 of the *Geography*, chapter 12, the polar altitude of Mount Athos, PB, is given as 41° 10′, and its complement BA as 48° 50′; the polar altitude of Myrina, RB, as 40° 56′, and its complement BM as 49° 4′; and the difference of longitude, that is, the angle ABM, as 1° 20′. Therefore, in the triangle ABM, given the sides AB and MB and the included

angle, the angle of position BAM is found, by [proposition] 5 of spherical oblique-angled triangles, to be 102° 38′, and BMA 76° 30′.

Diagram. A figure set at the right of the left column: a circle of the sphere crossed by several great-circle arcs — the meridians, their horizons, the vertical, the equator and the two tropics.

- M (top): Myrina
- C (upper left): on the tropic of Cancer
- E (upper left): on the equator
- K (upper left): on the tropic of Capricorn
- A (inside the circle, below M): Mount Athos
- B (upper right): the north pole of the world
- R (right): on the horizon HOR
- P (right): on the meridian NAP
- H (left): on the horizon HOR
- N (left): on the meridian NAP
- S (near the centre): the Sun, near setting
- O (centre): where the horizons meet
- F (lower right): on the tropic of Cancer
- Q (lower right): on the equator
- G (lower right): on the tropic of Capricorn
- V (bottom): the end of the vertical MAV

II. EXEMPLVM. *Second Example.*

Pro Tempore, quo Sol die Solſtitiali tranſit per Verticalem communem Atho & Myrinæ, & pro Altitudine Solis. *For the time at which the Sun, on the day of the solstice, passes through the vertical common to Athos and Myrina, and for the altitude of the Sun.*

In the same figure consider the triangle MBS, with the Sun at S. In this triangle there is given MB, the complement of the altitude of the pole of Myrina, which is 49° 4′; BS, the complement of the Sun's declination on the day of the summer solstice, which is 66° 30′; and the angle of position BMA, of 76° 30′. Therefore, by [proposition] 3 of spherical oblique-angled triangles, the angle MBS will be found to be 82° 2′, which measures the arc of the equator counted from noon; that is, a solar time of 5^{h} 27^{m} 6^{s} from noon, at which the Sun reached the already mentioned vertical common to both places — or 2^{h} 3^{m} before the true setting of the Sun. Then, by [proposition] 2 of the same, the base MS will be found to be 69° 4′; therefore the true altitude, OS, of the centre of the Sun at that time — that is, the complement of the arc MS — is 20° 56′.

III. EXEMPLVM. *Third Example.*

Pro abſoluta Altitudine Montis Atho. *For the absolute height of Mount Athos.*

Let us now return to Problem 35, to solve it, and take up again its figure from Problem 33. First, the angle MKN is 68° 45′. For the true altitude of the centre of the Sun was found at the end of the second example to be 20° 56′; when our parallax of 20″ is subtracted from it, and the refraction of 4′ is added, together with the apparent semidiameter of the Sun, 15′ 25″, the visible altitude of the upper limb of the Sun, which sends out the ray MK, comes out 21° 15″ 5″[57]. Therefore the visible distance of the Sun from the zenith of Myrina is 68° 44′ 55″, or in round figures 68° 45′. The angle CKM, therefore, is 111° 15′. The length of the shadow GK, from the foot of Mount Athos to the shore of the island of Lemnos, is given as 86 000 ancient Roman paces, from Solinus, chapter 21; and to these, on our opinion of the circumference of the Earth, correspond 57′ — that is, the angle MCK — even though from the altitudes of the pole and the difference of longitude set by Ptolemy an arc of distance of 1° 2′ 39″ follows. But since, because the places are so close together, it is easy to slip into error over the difference of longitude, we shall rather follow the shadow.

Hence the sum of the angles C and MKC comes out 112° 12′, and the remainder to two right angles is the angle CMK, 67° 48′. With these, and with the side CK of 5174 Roman miles, according to what was said in Book 2, chapter 7, the side CM is found in the triangle MCK, by [proposition] 2 of plane oblique-angled triangles, to be 5209 miles. When CG, 5174 miles, is subtracted, then, there remains the height of Mount Athos, GM, of 35 Roman miles, or 28 Bologna miles.

[Margin: The huge height of Mount Athos.]

Rightly, then, did Bellonius [Pierre Belon] say in his description of Greece: "Athos, of all things the most memorable, huge, famous, very hard of access, and of such height that the winds do not climb to its summit," and so on. On the winds Pomponius Mela agrees with him; and on its circuit of 150 miles, Pliny the Elder, Book 4, chapter 10, who also places on its summit the town of Acrothon, later Uranopolis, or the city of heaven, as being nearer to heaven than to earth, and Apollonia, whose inhabitants were called Macrobii, that is, long-lived. Finally, "not without reason have they noted among the wonders so long a shadow from so great a height," says Solinus, chapter 21.

36. Probl. Montis Altitudinem veſtigare, Datis ſemidiametro Terræ & Atmoſphæræ refractiuæ; Refractione horizõtali Solis, & Temporis differentia, qua Solis centrum priùs oritur vertici, quàm imo montis, in data Poli altitudine datoq. die. Qua occaſione de admirabili altitudine Montis Caucaſi & Caſij. *Problem 36. To track down the height of a mountain, given the semidiameter of the Earth and of the refractive atmosphere, the horizontal refraction of*

[57]so printed, the 15 with the seconds mark; the sum above gives 21° 15′ 5″

the Sun, and the difference of time by which the centre of the Sun rises for the summit earlier than for the foot of the mountain, at a given altitude of the pole and on a given day. On which occasion, on the wonderful height of Mount Caucasus and of Casius.

[Margin: Problem 36.]

From the centre of the Earth, A, describe in the heaven of the Sun, S, a semicircle BCD of a vertical circle; beneath it let there be the semicircle HKL, and another, EFG, described from the same centre; and let BAD be the vertical line, perpendicular to the horizon AC. On this line, if, as Nonius conceives it, HKL is the semicircle of the Earth, the height of the mountain will be HM, whose summit will be lit by the ray SKM, touching the Earth at K, before the foot of the mountain, H, is lit, afterwards, by the horizontal ray. Now if the ray drawn from the centre of the Sun, which lights the summit of the mountain at the very first moment, were unrefracted, as Nonius supposes, as cited in Section 3, Problem 35, the height of the mountain could be found by the solution of a single triangle, as follows. From A let the straight line AS be drawn to the centre of the Sun, S, and to the point of contact K the straight line AK, making the angle AKS a right angle, by [proposition] 18 of the third book of Euclid. Then, from the given altitude of the pole, the declination of the Sun, and the time before noon at which the Sun shines on the summit of the mountain, let the depression of the Sun below the true horizon, which is the arc CS, be found by Problem 223 of Section 2; and thus the angle CAS will be known. But since in the triangle AKS, besides the right angle AKS, the angle S is given, which is very nearly the horizontal parallax of the Sun — for TK is supposed very small with respect to AT, and, because AS is so great, the rays SK and ST are sensibly parallel — if you subtract the angle S from a right angle, the angle KAS will remain known. Subtracting from it the angle CAS already found, the angle KAC will remain; and this, taken in turn from the right angle MAC, makes the angle MAK known. With it, and with the semidiameter of the Earth, AK, in the right-angled triangle AKM, you will find the base AM by [proposition] 3 of plane right-angled triangles; and when the semidiameter AH is subtracted from it, the height of the mountain, HM, will be known. But

[Margin: First method, for unrefracted rays.]

Diagram. A figure set at the right of the right column. A large semicircle stands on the vertical BD at the left, its horizontal radius running from A to C on the right. Down the vertical, from the top, stand B, M, R, O, H, E, A, G and L, with D at the foot. Small arcs about A pass through H and L and through E and G. Lines run from A out to P and to S at the lower right; a line from S rises through K towards M; a dotted horizontal runs from E through K to V on the right.

- B (top of the vertical)
- M (on the vertical, below B): the summit of the mountain
- R (on the vertical, below M)
- O (on the vertical, below R)
- H (on the vertical, below O): the foot of the mountain

- E (on the vertical, below H): an end of the semicircle EFG
- A (on the vertical): the centre of the Earth
- G (on the vertical, below A): an end of the semicircle EFG
- L (on the vertical, below G): an end of the semicircle HKL
- D (foot of the vertical)
- P (upper middle)
- I (just left of K)
- K (middle): the point of contact of the ray SKM
- T (below K)
- F (below T, near A): on the semicircle EFG
- V (right, end of the dotted horizontal)
- C (right, end of the horizontal AC)
- S (lower right): the centre of the Sun since the ray by which the summit of the mountain first sees the Sun is refracted in the denser air around us, we need another method.

[Margin: Order of the problems.]
[Margin: Order of the problems.]
[Margin: Second method, for refracted rays.]

Let HKL, then, be the surface of the denser air, and EFG that of the Earth, and let the angle MAK be found as in the first method. Next: the ray placed immediately below SK does not touch at K, but cuts and enters the surface of the air HKL at a point as close as possible to K; nor does it go straight on to M, but is refracted towards the perpendicular AK, so that the refracted ray is KR and the angle MKR measures the given refraction. Therefore, if the horizontal refraction of the Sun is subtracted from the right angle AKM, the angle AKR will remain. With this angle, with the angle HAK found above, and with the semidiameter of the atmosphere AK, find the side AR by [proposition] 8 of plane oblique-angled triangles; subtract from it the semidiameter of the Earth, AE, and the remainder will be the height of the mountain, ER. If this is equal to or less than the height of the refractive air — that is, than the excess of the semidiameter of the atmosphere over the semidiameter of the Earth — it will be the correct height of the mountain. But if it is greater, that is a sign that the ray KR, having entered near K, afterwards passed out of the denser air into the rarer and underwent a double refraction: one towards the perpendicular at K, the other away from the perpendicular at I. Therefore, when the perpendicular AIP is drawn, the ray KIR, refracted once, will be refracted again from I to O; the ray refracted the second time will be IO; and because the inclination is sensibly the same, the second refraction, OIR, will be as great as the first, RKM, as can be gathered from what was said in Book 5, chapter 5, number 5.

Now the triangle AIK is isosceles. Therefore, by [proposition] 5 of the first [?] book of Euclid, the angle AIK is as great as AKI, which was known above; and its supplement to two right angles, by [proposition] 13 of the first book of Euclid, is the angle AIR. The supplement to two right angles of this angle and of the angle ARI, taken together, is by [proposition] 32 of Euclid the angle RAI.

When the second refraction, RIO, is subtracted from the angle AIR itself, the angle AIO becomes known, in the triangle AIO, in which there is also known the angle OAI, the same as RAI, and the base AI, that is, the semidiameter of the atmosphere. Therefore, by [proposition] 8 of plane oblique-angled triangles, you will find the side AO; subtract from it the terrestrial semidiameter AE, and the corrected height of the mountain, EO, will be known.

EXEMPLVM. *Example.*

In Monte Caucaſo. *On Mount Caucasus.*

Aristotle, *Meteorologica* Book 1, summa 4, chapter 1, text 63, says this: "The Caucasus is the greatest of the mountains towards the summer rising, both in its extent and in its height. Signs of its height are that it is seen both from the so-called Deeps and by those sailing into the lake. Moreover, its summits are lit by the Sun up to a third part of the night, both from dawn and again from evening."

On these words the height of the Caucasus has been discussed learnedly, above all by Jacopo Mazzoni in the *Comparison of Plato and Aristotle*, section 3, chapter 5, and section 4; by Biancani in his *Loca mathematica Aristotelis* on this text; and by Cabeo on Book 1 of the *Meteorologica*, text 63, question 2. Among other heights of the Caucasus, Mazzoni gathered a height of at least 76 or 78 Italian miles, though Biancani contends that he was mistaken, while Cabeo holds it is not greater than 15.

I, however, suppose, first, that Aristotle is not speaking of a third part of the mountain, as it seemed to the interpreter Alexander. This is both because, since the whole height of the mountain was uncertain, not even a third part of it could have been marked out with certainty; and because he would then have said nothing unusual or wonderful, since there is no mountain whose fourth part, then its third part, and afterwards its half is not lit by the Sun before its lowest part. Second, I suppose that Aristotle is speaking of a third part of the night, considered as much at dawn as in the evening twilight. For in the Greek it stands in the genitive case, which the interpreter wrongly turned into the ablative, reasoning that, because the Greeks lack a sixth case and use the genitive in its place, here too τῆς νυκτὸς [Greek: tēs nyktos, "of the night"] was to be turned into the sixth case. Let it stand, then, that the Caucasus is regularly lit through a third part of the night, both before the rising and after the setting of the Sun proper to the horizon on which the Caucasus stands perpendicularly. These things being laid down:

[Margin: Step 1.]

First: the polar altitude of the Caucasus, from the third map of Asia and from Book 5, chapter 9, of Ptolemy's *Geography*, is between 47° and 48°. The shortest night of the whole year (to take it as small as possible), that is, the

solstitial and summer night, is there of 8^h 13^m. Its third part is 2^h $44½^m$[58]; added to the 7^h and 53½ minutes of the semidiurnal arc, this makes 10^h 38^m before noon, to which corresponds an arc of the equator, or angle at the pole of the world, of 159° 32′. Hence, from the complement of the altitude of the pole, which is 42° 30′, and the complement of the Sun's summer declination, which is 66° 30′, there follows, by Problem 223 of Section 2, the depression of the Sun below the true horizon, that is, the angle CAS: 13° 10′ 30″.

[Margin: Step 2.]

Second: in the triangle AKS, right-angled at K, the angle S is given from Book 3, chapter 8 — that is, the horizontal parallax of the Sun at apogee, 27″. If you subtract this from a right angle, SAK remains, 89° 59′ 33″. Subtracting from it the angle CAS, 13° 10′ 30″, leaves KAC, 76° 49′ 3″; and this, taken from the right angle HAC, leaves MAK, 13° 10′ 57″. Then subtract the horizontal refraction of the Sun, MKR — which Tycho, because of the excessive parallax of the Sun at apogee, 2′ 54″, made 34′, as Kepler notes in the *Rudolphine Tables*, precept 197; but had he used our parallax of 27″, he would have made it 31′ 33″, or at most 32′, as we shall teach in Problem 25 of the last section. Subtracting, I say, the refraction of 31′ 33″ from the right angle MKA leaves the angle RKA, 89° 28′ 27″. In the triangle RKA, in which RAK was found to be 13° 10′ 57″, ARK is therefore 77° 20′ 36″.

[Margin: Step 3.]

Third, then: from the angles already mentioned, and taking the smallest height of the refractive air, TK, which Kepler in the *Astronomiae Pars Optica* sets at 2 Italian miles, and AT, from Book 2, chapter 7, at 4139 miles — so that the whole AK is 4141 miles — I find AR to be 4244 miles.

[Margin: Step 4.]

Fourth: with this, with AI, 4141 miles, and with the angle ARK, 77° 20′ 36″, I find the angle AIR to be 89° 28′ 30″; and so the supplement of these to two right angles, that is, the angle RAI, is 13° 10′ 54″.

[Margin: Step 5.]

Fifth, and finally, I subtract the second refraction of the emerging ray, which is 31′ 33″ — that is, the angle OIR — from the angle AIR, found to be 89° 28′ 30″, and AIO remains, 88° 56′ 56″. In the triangle AIO the angle OAI was also 13° 10′ 54″; therefore AOI comes out 75° 46′ 2″. With these angles, and with AI, 4141 miles, AO is found to be 4174 miles; if you subtract from these AE, 4139 miles, there remains the height of the Caucasus, EO: 35 Italian miles. This is not much greater than the height of Mount Athos. It is great indeed, though a greater height is to be asserted on other grounds, by Problem 30, and finally from what will be said in Problems 50 and 51 of Section 6; and it is not unworthy of Aristotle's assertion, whatever has been said against it on this matter so far by those who have not considered the force of refractions. Now if you increase the height of the refractive air, the height of the Caucasus will

[58] so printed; a third of 8^h 13^m is strictly 2^h $44⅓^m$

come out greater by nearly the same increment: if you make it 10 miles, the Caucasus would be 43 miles high; if 20, the Caucasus would be 53 miles high, and so on.

[Margin: The height of the Caucasus.]

From this the height of Mount Casius in Syria comes out much more tolerable. From its summit the rising Sun is seen in the fourth watch of the night, or at the second cockcrow, as Mela, Book 1, chapter 49, Pliny the Elder, Book 5, chapter 22, Solinus, chapter 37, and Ammianus Marcellinus, Book 22, have consistently affirmed. But we have treated these matters at length in the Geographical book, where I also gave several other methods of investigating, by probable conjecture, the height of mountains from the ascent, or from the fall of the rivers running down from them. I only give this warning: some mountains at sea are not seen, although they are higher than others which are seen, because small mountains stand in the way. For let ABC be the hemisphere of the Earth, G its centre, and the eye at B: seeing the summit K of a mountain, it will nevertheless not see the summit Q of the higher FQ, because the lower mountain MN stands in the way, and so on.

[Margin: The height of Mount Casius.]

[Margin: Higher mountains are nevertheless hidden by lower ones.]

Diagram. A small figure at the right of the right column, beside the passage on hidden mountains. A rectangle stands on the base AC, with a semicircle drawn on AC inside it; lines run from G, at the middle of the base, to the upper corners and to points along the top; a mountain profile runs from M at the top to Q at the upper right and down the right side towards C.

- K (upper left corner)
- B (top, middle): the eye
- M (top, right of B): summit of the lower mountain
- Q (upper right): summit of the higher mountain
- N (inside, below M)
- F (inside, lower right)
- A (lower left corner)
- G (base, middle): the centre of the Earth
- C (lower right corner)

37. Probl. Data altitudine abſoluta Montis aut Turris, & ſemidiametro Terræ, inueſtigare Altitudinem abſolutam alterius Mõtis aut Turris, inde ſpectabilis, & notâ diſtantia ab altero. *Problem 37. Given the absolute height of a mountain or tower and the semidiameter of the Earth, to find the absolute height of another mountain or tower visible from it, its distance from the first being known.*

[Margin: Problem 37.]

In the figure of Problem 33, let the height KN be known and GM unknown; and let the distance GK be known in degrees — or indeed in miles, but converted into degrees — so that from the arc GK the angle MCN is known. Then let

there be observed with a quadrant, sighting the summit M from N, the angle MN

[Margin: Order of the problems.]

C. For thus, in the triangle MCN, two angles will be given, C and N — indeed M as well, as their supplement to two right angles — and also the side CN, made up of the height KN and the semidiameter of the Earth CK. Therefore, by [proposition] 2 of plane oblique-angled triangles, the side CM will become known; subtract from it the semidiameter of the Earth, CG, and the height GM will be known.

38. Probl. Data ſemidiametro Terræ, & Diſtantia inter perpendicula duorum Montium, aut Turrium, quorum vertex ex alterius vertice videri poſſit; inuenire Altitudinem aut vtriuſque, aut minimam illius, qui altero maior ſupponatur. *Problem 38. Given the semidiameter of the Earth and the distance between the perpendiculars of two mountains or towers, the summit of one of which can be seen from the summit of the other, to find the height either of both, or the least height of the one that is supposed greater than the other.*

[Margin: Problem 38.]

Look at the attached figure, in which FMG is the hemisphere of the Earth and C its centre; A is the summit of one mountain — say, the greatest of the Graian Alps — and AL its perpendicular height, which is to be continued to C. Let the height of the other — say, of Haemus — be EH, equal to AL, with the line continued as far as C; and through the summits of both let the straight line AMH be drawn, touching at M the orb of the Earth, or the surface of the sea. Let this line be bisected by the perpendicular CM, which makes right angles at M, by [proposition] 10 of the first book of Euclid. For both the arc LME — known from the given distance, converted into degrees and minutes — and the angle ACH will be bisected (although in this figure the opposite is represented, just as the height of the mountain AL is not equal to EH either). Therefore its half, ACM, will be known, in the triangle ACM, right-angled at M, in which the semidiameter CM is given. Hence, by [proposition] 3 of plane right-angled triangles, the base CA will be known; and when CL is subtracted, AL will be known, which is supposed equal to EH. And this is the true height of the mountains AL and HE, which are supposed equal. It may nevertheless be found in the same way even if AMH does not touch the Earth at M, provided that it is parallel to AMH. Taken either way, however, this height is the least of those that ought to be granted to the greater height EO, of the mountain which is supposed greater than the mountain AL.

Diagram. A figure in the left column, at the right of the opening lines of Problem 38. A semicircle stands on the base FG with its centre C at the middle of the base. Straight lines run from C up to A at the upper left, to M at the top of the arc, and to H at the right; the straight line from A through M to H touches the arc at M. A further line runs from A to O at the upper right, and from O down to H. L and E stand where the lines CA and CH cross the arc.

- O (upper right, above H)
- A (upper left): the summit of one mountain
- L (on the arc, below A): the foot of the mountain AL
- M (top of the arc): the point of contact of AMH
- H (right): the summit of the second mountain
- E (on the arc, below H): the foot of the mountain EH
- F (left end of the base)
- C (middle of the base): the centre of the Earth
- G (right end of the base)

E X E M P L V M. *Example.*

De Alpibus & Hæmo. *On the Alps and Haemus.*

[Margin: The height of Haemus and of the Alps.]

Livy, decade 4, book 10, relates that Philip, King of Macedon, having heard that the Alps of Italy could be seen from Haemus, a mountain of Thrace — as Strabo, Mela and Pliny the Elder have it — climbed it; but, his progress hindered by clouds, he came down again disappointed of his wish. Mount Haemus, moreover, is called by Pinto the Chain of the World, or the Silvered Mountain. Now the Alps that divide Italy from Greece, or from Illyricum, are distant from Mount Haemus by at least 10 degrees of a vertical circle; and so the angle ACM is 5 degrees, and CM is 4139 modern Italian miles, from what was said in Book 2, chapter 7. Therefore LA is 15 such miles. But perhaps they are not the Italian Alps, but the mountains of Illyricum or of Dalmatia, which are seen from Haemus.

39. Probl. Data ſemidiametro Terræ, & Altitudine oculi ſupra conuexum Terræ Mariq. commune eleuati : Inuenire Arcum Terreſtrem ab oculo viſibilem verſùs vnam partem, ſeu Diſtantiam viſùs reſpectù obiecti nihil à conuexo prædicto eleuati. *Problem 39. Given the semidiameter of the Earth and the height of the eye raised above the convex surface common to land and sea, to find the terrestrial arc visible from the eye in one direction, or the distance of sight with respect to an object raised not at all above that convex surface.*

[Margin: Problem 39.]

I treated this problem in Book 2, chapter 10, and in its scholium; indeed, I added a table in which, supposing the terrestrial degrees visible from the eye, I found the height of the eye in ancient Roman miles. Now I wish to construct another small table, in which, assuming the height of the eye in both ancient Roman miles and Bologna Italian miles, I have found the arc already mentioned and placed it in the second column. When this arc is doubled, one has the portion of the terrestrial globe visible all round from such an eye — provided, that is, that the view runs free both in one direction and in the other as far as the horizon, and that the horizon is raised neither by mountains, nor by woods, nor by any other swelling of the land, but ends either in the very surface of the

sea, or in a land surface, but one no farther from the centre of the Earth than the surface of the sea.

[Margin: Order of the problems.]

40. Probl. Data Altitudine obiecti, puta Montis, Turris, aut mali nautici; ac Semidiametro Terræ. Ex quanta diſtantia videri poſſit eius apex ab oculo nihil à terra mariue eleuato : aut Quanta debeat eſſe altitudo obiecti, à tali oculo viſibilis. *Problem 40. Given the height of an object — say, of a mountain, a tower, or a ship's mast — and the semidiameter of the Earth: from how great a distance its top can be seen by an eye raised not at all above land or sea; or how great the height of an object visible from such an eye must be.*

[Margin: Problem 40.]

On this too enough was said in Book 2, chapter 10, and in its scholium 2, to which the preceding tables also contribute.

41. Probl. Data altitudine tam Obiecti quàm oculi ſupra Terram, inuenire maximam Diſtantiam, ex qua videri poterit obiectum : Si detur ſemidiameter Terræ. *Problem 41. Given the height both of the object and of the eye above the Earth, to find the greatest distance from which the object can be seen, if the semidiameter of the Earth is given.*

[Margin: Problem 41.]

For this problem likewise see Book 2, chapter 10, scholium 3.

42. Probl. Data diſtantia Fontis à mari, inuenire Altitudinem Libramenti, ſeu fontis, neceſſarium, vt flumen per eumdem tramitem rectum decurrens, poſſit ad Mare deſcendere. *Problem 42. Given the distance of a spring from the sea, to find the height of fall, or of the spring, needed for a river running down by the same straight course to be able to descend to the sea.*

[Margin: Problem 42.]

See Book 2, chapter 10, scholium 4, with the warning given there, and chapter 4 of the same book, number 9.

43. & 44. Probl. Data diſtantia duorum Locorum, & Altitudinibus Poli, inuenire Differentiam Longitudinis Geographicæ,Angulos Poſitionis, & Azimutha communis Verticalis. *Problems 43 and 44. Given the distance of two places and their altitudes of the pole, to find the difference of geographical longitude, the angles of position, and the azimuths of the common vertical.*

[Margin: Problem 43.]

In the figure immediately following, the poles of the world are A, the southern, and B, the northern. Through them are drawn the semicircles of the meridians, or of declinations, BEA, the western, and BQA, the eastern, intercepting the arc of the equator EQ — that is, the difference of longitude, or distance of the meridians, which either angle, A or B, measures.

[Margin: First case.]

Let there be on these, then, two northern places, C and D, through which let the arc CD of a vertical circle be drawn. For in the triangle CBD the angle B, that is, the difference of longitude, can be found by [proposition] 14 of spherical oblique-angled triangles: for there are given the distances of the zeniths from the pole B — that is, the complements of the polar altitudes, BC and BD — and the base CD, from the distance of the places, which is to be converted from miles into degrees according to the opinion chosen in Book 2, chapter 7. Likewise, if two southern places are given, such as F and G, the complements of the polar altitudes, AF and AG, will be given, and the base from the distance FG; with these, find the angle A.

[Margin: Second case.]

Next let one place be given on the equator, as at E, and the other on this side of it or beyond, as at F; then use the triangle EAF, in which there are given AF, the complement of the altitude of the pole, AE, a quadrant, and the base EF, from the known distance; and so, by the same [proposition] 14, finding [?] the angle A, which measures the difference of longitudes.

[Margin: Third case.]

Finally, let two places be given, one on this side of the equator, at C, the other beyond it, at F; then use the triangle CAF, and find by the same [proposition] 14 the angle A, since there are given the base CF, from the distance converted

into degrees, AF, the complement of the altitude of the pole, and AC, made up of the quadrant AE and of the latitude, or polar altitude, EC.

The angles of position, however — say at C and at D, and so on — you will find by the same [proposition] 14, if you make the base the arc opposite the angle sought; and their supplement to 180° will be the azimuth.

[Margin: Problem 44.]

Diagram. A figure at the right of the right column, beside the cases of Problems 43 and 44. Two semicircles of meridians form a tall lens, meeting at B at the top and at A at the foot. On the left meridian stand, from the top, C, E and G; on the right meridian D, Q and F. Arcs join C to D, E to Q (the equator), and G to F; further arcs run from C down to F and from E to F.

- B (top): the northern pole
- D (right meridian, upper): a northern place
- C (left meridian, upper): a northern place
- E (left meridian, middle): on the equator
- Q (right meridian, middle): on the equator
- F (right meridian, lower): a southern place
- G (left meridian, lower): a southern place
- A (foot): the southern pole

45. & 46. Probl. Data duorum locorum Altitudine Polari, & Differentia Longitudinis, Inuenire Diſtantiam eorumdem & Azimutha communis Verticalis. *Problems 45 and 46. Given the polar altitude of two places and the difference of longitude, to find their distance and the azimuths of the common vertical.*

[Margin: Problem 45.]

In the preceding figure, if the places are C and D, the complements of the polar altitudes, BC and BD, are given, and from the difference of longitude the angle B; therefore, by [proposition] 4 of spherical oblique-angled triangles, the base CD becomes known, to be converted afterwards into miles according to the opinion on the size of the Earth's circumference chosen in Book 2, chapter 7. But if one place is on this side of the equator and the other beyond it, as C and F, you can use the triangle CBF, in which there are given the angle B, that is, the difference of longitude, BC, the complement of the altitude of the pole, and BF, made up of the quadrant BQ and of the latitude, or altitude of the pole, FQ. You can also use the triangle CAF, in which there are given, from the difference of longitude, the angle A, AF, the complement of the altitude of the pole, and AC, the sum of the quadrant AE and of the altitude of the pole, or EC; and in either triangle you can find the distance CF by the same [proposition] 4.

The angles of position, however — that is, those situated at the base CD, or CF — you will find by [proposition] 5 or 6 of spherical oblique-angled triangles; and their supplements to 180° will be the azimuths.

[Margin: Problem 46.]

47. & 48. Probl. Data vnius loci Altitudine Poli & Diſtantia ab altero loco, cum Differentia Longitudinis, Inuenire alterius loci Altitudinem Poli, Poſitionis angulos, & Azimutha verticalis per vtrumque locum ducti. *Problems 47 and 48. Given the altitude of the pole of one place and its distance from another place, together with the difference of longitude, to find the altitude of the pole of the other place, the angles of position, and the azimuths of the vertical drawn through both places.*

[Margin: Problem 47.]

In the preceding diagram, let there be two northern places, C and D; and in the triangle CBD let there be given the altitude of the pole of the place C, and hence its complement BC; the distance CD, converted into degrees; and the angle opposite it, B, that is, the difference of longitude. For by [proposition] 2 of spherical oblique-angled triangles you will find the base BD, which is the complement of the altitude of the pole for the place D; by [proposition] 1 of the same, the angle of position CDB; and by 3, the angle of position DCB. And you will proceed by the same rules if the two places are C and F, or E and F. Further, the supplement of the angle of position to 180° is the azimuth, and sometimes the angle of position itself coincides with the azimuth.

[Margin: Problem 48.]

49. Probl. Meridianam lineam inuenire ope duarum Vmbrarum Rectarum. *Problem 49. To find the meridian line by means of two right shadows.*

[Margin: Problem 49.]

I have already given this problem, with a suitable diagram, in Book 1 of this work, chapter 10, adding two scholia for finding it more exactly. Go back there, then, and remember that the Sun must be so high as to be clear of the sensible refractions, that is, higher than 25°; and take care not to neglect even the least thing in this.

[Margin: Order of the problems.]

[Margin: Order of the problems.]

50. 51. 52. Probl. Meridianam Lineam per vmbras rectas aut aliter inuentam examinare. *Problems 50, 51, 52. To examine a meridian line found by right shadows or otherwise.*

[Margin: Problem 50.]

In Book 1, chapter 10, scholium 3, we indicated three ways of making this correction. The *first* is by equal altitudes of the Sun, one before noon and one after noon, especially on the day of the summer solstice, and by equal azimuths on either side, counting them from the meridian line, which is as yet uncertain. For if, at an equal distance from the meridian — that is, in an equal azimuth on either side — the Sun's afternoon altitude is found exactly equal to its morning altitude, that is evidence that the meridian line is correct. Otherwise it must be corrected: the part of it facing south must be made more easterly if the Sun's

morning altitude is greater, or more westerly if it is less, than the afternoon altitude. How much it must be changed I shall teach in Problem 53.

[Margin: Problem 51.]

Second, you will achieve the same thing more surely on any clear night if, in an equal azimuth on either side, counted from the meridian once it has been found, you observe with an exact quadrant two altitudes of the same fixed star: one before the star's transit through the meridian, the other after the transit. But you must choose a star that is higher than 20 or 25 degrees above the horizon, so that it is not subject to sensible refraction, since the evening refraction is usually less than the morning one and the two do not exactly compensate each other. Nor, however, should the star be near the meridian; otherwise the increase and decrease of its altitude could become imperceptible. Now if the altitudes already mentioned are equal, the meridian line will be exact; but if they are unequal, its part towards the south must be drawn back towards the quarter in which the altitude was greater. How much it must be drawn back I shall say in Problem 53.

[Margin: Problem 52.]

Third, with the help of a pendulum that shows the times of the primum mobile precisely, such as we described in Book 2, chapter 20, let the time be counted from an eastern altitude of a fixed star, taken by another companion (the star appearing far from the horizon and from the meridian, but farther from the horizon), until its transit through the plane of the supposed meridian, indicated by two perpendicular threads or by that thread triangle which we described in Book 5, chapter 15, problem 8. Next let the time be counted from the transit through the supposed meridian until the western altitude of the same star equal to the first, observed by the companion as above. Or at any rate, when the later time has become equal to the earlier, let the star's altitude be taken at once, with the instrument already prepared, so that no delay slips in. For if equal altitudes and at the same time equal times are found, they will be evidence of a perfectly correct meridian.

[Margin: Correction of the meridian line.]

Otherwise the southern part of the meridian line must be bent towards the side in which the greater time was counted — bent, I say, by as many degrees or minutes as correspond on the equator to the half-difference of the times counted. But if you have used equal times, and the altitudes taken at their ends are unequal, you will bend the meridian towards the quarter in which the altitude was greater. How much it must be bent I shall teach in the problem immediately following.

53. Probl. Meridianæ lineæ Fallaciam per duas altitudines Solis aut Stellæ Fixæ in Azimuthis, aut temporibus æqualibus captas, vt ſuprà inuentam Corrigere. Data præter Altitudines & Azimuthum, Declinatione Sideris.

Problem 53. To correct the error of a meridian line found, as above, by two altitudes of

the Sun or of a fixed star taken in equal azimuths or at equal times; given, besides the altitudes and the azimuth, the declination of the heavenly body.

[Margin: Problem 53.]

In the following figure let the supposed meridian be AVQ, the horizon HOR, and the equator AOQ, whose pole is P; let the vertex be V, and VT the quadrant of a vertical circle, in which the centre of the Sun or star stands once at G and once at F, now on this side of the meridian, now beyond it. And through the centres of the body let the quadrants of declination PGM and PFK be drawn from P. Now suppose it is established by Problem 50 or 51 that the meridian line must be corrected, because in equal azimuths the body's true altitude TG was found greater than its altitude TF.

[Margin: Step 1.]

First, in the triangle VGP, find the angle VPG by the first [proposition] of spherical oblique-angled triangles. For in it are given the side GP, which is the complement of the body's declination; the opposite angle GVP, which is the supplement to two right angles of the given azimuth HVT; and the side opposite the angle sought, namely VG, which is the complement of the true altitude. For I suppose that the apparent altitude, if it is the Sun's, has been corrected by adding the parallax, and that the body is clear of the sensible refractions.

Diagram. A circle representing the supposed meridian, with V at the top. A and P stand on the circumference at the upper left and upper right; H and R at the left and right ends of the horizon line, which passes through O; Q on the circumference at the lower right. A line runs from V down through F and G to T near the horizon; lines run from P through F towards K and through G towards M; a line runs from A through O towards Q.

- V (top): the vertex
- A (upper left, on the circle)
- P (upper right, on the circle): the pole
- F, G (inside, on the line VT): the two positions of the body
- K, M (near the horizon line, left of centre): the feet of the quadrants of declination PFK and PGM
- H (left) and R (right): the ends of the horizon HOR
- O (on the horizon line)
- T (on the horizon line): the foot of the vertical quadrant VT
- Q (lower right, on the circle)

[Margin: Step 2.]

Second, in the triangle VFP, find the angle VPF by the same first [proposition], since in it are given FP, the complement of the body's declination; the opposite angle FVP, from the equal and known azimuth, as above; and VF, the complement of the true altitude. Then subtract the smaller angle VPF from the greater VPG, and keep half the difference, or remainder.

[Margin: Step 3.]

Third, taking a centre on the meridian line and describing a circle of large radius in the plane of the horizon, divide the circle so that near the meridian to be corrected you have some degrees on either side, and single minutes of the degrees, by transversal lines, as is done in Tycho's quadrants, or in ours, to be described in volume 2, book 2. And in the arc through which the meridian line passes, take as many degrees or minutes as there are in the half-difference of the angles found in steps 1 and 2; and, at that distance taken from the meridian, mark two points in the arc, one on either side. Now if the altitude of the body was greater towards the east than towards the west, draw a straight line through the eastern point marked and through the centre of the circle; but if the altitude was greater towards the west, draw it through the western point. That line will be the corrected meridian line.

But if you have used Problem 52 with unequal times, convert the half-difference of the time into degrees of the equator, and you will have the half-difference of the angles at the pole P, to be applied as above. For although the angles made at the meridian — one by the circle of declination, the other by the vertical circle drawn through the centre of the same body at the same time — are not equal, yet when one of them is corrected the other is corrected too.

Finally, if you have used Problem 52 but with equal [?] times, and have found unequal altitudes, choose either of the altitudes, say TG, and in the triangle VGP find, by the first [proposition] of spherical oblique-angled triangles, the azimuthal angle GVP; for there are given GP, the complement of the declination; GV, the complement of the altitude; and the angle GPV, from the time counted and converted into degrees of the equator. Then in the triangle VFP, using the other altitude, find the angle FPV as above, and, subtracting the smaller from the greater, apply the half-difference to correcting the meridian line as above.

54. Probl. Meridianam Lineam inuenire, Datis Declinationibus & Aſcenſionibus Rectis duarum Stellarum in eodem Verticali apparentium, vnà cum vnius Altitudine vera. *Problem 54. To find the meridian line, given the declinations and right ascensions of two stars appearing in the same vertical, together with the true altitude of one of them.*

[Margin: Problem 54.]

Although anyone about to observe the declinations and right ascensions of the stars must presuppose a meridian line, yet if someone trusts declinations observed by another astronomer, or indeed his own, but has lost the meridian he once had, he will be able to test the usefulness of this problem. Let there be, then, in the preceding figure two stars, F and G, appearing in exactly the same vertical TV (which can best be observed with the help of our thread triangle, described in Book 5, chapter 15, problem 8); and then let the altitude of one of them, say of the star F, be taken by you or by your companion; and meanwhile let the thread triangle be kept in the same position, or that plane by whose help was determi- [Margin: Order of the problems.]

ned the vertical in which the two stars appeared.

[Margin: Step 1.]

First, then, in the triangle FPG find the angle GFP by [proposition] 5 or 6 of spherical oblique triangles. For there are given the complements of the declinations, FP and GP, and the included angle FPG, since it is the difference of the given right ascensions.

[Margin: Step 2.]

Second, in the triangle VFP there are likewise given the sides FP, the complement of the declination of the star F, and FV, the complement of the true altitude — that is, of the altitude corrected by subtracting the refraction, if the star F was subject to it. The included angle VFP is also given, since it is the supplement to two right angles of the angle GFP already found. Therefore, by [proposition] 5 or 6 of spherical oblique triangles, find the azimuthal angle FVP, whose supplement to 180 degrees will give the angle HVT, that is, the azimuth itself.

[Margin: Step 3.]

Third, draw a straight line through the plane in which the stars already mentioned appeared, and, taking a centre on that line, describe a circle with a radius of two or three feet, such that at least those of its degrees which you judge to be nearer the meridian are subdivided into minutes. For if in this circle you count off from the plane of the vertical the degrees and minutes found in the angle HVT, and draw a straight line through the end of that arc and the centre of the circle, that will be the meridian line. The arc already mentioned, however, must be counted towards the west if the stars were eastern, but towards the east if they were western.

55. Probl. Meridianam Lineam inuenire per Maximam vtrimque Digreſſionem ſtellæ Fixæ ſemper apparentis. *Problem 55. To find the meridian line by the greatest digression, on either side, of a fixed star that is always visible.*

[Margin: Problem 55.]

Tycho strongly recommends this method, as one he used himself. Let some fixed star near the pole be chosen, then, both of whose digressions, to the east and to the west, can be observed on the same night; and let it be observed on either side with the help of an azimuthal quadrant or of our thread triangle (on which see Book 5, chapter 15, problem 8). On either side let straight lines be marked in the planes of the two verticals in which the star reached its greatest digression; for these lines, when produced, will intersect at a point. Taking that point as centre, let an arc be described that is contained between the two lines, and let the arc be divided in half. For if you draw a straight line through the point of this division and through the centre of the arc, that will be the meridian line. Related to this method is another, but far too laborious, which Father Emmanuel Maignan gives on page 137 of his *Perspectiva horaria*.

56. Probl. Meridianam Lineam inuenire duabus eiuſdem ſideris Altitudinibus æqualibus eadem die vel nocte captis. *Problem 56. To find the meridian line by two equal altitudes of the same heavenly body taken on the same day or night.*

[Margin: Problem 56.]

With an azimuthal quadrant set exactly in place, take a rising altitude of some star by night, or of the Sun by day, and draw a straight line through the plane of the vertical in which the body stood. Then, when you are certain from the magnetic needle or some other indication that the star has passed the meridian and is inclining towards the west, follow the same star, taking its altitudes again and again until you reach the one that is equal to the first, rising one; and through the plane of this vertical draw a second straight line until it intersects the first, and do the rest as was said at the end of the preceding problem. You will do better, however, if you use a fixed star, or the Sun indeed but on a solstitial day, clear of the danger of refractions, and determine the planes of the verticals with the help of our thread triangle described in Book 5, chapter 15, problem 8; or if, with the help of a double plumb line at rest, you mark two solar shadows intersecting each other when the Sun has reached an equal altitude on either side.

57. Probl. Meridianam Lineam inuenire, Datis Altitud. Poli ac Stellæ, huiuſq. Declinatione,& ſitu circuli altitudinis ſtellæ. *Problem 57. To find the meridian line, given the altitudes of the pole and of a star, the star's declination, and the position of the star's circle of altitude.*

[Margin: Problem 57.]

In the figure of Problem 53 let the star be F; and by the thread triangle (on which see Book 5, chapter 15, problem 8), or by an azimuthal quadrant, let a plane be determined. When the star has come to that plane, let its altitude be taken, and let a straight line be drawn marking the plane. Then, having taken the altitude TF of the star F, find in the triangle FVP the angle FVP by [proposition] 14 of plane oblique-angled triangles. For FV is given, the complement of the star's altitude; FP, the complement of the declination; and VP, the complement of the altitude of the pole. The supplement to 180 degrees of the angle FVP will be the azimuthal angle HVT; do the rest as in Problem 54, step 3.

58. Probl. Meridianam Lineam deſignare, Data duorum locorum, quorum alter ex altero ſit ſpectabilis, Altitudine Poli, & aut Diſtantia in Milliaribus, aut Differentia Longitudinis. *Problem 58. To lay out the meridian line, given the altitude of the pole of two places, one of which can be seen from the other, and either their distance in miles or their difference of longitude.*

[Margin: Order of the problems.]

[Margin: Problem 58.]

Consider the figure placed below, in which there are two places on the Earth, B and C. Through them let quadrants of declination PBA and PCQ be drawn from P, the pole of the equator AQ, and let those places be joined by the arc BC of a vertical circle. The angle PBC must now be found, if the place where the observer stands is B, or PCB if it is C; and this by [proposition] 5 or 6, or by 14, of spherical oblique triangles. For in the triangle BPC are given the sides PB and PC, since they are the complements of the altitudes of the pole, and either the angle P, which measures the difference of longitude, or the arc BC, which is the distance converted into degrees and minutes.

Diagram. A spherical triangle with the pole P at its apex and the curved base AQ (the equator) below. B stands on the side PA, C on the side PQ. A straight line runs from B through K up to F; the chord BOC and the arc BC join the two places; a small arc runs from G through K to O about the centre B.

- P (apex): the pole of the equator
- A (lower left) and Q (lower right): the ends of the equator AQ
- B (on PA): the observer's place
- C (on PQ): the other place
- F (above K): the end of the meridian line BF
- K (on the arc GKO and the line BF)
- O (on the chord BC and the arc GKO)
- G (left end of the arc GKO)

Now suppose the observer's place is B, and at it let some plane standing perpendicular to the horizon be directed towards C — or a thread triangle (on which see Book 5, chapter 15, problem 8), or the rule of a dioptra — so that the straight line BOC can be drawn, representing the chord of the arc BC. Then, taking B as centre and describing from it the arc GKO, let the arc KO be taken in it, of as many degrees and minutes as were found in the angle PBC. For if you draw the straight line BF through the points B and K, that will be the meridian line.

59. Probl. Meridianam Lineam inuenire per vnicum Vmbræ punctum, Data Poli Altitudine, & Declinatione Solis, ac Altitud. *Problem 59. To find the meridian line by a single point of shadow, given the altitude of the pole and the declination and altitude of the Sun.*

[Margin: Problem 59.]

From the centre A, on a precisely horizontal plane, describe the circle BCI with as large [?] a radius as you have found, from a test made beforehand on the preceding day, to be required for the shadow of the style AB to reach its circumference; and from A erect the style AB perpendicularly.

Diagram. A large circle with V at the top, P at the upper left and Q at the upper right on the circumference; D at the left and R at the right joined by a horizontal diameter through A; K on the circumference at the lower right and E at the lower left. A small inner circle about A carries B above A, C at its upper left, L to the left, I below and M to the right, with a dotted line from C

through A towards I. Lines run from V through S to K, from P to S, from S through G, and from Q through G towards H; curved arcs run from D through H towards E and from E through M towards R; B is joined to S and to C.

- V (top): the vertex
- P (upper left) and Q (upper right), on the circle
- S (upper right, inside): the Sun
- B (above A): the tip of the style AB
- C (upper left of the inner circle): the point of the shadow on the circumference
- G (right, inside)
- D (left) and R (right): the ends of the horizon DHR
- L, A, M, I: on and about the inner circle BCI, A being its centre
- K (lower right, on the circle): the foot of the vertical circle VK
- H (lower, inside): on the horizon DHR
- E (lower left)

Then, when about two or three hours before or after the moment of noon — known in any way whatever — the Sun S, raised above the horizon DHR by the arc KS of the vertical circle VK, has cast the ray SBC through the tip B of the style to C, and the shadow AC has reached the circumference of the circle already mentioned, mark the point C on it; and at the same moment let a companion be present to take the exact altitude of the Sun. But if it does not reach the circumference, but falls inside or

[Margin: Order of the problems.]

[Margin: Order of the problems.]

outside it — the tip of the shadow, that is — you can nevertheless, once the end of the shadow has been marked, mark on the circumference itself, by means of a thread stretched from the centre A of the style through that end, the point C, which lies in the same straight line with the tip of the shadow and with the centre of the style. Indeed, with the style removed, you can mark with the help of the thread the point I, diametrically opposite the point C, although this is not at all necessary.

With these points marked, let the meridian DVRE be understood as described from A, as from the centre of the Earth, with V as its vertex, and P the pole of the equator EHQ; and from P let the quadrant of declination PSG be drawn through the centre of the Sun S. For in the triangle PSV the three sides will be given: PS, the complement of the Sun's declination; VS, the complement of the altitude taken, but corrected by adding the parallax and subtracting the solar refraction; and PV, the complement of the altitude of the pole. Therefore, by [proposition] 14 of spherical oblique-angled triangles, the azimuthal angle SVP will become known to you. It measures on the horizon the arc DHK, whose supplement to a semicircle is the arc KR, similar to the arc CL or IM, taken on the circumference of the circle BCI beginning from the point marked by the shadow. For if you draw the straight line LM through the end L or M of the arc already mentioned and through the centre of the style, that will be the

meridian line, coinciding with the horizontal meridian DAR. But it must be possible to take the arc already mentioned accurately from the circle already mentioned, or from another one subdivided into single minutes; and for the day on which the operation is to be done you must have the Sun's declination known, not only for the noon of that day but also for the hour before or after noon, known approximately — especially if the day is very distant from both solstices.

Another method, by means of the almucantar circle [circuli Almuncatarath] — certainly ingenious, but mechanical, and not attaining trigonometric precision, though very sure for gnomonic operations — is taught by Father Emmanuel Maignan in his *Perspectiva horaria*, page 128. But for astronomical operations, and indeed for nautical ones, the more suitable method is the one I gave above, taken from Athanasius Kircher's *Magnes*, page 500, but developed and perfected. For a plane, moreover, that is either perpendicular to the horizon or inclined, the same Father Maignan suggests certain mechanical methods on pages 131 and 133.

Problema. 60. 61. 62. 63. 64. Meridianam Lineam inuenire alijs 5. Modis, licèt non omnibus ita exactis. *Problems 60, 61, 62, 63, 64. To find the meridian line by 5 other methods, though not all of them so exact.*

[Margin: Problem 60.]

First, it can be done by the shadow of a gnomon together with an astrolabe or analemma, as our Clavius teaches in Book 1 of the *Gnomonice*, proposition 23, in the scholia; since this is readily available, there is no reason for us to copy it out here. Or it can be done by the method that Father Emmanuel Maignan gives on page 134 of the *Perspectiva horaria*.

[Margin: Problem 61.]

Second, by the shadow of a gnomon or of a style erected perpendicularly on the plane of the horizon, observed on the days of the equinox. For if at different hours two or more points marked by the tip of the shadow are noted, and a straight line is drawn through them, it will mark out the equator or a parallel of the equator. Therefore, if another line is drawn to it at right angles, that will be the meridian line, as Father Emmanuel Maignan demonstrated in his *Perspectiva horaria*, page 136. Nor do refractions stand in the way, if the observed points are noted when the Sun is very high.

[Margin: Problem 62.]

Third, the decrease of the right or versed shadow can be observed in the morning until the shadow becomes least. For if you draw [?] a straight line through the end of the least shadow and its beginning, that is, the centre of the style, that will be the meridian — found, however, rather crudely, because for some time near noon the decrease or increase of the shadow is not discerned. Or [it can be done] if the points of the rising and setting of the Sun on the same day are observed by two planes, or by straight lines intersecting each other on

the horizontal plane, and the arc described from the point of intersection and intercepted between them is divided in half.

[Margin: Problem 63.]

Fourth, it can be done with the help of the magnetic needle, but only loosely [eminus], because in many places these needles decline from the true position of the meridian, and much more so if iron objects are not far off, or stones approaching the nature of the magnet, which draw the needle towards themselves. If, however, you had once obtained a meridian line, and with its help the magnetic declination, you could afterwards recover the meridian if it were lost, taking account of the declination at least in the nearest years; for there are some who think that the declination in the same place varies after many years.

[Margin: Problem 64.]

Finally, when trees are cut on a plane parallel to the horizon, veins of the tree are seen on the surface of the trunk, arranged as if in a circle, in such a way that towards one pole of the world the intervals between their circumferences are widest, and towards the other narrowest. Therefore a straight line drawn through the narrowest and the widest position of them will indicate the meridian, after a fashion.

65. & 66. Probl. Meridiana Linea inuenta, quotuis alias in plano Horizontis aut Verticalis parietis deſignare. *Problems 65 and 66. Once a meridian line has been found, to lay out as many others as you like on the plane of the horizon or of a vertical wall.*

[Margin: Problem 65.]

First, if you want to lay out another meridian line on the plane of the horizon, but near the first, draw a straight line parallel to the first by [proposition] 31 of Book 1 of Euclid. But if you want one far off, erect on the horizontal plane a gnomon as exactly perpendicular to the horizon as possible; and when a companion gives the signal that the shadow is now falling on the first line, you will mark the end of the shadow of your gnomon, and through that point and the centre on which the side of the gnomon stands perpendicularly you will draw a straight line; for that will be the meridian line. And the same is done if the point of noon is indicated by some sundial.

[Margin: Problem 66.]

Second, if you want a meridian line on the plane of a wall perpendicular to the horizon, fix a style in it; and when the moment of noon arrives, as indicated by another meridian line already shaded by its own style, or by a sundial, mark on the wall the point that ends the shadow of the style. For if you draw through that point a straight line perpendicular to the horizon, that will be the meridian with respect to the style already mentioned.

Probl. 67. 68. 69. 70. Altitudinem Poli per Altitudines Meridianas Solis aut Fixæ alicuius inquirere modis 4.abſq. Trigonometria. *Problems 67,*

68, 69, 70. To find the altitude of the pole by the meridian altitudes of the Sun or of some fixed star, in 4 ways, without trigonometry.

It must be noted that every altitude of the Sun observed with a quadrant, an astronomical square, a sextant, a ring or an astrolabe must be corrected by adding the parallax due to that altitude and subtracting the refraction, if there is any, so that the apparent altitude may be converted into the true one. This being laid down:

[Margin: Problem 67.]

First, let the meridian altitude of the Sun's centre be observed on the two solstitial days of the same year, or on two that follow each other most closely; and, both being corrected, let the smaller be subtracted from the greater, and half the difference added to the smaller of the meridian altitudes. This gives the altitude of the equator; if you subtract it from 90 degrees, the altitude of the pole will remain — the more correct, the nearer to noon the moment of the solstice fell, which you will learn from the ephemerides.

[Margin: Problem 68.]

Second, if the obliquity of the ecliptic, that is, the Sun's greatest declination, is known and certain from elsewhere, it is enough to observe the meridian altitude of the Sun's centre at either solstice, but chiefly at the summer one, and to correct it as above. For the obliquity of the ecliptic, added to the Sun's true winter altitude or subtracted from its summer one, will give the altitude of the equator; and this, subtracted from 90 degrees, will give the altitude of the pole.

[Margin: Problem 69.]

Third, if it is the day of an equinox, the altitude of the Sun's centre, observed and corrected as above, will give the altitude of the equator, provided the equinox falls at noon (on which consult the ephemerides or astronomical tables). Otherwise, for as many hours before or after noon as it falls, you must add as many minutes to the Sun's altitude already corrected, or subtract them: add them, that is, if the vernal equinox falls after noon or the autumnal before noon; but subtract them if the vernal falls before, or the autumnal after, noon. Then subtract this altitude, thus corrected again, from 90 degrees, and the altitude of the pole will remain.

[Margin: Problem 70.]

Fourth, on any day, having observed and corrected the meridian altitude of the centre of the Sun or of a fixed star, find from an ephemeris or by tables the Sun's place at that noon, and with it, in the tables indicated in section 2, problem 15, find the Sun's declination; and this (as also the declination [?] of the fixed star, already known), if it is southern, add; if northern, subtract from the true

[Margin: Order of the problems.]

[Margin: Order of the problems.]

altitude of the Sun or of the fixed star, and the result will be the altitude of the equator, which is to be subtracted from 90 degrees so that the altitude of the pole remains.

Probl. 71. 72. 73. 74. Altitudinem Poli ex Altitudine Meridiana Stellæ Circumpolaris deducere modis 4. abſq. Trigonometria. *Problems 71, 72, 73, 74. To derive the altitude of the pole from the meridian altitude of a circumpolar star, in 4 ways, without trigonometry.*

[Margin: Problem 71.]

The *first* and most excellent way is to observe the greatest and the least meridian altitude of the same fixed star — one that turns about the pole in such a way that it never sets, and that at its least altitude is so far removed from the horizon as to be beyond the hazard of sensible refractions; or at any rate the refraction must be known, so that it may be subtracted from that altitude. Then subtract the least of the altitudes from the greatest, divide the resulting difference in half, and add half of it to the least of the altitudes: this gives the altitude of the pole. It is not necessary that both altitudes be taken on the same night, but it is expedient that they be taken within the same year. You have a diagram of this practice and some examples in Book 1, chapter 12, and in Book 6, chapter 4, in the Appendix.

[Margin: Problem 72.]

Secondly, if the declination of some fixed star is certain, it is enough to observe its greatest meridian altitude above the pole, or its least below it. For if the star is between the vertex and the equator, its declination — added to the greatest altitude if it lies towards the hidden pole, or subtracted if towards the visible pole — will give the altitude of the equator; and this, subtracted from 90 degrees, will leave the altitude of the pole. But if the star is between the visible pole and the vertex, the complement of the declination to a quadrant, subtracted from the greatest altitude, will leave the altitude of the pole. And if it is the least of the meridian altitudes, the complement of the declination to a quadrant, added to the altitude, will produce the altitude of the pole.

[Margin: Problem 73.]

Thirdly, if one knows the approach by which the Pole Star each year approaches the pole of the world, or recedes from it, and its distance from the pole of the world at some past moment of years gone by, it is enough to observe its meridian altitude, either the greatest or the least. For if you subtract its distance from the pole from the greatest altitude, or add it to the least — that distance being first corrected as the annual approach or recession requires — you will have the altitude of the pole. For an example of this, see Book 6, chapter 4, in the Appendix.

[Margin: Problem 74.]

The *fourth* way, though not so exact, and serving only this present century, is to take the altitude of the Pole Star at the moment when the Fidicula of Lyra, or the bright star in the mouth of Canis Major, crosses the meridian; for at that time [?] the altitude of the pole is as great as that of the Pole Star.

Probl. 75. 76. 77. 78. Data Proportione Vmbræ ſeu Rectæ ſeu Verſæ ad Gnomonem, inquirere Altitudinem Veram Solis: & viciſſim Data

vera altit Solis, Vmbræ rationem ad Gnomonem: & Triplicem Tabulam Gnomonicam conſtruere, Erroreſq. multorum in hoc Geometrarum Corrigere. *Problems 75, 76, 77, 78. Given the proportion of the shadow, whether right or versed, to the gnomon, to find the true altitude of the Sun; and conversely, given the true altitude of the Sun, [to find] the ratio of the shadow to the gnomon; and to construct a threefold gnomonic table, and to correct the errors of many geometers in this matter.*

The first table is for the right shadow [Vmbra Recta]. For it, look at the following figure. In it let the horizontal line be AB, and erected perpendicularly on it the style, or gnomon, AC, through whose tip C there passes, from the upper limb D of the Sun S, the ray DCE, which ends the shadow AE. This is called the right shadow because the gnomon is upright [rectus] to the horizon. The gnomon AC must be of known size, say one or two feet; or, if it is too tall for the end of its shadow to be distinguished, a globe must be fixed on top of the tip C of the gnomon. For it was for this purpose that Manilius the mathematician placed a gilded ball on the obelisk that stood in the Campus Martius at Rome, to gather the shadow, as Pliny the Elder relates (Book 36, chapter 10). Furthermore, the gnomon AC, or a ruler or straight line equal to the gnomon, must be divided into equal parts as small as possible, say 12, or 60, or 100, or 1000, etc. — and indeed the shorter the gnomon, the smaller the parts — so that with the help of very sharp compasses the length of the shadow AE can be determined in parts of the kind into which the gnomon is divided, that is, the proportion of the shadow to the gnomon. Similarly, if a gnomon HF is fixed at right angles into a wall FG upright to the horizon, and the ray MHV from the Sun's lower limb M passes through its tip H, FV will be the versed shadow [Vmbra verſa]. So that it can be known, the gnomon HF must be divided into equal parts, 12, or 60, or 100, or 1000, etc.

Diagram. Set at the right of the narrow lines in the left column. At the upper left a small circle with S at its centre, D on its rim at the upper right and M on its rim at the left. Two straight lines run down to the right from the circle to a horizontal base line: the base line ends at A [?] at the left and B at the right. A vertical line rises from A [?] to C. A short horizontal segment runs from H to F, with a vertical line from F down towards the base. A quarter-arc curves down through the lower part of the figure to the base line. V stands on one of the descending lines at the right of the vertical through F; E and G stand together on the base line, to the right of A [?].

- S (centre of the circle): the Sun
- D (upper right on the circle): the Sun's upper limb
- M (left on the circle): the Sun's lower limb
- C (on the vertical from the base): the tip of the gnomon AC
- H (upper left of the short horizontal segment): the tip of the gnomon HF
- F (right end of the short horizontal segment)
- V (lower right, on a descending line)
- A [?] (left end of the base line): the foot of the gnomon

- E, G (on the base line, right of A [?])
- B (right end of the base line)

[Margin: Problem 75.]

On these assumptions: if the right shadow AE is given in terms of parts of which the gnomon AC is known, then in the triangle CAE, right-angled at A, two sides about the right angle are given. Therefore, by [proposition] 5 of right-angled plane triangles, one can find both the angle AEC, which measures the altitude of the Sun's upper limb, and the angle ACE, which measures the distance of the same limb from the vertex. These are the true ones if the foot A of the gnomon, or its tip C, were at the centre of the Earth and AB were the rational horizon; but the seen or apparent ones if, as commonly happens, A or C is on the surface of the Earth and AB is the sensible horizon. In that case the parallax must be added to the altitude already mentioned and the Sun's refraction subtracted; conversely, the refraction must be added to the distance from the vertex and the parallax subtracted, so that the one becomes the corrected or true altitude, the other the true distance of the limb D from the vertex. Finally, from the altitude of the limb thus corrected the Sun's apparent semidiameter must be subtracted, and to the distance from the vertex it must be added, so that the true altitude of the Sun's centre, or its true distance from the vertex, may be had.

[Margin: Problem 76.]

But if the versed shadow FV is given, known in parts of which the gnomon HF is known, the sides about the right angle F are likewise given. Therefore, by the same [proposition] 5 of right-angled plane triangles, one can find both the angle FHV, which measures the altitude of the Sun's lower limb M, and the angle FVH, which measures the distance of the same limb from the vertex: the true ones if F is at the centre of the Earth and HF is the rational horizon, but the seen ones if F is on the surface of the Earth. In that case each must be corrected in the way stated in Problem 75. But to the corrected altitude the Sun's apparent semidiameter must be added, and from the distance from the vertex it must be subtracted, so that the true altitude of the Sun's centre, or its distance from the vertex, may be had. And so the 2nd table is constructed.

[Margin: Construction of table 2.]

[Margin: Problem 77.]

Conversely, if the true altitude of the Sun is given, and A is supposed to be at the centre of the Earth, the Sun's apparent semidiameter will have to be added to it, and the angle AEC will become known. With it and with the gnomon, that is, the opposite side AC, you will find the right shadow AE by [proposition] 7 of right-angled plane triangles. But if the Sun's true distance from the vertex is given, and you subtract from it the Sun's apparent semidiameter, you will have the angle ACE; with it and with the adjacent side AC you will find the right shadow AE by [proposition] 4 of the same triangles. But if A is on the surface of the Earth, everything must be done as above, except that the parallax must first be added to the altitude and the refraction subtracted, while from

the distance from the vertex the parallax must be subtracted and the refraction added. In this way, by Problem 75 or 77, a gnomonic table can be constructed in which the Sun's altitude can be found at once from the right shadow, and the proportion of the right shadow to the gnomon from the Sun's altitude.

[Margin: Construction of table 1.]

[Margin: Problem 78.]

For the versed shadow, on the other hand, subtract the Sun's apparent semidiameter from the given altitude of the Sun, and you will have the angle FHV; with it and with the gnomon FH, find the versed shadow FV by [proposition] 4 of right-angled plane triangles. But if the Sun's distance from the vertex is given, add to it the Sun's apparent semidiameter, and you will have the angle FVH; with it and with the opposite gnomon HF, find the versed shadow FV by [proposition] 7 of the same triangles. But if A or F is on the surface of the Earth, the altitude must first be corrected by adding the parallax to it and subtracting the refraction; and the distance from the vertex by subtracting the parallax from it and adding the solar refraction. And so, by Problem 76 or 78, a gnomonic table can be constructed that shows the versed shadow from a given altitude of the Sun, or the altitude of the Sun from a given versed shadow.

[Margin: Construction of table 2.]

[Margin: Order of the problems.]

[Margin: Order of the problems.]

[Margin: Table 3.]

Third, and last, a table is constructed for the three more notable shadows, namely the winter [Brumali], the equinoctial and the solstitial or summer shadow, and these at noon: either by deriving from such a shadow the Sun's meridian altitude at the equinoxes and at each solstice, or by deriving the shadow from this altitude. For these, let the following diagram serve as well. In it let the rational or astronomical horizon be HQR, and in it let the centre of the Earth be Q; but let the sensible or physical horizon be FGN, on which the gnomon GD is erected perpendicularly; and from the centre of the Earth Q let the semicircle of the meridian HZR be described.

Diagram. Set across the left column. A semicircle of the meridian stands on a lower straight line HQR, with a second straight line FGN drawn parallel to it a little above. From the point D, at the tip of a short dark upright gnomon standing on FGN at G, lines fan out up to the right to the arc, where small circles mark the Sun at three places; further lines run from those places through D down to the left, to points on FGN. A vertical line runs from Z at the top of the arc down through D to the gnomon; dotted lines run from Q under the gnomon up to the right towards the arc.

- Z (top of the arc)
- C, ♋ (top of the arc, right of Z): the Sun's upper edge at the beginning of Cancer, with the sign of Cancer
- I (in a small circle on the arc): the Sun's centre at the beginning of Cancer

- L (on the arc, further right), followed by two small sorts [?] [?]: the limb L at the equinox
- M (on the arc, right): the Sun's limb M
- ♑ (right of the arc, below M): the sign of Capricorn
- O (in a small circle on the arc, lower right): the Sun's centre at the beginning of Capricorn
- P (on the arc, left)
- D (centre): the tip of the gnomon
- F (left end of the line FGN), N (right end)
- B, b, A, a, S, f, G (along FGN, left to right): the ends of the shadows and the foot G of the gnomon
- H (left end of the lower line), Q (beneath the gnomon): the centre of the Earth, R (right end)

[Margin: Description of the solstitial and equinoctial shadow.]

Now when the Sun's centre is at O, the beginning of Capricorn, the ray of the limb M passing through the tip D will be MDb, ending the right winter shadow Gb. The angle DbG will measure the visible altitude NM of the limb M, which is certainly greater than that given by the angle DBG, measuring NO, the visible altitude of the centre O — an altitude less than the one measured by the angle OQR, measuring RO, the true altitude of the centre O. But when the Sun's centre is at ♈ or ♎, either of the equinoctial points — that is, at the beginning of Aries or of Libra — the ray LDa will end the equinoctial shadow Ga, and the angle DaG will measure the visible altitude NL of the limb L, greater than the visible altitude N♈ of the Sun's centre, measured by the angle DAG; and this is less than the true altitude R♈, measured by the angle ♈QR. Finally, when the Sun's centre is raised to I, the beginning of Cancer, the upper edge C will send its ray through D to f, ending the solstitial shadow Gf; and the angle DfG will be the measure of the visible altitude NC, which will be, or will appear, greater than the visible altitude NI, measured by the angle DSG; but this is less than the true altitude RI, measured by the angle IQR.

De Auctoribus Tabularum Gnomonicarum. *On the authors of gnomonic tables.*

The construction of the gnomonic table, the 3rd in particular, was taught by Ptolemy in Book 2 of the *Almagest*, chapters 5 and 6, and by Georgius Purbachius [Georg von Peuerbach], and after him by Daniel Santbech. In that table the gnomon is supposed to be of 1200 parts; at its head are the hundreds of parts, in the left margin the parts of the right shadow from 1 up to 100, and in the following columns the degrees, minutes and seconds of the Sun's distance from the vertex. Orontius Fineus, on the other hand, in Book 4 of his *Cosmographia*, chapter 4, presents a gnomonic table in which he takes the gnomon as 12 parts; in its left margin [?] stand the single degrees of the whole quadrant, and in the other columns the parts of the right shadow, of which the gnomon is 12.

Erasmus Reinhold, however, in his *Tables of Directions*, having taught in precepts 46 and 47 how to find the shadow from the Sun's altitude and the Sun's altitude from the shadow, afterwards, from page 17 of the tables, gives the fecund table [Canonem fœcundum], in which the radius, or whole sine, is supposed to be of at least 10 000 000 parts. At its head and foot are placed the degrees up to 45; in the right and left margins the minutes — or rather, towards the beginning and the end of the quadrant, single decades of minutes — of the Sun's distance from the vertex; and in the body of the columns are placed the tangents of any arc or angle, which serve for the quantity of the right shadow and for its proportion to a gnomon of 10 000 000 parts. For in the earlier figure, set out before Problem 75, if, with the centre placed at C and the radius AC taken as the semidiameter or whole sine, you describe the quadrant AV, the shadow AE will turn out to be the first tangent of the angle ACE, but the second tangent of the angle AEC, which is its complement to a quadrant. Then at the end of that book, on page 235, he gives a table of the threefold meridian shadow — namely the solstitial, the equinoctial and the winter shadow — for single degrees of the latitude, or altitude of the pole; and indeed a double one: the earlier, in which the gnomon is taken as 10 000 000 parts, the later, in which the gnomon is of 60 parts.

Afterwards Giuseppe Moletti, in Book 1 of Ptolemy's *Geography*, set out a double small table: one that gives, for the single degrees of the Sun's altitude, the quantity of the right shadow in parts of which the gnomon is 60; the other, in which the gnomon is taken as 100 000 parts. This is a fecund table showing the right shadow in the body of the columns, but only for whole degrees of altitude. Again, Maginus, in Book 5 of *De dimetiendi ratione*, page 118, gives a gnomonic table in which the gnomon is taken as 1000 parts; at its head are the hundreds of parts of the shadow, in the left margin the single parts from 1 to 100, and in the body of the following columns the degrees, minutes and seconds of the Sun's distance from the vertex. Finally our Clavius, in Book 5 of the *Gnomonice*, proposition 2, and on page 475, sets out a table he constructed himself, in which the gnomon is taken as 12 parts. At its head are placed the whole degrees of the Sun's altitude, in the left margin the single minutes of the degrees, and in the remaining columns the right shadow in whole parts and in sexagesimal minutes. At the foot of the table, however, are the degrees of the Sun's altitude, and in the right margin the minutes of the degrees, but the shadow shown in the body is the versed shadow. For as great as the right shadow of a given altitude is, so great is the versed shadow of the complement of the given altitude to a quadrant; or, as great as the right shadow of one altitude of the Sun is, so great is the versed shadow of that altitude which is the complement of the former altitude to a quadrant — as Clavius demonstrates there, and Orontius above.

De Errore aut Incuria prædictorum Auctorum. *On the error or carelessness of the authors already mentioned.*

Moreover, all the authors already mentioned supposed the tip of the gnomon to be at the centre of the Earth, neglecting parallax and refraction; and they used the ray of the Sun issuing from the Sun's centre, as if the right or versed shadow were bounded by this ray, neglecting the difference that can arise from the Sun's apparent semidiameter when the Sun's altitude is to be derived from the shadow, or the shadow from the Sun's altitude. Granted that this threefold error — of parallax, of refraction and of the solar semidiameter — may be disregarded in the construction of dials and in certain other geographical operations, and is no proof of error or ignorance in such great men, I still cannot approve their carelessness. For they gave occasion of erring not only to others but even to themselves — as I shall show below of Ptolemy, Maginus and others — in astronomical operations, and especially in investigating by tables of this kind the altitude of the pole, the obliquity of the ecliptic, or the days or hours of the equinoxes and solstices. This error can sometimes grow, in the altitude of the pole, beyond 45 minutes; at the time of the equinoxes, to almost two whole days; and at the moments of the solstices, to an error of still more days.

79. 80. 81. Probl. Data Vmbra Meridiana Solari ſiue Solſtitiali, ſiue Aequinoctiali, ſiue quacumque, ideſt vmbræ ratione ad Gnomonem, inuenire Altitudinem Poli. Vbi de Errore in hoc non ſolùm Priſcorum ſed etiam recentium Coſmographorum. *Problems 79, 80, 81. Given the Sun's meridian shadow — solstitial, or equinoctial, or any other whatever, that is, the ratio of the shadow to the gnomon — to find the altitude of the pole. Where [we treat] of the error in this of not only the ancient but also the recent cosmographers.*

[Margin: Problem 79.]

First, let the ratio of the solstitial shadow, either summer or winter, to the gnomon be given; and with it, by Problem 75 or 76, find the true altitude of the Sun's centre. From it subtract the Sun's greatest declination if the shadow is a summer one, or add it if a winter one; and subtract the sum or remainder from 90 degrees, for the altitude of the pole will remain.

[Margin: Order of the problems.]

[Margin: Order of the problems.]

[Margin: Problem 80.]

Secondly, let the equinoctial shadow be given; and with it, by Problem 75 or 76, find the true altitude of the Sun and subtract it from 90 degrees, for what remains is the altitude of the pole.

[Margin: Problem 81.]

Thirdly, let any meridian shadow whatever be given; and with it, by Problem 75 or 76, find the true altitude of the Sun. Then, with the Sun's place in the ecliptic, find in the table indicated in section 2, problem 15, the Sun's declination; if it is southern, let it be added to the Sun's altitude, if northern, subtracted from it. For what comes out of this, subtracted from 90 degrees, gives the altitude of the pole. But the precept must be illustrated by examples, and the errors of some cosmographers called out of the shadow into the light.

I. EXEMPLVM. Pro Altitudine Poli Alexandriæ ex Vmbra Æquinoctiali.
Example 1. For the altitude of the pole at Alexandria from the equinoctial shadow.

[Margin: Look at the figure before Problem 75.]

Vitruvius affirms (Book 9, chapter 8) that at Alexandria in Egypt the equinoctial shadow was observed to stand to the gnomon as 3 to 5. Therefore if, by [proposition] 5 of right-angled plane triangles, one makes: as 3 is to the whole sine of 100 000 parts, so is 5 to another, the result will be 166,666⅔, namely the tangent of the angle AED, that is, of 59° 2′ 10″, which measures the visible altitude of the Sun's upper limb. But we need the true altitude, and that of the Sun's centre. We shall therefore add our parallax of 6″ — for no sensible refraction intervenes — and subtract the Sun's apparent semidiameter of 16′, and there will remain the true altitude of the Sun's centre, 58° 46′ 16″: that is, the altitude of the equator, if at the moment when such a shadow was observed there was a true equinox. And when these are taken from 90 degrees, there remains the altitude of the pole at Alexandria, 31° 13′ 44″.

[Margin: Error of Gemma Frisius and of Ptolemy.]

Gemma Frisius, however, in chapter 21 of the *Radius Astronomicus*, and Snel, in Book 1 of the *Eratosthenes Batavus*, chapter 8, from the analysis of the triangle already mentioned and the ratio of the shadow to the gnomon as 3 to 5, rightly enough gather the angle AED as 59° 2′; but they wrongly conclude from it that this is the true altitude of the equator, and that the altitude of the pole at Alexandria follows from it as 30° 58′ — so as not, that is, to depart from Ptolemy, who in Book 5 of the *Almagest*, chapter 13, and in Book 4 of the *Geography*, chapter 13, puts the same altitude of the pole, 30° 58′. From this we gather that he fell into the same error, especially since in Book 2 of the *Almagest*, chapters 3 and 5, he teaches no other way of gathering the altitude of the pole than either by the longest day or by the equinoctial or solstitial meridian shadow, with no mention made of the Sun's apparent semidiameter, none of parallax or of refraction.

II. EXEMPLVM. Pro Altitudine Poli Romæ ex Vmbra Æquinoctiali.
Example 2. For the altitude of the pole at Rome from the equinoctial shadow.

[Margin: See the figure before Problem 75.]

The same Vitruvius (Book 9, chapter 8) and Pliny the Elder (Book 2, chapter 72) report that the equinoctial shadow at Rome at noon was observed to stand to the gnomon as 8 to 9. Therefore if, by [proposition] 5 of right-angled plane triangles, one makes: as the shadow AE, which is 8, is to the whole sine of 100,000 parts, so is the gnomon AC, which is 9, to another, the result will be 112 500, namely the tangent of the angle AEC, of 48° 22′, which measures the visible altitude of the Sun's upper limb. But if you add our parallax of 10″ and subtract the refraction of 1′ 57″ and the Sun's apparent semidiameter of 16′, the true altitude of the Sun's centre will be 48° 4′ 13″; and when these are taken from a quadrant, there remains the altitude of the pole at Rome, 41° 55′ 47″, or

41° 56′, which is the amount Clavius puts in his table. But it is not certain that such a shadow was observed at the very moment of the equinox.

[Margin: Maginus's slip.]

Maginus, for his part, in Book 11 of the *Problems of the Primum Mobile*, problem 10, gathers from the ratio of the shadow to the gnomon as 8 to 9 a visible altitude of the Sun's limb of 48° 7′. Supposing a refraction of 2′ 15″ and a parallax of 2′ 45″, he turns this into a true altitude of 48° 7′ 30″; but, neglecting the 30″, [he keeps] 48° 7′, and concludes its complement, namely 41° 53′. Yet he ought to have put the altitude of the limb at 48° 22′; or else he ought to have called the altitude of 48° 7′ the altitude not of the limb but of the centre.

Probl. Altitudinem Poli adipiſci, Datis 82. Die maxima aut minima, & Obliquitate Eclipticæ 83. Semidiurno arcu, vel Differentia Aſcenſionali, & Declinatione Solis aut Stellæ 84. Semidiurno arcu vel Differ. Aſcenſionali & Amplitudine ortiua Solis aut Stellæ 85. Amplitudine ortiua, & Declinatione Solis aut Sideris. *Problem. To obtain the altitude of the pole, given: 82. the longest or the shortest day, and the obliquity of the ecliptic; 83. the semidiurnal arc, or the ascensional difference, and the declination of the Sun or of a star; 84. the semidiurnal arc or the ascensional difference, and the rising amplitude of the Sun or of a star; 85. the rising amplitude, and the declination of the Sun or of a heavenly body.*

In the adjoining figure let the meridian be HCPN and the horizon HMR; and let P be the visible pole of the equator AMQ. Let the Sun be at D, a point common to the parallel CT and to the horizon, on this side of the equator, through which [passes] the quadrant of declination PDL; but if the Sun were at B, a point of the parallel KN beyond the equator, draw the arc of declination PB.

Diagram. Set at the right of the short lines in the right column. A circle (the meridian) with a horizontal diameter from H at the left to R at the right, on which stand B, M and D. Oblique straight lines cross the circle: one from A at the upper left down to Q at the lower right, others joining K, P, C, T and N on the rim; I and L stand at intersections inside the circle, I above the diameter and L below it.

- C (top of the circle)
- A (upper left, on the circle)
- K (left, on the circle)
- P (upper right, on the circle): the visible pole
- H (left end of the diameter), R (right end): the horizon HMR
- B, M, D (on the diameter, left to right)
- I (inside, above the diameter)
- L (inside, below the diameter)
- T (lower right, on the circle)
- Q (bottom, right of centre, on the circle)
- N (bottom, on the circle)

[Margin: Problem 82.]

First, then, if the longest artificial day is given, the Sun will rise at D, a point of the tropic lying on this side of the equator, and PD will be the complement of the Sun's greatest declination, or of the obliquity of the ecliptic. And when half the artificial day has been converted into parts of the equator corresponding to the solar time, the angle APL will be known, which measures the greatest semidiurnal arc AL; and its supplement to 180 degrees will be the angle DPR. With this and with the base PD, in the triangle DPR, right-angled at R, find the altitude of the pole PR by [proposition] 2 of right-angled spherical triangles.

[Margin: By the longest day.]

[Margin: Otherwise.]

Or otherwise: in the triangle MLD, right-angled at L, find the angle LMD by [proposition] 14 of the same triangles. For the side ML is given, if you subtract 6 hours from the greatest half-day and convert the remainder into parts of the equator; and so is the side LD, which is the Sun's greatest declination, or the obliquity of the ecliptic. Now the angle LMD is equal to the angle HMA, which measures the altitude HA of the equator; therefore, when it is subtracted from 90 degrees, the remainder will be the altitude of the pole, since this is as great as the distance of the equator from the vertex.

[Margin: By the shortest day.]

But if the shortest day is given, the Sun will rise at B; and then, when the complement of half that day to 6 hours has been converted into parts of the equator, the arc IM will be known, and BI will be the Sun's greatest declination, as great as the obliquity of the ecliptic. Therefore in the triangle BIM, right-angled at I, with the sides given, you will find by the same [proposition] 14 the angle BMI; subtract it from 90 degrees, and the altitude of the pole will be known.

[Margin: Problem 83.]

Secondly, let the semidiurnal arc of the Sun or of a star be given, say the arc AML (for I now call the semidiurnal arc of a star the arc that it uses up from its rising to the meridian, whether it is really day or night). For when the quadrant AM of the equator is subtracted, ML, the ascensional difference, will remain — unless it had been given directly. With it and with the declination LD of the heavenly body, find by [proposition] 14 of right-angled spherical triangles the angle LMD, and subtract it from 90 degrees, so that the altitude of the pole becomes known. But if the semidiurnal arc were less than a quadrant, the Sun or the star will rise, for example, at B, and the triangle BMI would have to be used, as I said of the shortest day. The altitude of the pole itself could, however, also be found by tables of semidiurnal arcs, the Sun's place being given.

[Margin: Problem 84.]

Thirdly, let there be given, from the semidiurnal arc, the ascensional difference ML or MI, and the rising amplitude MD or MB. For in the triangle LMD or IBM, right-angled at L or at I, one side and the base MD or MB will be given; therefore by [proposition] 5 of right-angled spherical triangles you will

find the acute angle M, and when it is subtracted from 90 degrees you will have the altitude of the pole.

[Margin: Problem 85.]

Fourthly, let the rising amplitude MD be given as the base, and the northern declination LD as a side; or the rising amplitude MB, and the declination BI as a side. For in the triangle MLD or MIB, right-angled at L or at I, by [proposition] 4 of right-angled spherical triangles you will obtain the acute angle at M, whose complement to 90 degrees will be the altitude of the pole.

[Margin: Order of the problems.]

[Margin: Order of the problems.]

[Margin: A caution concerning the problems already mentioned.]

It must be noted, however, that because of refraction — and also, if it is the Sun, of parallax — the rising amplitude and the semidiurnal arc vary somewhat; and therefore, if one of these is given by observation, the altitude of the pole deduced from it is not quite so exact.

86. Probl. Altitudinem Poli definire, Dato Arcu Eclipticæ ſemper Apparente, & Obliquitate Eclipticæ. *Problem 86. To define the altitude of the pole, given the arc of the ecliptic that is always visible, and the obliquity of the ecliptic.*

[Margin: Problem 86.]

How the arc of the ecliptic that is always visible is investigated was stated in section 2, problem 217, whose figure can serve for the present business. I add, however, that the arc of the ecliptic that is always visible is not to be reckoned from the time when a day without any night begins, or ends, but from the time when the centre of the Sun is on the horizon and moves in the circle of perpetual apparition. This arc being given, then, take its half, and find the second sine of that half; multiply it by the sine of the obliquity of the ecliptic, and divide the sum by the whole sine, or radius. For the quotient will be the sine of the angle that measures the altitude of the equator; subtract this from 90 degrees and you will have the altitude of the pole.

87. Probl. Altitudinem Poli determinare, Datis Climate & Obliquit. Eclipticæ. *Problem 87. To determine the altitude of the pole, given the clime and the obliquity of the ecliptic.*

[Margin: Problem 87.]

A clime is understood to be given when the longest day is given on the parallel passing through the middle or through the end of the clime. The extremes of the climes are usually distinguished by a difference of half an hour, although the parallel through the middle of a clime does not differ from the parallel through the beginning or end of the clime in the longest day of the year except by a quarter of an equal hour. And so it goes, beginning from the equator, which is the first of the parallels and their beginning, as far as the frigid zones, in which the longest day is greater than 24 hours. As many half-hours, therefore, as the longest day exceeds 12 hours — that is, the equinoctial day

— so many is the number of the completed clime. Hence, if the first clime is given, the longest day on the parallel through its middle is $12^h\ 15^m$, but on the parallel that bounds it, $12^h\ 30^m$. If, on the other hand, the 7th clime is given, then, since seven half-hours make $3^h\ 30^m$, these added to 12 hours make the longest day on the bounding parallel, $15^h\ 30^m$. The number of the climes being given, therefore, the longest day is given; and its half, converted into parts of the equator, will give the greatest semidiurnal arc. With this and with the obliquity of the ecliptic — that is, the Sun's greatest declination — or its complement, find the altitude of the pole by Problem 82, set out a little earlier. But if the longest day exceeds 24 hours, turn to Problem 86. And if it is exactly 24 hours, the altitude of the pole will be 66° 30′.

88. Probl. Data Poli Altitudine, determinare Clima, immò & Parallelum Climatis. *Problem 88. Given the altitude of the pole, to determine the clime, and indeed the parallel of the clime.*

[Margin: Problem 88.]

Find the greatest semidiurnal arc — the Sun, that is, holding its greatest declination — either by Problem 122 of Section 2 or by the tables indicated there; double it, and from the sum throw away 180 degrees. Convert the remainder into time of the equator, that is, into hours and minutes. For as many half-hours as there are in that remainder, so many is the number of the climes within which the place of the given altitude of the pole does not lie. If nothing is left over beyond the half-hours, the place will be on the parallel bounding the clime indicated by the number of half-hours. But if some minutes of an hour remain, either they will be 15^m, and then the place will be on the middle parallel of the following clime; or they will be fewer than 15^m, and it will lie between the parallel already mentioned and the parallel bounding the next clime towards the equator; or, finally, they will be more than 15^m, and it will lie between the middle parallel already mentioned and the parallel bounding the clime that follows towards the visible pole. Thus, since here at Bologna the altitude of the pole is 44° 29′ 30″, and so the greatest semidiurnal time is $7^h\ 35^m$ and the longest day $15^h\ 10^m$ — granted that, owing to the refractions, it is apparently lengthened at both ends, so that it seems to be 15^h and nearly 15^m — therefore, when the 12 hours are thrown away, there remain $3^h\ 10^m$, that is, 6 half-hours and 10^m. We are therefore outside the 6th clime and are in the 7th, but within the parallel drawn through the middle of the seventh and the one drawn through the end of the sixth.

Probl. Altitudinem Poli determinare ex Altitudine Solis aut Fixarum extra Meridianum capta, Datis 89. Altitudine, ac Declinatione Sideris, & Azimutho 90. Altitudine, ac Declinatione Sideris, & Diſtantia Aequatoria à Meridiano 91. Altitudine, Declinatione, & Aſcenſione Recta Sideris, vnà cum Aſcenſ. Recta Medij Cæli 92. Altitudine, Azimutho, & Diſtantia

Aequatoria Sideris à Meridiano 93. Altitudine, Azimutho, & Aſc. Recta Sid. cum Aſc. Recta Medij Cæli 94. Declinatione, Azimutho, & Diſtantia Sideris Aequatoria à Meridiano 95. Declinatione, Azimutho, & Aſc. Recta Sid. cum Aſcenſ. Recta Medij Cæli. *Problem. To determine the altitude of the pole from an altitude of the Sun or of the fixed stars taken outside the meridian, given: 89. the altitude and the declination of the star, and the azimuth; 90. the altitude and the declination of the star, and its equatorial distance from the meridian; 91. the altitude, the declination and the right ascension of the star, together with the right ascension of the midheaven; 92. the altitude, the azimuth, and the equatorial distance of the star from the meridian; 93. the altitude, the azimuth, and the right ascension of the star with the right ascension of the midheaven; 94. the declination, the azimuth, and the equatorial distance of the star from the meridian; 95. the declination, the azimuth, and the right ascension of the star with the right ascension of the midheaven.*

For all these, let the following figure serve, in which the meridian is HZQ, the horizon HR, and the equator EOQ, whose pole is P. Let the Sun, or any other star whatever, be either at B, on this side of the equator, so that the arc BP is the complement of the declination to 90 degrees; or at G, a point of the equator, and then GP is a whole quadrant; or at I, beyond the equator, and then the arc IP is made up of the declination IC and the quadrant CP. Hence what will be said of the triangle ZBP, using the side BP, is to be understood of the triangles ZGP and ZIP, when the side GP or IP, known from the declination, is to be used. Further, the angles at the pole of the world P, made by the meridian and another circle of declination, measure the equatorial distance of the star from the meridian. This can be known either by counting the time that passes from the taking of the star's altitude or azimuth until its transit through the midheaven, and converting it into parts of the equator; or from the difference between the right ascension of the star and the right ascension of the midheaven. The ascension of the midheaven can be observed by waiting until one fixed star of known right ascension passes through the meridian, and at the same moment having another companion take the altitude or azimuth of another star whose right ascension is likewise known. Finally, the transit through the meridian and the position of the azimuth are best marked by our thread triangle, on which see Book 5, chapter 15, Problem 8.

Diagram. Set at the right of the short lines in the right column. A circle (the meridian HZQ) with Z at the top, H at the left and R at the right of a horizontal line (the horizon) on which A stands; P, the pole, at the upper right on the rim, with arcs drawn towards it from E, N and B at the upper left; G and C close together inside the circle, I below them, O below the centre, Q at the lower right on the rim.

- Z (top of the circle)
- E (upper left, on the circle)
- B (upper middle, inside)
- P (upper right, on the circle): the pole
- N (left, below E)

- G, C (inside, left of centre)
- I (inside, below G)
- H (left end of the horizon), R (right end)
- A (on the horizon, left of centre)
- O (below the centre)
- Q (lower right, on the circle)

Now, the azimuth HZA being given, its supplement to 180 degrees is given, namely the angle AZP, which from here on we shall call, for brevity, *the angle Z*; just as the angle known from the distance from the meridian we shall call *the angle P*. And the complement of the altitude AB to 90 degrees is the side BZ. We shall therefore use the triangle BZP. But what we say of it holds for the two others, with the side BP and the angle P changed; and in it we shall always investigate the arc ZP, which is the complement of the polar altitude PR.

[Margin: Problem 89.]

First: since the side BZ is given from the altitude, and BP from the declination, and the angle Z from the azimuth, you will obtain the ba- se PZ, that is, the complement of the altitude of the pole, by [proposition] 2 of oblique-angled spherical triangles.

[Margin: Order of the problems.]

[Margin: Order of the problems.]

[Margin: Problem 90.]

Secondly: since the side BZ is given from the altitude, and BP from the declination, and the angle P from the distance from the meridian, you will obtain the base PZ by the same [proposition] 2.

[Margin: Problem 91.]

Thirdly: since BZ is given from the altitude, and BP from the declination, and the angle P from the difference between the right ascensions of the star B and of the midheaven, you will have the base PZ by the same [proposition] 2.

[Margin: Problem 92.]

Fourthly: since BZ is given from the altitude, and the angle Z from the azimuth, and P from the distance from the meridian, you will obtain the base PZ by [proposition] 8 of oblique-angled spherical triangles.

[Margin: Problem 93.]

Fifthly: since BZ is given from the altitude, and the angle Z from the azimuth, and the angle P from the difference of the right ascensions of the star B and of the midheaven, you will acquire the base PZ by the same [proposition] 8.

[Margin: Problem 94.]

Sixthly: since BP is given from the declination, and the angle Z from the azimuth, and the angle P from the equatorial distance from the meridian, the base PZ will become known by [proposition] 8 of the same triangles.

[Margin: Problem 95.]

Seventhly: since BP is given from the declination, and the angle Z from the azimuth, and the angle P from the difference of the right ascensions of the star and of the midheaven, you will therefore have the base PZ by the same

[proposition] 8; and when it is subtracted from 90 degrees, the altitude of the pole RP will be known.

Probl. Altitudinem Poli venari per duas ſtellas, in eodem Verticali exiſtentes, quarum nota ſit Declinatio & Aſcenſio Recta, & præterea Datis 96. Altitudine vnius Stellarum prædictarum 97. Azimutho vnius Stellarum prædict. 98. Aſc. Recta Medij cæli. *Problem. To hunt out the altitude of the pole by means of two stars standing on the same vertical, whose declination and right ascension are known, and given in addition: 96. the altitude of one of the stars already mentioned; 97. the azimuth of one of the stars already mentioned; 98. the right ascension of the midheaven.*

In the following figure the meridian is HVQ, the horizon HR, the equator AOQ, and the quadrant of the vertical circle VT, on which are the two stars F and G. Through their centres, from the pole of the world P, let the quadrants of the circle of declination PFK and PGM be drawn.

For the three problems that follow, then, the first thing to be found is the angle VFP or VGP, and it is found easily. For in the triangle FPG the sides FP and GP are given, being the complements of the given declinations; and so is the angle FPG, since it is the difference of the given right ascensions. Therefore, by [proposition] 5 or 6 of oblique-angled spherical triangles, you will find the angle FGP, that is VGP, and the angle GFP; and when this is subtracted from 180 degrees, the angle VFP becomes known. These having been found:

Diagram. Set at the right of the short lines in the left column. A circle (the meridian HVQ) with V at the top, H at the left and R at the right of the horizon line; A at the upper left on the rim and Q at the lower right, joined by the equator through M and O; P, the pole, at the upper right on the rim, with lines drawn to it from K and from G; F inside below V; T on the lower part of the vertical through O.

- V (top of the circle)
- A (upper left, on the circle)
- F (inside, below V)
- P (upper right, on the circle): the pole
- K (left, inside)
- G (inside, right of centre)
- H (left end of the horizon), R (right end)
- M (on the equator, left of centre)
- O (below the centre)
- T (below and right of O)
- Q (lower right, on the circle)

[Margin: Problem 96.]

First: if the altitude of the star F is given, find VP, the complement of the altitude of the pole, by [proposition] 4 of oblique-angled spherical triangles. For in the triangle VFP there are given VF, the complement of the altitude TF; FP, the complement of the declination of the star F; and the included angle VFP.

But if the altitude of the star G was taken, use the triangle VGP, in which VG is the complement of the altitude and GP the complement of the declination of the star G, together with the included angle VGP found above; and by the same [proposition] 4 find VP.

[Margin: Problem 97.]

Secondly: if the azimuth is given, its supplement to 180 degrees is the angle FVP. With it, and with the angle VFP already found, and with FP, the complement of the declination of the star F, the higher one, find by [proposition] 7 of oblique-angled spherical triangles the side VP, which is the complement of the altitude of the pole.

[Margin: Problem 98.]

Thirdly: if the right ascension of the midheaven is given, the difference between it and the right ascension of the higher star F will give the angle VPF. With it, and with the angle VFP found above, and with the adjacent arc FP, which is the complement of the declination of the star F, find VP by [proposition] 11 or 12 of oblique-angled spherical triangles; and when it is taken from 90 degrees, the altitude of the pole RP will be known.

99. Probl. Poli Altitudinem Inquirere, Data Aſcenſione Recta duorum Siderum, quorum vnum ſit in Merid. quando alterum eſt in Horizonte, & huius Declinatione. *Problem 99. To find the altitude of the pole, given the right ascension of two stars, one of which is on the meridian when the other is on the horizon, and the declination of the latter.*

[Margin: Problem 99.]

In the following scheme the meridian is HKQ, the horizon HR, and the equator AMQ, whose pole is P; and the star rising or setting is at the point B of the horizon, through which let the quadrant PBC be drawn, so that its given declination is BC and the complement of the declination BP. But if the star were on the equator, that is, at the point M, a whole quadrant would have to be used in place of BP; and if beyond the equator, the sum of the declination and the quadrant would have to be used. It is enough, however, to indicate the problems in the triangle BPR, right-angled at R. In it, besides the base BP, the angle BPR is given, which is as great as the difference of the right ascensions of the star B and of the star L, which appears between the pole, roughly known, and the horizon; or it is the supplement of that difference to 180 degrees when the star K appears between the visible pole and the equator. Therefore, by [proposition] 2 of right-angled spherical triangles, obtain the altitude of the pole RP. But note that the star at B appears sooner because of horizontal refraction, and that it is therefore better to observe it when it appears raised about half a degree above the horizon; for then it will really be on the horizon. And if at that moment another known star is on the meridian, you will be able to dispatch this problem.

Diagram. Set at the right of the short lines in the right column, beside Problem 99. A circle (the meridian HKQ) with H at the left and R at the right

of the horizon line; K at the top, P at the upper right and L at the right on the rim, K and L each marked with a small star sign; A at the upper left on the rim, joined to Q at the lower right through M (the equator AMQ); B on the horizon right of centre, marked with a small star sign, with the line PBC through it down to C.

- K (top of the circle, star sign)
- A (upper left, on the circle)
- P (upper right): the pole[59]
- L (right, on the circle, star sign)
- H (left end of the horizon), R (right end)
- B (on the horizon, right of centre, star sign): the rising or setting star
- M (on the equator, below the horizon)
- C (bottom, on the circle)
- Q (lower right, on the circle)

100. Probl. Poli Altitudinem inquirere, Datis duabus Stellis notæ Declinationis & Aſc. Rectæ ſimul orientibus, aut occidentibus. *Problem 100. To find the altitude of the pole, given two stars of known declination and right ascension rising, or setting, at the same time.*

[Margin: Problem 100.]

In this second diagram the meridian is HPQ, the horizon HR, and the equator AMQ, whose pole is P; and the stars rising or setting at the same time are O and B. Through them let the quadrants of declination PBD and POC be drawn; for the declination of the star O will be CO and its complement OP, while that of the star B will be DB and its complement BP. These being given in the triangle BPO, with the vertical angle BPO, which measures the difference of the right ascensions, you will find:

[Margin: Step 1.]

first, the angle POB, by [proposition] 5 or 6 of oblique-angled spherical triangles.

[Margin: Step 2.]

Secondly, in the triangle OPR, right-angled at R, in which the base OP is given from the declination of the star O, and the angle POR has been found, find the altitude of the pole PR by the first [proposition] of right-angled spherical triangles. It may happen, however, that the arcs PO and PB, both or one of them, are a quadrant, or are made up of a quadrant and the declination, if both stars or one of them is either on the equator or beyond it. It is advisable, moreover, to wait for two stars that appear raised together about 30′ above the horizon; for then they will really be on the horizon.

Diagram. Set at the right of the short lines in the right column, beside Problem 100. A circle (the meridian HPQ) with H at the left and R at the right of the horizon line; A at the upper left and P at the upper right on the rim; O

[59] no star sign at P, where the meridian line meets the rim.

and B on the horizon right of centre; M below the horizon left of centre; C and D below; Q at the lower right on the rim.

- A (upper left, on the circle)
- P (upper right, on the circle): the pole
- H (left end of the horizon), R (right end)
- O, B (on the horizon, right of centre): the two stars
- M (below the horizon, left of centre)
- C (below M)
- D (lower right, inside)
- Q (lower right, on the circle)

101. Probl. Data Vnius loci Altitudine Poli, & Differentia longitudinis inter ipſum & alterum locum, cum alterutro Poſitionis angulo; Inuenire alterius Altitudinem Poli, ac Diſtantiam horum Locorum. *Problem 101. Given the altitude of the pole of one place, and the difference of longitude between it and another place, with either of the angles of position: to find the altitude of the pole of the other, and the distance of these places.*

[Margin: Problem 101.]

In the next figure let there be two northern places, C and D, through which, and through the northern pole of the world B and the southern A, let two semicircles of meridians BCA and BDA be drawn, intercepting the arc EQ of the equator, that is, the difference of longitude, which either angle B or A measures. And let the arc CD of a vertical circle be drawn, which contains the distance between the two places; for the angles of position will be BCD and BDC. Therefore in the triangle CBD, if the altitude of the pole of your place C is given, its complement will be CB. With it, and with the angle B, known from the difference of longitude, and with the angle of position, observed or given, find BD, the complement of the altitude of the pole of the place D, and the distance CD, by [proposition] 11 or 12 of oblique-angled spherical triangles. But if the altitude of the pole of the place D is given, its complement BD will be given; with it, and with the angles B and CDB of position, find by the same [proposition] 11 or 12 the arc CB, which is the complement of the altitude of the pole at the place C, and the distance CD. From these you understand what is to be done in the triangle CFB if one place is northern and the other southern; for then BF will be made up of the quadrant BQ and the latitude QF.

[Margin: Order of the problems.]

[Margin: Order of the problems.]

Diagram. Set at the right of the short lines in the left column. Two curved meridians join B at the top and A at the bottom in a lens shape; D stands on the right meridian and C on the left, joined by a straight line (the vertical arc CD); E at the left and Q at the right of a horizontal line across the middle (the arc EQ of the equator); F on the right meridian below the equator and G on the left, with straight lines drawn from C, E and G to F.

- B (top): the northern pole of the world

- D (right meridian, upper)
- C (left meridian, upper)
- E (left, on the equator)
- Q (right, on the equator)
- F (right meridian, below the equator)
- G (left meridian, lower)
- A (bottom): the southern pole

102. Probl. Data Altitudine Poli duorum locorum & alterutro Poſitionis angulo; inuenire Differentiam Longitudinis, ac Locorum Diſtantiam. *Problem 102. Given the altitude of the pole of two places and either angle of position: to find the difference of longitude and the distance of the places.*

[Margin: Problem 102.]

In the triangle CBD, given CB and DB, the complements of the altitudes of the pole, and the angle BCD or BDC, you will find the angle B, that is, the difference of longitude, by [proposition] 3, and the base CD, or the distance, by [proposition] 2 of right-angled spherical triangles. The angles of position, moreover, are known to ship-masters by loxodromy and by the line that the rhumbs of the winds make with the meridian line; and as long as they use the same wind, they are believed to sail along nearly the same circle — but more on these matters in the book on geography. I add that if the difference of longitude is given, that is, the angle B, and, from the altitudes of the pole, the complements BC and BD, then the distance CD is to be found by the fourth [proposition] of oblique-angled spherical triangles.

103. Probl. Data Diſtantia duorum locorum inter ſe, ac Differentia longitudinis, cum alterutro Poſitionis angulo, inuenire vtriuſque Altitudinem Poli. *Problem 103. Given the distance of two places from each other, and the difference of longitude, with either angle of position: to find the altitude of the pole of each.*

[Margin: Problem 103.]

In the figure of Problem 101 let CD be given, in degrees and minutes, or in miles but converted into degrees and minutes; and the difference of longitude B, and the angle of position C or D. For in the triangle CBD you will be able to find the side either opposite or adjacent to the angle of position, by [proposition] 7 or 8 of oblique-angled spherical triangles; and so the complements of the polar altitudes, BC and BD, can be known. When these are subtracted from 90 degrees, the altitude of the pole will remain.

104. Probl. Data duorum locorum Diſtantia & vnius Altitudine Poli, cum angulo Poſitionis, inuenire alterius Altitudinem Poli, & Differentiam Longitudinis. *Problem 104. Given the distance of two places and the altitude of the pole of one, with the angle of position: to find the altitude of the pole of the other, and the difference of longitude.*

[Margin: Problem 104.]

In the same preceding figure and its triangle CBD, if the polar altitude of the place C is given, its complement CB is given; if that of the place D, the complement BD is given. Therefore, with the distance CD, and with the angle of position C or D, either included by the sides or opposite to one of the given sides, you will find the angle B, or the difference of longitude, by [proposition] 5 or 3 of oblique-angled spherical triangles; and you will find the complement of the altitude of the pole, that is, either CB or DB, by [proposition] 4 or by [proposition] 2 of the same. But if the distance of the places is taken from the travelled interval and is too great — say, more than 300 or 400 miles — Ptolemy declares (*Geography* Book 1) that long journeys are not to be trusted, because of their various windings, which are not reduced with certainty to a straight route by subtracting a third part, as Marinus of Tyre thought, or a sixth, as Kepler does (chapter 16 of the *Rudolphine Tables*).

105. Probl. Data duorum locorum Diſtantia, & vtriuſque angulo Poſitionis, inuenire vtriuſq. Altitudinem Poli, & Differentiam Longitudinis. *Problem 105. Given the distance of two places and the angle of position of each: to find the altitude of the pole of each, and the difference of longitude.*

[Margin: Order of the problems.]

[Margin: Order of the problems.]

[Margin: Problem 105.]

Keeping to the same figure of Problem 101 and to the triangle CBD (for what is said of it is easily understood of the other cases): since the base CD is given, from the distance converted, if need be, into degrees and minutes, and both angles at the base, namely the angles of position C and D, the angle B, which measures the difference of longitude, can indeed be found by [proposition] 10 of oblique-angled spherical triangles, and by [proposition] 11 or 12 each side, CB and DB, which is the complement of the altitude of the pole. But beware of long journeys; for then it is better to use eclipses and Problem 106 or 107, which are to be given below. Conversely, if the places are very near, it is better to use this problem or Problem 104.

[Margin: A caution on the use of these problems.]

Monitum Pro reliquis modis inueſtigandæ Altitudinis Poli. *A caution concerning the remaining ways of investigating the altitude of the pole.*

For the remaining ways and problems given by means of the figure of Problem 101, see Problems 43 to 49. The others we have neglected for this reason: they presuppose the altitude of the pole as known beforehand, and they have neither such ease nor such certainty that it would be worth testing by them an altitude of the pole once known. Nor is it worth the trouble to turn to them, leaving aside these 32, which we have given from Problem 67 to 104, with a few inserted as occasion offered. We shall therefore move on to other

problems, for the difference of longitude, already found above in several ways, and now to be found in other ways.

[Margin: For the altitude of the pole the 32 problems given are amply sufficient.]

Problem. Longitudinis Differentiam, ſeu Diſtantiam Meridianorum inueſtigare 106. 107. 108. per Eclipſes Luminarium, modis 3. Et vtræ Eclipſes ſint ad id meliores. *Problem 106, 107, 108. To investigate the difference of longitude, or the distance of the meridians, by eclipses of the luminaries, in 3 ways; and which eclipses are better for it.*

[Margin: Problem 106.]

The *first way* is by eclipses of the Moon observed accurately at two places on the Earth, at both of which the beginning, or the end, or the middle (in partial eclipses of six digits), or the beginning of total obscuration, or the beginning of emersion from the shadow has been observed with the care we called for in Book 5, chapter 15. For the difference of time, converted into parts of the equator, will give the difference of longitude. You have some examples of this practice, with their scheme, in Book 1, chapter 13. The same can, however, be obtained by lunar eclipses of which one phase was observed at one place and another at the other, provided that at one of the two, or at some other place, the duration of the whole eclipse, or of the stay in the shadow, or the half-duration or half-stay, was also observed. For by adding or subtracting the duration or the stay, or the half-duration or the half-stay, the observation of the other place will easily be reduced to the same kind of phase; and so the difference of longitude will be obtained by the first way. For example, suppose that at Rome the beginning of the eclipse was observed, and at Bologna the middle and the end. The difference between the middle and the end will be the half-duration of the eclipse; doubled, it will give very nearly the whole duration; and this, subtracted from the time of the end observed at Bologna, will give the beginning of the eclipse at Bologna; or, added to the time of the beginning observed at Rome, it will give the end of the eclipse with respect to Rome. By comparing, then, the time of the end in both places, or the time of the beginning, this problem can be completed by the preceding one.

[Margin: Problem 107.]

The *second way* is by the observation of an eclipse at a place of unknown longitude, and by the time due to the same eclipse on the meridian for which very exact tables have been constructed. For let the beginning of a lunar eclipse have been observed at Goa at 10^h after noon, and from Lans- [Margin: Order of the problems.]

[Margin: Order of the problems.]

bergen's tables let the beginning of the same eclipse have been due at Goes at $4^h\ 50^m$ after noon. From this it follows that Goa is more easterly than Goes by $5^h\ 50^m$, that is, by $77°\ 30'$. Yet since astronomers usually go astray or

disagree in observing the beginning and end of eclipses, our Georges Fournier (*Hydrographia* Book 12, chapters 27 and 28) puts little trust in them.

[Margin: Problem 108.]

The *third way* is by eclipses of the Sun, provided that the difference of longitude, which otherwise appears from them, is corrected by computing the parallax. For this purpose, however, eclipses of the Moon — especially the immersions or emersions of total ones — are preferred by Hipparchus (in Strabo, Book 1); by Ptolemy (*Geography* Book 1, chapter 4), and there, in their commentaries, by Vernerius [Johannes Werner], Moletti, Maginus and Bercius; by al-Battānī (chapter 6); by Clavius (on the *Sphere*, chapter 2, page 284); by Tycho (in his *Letters*, page 73); by Peter Apian (*Cosmographia* Part 1, chapter 10); by Orontius (*Cosmographia* Book 5, chapter 3); by Iunctinus [Francesco Giuntini] (chapter 2 on the *Sphere*, page 469); by Maurolycus (*Cosmographia*, dialogue 3, page 67); by Daniel Santbech (proposition 14, on observation); by Cavalieri (in the *Centuria*, problem 47); by Biancani (in the *Introduction to Geography*); and by Hérigone (volume 4 of the *Cursus Mathematicus*, page 485). Kepler, by contrast (*Rudolphine Tables*, chapter 16, precept 61), affirms that solar eclipses are better suited to this purpose than lunar ones, because the beginnings and ends of solar eclipses are discerned much more certainly; and he says that the method of removing the parallaxes in his tables is most certain and most refined. He repeats the same in chapter 31, precept 176, where he also teaches this method:

[Margin: Which eclipses are better for it?]

"From the observation of each place, for the apparent time at it, let the true places of the Moon from the Sun be sought. When these are compared with each other — if they are of different sides, their sum, or if of the same side, their difference — divided by the true hourly motion of the Moon from the Sun, will yield the corresponding hours and minutes. Let these be added to the apparent time of the place for which the place of the Moon came out the earlier; let the time so altered be compared with the observed time of that place, and the difference of the meridians will be evident." He goes on, and illustrates the precept with an example, as follows.

[Margin: Kepler's precept for the difference of meridians from a solar eclipse.]

EXEMPLVM. *Example.*

At Graz let the end of a solar eclipse have been observed at exactly $12^h\ 47^m$, in the year 1598 February 25, when the Moon truly followed the Sun by 52′ 29″ ♓. But at Uraniborg the beginning was observed at $10^h\ 10^m$, when the Moon truly preceded the Sun by 26′ 8″. The sum is 1° 18′ 37″; divided by the hourly motion of the Moon from the Sun, which was 33′ 54″, it gives a quotient of $2^h\ 19^m$. And since at Uraniborg the Moon's place precedes, add the time found to its time: it becomes $12^h\ 29^m$. But at Graz the Moon reached that later place at $12^h\ 47^m$. The difference of these meridians would therefore be 18^m of time.

He warns, however, in chapter 16, that if the visible latitude becomes large, as it did at the end of the eclipse already mentioned, the longitude obtained from it is less reliable. And in the Catalogue of the *Rudolphine Tables*, page 33, he puts the difference between Graz and Uraniborg at only 14 minutes of hours, following, of course, partly the itinerary distance and partly observations of lunar eclipses — as is clear from his reasoning in chapter 16, from page 36 to 40, and from page 11 of his *Ephemerides*, which I have examined more fully in my book on geography. All things considered, therefore, this method by solar eclipses is not only more laborious but also more uncertain, because of many perplexities, and more hazardous — granted that their beginnings, or at least their ends, especially those of large eclipses, are in fact discerned more clearly than those of lunar eclipses, which suffer from the smoke and the shadowy fringe [vmbrago]; this, however, can be told apart from the true eclipse by telescopes and by certain other signs from small spots, as I taught in Book 5, chapters 5 and 15. Moreover, neither I hitherto, nor Father Bonaventura Cavalieri, chief Professor of Mathematics at Bologna, in a letter on this controversy sent to me while I was staying at Parma, in the year 1645 October 8, could understand how the true place of the Moon from the Sun at Graz could be found for a given time by tables that suppose, in their epochs, the meridian of Uraniborg or another one different from that of Graz — unless the distance of the meridians is known beforehand, which here, however, is being sought as unknown. Father Cavalieri suspected, however, that Kepler thought this problem was to be solved not by tables but by the analysis of triangles, from the lunar latitude and the sum of the visual semidiameters of the Sun and the Moon.

[Margin: Kepler's caution.]

[Margin: Kepler's inconsistency.]

[Margin: In the end, lunar eclipses are preferred.]

For in the following figure let ABC be the ecliptic, in which B is the centre of the Sun, and OML, etc., its disc; and DC the apparent path of the Moon, in which let P be the centre of the Moon at the beginning of the observed eclipse, when the Moon's disc began to graze the Sun's disc, or to pass apparently under it, at L.

Diagram. Set in the right column. A straight line (the ecliptic) runs from A at the left to a point at the right where it meets an oblique straight line rising from D at the lower left (the Moon's apparent path). A large circle stands about the ecliptic line, with G, B and E on the line near its lower edge; three equal circles stand along the oblique line, at F (lower left), at M (middle, its lower half shaded) and at P (right); straight lines run from B down to the circles.

- A (left end of the ecliptic)
- G (on the ecliptic, left of B): foot of the perpendicular FG
- B (on the ecliptic): the centre of the Sun
- E (on the ecliptic, right of B)
- I (above P): foot of the perpendicular PI

- L (between the Sun's disc and the circle P): where the Moon's disc first grazes the Sun's
- C (right end, where the two lines meet)[60]
- O (between the Sun's disc and the circle F)
- M (on the shaded circle in the middle)
- F (lower-left circle): the Moon's centre at the end of the eclipse
- P (right circle): the Moon's centre at the beginning of the eclipse
- D (lower-left end of the Moon's path)

For when the perpendicular PI is drawn to the ecliptic — this is the apparent latitude, and is known by observation — and BP is the known aggregate of the Sun's visual semidiameter BL and the Moon's IP, then in the triangle BPI, right-angled at I, given the side IP and the base BP, the side BI can certainly be known by [proposition] 9 of right-angled plane triangles; it is the Moon's lead [anteceſſio] in the ecliptic with respect to the Sun. So too at the end of the eclipse: with the Moon's centre placed at F, and the perpendicular FG drawn and given — namely the visible latitude — and given the sum of the semidiameters BO and OF, the side BG, or the Moon's lag [ſucceſſio], can be known. But this lead and lag is apparent, not true; and yet Kepler requires the true one, which — whether it is gathered from the true latitude of the Moon or from the true longitude of the luminaries — cannot be known unless tables adapted to the meridian of each place are to hand, or unless recourse is had to other particular observations, and to methods not included in that precept of the *Rudolphine Tables*,

109. Probl. Diſtantiam Meridianorum inueſtigare per Horologia in principio ac fine itineris inſpecta. *Problem 109. To investigate the distance of the meridians by clocks inspected at the beginning and at the end of a journey.*

[Margin: Problem 109.]

At the beginning of the journey by which you depart from one place, have a portable clock which shows the hours of that place exactly, by striking or by the fall of sand, and whose motion is never interrupted or varied on the journey by jolting or by a change of air. Then, at the end of the journey, inspect that same clock. If it shows the same hours as are observed at the second place, both places lie under the same meridian. But if the portable clock shows more hours or minutes than are reckoned at the second place, the second place will be more westerly than the one you left; if fewer, more easterly. Cavalieri admits, however (in the *Centuria*, problem 47), that it is difficult on a journey to keep a clock exactly in its state — that is, so that it imitates exactly the daily revolutions of the primum mobile or of the Sun, and their parts. Yet this method is not spurned by Maurolycus (*Cosmographia*, dialogue 3, page 67½), Gemma Frisius (*De usu globi*, chapter 19), Biancani (in the *Introduction to Geography*, before the

[60] the printed sort may be G: one reading of the page finds a round letter with a vertical spur at its lower right, another C with no spur; C is kept because the text names the ecliptic ABC and the Moon's path DC.

Table of Longitudes) and Hérigone (volume 4 of the *Cursus Mathematicus*, page 482). Hérigone adds that the imperfection which can arise from the clock's construction can be corrected by the method of Bulengerus, by means of a large equinoctial sundial, with which tables of equations may be constructed and the irregular motion of the clock reduced to regularity; and the clock is to be kept immune from changes of the air. But the reliability of the clock can be tested far more exactly by means of the pendulum described by us in Book 2, chapter 20, if the traveller halts his journey from time to time.

110. Probl. Diſtantiam Meridianorum Inueſtigare per Eclipſes Satellitum Iouis. *Problem 110. To investigate the distance of the meridians by eclipses of the satellites of Jupiter.*

[Margin: Problem 110.]

Since those four little wandering stars which were detected around Jupiter by Galileo with the telescope, and called the Medicean stars, or the Jovial Companions, perform their epicycles and circuits in such a way that, on the upper side, they fall some- [Margin: Order of the problems.]

[Margin: Order of the problems.]

times into the shadow of Jupiter's globe and suffer eclipse — as is clear from the scheme set out in Book 7, Section 1, chapter 3 — and since they complete very many revolutions within a year: if the moments of these eclipses are observed with a perfect telescope at two places on the Earth far apart, and the time is then deduced from an altitude of the fixed stars taken by Problem 25 of Section 3, the distance of the meridians can be known from the difference of time converted into parts of the equator, and it can be confirmed frequently, since eclipses of these are much more frequent than those of the luminaries. So that observers might be ready, Galileo once set about ephemerides of the motions and eclipses of these satellites, and afterwards so did his pupil Dom Vincentius Renerius [Vincenzo Renieri], Olivetan[61], chief mathematician of the University of Pisa; he sent me a specimen and sample of them more than once. But alas, just as he was about to put them to the press, he was carried off by death outside his monastery, and his writings on this subject could never be found.

That Galileo was the inventor of this device for observing longitudes, and that he proposed it to the Catholic King in the year 1631, is attested by Michaël Florentius Langrenus [Michael Florent van Langren] at the beginning of his *Selenographia* — although the same Galileo had also proposed it to the States of Holland, through Signor Deodatus of Lucca, as Father Bonaventura Cavalieri once told me. Yet I would not wish anything taken from Petrus Herigonius [Hérigone], who asserts in volume 5 of the *Cursus Mathematicus*, page 872, that this same idea came to him two years before Galileo published it. On a moving ship, however, it is hard to use a telescope with the steadiness and firmness that

[61]printed "Obuetanus", the b with a broken bowl; read as Oliuetanus

would be needed to observe the true moment of these eclipses. For the rest of what bears on this, go back to Book 7, Section 1, chapter 4, and its scholia. Besides, unless the ship-masters are very skilled, there is a danger that they will take for these satellites little fixed stars near Jupiter.

111. Probl. Diſtantiam Meridianorum Inuenire per Eclipſes, aut Illuminationes Lunarium Macularum. *Problems 111 and 112. To find the distance of the meridians by the eclipses or the illuminations of the lunar spots.*

This, if I am not mistaken, is the invention of Michael Florent van Langren, which he indicated at the beginning of his *Selenographia*. When he was Cosmographer to the Catholic King, he proposed it to the Councillors for the affairs of the Indies in the year 1632 January 7 and in the year 1633 May 10. In it he also indicates and promises a method of observing the place of the Moon exactly, without the entanglements of parallaxes and refractions; and he states that he had observed the times and the differences of right ascension of certain fixed stars by counting the time by the oscillations of a pendulum, as early as the year 1627, before Galileo had published anything on this matter — which, as I have related in Book 2, chapter 20, happened to me also.

[Margin: Problem 111.]

The *first way*, then, is if one observes in eclipses of the Moon not so much their beginnings and ends as the moments at which certain named particles on the Moon, seen through the telescope and thought to be spots, or islands, or peaks, begin to be darkened or to be lit, and this at different places on the globe of the Earth at the same moment. For example, if the moment of time is observed at which the spot of Grimaldi (called that of Posidonius by Langren) begins to be darkened: when the times of the two observations are compared, their difference will give the distance of the meridians. And since there are very many islands or peaks, as it were of rocks, on the Moon's disc, one phase after another can be observed during the whole time of the eclipse in which some part of the Moon is visible, as was done by Langren and afterwards by Hevelius. Hevelius too approves this method, on page 486 of his *Selenographia*, adding on page 490 another method by the inclinations of the Moon's horns observed at different places.

[Margin: Problem 112.]

The *second way* is if, on each of the nights on which the Moon shines for us, the lunar particles are observed with the telescope from two places on the Earth, together with the moments at which certain peaks begin to be lit that had not before been lit by the Sun — provided that both observers use the same particle, distinguished from the others by its name or some other sign. For the difference of the times will make the distance of the meridians plain. But this very thing is difficult on a moving ship, since the eye wavers along with the telescopes; and the moments of these illuminations are hard to discern, since the Moon's disc is lit slowly, and not wholly except in about 15 days, that is, in 396 hours; and so one minute out of about thirty of the Moon's disc in 13 hours.

113. Probl. Diſtantiam Meridianorum Inueſtigare methodo Orontij per Lunæ locum, ſed fallaci. *Problem 113. To investigate the distance of the meridians by the method of Orontius, through the place of the Moon — but a deceptive method.*

[Margin: Problem 113.]

Orontius Finaeus, in the little work he wrote and entitled *On finding the longitude of places otherwise than by eclipses*, teaches a certain method in which he supposes that the Moon, when it reaches the meridian, lacks parallax, and that its true longitude and latitude therefore do not differ from the apparent — which is false. For as regards longitude this is not true, except when the nonagesimal point of the ecliptic, counted from the horizon, is on the meridian, namely when the Moon's centre is at once on the meridian and at the beginning of Cancer or of Capricorn — unless perhaps the Moon is at the zenith. This error in Orontius I afterwards found noted in Petrus Nonius, in his book *On the Errors of Orontius*, chapter 15; and so there is no reason for us to delay the reader with these entanglements by recounting it at length.

[Margin: Orontius's error.]

114. Probl. Diſtantiam Meridianorum venari methodo Verneri, Gemmæ Friſij, Apiani, & Santbechij, ſed fallaci. *Problem 114. To hunt out the distance of the meridians by the method of Werner, Gemma Frisius, Apian and Santbech — but a deceptive method.*

[Margin: Problem 114.]

Johannes Werner (on Book 1 of Ptolemy's *Geography*), Peter Apian (Part 1 of the *Cosmographia*, at the end of chapter 10), Gemma Frisius (*De usu globi*, chapter 18) and Daniel Santbechius [Daniel Santbech] (in the book *On the Observation of Phenomena*, proposition 14) direct that at the place whose longitude is unknown one take the distance of the Moon's centre from some fixed star not more than 5° distant from the ecliptic, and observe the moment of time then; and divide that distance by the hourly motion of the Moon, so as to obtain from it the moment of the conjunction of the Moon with that star, nearly true, neglecting the parallax, which they think does not appreciably hinder this business. Next they want the true place of the Moon and of the star to be found by tables fixed to some place, or meridian, so that the time may be known at which the Moon ought to be in conjunction with that star. For by comparing this time with the time of the conjunction due at the place of unknown longitude, the difference of the times indicates the difference of longitude. But Petrus Nonius (*On the Errors of Orontius*, chapter 15) rightly warns that an error of about one degree can be committed, because of the Moon's parallax in longitude; and so the visible conjunction can precede or follow the true one by two hours, to which 30° on the equator correspond, and so great an error could be committed in the difference of longitude. At the place where the Moon is observed, therefore, one must find the parallax of the Moon's longitude from the altitude of the pole and the visible altitude of the Moon, and know from the time of the observation the nonagesimal degree of the ecliptic; if the visible place of the Moon lies

between it and the ascending degree, the parallax is to be subtracted from it; if outside it, added, so as to obtain the true place and the true distance of the Moon from the fixed star. But Nonius adds that if, all things computed, an error of 15 minutes is committed in the Moon's motion, one can go wrong by 7½° in the distance of the meridians.

115. Probl. Diſtantiam Meridianorum tentare Methodo Hieronymi Ruſcelli. *Problem 115. To try for the distance of the meridians by the method of Hieronymus Ruscellus.*

[Margin: Problem 115.]

Hieronymus Ruscellus [Girolamo Ruscelli], on Book 1 of Ptolemy's *Geography*, chapter 4, attempts to investigate the longitude of places by means of an instrument that shows the positions of the Moon with respect to any fixed star, toward one of the 32 quarters of the winds marked on the horizon; and, the moment of time being taken then, he orders it to be computed at what time the Moon ought to have had such a position with respect to a meridian of known longitude, so that from the difference of the times there may be derived

[Margin: Order of the problems.]

[Margin: Order of the problems.]

the difference of longitude of the places. But besides omitting the parallax, he also errs in teaching that the instrument should be set on the meridian line as indicated by the magnetic needle alone, since the needle usually declines from the position of the meridian. And Maginus, on that chapter 4, concludes that all these ways are slippery, and that a slight error is easily committed which nevertheless produces a great deception in the longitude.

116. Probl. Diſtantiam Meridianorum inueſtigare methodo Longomontani & Kepleri, ſed corrigenda. *Problem 116. To investigate the distance of the meridians by the method of Longomontanus and Kepler — but a method that needs correcting.*

[Margin: Problem 116.]

Longomontanus in the *Astronomia Danica* (Book 1 of the *Theorics*, at the end of chapter 9) teaches this method more fully, and Kepler in the *Rudolphine Tables* (precept 61) more briefly. *First*: by the problem given in our Book 4, chapter 4, problem 8, find the moment of time at which, on the day of the observation to be made, the Moon will be in the nonagesimal. But this method supposes the longitude of the place known; so proceed otherwise. If the Moon is nearly on the ecliptic, wait for the moment at which both horns of the Moon appear on the same vertical circle; or, if the Moon is full, await the moment at which the lunar spots have exactly the same situation with respect to the vertical circle as you know, from a particular observation and from rules about this situation, they must have in the nonagesimal; or, if the Moon is at the beginning of Cancer or of Capricorn, wait until its centre is on the meridian — for by all these signs the Moon will be in the nonagesimal. At that moment

take the altitude of a fixed star, so as to know the moment of time from it by Problem 25 of Section 3; and at the same time observe the distance of the Moon's centre from some fixed star placed near the ecliptic.

[Margin: First step.]

Second: for that moment of time, gather from the most correct astronomical tables possible the true longitude of the Moon with respect to the meridian to which the roots of the tables are fixed, and the longitude of the fixed star already mentioned. When the smaller is subtracted from the greater, the difference of longitude will remain, and so very nearly the distance between the Moon and the fixed star (since the star chosen is one nearest the ecliptic, and the situation in the nonagesimal excludes all parallax of longitude).

[Margin: Second step.]

Third: divide this difference by the true hourly motion of the Moon, which you will easily gather from the daily motion in the ephemerides, or by the tables of the secondary movables; and the hours and minutes corresponding proportionally to that difference will come out. Convert them into parts of the equator, and you will have the distance of the meridians. The meridian of the observation will be more easterly than the meridian of the tables if the distance of the Moon from the fixed star is found smaller by the tables than by observation, and more westerly if it is greater. Longomontanus then adds 15 of the more notable stars nearer the ecliptic, with their latitude and longitude for the completed year 1620; the construction of a radius or astronomical staff suited to taking small distances between the Moon and the stars; and finally an example, which is as follows.

[Margin: Third step.]

EXEMPLVM. *Example.*

In the year 1617 October 6, Old Style, let the distance of the Moon's centre from Aldebaran have been observed as 10°, when the Moon was in the nonagesimal; and from the altitude of the stars and the altitude of the pole let that moment have been 11^h *after noon at the place of unknown longitude. For that moment the Danish tables give the place of Aldebaran in* ♊ *4° 26′, and the place of the Moon, with respect to the meridian of Copenhagen, in* ♉ *27° 20′. The difference of these places on the ecliptic is 7° 6′, and very nearly so great a distance of the Moon from Aldebaran ought to be observed if the place of observation were under the meridian of Copenhagen; but it was observed as 10°. The distances therefore differ by 2° 54′. Now on that day the daily motion of the Moon is 14° 41′ and the hourly 31′ 44″. Say therefore: if 31′ 44″ require 1 hour, how many hours do 2° 54′, or 174′, require? Surely* $4^h\ 45^m$*, that is, 71° 15′ of the equator. By just as many degrees, 71° 15′, then, the place of observation is more easterly than Copenhagen, because the observed distance is greater than the one deduced from the Copenhagen tables. Hence, if the longitude of Copenhagen from the Fortunate Isles is, as Longomontanus supposes, 36° 40′, it follows that the longitude of the place of observation is 107° 55′.*

117. Probl. Longomontani Methodum præcedentem Corrigere. *Problem 117. To correct the preceding method of Longomontanus.*

[Margin: Problem 117.]

The method already described is faulty, because — owing both to the true latitude of the fixed star and to the visible latitude of the Moon, altered by the parallax of altitude — the observed ecliptic distance can be notably smaller than the true one; especially since, among the 15 stars that Longomontanus proposes for use, he puts the bright star of Aries, whose northern latitude is, for him, 9° 57′; Aldebaran, whose southern latitude is 5° 31′; and the lower head of the Twins, whose northern latitude is 6° 38′. To correct this method, then, at the moment when one observer takes the visible distance of the Moon from the star, and a second the altitude of the same star, or of another suitable for drawing out the moment of time, a third must take the visible altitude of the Moon's centre when it stands in the nonagesimal. With these acquired: *first*, let everything be carried out as in the preceding problem; and, the time being equated according to the supposed difference of the meridians, let the true latitude of the Moon be sought by astronomical tables or ephemerides, together with the parallax of altitude corresponding to the observed altitude. Let this parallax be added to a true southern latitude, or subtracted from a northern one that is nevertheless greater than the parallax, and the visible latitude of the Moon will be had, of the same kind as the true latitude. But if the parallax of altitude is greater than the northern latitude, their difference will be the Moon's visible southern latitude. I speak, however, of an observer who is on this side of the ecliptic, toward the north; for if beyond it, the names of northern latitude must be changed into southern, and so on.

[Margin: First step.]

Second: from the given latitude of the fixed star and its visible distance, and from the visible latitude of the Moon, gather by Problem 102 of Section 2 the angle at the pole of the ecliptic, that is, the difference of longitude, or the ecliptic distance of the Moon from the fixed star; and use this difference in the same way as you used it in Problem 116. In this way you will obtain a more accurate distance of the meridians.

[Margin: Second step.]

EXEMPLVM Præcedens correctum. *Example: the preceding one corrected.*

In the case of the preceding problem, let the altitude of the Moon, standing in the nonagesimal, have been observed as 40°. Since in that year 1617, on October 6, or on the 16th by the New Style, at 11^h after noon at Copenhagen the true latitude of the Moon was northern, 4° 45′, and was decreasing, and since the place of observation was found more easterly by 4^h 45^m, the true latitude at the place of observation was certainly only 4° 42′. The Moon was then about 128° distant from the apogee; therefore the parallax of altitude (which, when the Moon is in the nonagesimal, is the same as the parallax of latitude) corresponding to the observed altitude of 40° is 47′ 58″, or 48′. When these are taken from the Moon's true latitude of 4° 42′, the visible northern

latitude of the Moon remains 3° 54′, and its complement to the quadrant is 86° 6′. At the same time the latitude of Aldebaran was southern, 5° 31′, and its visible distance from the Moon's centre was 10°. Therefore, in the following figure, let semicircles of latitude be drawn from the poles of the ecliptic P and Q, one, PDQ, through the centre of the Moon D, and the other, PRQ, through the centre of Aldebaran R.

Diagram. Set in the right column, beside the short lines of the example. Two curved arcs (the semicircles of latitude) join P at the top and Q at the bottom in a lens shape. On the left arc stand D and, below it, A; on the right arc M above, B in the middle and R below. A straight line runs from A across to B (the ecliptic arc AB); straight lines run from D to M and from D down toward R.

- P (top): the pole of the ecliptic
- M (right arc, upper)
- D (left arc): the centre of the Moon
- A (left arc, below D): on the ecliptic
- B (right arc): on the ecliptic
- R (right arc, lower): the centre of Aldebaran
- Q (bottom): the other pole of the ecliptic

Since in the triangle DPR there are given DR, the distance, 10°; DP, the complement of the Moon's visible latitude, 86° 6′; and PR, 95° 31′ (the quadrant PB being added, of course, to the star's latitude BR), the angle P is found by [proposition] 14 of oblique-angled spherical triangles to be 3° 23′. So great, then, is AB, namely the ecliptic distance of the Moon from Aldebaran — and not 2° 54′, as Longomontanus thought. Therefore, since the hourly motion of the Moon was 31′ 44″, surely $6^h\ 20^m$ are due to 3° 23′, to which 95° on the equator correspond, and not 71° 15′. Longomontanus therefore erred by

[Margin: A notable error of Longomontanus.]

[Margin: Order of the problems.]

23° 45′ in the distance of these meridians, through neglecting to take the latitudes into account.

118. & 119. Probl. Meridianorum Diſtãtiam Methodo Io. Bapt. Morini inquirere, ſed fallaciter. *Problems 118 and 119. To seek the distance of the meridians by the method of Jean-Baptiste Morin — but deceptively.*

Jean-Baptiste Morin, Royal Mathematician at Paris, in 1634 put his method before judges delegated for the purpose, and set it down in a book entitled *On the Science of Longitudes*, resting for the most part on the methods of Orontius and Werner. Among those judges was Pierre Hérigone, who declared, with the others, that these ways were useless for navigation. He reports and refutes them in volume 4 of the *Cursus Mathematicus*, at the end of the *Histiodromia*, that is, from page 489 on, and in volume 5, at the end, from page 862 on. The chief of them are two.

The first is as follows. In the semicircle of the meridian AEB, under which the place of unknown longitude lies, let a fixed star, say C, be observed crossing the

meridian together with the Moon's centre D. For once the right ascension of the star is given or found, the same will be the right ascension of the midheaven, and of the centre of the Moon as well. At the same moment let the meridian altitude AD of the Moon be observed; and from this and the altitude of the pole BF let the declination of the Moon be gathered by Problem 3 of Section 2. With this and with the right ascension of the Moon, let the place of the Moon in the zodiac be sought by Problem 48 of Section 2. From this, look up in the ephemerides the hour with respect to the place to whose meridian the ephemerides are computed, and the degree of the zodiac in which the Sun stands at the time of the observation, and so, through this degree, the right ascension of the Sun. Compared with the right ascension of the midheaven mentioned above, it will give the hour at the place of observation; and from the difference of the two times, the difference of geographical longitude between the place of observation and the place of the tables or ephemerides will become known.

[Margin: Problem 118.]

Diagram. Set in the left column beside the first way. A semicircle (the meridian) on a straight base. E stands at the top, D at the upper left, C at the left beside a small dot, F at the right on the arc, G inside above the base, A at the lower left end of the base and B at the lower right. A straight line runs from G up to the arc near E, and another from G toward F.

- E (top of the arc)
- D (upper left): the Moon's centre
- C (left, with a dot): the fixed star
- F (right, on the arc)
- G (inside, above the base)
- A (lower left end of the base)
- B (lower right end of the base)

The second way is as follows. Let the altitude of the pole FB be given; and while the Moon D crosses the meridian ADB, let the altitude of a star G be observed, beyond the hazard of sensible refractions. For given the complement of the altitude GE, and the complement of the pole's altitude FE, and the arc FG known from the declination of the star, the angle GFE in the triangle EFG will become known by [proposition] 14 of oblique-angled spherical triangles. It is to be subtracted from the right ascension of the star G if the star is eastern, or added if it is western, so that the right ascension of the midheaven is had. The rest, then, is carried out as in the first way.

[Margin: Problem 119.]

But in these and other ways Morin errs: he uses the declination of the Moon deduced from the observed altitude as if it were the true one, when it is the visible one and subject to a notable parallax, which pours a conspicuous error into the distance of the meridians.

120. Probl. Diſtantiam Meridianorum inueſtigare Methodo Herigonij, & ea occaſione Declinationem Lunæ inuenire. *Problem 120. To investigate the distance of the meridians by the method of Hérigone, and on that occasion to find the declination of the Moon.*

Hérigone, in volume 4 of the *Cursus Mathematicus*, in the *Histiodromia*, proposition 23, page 486, sets out this lemma first. Let AI be a portion of the equator, AF of the ecliptic, and DEC of the Moon's path; let the Moon be at C, and let its circle of declination be IC.

[Margin: Problem 120.]

Diagram. Set in the left column beside the lemma of Problem 120. A stands at the upper left with the sign of Aries beside it, and C at the upper right. Two curves sag from the region of A to C and cross near the bottom middle, where the sign of the ascending node stands above the crossing and E below it. D at the left and F at the right lie on a nearly horizontal line through E. I is the bottom point, where straight lines from A and from C meet.

- A ♈ (upper left): the beginning of Aries
- C (upper right): the Moon
- ☊ (above the crossing): the ascending node
- D (left)
- E (below the crossing)
- F (right)
- I (bottom point)

First, then, in the triangle AFI, right-angled at I, from the obliquity of the ecliptic, that is, the angle IAF, and from the right ascension of the Moon AI, let the angle IFA, the side IF and the base AF be investigated by [propositions] 8, 7 and 9 of right-angled spherical triangles.

[Margin: First step.]

Second: from the base AF let there be subtracted the longitude of the Dragon's Head ☊ from the beginning of Aries, which is AE, and EF will be left known. For in the triangle CEF — in which the angle CEF, that is, the greatest latitude of the Moon, is in addition supposed given, and the angle EFC, the supplement of the IFA found to two right angles — the base will be given together with the adjacent angles. Therefore by [proposition] 11 or 12 of oblique spherical triangles seek the side CF; joined to the side IF, it will give the true declination of the Moon. Let the rest be done as in Problems 118 and 119. But the place at which the Moon is observed in the meridian must be known, so that there is no error in its longitude greater than 15 or 20 degrees, in order that the calculation of the longitude of the node ☊ and of the right ascension of the Moon can be transferred to it from the meridian to which the tables are fixed. With this assumed, no error is to be feared in the place of the node greater than 8″ or 10″, nor in the declination of the Moon greater than 43″ or 45″. Hérigone admits, however, at page 495, that this method of his has hardly any use in navigation, and that it is better to have recourse to loxodromic tables; and at page 496 he affirms that, owing to the diversity of the hypotheses of the best astronomers,

the place of the Moon is not so certain that an error of 18′ is plainly avoided — and from that an error of more than 8 degrees can overflow into the distance of the meridians.

[Margin: Second step.]

Monitum de Reliquis Modis inquirendi Diſtantiam Meridianorum. *A caution on the remaining ways of seeking the distance of the meridians.*

The remaining ways I have not thought fit to copy here from my Geographical Book, as being less certain — especially those which rest on the declination of the magnetic needle, and on the ship's course while the ship follows the guidance of the magnetic needle, granted that this latter is more certain than the former. For here we pursue only those problems that can serve astronomy; but the inquiry into longitude that pilots hunt by histiodromy and by loxodromic lines and angles can hardly serve astronomy, because they are often at sea away from islands and mainlands, or in places unsuited to astronomical observations. If anyone nevertheless wants this method, let him have recourse to Problem 102. For pilots, by observing the lines of the rhumbs and the angles made by them with the meridian line, and correcting these according to the declination of the magnetic needle, acquire the angles of position from one place to the other; and with the altitudes of the pole taken at both places, they find the difference of longitude. I hear also that Doctor Io. Marci [Jan Marek Marci] has published at Prague a little work on finding the difference of longitude by the true motion of the Moon, a truly learned one; but since I do not have that little work at hand, I am forced to go without so great a fruit, and cannot communicate it to my reader — just as I cannot communicate the ways that Robertus Dudlæus [Robert Dudley] likewise hands down by means of the Moon in *De arcanis maris*, Book 1, chapters 5 and 6, a book I was allowed to see only in haste.

Probl. 121. 122. 123. 124. 125. Dato temporis Momento, definire, Vbi tunc meridies, vbi media nox; Vbi dies, vbi nox ſit, intra Zonas ſaltem Temperatas & Torridam; & Quibus oriatur tunc Sol, quibus occidat; & Quota ſit hora cuiuſuis ſpeciei in quouis loco dato, ac viciſſim In quo loco terrarum ſint tales ac tot horæ & minutiæ horarum. *Problems 121, 122, 123, 124, 125. Given a moment of time, to determine where it is then noon and where midnight; where it is day and where night, at least within the temperate zones and the torrid; for whom the Sun is then rising and for whom it is setting; and what hour of any kind it is in any given place; and conversely, in what place on Earth there are such and so many hours and minutes of hours.*

[Margin: Problems 121, 122, 123, 124, 125.]

All these and other problems are solved by our Geographical Cross, which we published at Bologna in 1643, and which we shall publish again, God willing, in our Geographical Book, which will be the fourth of volume 2.

[Margin: Order of the problems.]

SECTIO QVINTA DE PARALLAXIBVS.

Section Five. On Parallaxes.

Although in the earlier books the occasion — indeed the necessity — of treating parallaxes presented itself more than once, it was nevertheless not proper to work through there everything that bears on the completeness of this doctrine. I therefore decided to set up this special Section on parallaxes, in which, discussing all the kinds of parallax in order, I would point out what we have already explained, and pursue the rest, which has been more advisedly put off to this place. This the more so because I have seen not a few things omitted by other authors: for most of them treated parallaxes only on the occasion of eclipses of the Sun, or of the Moon's distance from the Earth. I have listed their names in Book 5, chapter 10, number 1.

[Margin: Authors who have written on parallaxes.]

CAPVT I.

Chapter I.

De Parallaxi Altitudinis vel Diſtantiæ à Vertice in Communi. *On the parallax of altitude, or of distance from the vertex, in general.*

What the parallax of altitude, or of distance from the vertex, is, I taught in Book 1, chapter 35, adding five rules, or axioms, pertaining to this kind; and in its Scholium 3 I demonstrated which angle is the parallactic angle of altitude, that is, the angle that measures the quantity of this parallax at least indirectly, or by equivalence. That was as much as was then sufficient for the apprenticeship of the reader, who was to be grounded in that book in certain common principles and properties of the sphere. Afterwards, in Book 5, chapter 10, on the occasion of solar eclipses, I handed down to the reader, by then more advanced in astronomy, not only the definitions of this parallax, and what the true and the visible place of a star is, and what the true and the visible altitude and distance from the vertex are, but also other definitions, and selected theorems and problems bearing on the parallaxes that serve eclipses of the Sun. Lastly, in Book 8, Section 1, chapter 17, since the parallaxes of comets had to be dealt with, and since in a treatment in itself quite intricate and varied we did not want readers to have to beg this doctrine from elsewhere, we set out first the definitions of all the kinds of parallax and the more notable axioms of parallaxes; and in the same chapter, number 2, we explained what the parallax of altitude is formally, and what it is taken equivalently, that is, which angles are the measure of parallaxes, or equivalent to that measure. From the places already mentioned, then, taken together, and from what is to be said here, especially in chapter 12, let the reader seek this doctrine whole, just as if it had all been copied into this chapter.

I add, however, that Regiomontanus, in Problem 1 of *De cometis*, and Chiaramonti, in Book 1, chapter 1 of the *Antitycho*, and some others, are accustomed to draw from the centre of the Earth a line parallel to the line of the visible

place, and to use the arc of the Firmament intercepted between this parallel and the line of the true place as the parallax of altitude — understand it equivalently, as I set out in the same Book 8, Section 1, chapter 17, number 2, with a diagram suited to the purpose. Moreover, when the visible place or the visible altitude is distinguished from the true place or the true altitude, refraction is not considered in this Section — refraction, which can use up the whole parallax or diminish it — but parallax alone, by itself. For what happens to these through the mixture or concurrence of parallax with refraction must be told in the following Section.

CAPVT II.

Chapter II.

In quo Problemata ad Parallaxim Altitudinis ſpectantia. *In which are the problems bearing on the parallax of altitude.*

Since the altitude of a star is the complement of its distance from the vertex, and the distance from the vertex is the complement of the altitude to the quadrant, that is, to 90°, it is enough to give the problems bearing on altitude; for from these, what pertains to the distance from the vertex at once becomes known.

1. Probl. Diſtantiam Sideris à centro Terræ inuenire, Data Parallaxi Horizontali. *Problem 1. To find the distance of a star from the centre of the Earth, given the horizontal parallax.*

[Margin: Problem 1.]

In the following diagram, let BH be a quadrant of a great circle of the Earth, described from the Earth's centre A, under the quadrant KG of the vertical circle, which is to be conceived in the heaven of the star. In it let the star appear at L to the eye at B, placed on the surface of the Earth's convexity, along the straight line BL of the physical horizon, parallel to the astronomical horizon AG; on these let the vertical line ABK fall perpendicularly, tending toward the zenith of the observer B; and let the straight line AL be drawn from the Earth's centre to the centre of the star. Then in the triangle ABL, right-angled at B by construction and by the property of a perpendicular line, the angle L, the horizontal parallax of altitude, is given. With it, and with the opposite side, that is, the Earth's semidiameter AB, taken as unity, seek the base AL by [proposition] 6 of right-angled plane triangles — that is, the distance of the star from the Earth's centre — and it will be known in terrestrial semidiameters, that is, in parts of which the Earth's semidiameter is one. In this way, from the Moon's horizontal parallaxes, we drew out its varying distance from the Earth's centre in Book 4, chapter 14, with another diagram set out first in chapter 13.

Diagram. Set in the right column beside the construction of Problem 1. A quadrant arc runs from G at the lower left up through L and C to D near the top; a vertical straight line runs from A at the bottom right up through B to K

at the top; a horizontal base runs from G through H to A. A smaller arc about A passes through B toward H. Straight lines run down toward A from C, L and B, and lines from B fan out to E, I and F, at the right of B and below it.

- D (top of the arc)
- K (top of the vertical line): toward the zenith
- C (on the arc, upper left)
- B (on the vertical line): the observer's eye
- L (on the arc, left): the star's apparent place
- E (right of B)
- I (below E)
- F (below I)
- G (lower left end of the arc and base)
- H (on the base)
- A (bottom right): the Earth's centre

2. Probl. Parallaxin Sideris Horizontalem inueſtigare, Data eius diſtantia à centro Terræ in partibus, qualium Semidiameter terræ eſt vna. *Problem 2. To investigate the horizontal parallax of a star, given its distance from the centre of the Earth in parts of which the Earth's semidiameter is one.*

[Margin: Problem 2.]

In the preceding triangle ABL, right-angled at B, given the base AL, that is, the distance of the star in parts of which AB is one, you will certainly be able to investigate the opposite angle ALB, namely the horizontal parallax of the star, by [proposition] 2 of right-angled plane triangles. By this reasoning, in Book 3, chapter 8, we obtained the horizontal parallaxes of the Sun, taking its greatest, least and mean distance from the Earth's centre from various astronomers; and we did the same for the five lesser planets in Book 7, Section 6, chapter 7. Let the reader go there, then, if he wants an example; for there is no leisure to linger here — as there is none in the following problems either, which we did not wish to omit here, so that the whole doctrine of parallaxes might be had collected together, but which we ought not to treat anew, only point to as worked through elsewhere.

[Margin: Order of the problems.]

3. & 4. Probl. Parallaxim Datæ altitudini Veræ aut Viſæ conuenientem inuenire, Data Sideris diſtantia à Centro Terræ in ſemidiam. terræ. Vbi de Tabularum geminarum Auctoribus ſtructura & Vſu. *Problems 3 and 4. To find the parallax corresponding to a given true or visible altitude, given the star's distance from the centre of the Earth in semidiameters of the Earth. Where the twin tables are treated: their authors, construction and use.*

[Margin: Problem 3.]

In the preceding figure let the star be at C, AC its distance from the centre of the Earth, and CB its distance from the eye of the observer B. For in the triangle ABC there are given AB, namely one semidiameter of the Earth, and AC, the

distance of the star in terrestrial semidiameters. *First*, then, if the true altitude GC of the star is given, which the angle GAC measures, then by subtracting it from 90° the angle CAB will be known, contained by the known sides AB and AC; therefore by [proposition] 3 of oblique-angled plane triangles the angle ACB will become known, that is, the parallax corresponding to the given true altitude. By this device the table of parallaxes of the true altitude is constructed. These parallaxes are to be used when you wish to convert the true altitude of a star, known from astronomical calculation, into the visible altitude, that is, the altitude apparent to the eye at B, by taking the parallax away from the true altitude. Such is the table of parallaxes of the Sun and Moon given by Ptolemy in Book 5, chapter 18; by Copernicus in Book 4, chapter 24; by Reinhold in the *Prutenic Tables*, page 120; by Maginus in the *Secunda Mobilia*, page 678, and in the *Supplement to the Ephemerides*, pages 59 and 293; by Tycho in volume 1 of the *Progymnasmata*, pages 80 and 120; by Longomontanus in the *Astronomia Danica*, Book 1 of the *Theorics*, chapter 8; by Giuseppe Moletti in his Tables, page 82; by Mulerius in the *Frisian Tables*, page 421; by Kepler in the *Rudolphine Tables*, page 98; by Reinerus [Vincenzo Renieri] in the *New Medicean Tables*, pages 311 and 364; by Lansbergen in his tables, from page 46; by Pétau in Book 8 of *De doctrina temporum*, page 737; by Boulliau in the *Philolaic Tables*, page 138; and by Wendelen in the *Idea Tabularum Atlanticarum*, page 34.

[Margin: First case: for the true altitude.]

[Margin: Authors of these tables.]

Second, let the visible altitude LBC be given. Added to 90°, it makes the angle ABC; with this, and with the sides AB and AC given as above, you will find by the first [proposition] of oblique-angled plane triangles the parallactic angle ACB, that is, the parallax corresponding to the visible altitude. The same can, however, be found by right-angled triangles, producing the side CB to E, until the perpendicular AE from A meets it. For in the triangle ABE, right-angled at E, given the semidiameter of the Earth as one, and the angle ABE, that is, CBK, which is the complement of the visible altitude, you will find the side AE by the first [proposition] of right-angled plane triangles. Then in the triangle ACE, right-angled at E, from the side AE now found and the given distance AC, you will seek the parallax ACE corresponding to the visible altitude. In this way the second table of parallaxes of altitude is constructed, which is to be used when the visible altitude is to be converted into the true one, by adding the parallax to the visible altitude. A table constructed for true altitudes can, however, serve for visible ones, if you keep our precept handed down in Book 3, chapter 8, number 7.

[Margin: Second case: for the visible altitude.]

[Margin: Problem 4.]

5. & 6. Probl. Diſtantiam Sideris inquirere, Data Altitudine ipſius vera aut viſa, cum Parallaxi altitudinis. *Problems 5 and 6. To seek the distance of a star, given its true or visible altitude together with the parallax of altitude.*

[Margin: Problem 5.]

In the triangle ABC of the preceding figure, if the true altitude is given, its complement is the angle CAB. With this, and with the angle C of the parallax, and so with the remainder to two right angles, ABC, and with the semidiameter of the Earth AB as one, seek the distance of the star AC by [proposition] 1 of oblique plane triangles. But if the visible altitude CBL is given, add it to 90°, and the angle ABC will result; with this, and with the parallactic angle C, and with the semidiameter of the Earth AB as one, seek the distance AC.

[Margin: Problem 6.]

7. & 8 Probl. Data Parallaxi Horizontali, inuenire Parallaxim cuiuis altitudini viſæ conuenientem, & viciſſim Data Parallaxi conueniente altitudini viſæ; inuenire Parallaxim Horizontalem. *Problems 7 and 8. Given the horizontal parallax, to find the parallax corresponding to any visible altitude; and conversely, given the parallax corresponding to a visible altitude, to find the horizontal parallax.*

[Margin: Problem 7.]

First: if the horizontal parallax is given, even if the distance of the star from the Earth is not known, let the proportion be made: as the radius, or whole sine, is to the sine of the horizontal parallax, so is the second sine of the given visible altitude to the sine of the parallax corresponding to that altitude.

Second: if the parallax corresponding to a given visible altitude is given, let the proportion be made: as the second sine of the given altitude is to the given parallax, so is the radius to the horizontal parallax. These problems are very useful for the parallaxes of the five lesser planets, for which tables are not usually constructed, except perhaps of the horizontal parallaxes, as we did in Book 7, Section 6, chapter 7.

[Margin: Problem 8.]

[Margin: Note for the parallaxes of the five planets.]

The reason for these problems is this. In the preceding figure LB falls perpendicularly on AB, and CE on AE, by construction; therefore AB comes out as the right sine of the horizontal parallax L, and AE as the right sine of the parallax ACE, while the bases subtending the right angles, namely AL and AC, come out as the radius, or whole sine — as is plain from the definitions of sines. Thus in the triangle ABE, if AB is the radius, AE will be the right sine of the angle ABE, that is, of its vertically opposite angle CBK, which is the complement of the visible altitude. With these laid down, there arises a lemma that is the foundation of Problems 7 and 8. For I say, with our Cysatus [Johann Baptist Cysat], *De cometis*, chapter 3, lemma 4: *As AB, the whole sine of the right angle AEB, is to the same AB, the right sine of the horizontal parallax ALB, so is AE, the sine of the angle ABE, the complement of the visible altitude, to the same AE, the sine of the parallax ACB; and conversely.* This lemma is founded on [proposition] 4 of Book 6 of Euclid's *Elements*, since the triangle ABE is considered in two ways: first, as the side AB in it is the whole sine and the side AE the right sine

of the angle ABE; second, as AE is the right sine of the parallax C, and AB in turn the sine of the horizontal parallax L. In fact, therefore, there are two equiangular triangles, having as homologous those sides that are subtended by equal angles.

[Margin: Lemma on which Problems 7 and 8 are founded.]

Diagram. Set in the right column beside the proof of the lemma; the same construction as the figure on p. 641. A quadrant arc runs from G at the lower left up through L and C to D near the top; a vertical line runs from A at the bottom right through B to K; the base runs from G through H to A; a smaller arc stands about A. Straight lines run down toward A from C, L and B, and lines from B fan out to E, I and F.

- D (top of the arc)
- K (top of the vertical line)
- C (on the arc, upper left): the star
- B (on the vertical line): the observer's eye
- L (on the arc, left)
- E (right of B): the foot of the perpendicular AE on CB produced
- I (below E)
- F (below I)
- G (lower left end of the arc and base)
- H (on the base)
- A (bottom right): the Earth's centre

9. Probl. Data Parallaxi conueniente vni Altitudini Viſæ minori, inuenire Parallaxin conuenientẽ alteri viſæ Altit.datamaiori. *Problem 9. Given the parallax corresponding to one smaller visible altitude, to find the parallax corresponding to another, greater, given visible altitude.*

[Margin: Problem 9.]

Let the proportion be made: as the second sine of the smaller altitude is to the second sine of the greater altitude, so is the right sine of the parallax corresponding to the smaller altitude to the right sine of the parallax corresponding to the greater visible altitude. For as Snel demonstrated in *De cometa anni 1618*, chapter 4, page 26; Chiaramonti in Book 3 of *De novis stellis*, chapter 19, and in the supplement to the *Antitycho*, part 2, chapter 35; and our Cysat in *De cometis*, chapter 3, lemma 5: *As the second sine of the smaller visible altitude is to the second sine of the greater, so is the sine of the parallax at the smaller visible altitude to the sine of the parallax at the greater.* For by proposition 1 of Clavius's rectilinear triangles, in these triangles the sines of the angles opposite the sides are to one another as side is to side, and so on.

[Margin: Lemma for Problem 9.]

10. Probl. Datis duabus Parallaxibus duarum Altitudinum Viſarum, inquirere Parallaxin Horizontalem. *Problem 10. Given two parallaxes of two visible altitudes, to seek the horizontal parallax.*

[Margin: Problem 10.]

First, subtract each of the visible altitudes from 90°; for the visible distances from the vertex will be left, and for these seek their right sines separately. Likewise, for the given parallaxes seek their right sines one by one. *Second*: let the proportion be made: as the difference of the sines corresponding to the visible distances from the vertex is to the difference of the sines corresponding to the parallaxes, so is the whole sine to the sine of the horizontal parallax. This practice rests on the second part of lemma 5, demonstrated by Cysat in *De cometis*, chapter 3; that part runs as follows: *As the difference of the sines of the complements of the star's visible altitudes is to the difference of the sines of the parallaxes, so is the whole sine to the sine of the greatest, or horizontal, parallax.*

[Margin: Order of the problems.]

11. Probl. Data Differentia duarum Parallaxium, cum proportione quam habent earum Sinus; vtramq. Parallaxim ſingillatim notam facere. *Problem 11. Given the difference of two parallaxes, together with the ratio that their sines have, to make each parallax known individually.*

[Margin: Problem 11.]

Let the proportion be made: as half the difference of the terms of the given ratio is to the tangent of half the difference of the parallaxes, so is the sum made up of half the difference of the terms of the ratio and the consequent term of the same ratio to the tangent of the angle that is to be added to half the difference of the parallaxes, so that the greater parallax becomes known, or to be subtracted, so that the smaller becomes known. See Clavius, proposition 7 on rectilinear triangles, and Cysat, *De cometis*, chapter 3, lemma 6. How the difference of parallax is to be understood will be stated below, on another occasion, in chapter 9.

12. Probl. Data Differentia duarum ignotarum Parallaxium altitudinis, & duabus Altitudinibus, ex quibus illa eſt obſeruata, reperire ſingillatim vtramq. Parallaxim, ſingulæ altitudini viſæ debitam. *Problem 12. Given the difference of two unknown parallaxes of altitude, and the two altitudes from which it was observed, to find each parallax individually, the one owed to each visible altitude.*

[Margin: Problem 12.]

First, seek the sines of the complements of the given altitudes to the quadrant, that is, of the visible distances from the vertex. Add these into a sum and take half of the sum; from this half subtract either of the sines, and the difference between that sine and the half-sum of the sines will remain. *Second*, let the proportion be made: as the difference between either sine and the half-sum of the sines is to the half-sum of the sines, so is the tangent of half the difference of the parallaxes to the tangent of half the sum of the parallaxes. If to this half-sum you add half the difference of the parallaxes, the greater parallax will result, owed to the smaller altitude; if you subtract it, the smaller parallax will result, owed to the greater visible altitude. For the theory of this problem see

Snel, *De cometa anni 1618*, chapter 4, and Chiaramonti, *De stellis novis*, Book 3, proposition 2.

13. Probl. Data Summa duarum Parallaxium ſingillatim ignotarum, & duabus Altitudinibus viſis, ex quibus ſumma illa fuit obſeruata, reperire vtramq. Parallaxim altitudinis ſingillatim. *Problem 13. Given the sum of two parallaxes that are individually unknown, and the two visible altitudes from which that sum was observed, to find each parallax of altitude individually.*

[Margin: Problem 13.]

Let the proportion be made: as the half-sum of the second sines corresponding to the altitudes is to the difference between either of these sines and their half-sum, so is the tangent of half the sum of the parallaxes to the tangent of half the difference of the parallaxes — which is to be added to their half-sum if you want the greater parallax, or subtracted if you want the smaller. This practice rests on the proposition demonstrated by the authors cited above, if its terms are converted.

14. Probl. Parallaxim Altitudinis Lunæ à Sole inquirere. *Problem 14. To seek the parallax of altitude of the Moon from the Sun.*

[Margin: Problem 14.]

Subtract the parallax of altitude of the Moon from the parallax of altitude of the Sun when the Sun stands at the same altitude as the Moon, and the parallax of the Moon from the Sun will be left.

15. Probl. Parallaxim Altitudinis Phænomeni inueſtigare, Datis Latitudine ac Longitudine ipſius obſeruata eodem momento in duobus terræ locis; quorum nota ſit altitudo Poli & diſtantia Meridianorum; Dato inſuper Momento temporis, & Eclipticæ puncto Culminante in vtroq. Meridiano, & Obliquitate Eclipticæ. *Problem 15. To investigate the parallax of altitude of a phenomenon, given its latitude and longitude observed at the same moment in two places on the Earth whose pole altitude and distance of meridians are known; given, moreover, the moment of time, the point of the ecliptic culminating in each meridian, and the obliquity of the ecliptic.*

[Margin: Problem 15.]

I have already given this problem, with its example, in Book 8, Section 1, chapter 19, numbers 11, 12 and 13. We owe this problem, however, to Scipione Chiaramonti.

16. Probl. Altitudinis Parallaxim inueſtigare, Datis Phænomeni ab eadem Fixa ſtella Diſtantijs viſis eodem momento temporis, ex duobus locis terræ, quorum nota ſit altitudo poli, ac diſtantia Meridianorum, & Momento temporis, cum Declinatione atq. Aſcenſione Recta ſtellæ Fixæ. *Problem 16. To investigate the parallax of altitude, given the visible distances of a phenomenon*

from the same fixed star at the same moment of time, from two places on the Earth whose pole altitude and distance of meridians are known, and given the moment of time, together with the declination and right ascension of the fixed star.

[Margin: Problem 16.]

This problem likewise was proposed by Father Francesco Maria Grimaldi while we were discussing the comet of the year 1618, and was solved by him at once; I have already set it out in Book 8, Section 1, chapter 22, number 25.

Monitum de Reliquis ad hoc caput ſpectantibus. *A notice on the remaining problems that belong to this chapter.*

The remaining problems that belong to this chapter contain ways of observing phenomena, especially new ones, and of gathering from them whether they have a parallax, or how great a one; for just reasons it seemed best to defer these to chapters 9, 10 and 11. Some also belong to chapters 6, 7, 8 and 9, insofar as the parallax of altitude can be confirmed from a given parallax of declination, of right ascension, of latitude or of longitude; but the parallax of altitude is in fact usually put first, as the foundation for investigating the remaining parallaxes.

CAPVT III.

Chapter III.

De Parallaxi Profunditatis. *On the parallax of depth [parallaxis profunditatis].*

Although this kind can be brought back to the parallax of distance from the vertex, it would not rightly be called a parallax of altitude above the horizon, since through it the star appears below the horizon, unless refraction prevents this; and distinguishing it is useful for phenomena, especially those nearer the Earth, if they are viewed from very high mountains. I should like, further, what I said about the sensible horizon, with respect to an eye raised above the Earth, in Book 1, chapter 8, scholium 2, to be read again.

17. Probl. Parallaxin Maximam Profunditatis Sideris in Horizonte Aſtronomico ſeu vero conſtituti explicare ac inuenire, Data Diſtantia Sideris à Centro Terræ. *Problem 17. To explain and find the greatest parallax of depth of a star set in the astronomical, or true, horizon, given the star's distance from the centre of the Earth.*

[Margin: Problem 17.]

In the present figure, about the Earth's centre H let the circle of the Earth be described, with its great circle AI, etc., and the vertical semicircle VRM, under which let AI, etc., lie. In this semicircle let the star be at R, a point of the astronomical, or true, horizon HR, which is parallel to the physical horizon AB; through these horizons let the vertical line VAHM be drawn at right angles. From R, the centre of the star, let the straight line RIC be drawn, touching the Earth at I and therefore making, by [proposition] 18 of Euclid's third [book], a

right angle with the semidiameter HI at the point of contact I; and parallel to RIC let HN be drawn. For CIR will be the sensible horizon with respect to the eye at C, just as AB is with respect to the eye at A, which is not raised. Lastly, just as the horizontal parallax with respect to the eye at A is the angle ABH, so with respect to the eye at C, and at I, the horizontal parallax will be the angle HRI; but with respect to the raised eye at C it is to be called the parallax of depth, not of altitude, because

Diagram. Set in the right column beside the construction of Problem 17. A semicircle runs from V at the top round the right side through B and R to M at the bottom; a smaller circle, the Earth, stands about H. A vertical line runs down the left through V, C, A, H and M. The horizontal HR runs from the Earth's centre to the star; a straight line runs from C through I to R; a line runs from A to B; a dotted line runs from A down to the right; a line runs from H down to N on the lower right.

- V (top of the vertical line and the semicircle)
- C (on the vertical line, below V): the raised eye
- A (on the vertical line, at the Earth's surface): the eye not raised
- I (right of A, on the Earth's circle): the point of contact
- B (on the semicircle, upper right): end of the physical horizon AB
- H (on the vertical line): the Earth's centre
- R (on the semicircle, right): the star
- N (on the semicircle, lower right): end of HN, drawn parallel to RIC
- M (bottom of the vertical line and the semicircle)

[Margin: Order of the problems.]

the star R will appear to the eye at C to be distant from the vertex V not only by a quadrant, as if the eye were at C and the star at B, but by more than a quadrant, by as much as the angle HRI; namely by the whole angle VCR, which by [proposition] 32 of Euclid's first [book] is equal to the two interior and opposite angles, namely the right angle CHR and the acute angle HRC. Therefore the angle R will be the amount by which the visible distance exceeds the quadrant. Further, the angle HRC is equal to the angle RHN, which measures the arc RN, because the lines CR and HN are parallel, and by [proposition] 29 of the first [book] of Euclid's *Elements*. Therefore the star will be thought to be below the horizon HR by the whole arc RN, although in reality it is supposed to be in that horizon.

Further, once the horizontal parallax has been found by Problem 2 with respect to the eye at I, which is not raised, this same will be altogether the horizontal parallax — but of depth — with respect to the raised eye at C, because the angle is identical.

18. Probl. Parallaxim Maximam Profunditatis Sideris infra Horizontem verum poſiti diſcernere atq. inuenire, Data Diſtantia Sideris à centro Terræ. *Problem 18. To distinguish and find the greatest parallax of depth of a star placed below the true horizon, given the star's distance from the centre of the Earth.*

[Margin: Problem 18.]

In the other figure, which follows, let three semicircles of vertical circles be described about the centre of the Earth: the first, BTM, on the Earth's surface; the second, AKL, in the heaven of the star; the third, FGI, in the highest heaven. Let one observer be at B, not raised at all; let his vertical line, drawn from the zenith to the nadir, be FCI, his sensible horizon BH and his rational horizon CG, each of them orthogonal to FCI. Now let the star be at S, and from its centre let the straight line STA be drawn, touching the Earth at T and making with the semidiameter CT a right angle at the point of contact T, by [proposition] 18 of Euclid's third [book]. For this same line will be the sensible horizon with respect to the raised eye at A, and along it the eye at A will first see the star S below the horizon (provided, that is, that refraction does not intervene, which we do not consider here in this section). The true depth of the star below the true horizon, however, will be the arc KS, which the angle KCS measures; but the greatest, or horizontal, parallax will be the angle CST, and it will better be called the parallax of depth. And this same will be the horizontal parallax, but of altitude, with respect to the eye at T, which is not raised, because the same line ATS is the sensible horizon for both eyes, A and T, and the triangle CTS is right-angled at T. Therefore, if the horizontal parallax is known by the problem 2 handed down in chapter 2, the greatest parallax of depth will also be known, because the parallactic angle is identical; and this, added to the true depth of the star known from elsewhere, will give the visible depth. But if one chooses to consider the places of the star in the highest heaven, its true place will be under Q, but its visible place under R; just as, if the star is at O, its true place is under P, but its place as seen from the eye at B is under H.

Diagram. Set in the left column beside the construction of Problem 18. Three concentric semicircles about C open to the right: the inner BTM (the Earth's surface), the middle AKL (the heaven of the star) and the outer FGI (the highest heaven). The vertical line F–A–B–C–M–L–I runs down the left side. A horizontal runs from C to G; a line runs from B out to H; a line runs from A through T to S; further lines run from C out to the outer arcs at the upper and lower right.

- F (top of the vertical line): on the outer semicircle FGI
- A (on the vertical line, below F): the raised eye, on the middle semicircle AKL
- B (on the vertical line, below A): the observer not raised, on the inner semicircle BTM
- C (on the vertical line): the centre of the Earth
- M (on the vertical line, below C): end of the inner semicircle BTM
- L (on the vertical line, below M): end of the middle semicircle AKL
- I (bottom of the vertical line): end of the outer semicircle FGI
- O (upper right): a position of the star
- P (upper right, beside O): the true place of a star at O in the highest heaven

- H (upper right, on the outer arc): end of the sensible horizon BH; the visible place of a star at O
- T (centre of the figure): the point of contact of STA
- K (right of T, on CG): on the middle semicircle
- G (right end of the horizontal from C): end of the rational horizon CG
- S (lower right): the star
- Q (lower right, beyond S): the true place of the star S in the highest heaven
- R (lower right, below Q): the visible place of the star S in the highest heaven

19. Probl. Data Sideris Diſtantia à centro Terræ ac Semidiametro Terræ; inuenire Altitudinem oculi neceſſariam, vt poſſit videre Sidus tunc primò, cùm erit verè in Horizonte Rationali, per radios irrefractos. *Problem 19. Given the star's distance from the centre of the Earth and the semidiameter of the Earth, to find the altitude of the eye needed for it to see the star for the first time just when the star is truly in the rational horizon, by unrefracted rays.*

[Margin: Problem 19.]

Let the figure set out in Problem 17 be repeated here. In it, seek the horizontal parallax HRI by Problem 2 of chapter 2; for this will be equal to the angle CHI. For CHR and RIH are both right angles, and equal; therefore, taking away the common angle IHR, which on the one side with IHC, and on the other with HRI, completes one of the right angles, by [proposition] 32 of Euclid's first [book], the angle CHI is left equal to the angle HRI. Then in the triangle CHI, right-angled at the point of contact I, there are given the angle CHI and the semidiameter of the Earth HI, in paces, or miles, etc., as I suppose; therefore by [proposition] 3 of right-angled plane triangles you will find the base HC. From this subtract the semidiameter of the Earth HA, and the altitude of the eye sought will be left.

20. Probl. Data Sideris Diſtantia à cẽtro Terræ, ac vera Profunditate ſub Horizonte vero, ac Semidiametro terræ, inquirere oculi Altitudinem primò viſuri ſidus per radios irrefractos. *Problem 20. Given the star's distance from the centre of the Earth, its true depth below the true horizon and the semidiameter of the Earth, to seek the altitude of an eye that is to see the star for the first time by unrefracted rays.*

[Margin: Problem 20.]

Let the figure explained in Problem 18 be repeated here. Having sought the horizontal parallax CST by Problem 2 of chapter 2, join it to the star's true depth, that is, to the angle SCK, and subtract the sum of these from 90°: the angle TCK will be left; and this in turn, subtracted from 90°, that is, from the right angle ACK, will leave the angle ACT. In brief, therefore, the angle ACT is as great as the aggregate of the star's true depth and its horizontal parallax. Therefore in the triangle ACT, right-angled at T, with the angle ACT and

the terrestrial semidiameter CT, investigate the base CA by [proposition] 3 of right-angled plane triangles; from this subtract the semidiameter CB, and the altitude of the eye sought, AB, will remain.

21. Probl. Data Oculi Altitudine ſupra terram, Semidiametro terræ ac Diſtantia Sideris à centro Terræ, Inuenire Profunditatem tum veram, tum apparentem Sideris primò ab oculo per radios irrefractos viſibilis. *Problem 21. Given the altitude of the eye above the Earth, the semidiameter of the Earth and the star's distance from the centre of the Earth, to find the depth, both true and apparent, of a star first visible to the eye by unrefracted rays.*

[Margin: Problem 21.]

In the same figure of Problem 18, and in its triangle CAT, right-angled at T, there are given CT, the semidiameter of the Earth, and CA, made up of the terrestrial semidiameter CB and the given altitude of the eye BA; with these, seek the angle CAT by [proposition] 2 of right-angled plane triangles. For its complement to 90° will be the angle ACT, which together with OCK completes the right angle BCK; therefore the angle CAT will be equal to the angle OCK. Then in the triangle CTS, right-angled at T, given CT as one semidiameter of the Earth, and the distance CS, seek the parallactic angle CST by the same [proposition] 2; and when this is taken from 90°, the remaining angle SCT, to the right angle, will be known. From it take away the angle OCK already found, and KCS will be left, measuring the true depth KS of the star below the true horizon; if you add to it the parallax CST, the visible depth below the true horizon will become known. Therefore, from first to last, the apparent depth below the true horizon is as great as the angle ACT, and so it is enough to have found that angle, in the Sun as well as in the Moon and the other stars. So that you may see, then, how great this depth could be if the unrefracted rays of a star reached our eyes, consult the small table placed in Section 4, Problem 39, where, for a given altitude of the eye up to 50 Italian miles, the visible arc of the Earth is set down, which here would be the arc BT, that is, the angle BCT; and that some mountains are 30 miles high perpendicularly is gathered from Section 4, Problem 35, Example 3. But because the star is raised in appearance by the force of refraction, it happens that the star can appear at so great a depth to an eye still less high, or that, to an eye so high, it can appear at a greater depth.

CAPVT IV.

Chapter IV.

De Parallaxi Orbis Annui. *On the parallax of the annual orb.*

Enough has been done by us on this in Book 6, chapter 7, from number 7, and again expressly in Book 9, Section 4, chapter 28, where we also pointed

out the errors of many who take only half the parallax. We therefore refer the reader there, so as not to repeat the same things here in vain.

[Margin: Order of the problems.]

CAPVT V.

Chapter V.

De Parallaxi Diſtantiæ inter duo Phænomena. *On the parallax of distance between two phenomena.*

The parallax of distance is *the difference between the apparent, or visible, distance of two phenomena and their true distance*. It arises from the parallax of altitude or of depth, either of both visible bodies or at least of one. When both phenomena are planets, or a comet appearing in the planetary heaven or below it, this parallax arises from the parallax of altitude of both. But if one of them is a fixed star, then, since the parallax of the fixed stars is commonly held by astronomers to be imperceptible, not even from it does a parallax of distance arise. For in the following scheme let the observer's vertex, or zenith, be A, and the nadir C; through these points let two semicircles of vertical circles, ABC and ADC, be drawn, enclosing the portion BD of the true horizon. And let there be two stars having equal altitude, one at H, the other at G, and let their true distance be the arc HG. For if each of them undergoes a sensible parallax of altitude, and H appears at E and G at F, their visible distance will be the arc EF, certainly greater than the true one; but if only one of them, say the star H, undergoes the parallax of altitude HE, the visible distance will be EG, likewise greater than the true one. Again, if the stars are in the true horizon, one at B, the other at D, and each undergoes a sensible parallax of depth, and the former is seen to be at K and the latter at M, the visible distance will be KM, but the true one BD; whereas if only one of them, say B, undergoes such a parallax, the visible distance will be the arc KD. From these it will not be difficult to understand the remaining cases.

Diagram. Set in the left column beside the opening of Chapter V. Two arcs, the vertical semicircles ABC and ADC, meet at the zenith A at the top and the nadir C at the bottom, forming a lens. On the left arc, from the top, stand H, E, B and K; on the right arc, from the top, G, F, D and M. Straight lines join H to G, E to G, E to F, B to D, K to D and K to M.

- A (top): the observer's zenith
- H (left arc, upper): the true place of the first star
- G (right arc, upper): the true place of the second star
- E (left arc, below H): the apparent place of H
- F (right arc, below G): the apparent place of G
- B (left arc, middle): a star in the true horizon
- D (right arc, middle): a star in the true horizon
- K (left arc, below B): the apparent place of B

- M (right arc, below D): the apparent place of D
- C (bottom): the nadir

22. 23. 24. Probl. Data Parallaxi veræ Altitudinis, aut Profunditatis, vtriuſque, aut vnius duorum Phænomenorum, & Diſtantia ipſorum vera, inuenire Diſtantiam eorumdem viſam ſeu apparentem. *Problems 22, 23 and 24. Given the parallax of the true altitude, or of the depth, of both or of one of two phenomena, and their true distance, to find their visible, or apparent, distance.*

[Margin: Problem 22.]

First: in the figure set out above, let each star, H and G, undergo a parallax of altitude. Therefore in the triangle HAG seek the angle A by [proposition] 14 of oblique-angled spherical triangles. For in it are given the base HG, which is the true distance; the side HA, which is the complement of the true altitude of the phenomenon H; and the side AG, the complement of the true altitude of the star G — for by the very fact that the parallax of the true altitude is given, the true altitude cannot be unknown. Then in the triangle EAF seek the visible distance EF, as the base, by [proposition] 4 of oblique spherical triangles. For in it the vertical angle A has already been found, and the sides AE and AF are given, if to the complements of the true altitudes there is added to each its own parallax of altitude, HE on the one side and GF on the other.

[Margin: Problem 23.]

Second: let only one of the stars be subject to a sensible parallax, namely the star H, while the star G is aparallactic; and then in the triangle HAG, as above in the first part of Problem 22, seek the angle A. Then in the triangle AEG, by [proposition] 4 of oblique spherical triangles, investigate the base EG, namely the apparent distance, since in it are given the vertical angle A; the side AG, the complement of the true altitude of the star G; and the side AE, made up of the complement of the true altitude of the star H and its parallax EH.

[Margin: Problem 24.]

Third: let the parallax of depth of the star B be BK, and that of the star D none, and let the true distance be BD. With this and with the quadrants CB and CD, seek the angle C by [proposition] 14 of oblique spherical triangles. Afterwards, in the triangle CKD, seek by [proposition] 4 the base KD, that is, the apparent distance, since the angle C is now given, and the side CD is a quadrant, while the side CK is the remainder of the quadrant CB once the parallax of depth BK has first been taken away. From these you will easily solve the remaining cases.

25. 26. 27. Probl. Data Parallaxi viſæ altitudinis aut Profunditatis datæ, & Diſtantia viſa duorum Phænomenorum; inuenire Diſtantiam eorumdem veram. *Problems 25, 26 and 27. Given the parallax of a given visible altitude or depth, and the visible distance of two phenomena, to find their true distance.*

[Margin: Problem 25.]

First: in the figure set out a little earlier, let there be two stars, H and G, each subject to parallax. Then in the triangle EAF seek the angle A by [proposition] 14 of oblique spherical triangles, since in it are given the base EF, which is the visible distance, and the sides AE and AF, because they are the complements of the visible altitude. Then in the triangle HAG seek by [proposition] 4 of the same the base HG, which is the true distance, since there are given the vertical angle A, just found, and the side AH, which [?] is the complement of the visible altitude BE if from the complement EA you take away the parallax EH; in the same way the side AG is given, by taking the parallax GF away from the complement AF of the visible altitude.

[Margin: Problem 26.]

Second: let only one of the stars, say H, undergo the parallax HE; and then in the triangle EAG seek the angle A by [proposition] 14 of oblique spherical triangles. For in it are given the base EG, which is the visible distance; AG, the complement of the true altitude; and AE, the complement of the visible altitude. Then in the triangle HAG seek, by [proposition] 4 of the same, the base HG, namely the true distance; for you have already obtained the vertical angle A, and there are given the side AG, the complement of the altitude, true and visible at once, and AH, if from the complement EA of the visible altitude BE you take away the parallax EH.

[Margin: Problem 27.]

Third: in the triangle KCD let there be given the visible distance KD, the quadrant CD, and KC, the complement of the visible depth; and therefore by [proposition] 14 of oblique spherical triangles seek the angle C. With it, then, in the triangle BCD, the angle C being now given together with the quadrants BC and BD, seek by [proposition] 4 of the same triangles the true distance BD; and so for the rest.

CAPVT VI.

Chapter VI.

De Parallaxi Declinationis & Aſcenſionis Rectæ. *On the parallax of declination and of right ascension.*

The parallax of declination, and of right ascension, is *the difference between the true and the apparent, or visible, declination or right ascension*, arising from the parallax of altitude or of depth. Now if the phenomenon is in the eastern hemisphere, the parallax increases the right ascension; if in the western, it decreases it — unless it is there at the end of Pisces or the beginning of Aries, and here at the end of ♍ or the beginning of ♎; for then it can decrease it in one respect and increase it in another. As for the declination, five cases can be given in which it is diminished or increased because of the parallax; I shall explain them more clearly by the following diagram. Let the horizon be HQR and the semicircle of the meridian HVR, in which the vertex is V and the visible

pole of the world B. Let the altitude of the pole be BR; given this, VB, the distance of the pole from the vertex, is given, if BR is subtracted from 90°. Let the quadrant of the equator be AQ, and that of altitude VC. The *first* case, then, is when both the true place of the star, E, and the visible place, D, are on this side of the equator, and the visible declination GD is less than the true FE. The *second*, when the true place is on this side, at D, but the visible place I is on the equator itself; and the true declination is GD, but the visible is none. The *third*, when the true place is on this side, at D, but the visible beyond, at M; and the true declination GD is of one kind, the visible MO of the other. The *fourth*, when the true place is at the point I of the equator, but the visible beyond, at M; and the true declination is none, but the visible is MO. The *fifth*, when both the true place M and the visible place N are beyond the equator, and the true declination MO is less than the visible NK.

[Margin: Case 1.]
[Margin: Case 2.]
[Margin: Case 3.]
[Margin: Case 4.]
[Margin: Case 5.]
[Margin: Order of the problems.]

Diagram. The diagram promised for the five cases of Chapter VI, set across the head of the left column. A semicircle stands on the straight diameter H–R, the horizon HQR, with V at the top of the arc. A lies on the arc at the upper left and B on the arc at the right. Below A, near the left part of the arc, stand F and G, and lower down M and N; E and D stand inside the figure below V, I and a small round letter o near the centre, and K below them. C and Q stand on the diameter, C left of centre and Q right of it. A straight line runs from V down to C, a straight line from A down to Q, and several curved lines run from B across to the left part of the arc.

- V (top of the arc): the vertex
- A (arc, upper left): end of the quadrant of the equator AQ
- B (arc, right): the visible pole of the world
- E (below V): the true place of the star in the first case
- D (below E): the visible place in the first case, the true place in the second and third
- F (left, near the arc): foot of the true declination FE
- G (below F): foot of the visible declination GD
- I (centre): a point on the equator
- o (beside I): the point O of the text
- M (lower left): a place beyond the equator
- N (below M): the visible place in the fifth case
- K (below I and o): foot of the visible declination NK
- H (left end of the diameter): the horizon HQR
- C (on the diameter, left of centre): end of the quadrant of altitude VC

- Q (on the diameter, right of centre): end of the quadrant of the equator AQ
- R (right end of the diameter): the horizon HQR

Probl. Parallaxim Declinationis Veræ & Aſc. Rectæ Veræ inuenire, vt vtraq. in Viſam commutetur, Datis 28. Parallaxi Altitudinis veræ datæ; Altitudine Poli, & Declinatione vera Sideris. 29. Parallaxi Altitudinis veræ, Altitud. Poli, & Azimutho 30. Parallaxi Altitudinis veræ, Declinatione vera, & Azimutho Sideris. *Problem. To find the parallax of the true declination and of the true right ascension, so that each may be converted into the visible, given — 28. the parallax of the true altitude, the altitude of the pole, and the true declination of the star; 29. the parallax of the true altitude, the altitude of the pole, and the azimuth; 30. the parallax of the true altitude, the true declination, and the azimuth of the star.*

[Margin: Problem 28.]

First: let the star be truly at E but apparently at D. By [proposition] 14 of oblique-angled spherical triangles, seek the angle EVB in the triangle EVB, in which are given EV, the complement of the true altitude; VB, the complement of the altitude of the pole; and EB, the complement of the true declination FE.

[Margin: Case 1.]

Then in the triangle DVB, by [proposition] 4 of the same, seek the base DB, which is the complement of the visible declination; when it is taken away from 90°, the visible declination GD will be known. For in that triangle are given the vertical angle at V, already found; VB, as above; and VD, if to the complement of the true altitude you add the parallax of altitude DE. Lastly, in the triangle EBD, by [proposition] 14 of the same, seek the angle EBD, which measures the parallax of right ascension FG, since in that triangle are given EB and DB, the complements of the true and of the visible declination, and the parallax of altitude DE.

[Margin: Case 2.]

But if the star is at D and appears at I, the quadrant IB will come out for you, and so the visible declination will be none. The parallax of right ascension, on the other hand, will be GI, whose measure is the angle DBI, to be sought with DB, IB and the parallax ID. The rest as above, using first the triangle DVB, then IVB, and lastly IDB.

[Margin: Case 3.]

If, however, the star is at D but appears at M, MB will come out for you greater than a quadrant, and the parallax of right ascension will be GO, etc., as above; but use the triangles DVB, MVB and MDB.

[Margin: Case 4.]

If, again, the star is at I but appears at M, the true declination will be none, IB a quadrant, and MB greater than a quadrant; and the parallax of right ascension will be IO. Carry out the rest as above, using the triangles IVB, MVB and MIB.

[Margin: Case 5.]

Finally, if the star is at M but appears at N, both MB and NB will be greater than a quadrant, the true declination will be MO and the visible NK, and the parallax of right ascension will be OK. Complete the rest by the same rules of triangles as above, using the triangles MVB, NVB and NMB.

[Margin: Problem 29.]

Second: let the star be at E and appear at D. First, then, in the triangle EVB, by [proposition] 4 of oblique spherical triangles, seek EB, the complement of the true declination, since in it are given VB, the complement of the altitude of the pole; EV, the complement of the true altitude; and EVB, the supplement of the azimuth to 180°.

[Margin: Case 1.]

Afterwards, by the same [proposition] 4, seek DB, the complement of the visible declination, in the triangle DVB, since VB and DVB are given, as above, and DV, if to the complement EV you add the parallax of the true altitude. Finally, in the triangle EBD, its three sides being now known, seek by [proposition] 14 of the same the angle EBD, that is, the measure of the parallax of right ascension FG.

[Margin: Case 2.]

But if the star is at D and appears at I, use the triangles DVB, IVB and IDB, performing the rest as above; and IB will come out for you a quadrant, etc.

[Margin: Case 3.]

If, however, the star is at D but appears at M, use the triangles DVB, MVB and MDB; the rest as above.

[Margin: Case 4.]

Now if the star is at I but appears at M, use the triangles IVB, MVB and MIB.

[Margin: Case 5.]

If, finally, it is at M but appears at N, use the triangles MVB, NVB and MNB. The rest as above, by the same rules.

[Margin: Problem 30.]

Third: let the star be at E but appear at D. First, then, in the triangle DVB, by [proposition] 2 of oblique spherical triangles, seek VB, since there are given in it EVB, the supplement of the azimuth to two right angles; EV, the complement of the true altitude; and EB, the complement of the true declination. Then, by [proposition] 4 of the same, seek in the triangle DVB the base DB, the complement of the visible declination, since there are given VB, now found; the azimuthal angle DVB; and DV, made up of EV, the complement of the altitude, and the parallax DE.

You now understand the remaining cases well enough — although it is more difficult for the azimuth to be given without the altitude of the pole than for the altitude of the pole to be given without the azimuth.

[Margin: Corollary.]

From what has been said it is clear how the true declination and right ascension are converted into the visible.

Probl. Parallaxim Declinationis Viſæ & Aſc. Rectæ Viſæ Inuenire, vt commutentur vtraque in Veram, Datis 31. Parallaxi Altitudinis viſæ datæ, Altitudine Poli, & Declinatione viſa Sideris. 32. Parallaxi Altitudinis viſæ datæ, Altitudine Poli, & Azimutho 33. Parallaxi Altitudinis viſæ datæ, Azimutho, & Declinatione viſa Sideris. *Problem. To find the parallax of the visible declination and of the visible right ascension, so that both may be converted into the true, given — 31. the parallax of the visible altitude, the altitude of the pole, and the visible declination of the star; 32. the parallax of the visible altitude, the altitude of the pole, and the azimuth; 33. the parallax of the visible altitude, the azimuth, and the visible declination of the star.*

[Margin: Problem 31.]

First: in the preceding figure let the star be at E but observed at D; and [let there be given] DV, the complement of the visible altitude; BD, the complement of the visible declination; and BV, the complement of the altitude of the pole. For in the triangle DVB, by [proposition] 14 of oblique spherical triangles, you will seek the angle DVB. With it, then, in the triangle EVB, by [proposition] 4 of the same, seek EB, the complement of the true declination, since VB is given, as above, and EV, if from the complement DV of the visible altitude you take away the parallax DE. Finally, in the triangle DEB, by [proposition] 14 of the same, seek the angle EBD, measuring [?] the parallax FG of right ascension, since in that triangle the sides DB and EB are now known from the complements of the visible and the true declination, together with the parallax DE.

From these, moreover, and from what was said in Problems 28 and 29, it will not be difficult to know how one should proceed in the other four cases enumerated at the beginning of this chapter.

[Margin: Problem 32.]

Second: if in the already mentioned triangle DVB there are given DV, the complement of the visible altitude; VB, the complement of the altitude of the pole; and, from the azimuth HVC, its supplement to 180°, EVB; then by [proposition] 4 of oblique spherical triangles you will seek DB, the complement of the visible declination. Then, in the triangle EVB, with EVB and VB known as above, and EV, the complement of the true altitude, known by subtracting the parallax DE from the arc DV, you will seek by the same [proposition] 4 EB, the complement of the true declination. Finally, in the triangle EBD, by [proposition] 14 of the same, you will investigate, as above, the angle EBD, which measures the parallax FG of right ascension; and you will proceed likewise in the other four cases.

[Margin: Problem 33.]

Third: if in the same triangle DVB there are given DV, the complement of the visible altitude; DB, the complement of the visible declination; and, from the azimuth, the angle DVB; then by [proposition] 2 of oblique spherical triangles seek the arc VB. With it, then, in the triangle EVB, by [proposition] 4 of the same, seek EB, the complement of the true declination; for there are

given the angle at V, as above; VB; and EV, once the parallax DE has been taken away from the complement DV. Finally, by [proposition] 14 of the same, seek as above the angle EBD, which measures the parallax of right ascension, etc.

34. & 35. Probl. Parallaxim Declinationis & Aſcenſionis Rectæ tam viſæ quàm veræ, aliter inueſtigare; per triangula ſphærica Rectangula, Datis præter Azimuthum, & Altitudinem Poli, Declinatione vera aut viſa, & Parallaxi Altitudinis veræ aut viſæ, Si Verticalis circulus per Aequatorem tranſeat. *Problems 34 and 35. To investigate in another way the parallax of declination and of right ascension, both visible and true, by right-angled spherical triangles; given, besides the azimuth and the altitude of the pole, the true or the visible declination and the true or the visible parallax of altitude, if the vertical circle passes through the equator.*

It must be recalled that, if the true declination and right ascension are to be converted into the visible, there must be given the true

[Margin: Order of the problems.]

declination and the true right ascension, and the parallax belonging to the true altitude; but if the visible is to be converted into the true, there must be given the visible declination and right ascension, and the parallax of the visible altitude. For either case, however, one must first seek the angle that the equator makes with the vertical circle drawn through the centre of the star. This is easily done in the triangle AIV of the preceding figure, by [proposition] 8 of right-angled spherical triangles; for in it are given the azimuth AVI and the adjacent side AV, which is as great as the altitude of the pole, and so the angle AIV, to which CIQ is equal, will not remain hidden. Once these angles have been obtained, the preceding problems of this chapter will easily be completed.

[Margin: Problem 34.]

First, then, let the star be truly at E but appear at D, and let its true declination FE be given. For in the triangle FIE, right-angled at F, from the given side FE and the angle FIE, as above, the base IE is sought by [proposition] 11 and the side FI by [proposition] 10 of right-angled spherical triangles. Then, when the given parallax DE has been taken away from the base IE, there remains the known base ID, in the triangle GDI, right-angled at G. With it and with the angle I there are sought, by [propositions] 4 and 5 of right-angled [triangles], the side GD, which is the visible declination, and the side IG; when IG is subtracted from the side IF, the parallax of right ascension FG remains.

[Margin: Problem 35.]

Second: let the star again be at E and appear at D, but let the visible declination DG be given. Then in the triangle GDI, right-angled at G, with the given side GD and the opposite angle GID, found at the beginning, the side GI is sought by [proposition] 10 of right-angled spherical triangles, and by [proposition] 11 the base DI, which is joined to the parallax DE to make IE. And then in the triangle FIE, with the base IE and the angle I, the true declination FE is sought

by [proposition] 1 of right-angled spherical [triangles], and by [proposition] 2 the side FI; if from it you take away the side GI already found, there remains the parallax of right ascension, namely the arc FG.

From what has been said, an industrious geometer can easily understand how he ought to proceed in the other 4 cases recounted at the beginning of the chapter. Yet, so as not to fail beginners, I shall point it out.

[Margin: Case 2.]

If the star is at D and appears at I, there is now no need to seek the visible declination, since it is none, but only the arc GI, which is the parallax of right ascension. This is done by [proposition] 6 of right-angled spherical triangles, since there are given the base ID, which is the parallax of altitude, and GD, which is the true declination. But if the true declination is to be sought, then GD, the true declination, is sought by [proposition] 1 of the same, since in the same triangle the base ID is given, as above, and the angle I is supposed already found at the beginning.

[Margin: Case 3.]

If, however, the star is at D but appears at M, and the true declination GD is given, then with it, in the triangle GID, right-angled at G, and with the acute angle I, GI is sought by [proposition] 10 and the base ID by [proposition] 11 of right-angled spherical triangles. Then in the triangle MIO, right-angled at M, with the angle I and the side IM (which is known if from the parallax MD you take away the arc ID that has been found), the visible declination MO, towards the other side, is sought by [proposition] 7 of the same, and by [proposition] 9 the base IO, which, joined to the arc GI, makes the parallax of right ascension GO. But if the visible declination MO is given, the triangle MIO must first be solved in the way we taught for GID, and then GID in the way we taught for solving MIO.

[Margin: Case 4.]

If, again, the star is at I and appears at M, there is nothing to seek but the apparent declination MO, by [proposition] 7, and the base IO, that is, the parallax of right ascension, by [proposition] 9 of right-angled spherical triangles; because in the triangle MIO, right-angled at O, the angle I and the parallax of altitude MI are given.

[Margin: Case 5.]

If, finally, the star, situated at M, appears at N, and the true declination MO is given, then with it and with the angle I, in the triangle MIO, right-angled at O, seek by [proposition] 10 of right-angled [triangles] the side OI, and by [proposition] 11 the base MI. Then join to the side MI the parallax of altitude MN, to make the base IN; with it and with the angle I, in the triangle NIK, right-angled at K, seek the visible declination NK by [proposition] 1 and the side IK by [proposition] 2 of the same; for if you take IO away from the whole IK, the remainder OK will be the parallax of right ascension. Conversely, if the visible declination NK is given, with it and with the angle I seek by [proposition] 10 the side KI and by [proposition] 11 the base NI; and when the

parallax of the visible altitude MN has been taken away from the side NI, the base MI will remain. With it, in the triangle MIO, and with the angle I, seek the true declination MO by [proposition] 1 and the side IO by [proposition] 2 of the same triangles; for when IO is subtracted from the whole KI, the parallax of right ascension OK will remain.

[Margin: The imperfection of the older trigonometry.]

This method is far more accurate, and no more difficult, than the one used by the ancients and proposed by Magini (Book 12 of the *Primum mobile*, Problem 14) and by Tycho (*Progymnasmata*, volume 1, pages 158, 162, 164). For, because of its nearness and smallness, they used an arc of a circle that is not a great circle, parallel to the equator, in place of an arc of a great circle, and employed it for the parallax of right ascension.

CAPVT VII.

Chapter VII.

De Parallaxi Latitudinis ac Longitudinis. *On the parallax of latitude and of longitude.*

The parallax of latitude and of longitude is *the difference between the true and the visible latitude and longitude*, arising from the parallax of altitude or of depth. Since it was dealt with at length in Book 5, chapter 10, on the occasion of eclipses of the Sun, the reader will not mind recalling that doctrine from there, just as if it had been copied out here.

CAPVT VIII.

Chapter VIII.

De Parallaxi Motûs. *On the parallax of motion.*

The parallax of motion is *the difference between the true and the visible motion*, and it is of as many kinds as motion is. Thus, for example, the Moon in the western quadrant of the ecliptic seems slower, and in the eastern faster, than it really is, because of its apparent motion in longitude, which there seems slower and here faster by force of the parallax. Moreover, it can happen that a phenomenon is so near the Earth that the apparent arc of its diurnal circle under the equator is of only 90°, and that to an inhabitant under the equator it seems to move for 6^h from its rising to its apparent setting, while a fixed star, completing its semicircle, spends 12^h from its rising to its setting; and so that phenomenon would seem twice as swift as the fixed stars, faster than it really is. This can be explained by the following diagram — drawn, however, for other purposes in Book 8, Section 1, chapter 15 — in which the celestial equator is HEFG; under it the terrestrial [circle] CBDO; and between the two the circle of the phenomenon LMP; and let the sensible horizon with respect to the eye B be IBK, cutting off from the circle of the phenomenon the quadrant LNM.

Diagram. Set in the right column within the first paragraph of Chapter VIII. A large circle carries E at the top, F at the right and G at the bottom, with H standing just outside it at the left; T and Q lie on it at the upper left and upper right, I and K at the left and right, R and S at the lower left and lower right. A straight line joins I to K, passing through L, B and M. About the centre A stand two small concentric circles: B above A, V below B inside the inner circle, c at the left and D at the right on the line running from H to F through the centre, o below A and P lower on the vertical, with N above B. Straight lines run from E through N down to the centre and on through P to G, from the centre out to T, Q, R and S, and from E to L and to M.

- E (top of the large circle): on the celestial equator HEFG
- F (right): on the celestial equator
- G (bottom): on the celestial equator
- H (left, outside the circle): on the celestial equator
- T (large circle, upper left): not named in the text on this page
- Q (large circle, upper right): not named in the text on this page
- R (large circle, lower left): not named in the text on this page
- S (large circle, lower right): not named in the text on this page
- I (large circle, left): end of the sensible horizon IBK
- K (large circle, right): end of the sensible horizon IBK
- L (on the line IK, left of B): where the phenomenon is seen to rise
- N (above B): on the quadrant LNM of the phenomenon's circle
- M (on the line IK, right of B): where the phenomenon is seen to set
- B (above the centre): the eye, on the terrestrial circle CBDO
- V (below B, inside the inner circle): not named in the text on this page
- c (left of the centre): the point C of the terrestrial circle CBDO
- D (right of the centre): on the terrestrial circle CBDO
- A (centre): not named in the text on this page
- o (below A): the point O of the terrestrial circle CBDO
- P (below o, on the vertical): on the circle of the phenomenon LMP

For it will be seen to rise at L and to set at M, having completed — by the motion of the primum mobile, which it is sup- [Margin: Order of the problems.]

posed to imitate — the arc LNM, of 6^h, while meanwhile a fixed star rising at I and setting at K completes almost the semicircle IEK in very nearly 12^h. And so the diurnal motion of that phenomenon will seem twice as swift as the motion of the fixed stars; but its nocturnal motion, on the contrary, one and a half times as slow, because it must complete the arc MPL, of 270°, or 18^h, while the fixed star completes the arc KGI, of very nearly 180°, or 12^h. On the same occasion I gave there, among other things, the following problems.

36. Probl. Data Semidiametro Terræ, & dato Tempore, quo Phænomenon apparet ſupra Horizontem Phyſicum, & interim mouetur ſub Aequatore

ad motum Primi Mobilis, inuenire quanta debeat eſſe ipſius Altitudo ſupra terram. *Problem 36. Given the Earth's semidiameter, and given the time for which a phenomenon appears above the physical horizon while meanwhile it moves under the equator with the motion of the primum mobile, to find how great its altitude above the Earth must be.*

[Margin: Problem 36.]

See Book 8, Section 1, chapter 15, Problem 1; it would be pointless to repeat it here.

37. Probl. Data Terræ Semidiametro, & Altitudine Phænomeni ſupra terram ſub Aequatore moti ad Primi Mobilis motum, Inueſtigare Tempus, quo apparere ſeu morari poteſt ſupra horizõtem Phyſicum. *Problem 37. Given the Earth's semidiameter and the altitude above the Earth of a phenomenon moved under the equator with the motion of the primum mobile, to investigate the time for which it can appear, or stay, above the physical horizon.*

[Margin: Problem 37.]

See Book 8, Section 1, chapter 15, Problem 2; here it had only to be proposed.

38. Probl. Data Diſtantia Phænomeni à centro terræ, veroq. ipſius Parallelo, in quo mouetur diurno motu; dataq. loci terræ Phænomenon obſeruantis Latitudine, ac Semidiametro terræ: Inueſtigare Differentiam inter moram Phænomeni ſupra Horizontem Phyſicum & Aſtronomicum in motu diurno. *Problem 38. Given the distance of a phenomenon from the centre of the Earth and its true parallel, in which it moves with the diurnal motion; and given the latitude of the place on Earth observing the phenomenon, and the Earth's semidiameter: to investigate the difference between the phenomenon's stay above the physical and above the astronomical horizon in its diurnal motion.*

[Margin: Problem 38.]

See Book 8, Section 1, chapter 15, Problem 7; let it suffice to have proposed it here.

39. Probl. Data Mora Phænomeni ſupra Horizontem tum Phyſicum, tum Aſtronomicum loci, cuius data ſit Latitudo, & data vera Declinatione paralleli, in quo verſatur Phænomenon, vnà cum Semidiametro terræ, Inueſtigare Diſtantiam Phænomeni à centro terræ. *Problem 39. Given the stay of a phenomenon above both the physical and the astronomical horizon of a place whose latitude is given, and given the true declination of the parallel in which the phenomenon moves, together with the Earth's semidiameter, to investigate the distance of the phenomenon from the centre of the Earth.*

[Margin: Problem 39.]

See Book 8, Section 1, chapter 15, Problem 8, where what we only propose here is explained.

CAPVT IX.

Chapter IX.

De Differentia Parallaxium Altitudinis, Locorumq. Viſorum. *On the difference of the parallaxes of altitude, and of the visible places.*

[Margin: What the difference of the parallaxes is.]

Although the difference between the true and the visible place of a phenomenon is the parallax, the difference between two visible places of the same phenomenon, viewed from the same or from different places on Earth at the same moment of time, is nevertheless not always the difference of the parallaxes: sometimes it is their sum, though more often it is their difference. Of this difference Longomontanus barely indicated a little (Book 2 of the *Spherics*, chapter 10, Problem 1); Cysat more (*De Cometis*, chapter 3, Lemma 8), and Chiaramonti in the *Antitycho* (Book 1, chapter 3) — in whom, however, an ambiguity must be guarded against, since more than once he calls the difference of two visible places the difference of the parallaxes. But in place of these, let there be some problems.

40. Probl. In Verticali circulo communi duobus terræ locis, Determinare Triplicem Situm Phænomeni, in quorum vno differentia duorum locorum viſorum ſit differentia parallaxium inæqualis, in altero æqualis, in tertio autem ſit Aggregatum parallaxium Altitudinis. *Problem 40. In a vertical circle common to two places on Earth, to determine the threefold position of a phenomenon: in one of these the difference of the two visible places is the difference of the parallaxes, being unequal; in another, being equal; and in the third it is the sum of the parallaxes of altitude.*

[Margin: Problem 40.]

In the present figure, let there be described from the Earth's centre A the terrestrial vertical semicircle CBE and the celestial vertical quadrant DS, and another quadrant below it, in the heavens or in the air, in which the phenomenon moves. Let one place on Earth, and the observer, be at B, through which let the vertical line AD be drawn from A, and let the horizon ES be orthogonal to it. Then let the other place on Earth be at G, through which let another vertical line, AGL, be drawn from A, and let the two places be connected by the chord GB. With these laid down:

Diagram. Set in the right column within the opening of Problem 40. A straight vertical line rises from A on the base to D at the top right; the base runs from S at the left through T, C and A to E at the right, and a short vertical stroke rises at its right end with a small m beside its top. A large arc runs from D at the top down to S at the lower left, carrying from the top Z, then H, F and I close together, then M and L, X, N, O, P and Y down its left side; Z, X and Y each stand beside a small star mark. A second arc inside it passes through K, Q and R. V stands beside the vertical line below D; B stands on the vertical

line above A, with G lower left of B, and an arc runs through G and B. Straight lines run from A, from B and from G up to the points on the arcs.

- D (top of the vertical line): the vertex of the place B; end of the celestial quadrant DS
- S (left end of the base): end of the celestial quadrant DS and of the horizon ES
- E (right end of the base): end of the terrestrial semicircle CBE and of the horizon ES
- A (on the base): the Earth's centre
- C (on the base, left of A): end of the terrestrial semicircle CBE
- B (on the vertical line above A): the first place on Earth and its observer
- G (lower left of B): the second place on Earth
- L (on the large arc): the vertex of the place G; the true place in the second case
- K (inner arc): the phenomenon in the first case
- F (on the large arc): the true place in the first case
- H (beside F): the place seen from B in the first case
- I (beside F): the place seen from G in the first case
- Q (inner arc): the phenomenon in the second case
- M (on the large arc): the place seen from B in the second case
- R (inner arc): the phenomenon in the third case
- N (on the large arc): the true place in the third case
- P (on the large arc): the place seen from B in the third case
- O (on the large arc): the place seen from G in the third case
- Z (top of the large arc, beside a star mark): not named in the text on this page
- X (left of the large arc, beside a star mark): not named in the text on this page
- Y (lower left, beside a star mark): not named in the text on this page
- V (beside the vertical line below D): not named in the text on this page
- T (on the base, beside S): not named in the text on this page
- m (top of the short stroke at the right): not named in the text on this page

[Margin: Case 1, of the sum of the parallaxes.]

First: let the phenomenon be at K, between the vertices D and L of the two places; and through its centre let the straight line AKF be drawn from the centre of the Earth, and through the same point the straight lines BKH and GKI from the two places. Then the true place of the phenomenon under the highest heaven will be the point F; but the place seen by the eye at B will be H, and by the eye at G, I; and the difference of the visible places will be the arc HI, which will be equal to the sum of the parallaxes of altitude. For the parallax with respect to the eye B is the angle AKB, while with respect to the eye G it is the angle AKG — if not formally, at least dimensively and equivalently, as was shown in Book 1, chapter 35, Scholium 2, and in Book 8, Section 1, chapter 17,

number 2. It is clear, moreover, that if the phenomenon were equally distant from each vertex, the parallaxes would be equal.

[Margin: Case 2, of a single parallax.]

Second: let the phenomenon be under the vertex of one place, say at Q, under the vertex L of the place G, through which let the vertical line AGL be drawn, and from the place B the line of the visible place, BQM. For with respect to the place G there will be no parallax, nor any difference between the true and the visible place, since to that place the phenomenon appears in the vertex; but with respect to the place and eye B, the difference of the true place L from the visible place M will be the parallax itself, not merely equal to it, and the angle AQB measures it.

[Margin: Case 3.]

Third: let the phenomenon be outside the vertex of either place, towards the same side, that is, outside the arc intercepted between the vertices of the two places — say at R, through which let three straight lines be drawn: one, ARN, marking the true place N under the highest heaven; another from the place B, BRP, marking the visible place P with respect to the eye B; and the third, GRO, marking the visible place O with respect to the eye G. For the difference of the visible places will be the arc PO, to which the difference of the parallaxes, GRB, will be equal. For the parallax with respect to B is the angle ARB, but with respect to G it is the angle ARG; when this is subtracted from the angle ARB, there remains the difference of the parallaxes, namely GRB. And this third case is more frequent than the others.

[Margin: Order of the problems.]

Probl. 41. 42. 43. Data, vel per Problema 44. aut 45. inuenta Differentia locorum viſorum Phænomeni, ſub eodem verticali ex duobus terræ locis ſimul viſi, & Diſtantia Phænomeni apparente à vertice alterutrius loci, cum arcu diſtantiæ locorum; Inueſtigare ſeorſim Parallaxes Altitudinis cuiuis loco conuenientes, in triplici caſu Problematis 40. Secluſa Refractione.

Problems 41, 42, 43. Given — or found by Problem 44 or 45 — the difference of the visible places of a phenomenon seen at the same time from two places on Earth under the same vertical, and given the apparent distance of the phenomenon from the vertex of either place, together with the arc of the distance between the places: to investigate separately the parallaxes of altitude belonging to each place, in the threefold case of Problem 40, refraction being set aside.

[Margin: Problem 41.]

[Margin: Case 1.]

First: if the phenomenon appears between the vertices of the two places — that is, if to one place it appears towards one region of the world and to the other towards the opposite region — look at the figure set out before. In it, for the given arc BG, seek the chord in the tables of sines, that is, the sine of half the said arc, doubled. With this chord, in the triangle BKG, seek the sides BK and BG by no. 2 of the plane oblique-angled triangles, in the parts of

which the radius AG is known. For in that triangle the angle GKB is given, because, from what was said in Problem 40, it is equal to the difference of the visible places; and the angle KBG or KGB is given. For if the visible distance of the phenomenon from the vertex D is given, which is the angle HBD, its supplement to two right angles is the angle KBA; but if the visible distance from the vertex L is given, which is the angle LGI, its supplement to two right angles is the angle KGA, by Euclid I.13. Moreover, once the arc GB is known, the angle A is also known, and its supplement to two right angles is, by I.32 of the same, the sum of the angles ABG and AGB. These angles stand at the base BG of the isosceles triangle ABG; therefore either of them, by I.5 of the same, is half the said sum. So, when ABG is subtracted from the angle KBA, and AGB from the angle KGA, the angles KBG and KGB will be known. After this, in the triangle KBA, with the radius AB, the side BK and the angle ABK, seek the parallax AKB with respect to the place B, by no. 3 of the plane oblique-angled triangles; and by the same, in the triangle AGK, with the radius AG, the side GK and the angle AGK, seek the parallax AKG with respect to the place G.

[Margin: Problem 42.]

[Margin: Case 2.]

Second: if the phenomenon is under the vertex L of one place, say G — as when it is at Q — there is no need of trigonometry, because ML, the difference of the visible places, is equal to the parallax BQG. Therefore, since the arc GB is known, and the arc DL is similar to it, if the arc DL is taken from the visible distance of the phenomenon from the vertex D, that is, from the arc MD, ML will remain, and so the parallax BQG with respect to the place B; for at G there will be no parallax.

[Margin: Problem 43.]

[Margin: Case 3.]

Third: if the phenomenon appears to both places towards the same region, and is therefore outside the arc of the vertical circle intercepted between the vertices of the places — as when it is at R — then, if its visible distance from the vertex D is given, that is, the angle DBR, its supplement to two right angles is given, which is ABR. From this subtract the angle ABG, known as I taught above in Problem 41, and GBR remains. But if the visible distance from the vertex L is given, the angle LGR, its supplement to two right angles, AGR, together with AGB, known as noted above, will make up the sum to be taken from four right angles, or 360°, so that the angle RGB becomes known, by Euclid I.13. Therefore, with either of these, and with the difference of the visible places, that is, the angle BRG, and with the base BG, that is, the chord of the arc BG, known in the parts in which the radius is AG — it is taken from the tables of sines — you will find the side GR by no. 2 or no. 7 of the plane oblique-angled triangles. For the third angle will be the supplement of the other given angles to two right angles, by Euclid I.32. Then, in the triangle AGR, with the radius AG, the side GR and the angle QGR, the supplement of AGR to two right angles, find the parallax ARG for the place G by no. 3 of the

same triangles; add it to the angle BRG, that is, to the difference of the visible places, and the whole parallax ARB for the place B will result. See an example in Book 8, Section 1, chapter 21, number 7, and chapter 19, number 2.

44. Probl. Data Diſtantia duorum terræ locorum ſub eodem verticali, ac Phænomeni Diſtantijs à vertice, eodem momento temporis vtrobique viſis in eodem verticali, Inueſtigare Differentiam locorum vtrobique viſorum; vt per eam, & per problema 41. 42. aut 43. inquiri poſſint Parallaxes Altitudinis. *Problem 44. Given the distance between two places on Earth under the same vertical, and the distances of a phenomenon from the vertex, seen at the same moment of time at both places in the same vertical: to investigate the difference of the places seen at the two, so that by means of it, and of Problem 41, 42 or 43, the parallaxes of altitude can be found.*

[Margin: Problem 44.]

Look at the figure immediately preceding. In it, if the phenomenon is at Q, under the vertex of one place, the arc of distance BG, that is DL, taken from the arc DM, the visible distance from the vertex D, leaves the difference of the visible places — indeed the very parallax of altitude with respect to the place B. But if the phenomenon is within both vertices, as at K — that is, it appears to one observer towards one region and to the other towards the opposite — then subtract the angle BAG, known from the arc of distance BG, from 180°; to this remainder, that is, to the angles ABG and AGB taken together, add the angles of the visible distances, DBK and LGK, and subtract the whole sum from four right angles, or 360°. For the sum of the angles KBG and KGB will then be known; finally subtract it from 180°, and the angle BKG will remain, that is, the difference of the visible places.

But if the phenomenon is outside the vertex of either place, and appears to both towards the same region, then subtract from 180° the angle BAG, known from the given arc BG, and add the remainder, bisected — that is, the angle ABG — to the angle DBR of the visible distance from the vertex; and the sum is to be taken from 180°, so that the angle GBR becomes known: keep it. Similarly, subtract the angle RGL of the other visible distance from the vertex from 180°; the angle AGR will remain. Join it to the angle AGB, and take the sum from four right angles; the angle BGR will remain. Join this to the angle GBR kept back, and take the total from 180°: there will remain the angle sought, BRG, that is, the difference both of the visible places and of the parallaxes.

45. 46. 47. Probl. Datis Phænomeni Diſtantijs ab eadem Fixa ſtella viſis ex duobus terræ locis, in eodem verticali circulo omnibus his exiſtentibus, Inuenire Differentiam locorum viſorum in triplici caſu problematis 40. ſecluſa Refractione. *Problems 45, 46, 47. Given the distances of a phenomenon from the same fixed star, seen from two places on Earth, all these lying in the same*

vertical circle: to find the difference of the visible places in the threefold case of Problem 40, refraction being set aside.

[Margin: Problem 45.]

[Margin: Case 1.]

First: in the figure set out before, let the phenomenon be at K, within the two vertices and below the star F, appearing at I to the eye G and at H to the eye B. Then the sum of the visible distances from the fixed star, that is, the arc HI, will be the difference of the visible places, and equal to the sum of the parallaxes. But if, with respect to one place, say G, it is above the star Z, and with respect to the other, B, below it, subtract the lesser of the visible distances from the fixed star, IZ, from the greater, HZ; and HI, the difference of the visible places, will remain.

[Margin: Problem 46.]

[Margin: Case 2.]

Second: let the phenomenon be at Q, under the vertex L of the one place G. Whether the star, like X, is below the phenomenon for both eyes, or, like Z, below it with respect to one and above it with respect to the other, yet within the vertices — in either case the lesser of the visible distances from the star, subtracted from the greater, will give the difference of the visible places, or the arc ML. But if the star is below with respect to one and above with respect to the other, but outside the vertices, the visible distances from the star are to be added together to give the difference of the visible places. Further, if the star lies towards the same region for both places, it will be outside the vertices; if towards opposite regions, it will be within the vertices.

[Margin: Problem 47.]

[Margin: Case 3.]

Third: let the phenomenon be at R, outside the arc LD intercepted between the vertices of the places, and let the fixed star be, with respect to both observers, either lower than the phenomenon, as Y is, or higher, as X is. Then in either case the lesser visible distance from the fixed star, taken from the greater, will give the difference of the visible places, OP. But if the star is below the phenomenon with respect to one observer and above it with respect to the other, then the sum of the visible distances from the star will be the difference of the visible places, or the arc OP.

[Margin: Order of the problems.]

48.Probl. Dato Phænomeni vero Motu, ſiue communi tantùm, ſiue proprio, & communi, cum diſtantijs eius ab eadem Fixa ſub eodem circulo maximo, viſis ex eodem terræ loco, in eodem quadrante hemiſphærij, dummodo ſtella Fixa ſit extra arcum, quem ſuo motu deſcribit Phænomenon ab vna ad alteram obſeruationem: Inueſtigare Differentiam parallaxium liberarum, aut liberatarum à Refractione. Immò hoc ipſum præſtare, etiam quando ſtella Fixa eſt intra prædictum arcum, Phenomeni motu deſcriptum. *Problem 48. Given the true motion of*

a phenomenon — either the common motion only, or the proper and the common together — with its distances from the same fixed star under the same great circle, seen from the same place on Earth in the same quadrant of the hemisphere, provided that the fixed star is outside the arc which the phenomenon describes by its motion from the one observation to the other: to investigate the difference of the parallaxes, either free of refraction or freed from it. And indeed to accomplish this same thing even when the fixed star is within the already mentioned arc described by the phenomenon's motion.

[Margin: Problem 48.]

For in this way Lemma 8 [?] of our Father Cysat, chapter 8 of *De Cometis*, must be limited; take this rule from it. Subtract the lesser of the visible distances from the greater; the remainder will be the visible motion. From this take the true motion, and the remainder will be the difference of the parallaxes. He shows this by an induction made from the following cases.

[Margin: Summary of the problem.]

[Margin: Case 1, of a phenomenon rising and approaching the star.]

The first is when the phenomenon, rising from the horizon, approaches by its true proper motion against the order of the signs a star more westerly than itself. In this case the visible distance decreases more and more, both because of the approaching proper motion and because of the diminution of the depressing parallax. For imagine that a comet near the horizon is visibly distant from Spica, which is more westerly, in the same vertical circle — and, for ease, in the equator — by 15° 20′, and at that time has a parallax of 16′; then, after 3 hours, having been raised, it has a parallax of 9′, having meanwhile advanced towards the west by its true motion by 3′. It will now seem distant from Spica by only 15° 10′, because of the 20′ the proper motion has taken away three, and the decrease of the parallax 7′. The visible motion, therefore, will appear to be 10′; if you subtract from it the true motion of 3′, 7′ will remain, which is the very difference of the parallaxes. And the same will happen, the proportion being kept, with all other numbers you may imagine in this first case.

[Margin: Case 2, of a phenomenon rising and receding from the star.]

The second case is that of a phenomenon rising, but receding from a more easterly star because of its motion against the order of the signs. For then the visible distance of the phenomenon from the star is smaller near the horizon than far from it, both because of the recession from the star by force of the motion and because of the lessened parallax, which earlier, by depressing the phenomenon towards the star, was diminishing the distance. For example, if earlier it seemed distant 15° 10′, having a parallax of 16′, and after three hours has a parallax of 9′, and by its true motion has advanced 3′ against the order of the signs, it will now seem distant 15° 20′, because the true motion has taken 3′ from the approach to the star, and the difference of the parallax 7′. Therefore the difference of the visible distances, that is, the visible motion, will be 10′; and when the true motion of 3′ is taken from it, 7′ will remain, that is, the difference of the parallaxes.

[Margin: Case 3, of a phenomenon descending and approaching the star.]

The third case is that of a phenomenon descending from the meridian towards the horizon and approaching a star more westerly than itself. For then the visible distance will be smaller near the horizon than far from it, both because of the approaching true motion and because of the increase of the parallax towards the star; and in this case the rule already given will hold, as will be clear to anyone who works it out.

[Margin: Case 4, of a phenomenon descending and receding from the star.]

The fourth case is that of a phenomenon descending, but receding from a more easterly star. In this case the visible distance will be greater near the horizon than far from it, partly because of the phenomenon's motion against the order of the signs, partly because of the greater parallax towards the same region as the true motion; and in this case too a careful computer will recognise that the said rule holds.

[Margin: The remaining 4 cases, of a phenomenon going in the order of the signs.]

The remaining four cases are those of a phenomenon moving by its proper motion in the order of the signs, and so, while rising, approaching a star more easterly than itself or receding from a more westerly star; or, while descending, receding from the star or approaching it, according as the star is more easterly or more westerly. It is enough to have indicated these, so that it may be clear to a careful examiner that the rule given holds in all of them: that the difference of the visible distances is always equal to the visible motion, and always greater than the true motion, and that the true motion, subtracted from the visible, leaves the difference of the parallaxes — provided that the star is not within the arc of the phenomenon's true motion.

[Margin: What is to be done if the star is within the arc of the phenomenon's motion.]

For if at the beginning the star were within the arc which the phenomenon traversed by its true motion from the first observation to the second — which would happen if the phenomenon moved very swiftly against the order of the signs — then the sum of the two visible distances from the fixed star and of the motion of the fixed star will be the visible motion of the phenomenon; and when the phenomenon's true motion is subtracted from this, the difference of the parallaxes will remain. For if the fixed star stood still, and the phenomenon, from the first observation to the second, reached it exactly by its visible motion, the visible motion would certainly be as great as the visible distance had been at the first observation; but if it did not merely reach the resting fixed star but passed beyond it, it would certainly cover by its visible motion a space as great as the earlier and the later visible distances taken together. But meanwhile the fixed star moves with the diurnal motion towards the same part towards which the phenomenon moves by its own proper motion, to say nothing of the motion it shares with the star; therefore the visible motion comprises, besides the two visible distances, the whole arc which the fixed star has completed as well. Finally, if the phenomenon's motion is in the order of the signs, contrary

to the motion of the primum mobile, and so overcomes it that it leaves the star, previously more easterly, behind it towards the west, the sum of the visible distances from the fixed star, subtracted from the motion of the fixed star, leaves the visible motion of the phenomenon. Care must be taken, however, that a difference of the parallaxes gathered in a circle other than the vertical is not carried over to the difference of the parallaxes of altitude — a matter in which, as I showed in Book 8, Section 1, chapter 20, numbers 16 and 17, Father Cysat went wrong.

49.Probl. Datis diſtantijs duabus viſis à polo Mundi, in Meridiano eodem obſeruatis, Phænomeni alium quàm primi Mobilis motum non habentis, Inuenire aut Aggregatum, aut Differẽtiam Parallaxiũ vtrique altitudini Meridianæ conuenientem: Diſſimulata interim Refractione. *Problem 49. Given two visible distances from the pole of the world, observed in the same meridian, of a phenomenon that has no motion other than that of the primum mobile: to find either the sum or the difference of the parallaxes belonging to the two meridian altitudes, refraction meanwhile being disregarded.*

[Margin: Problem 49.]

If the phenomenon at its greatest altitude still remains between the pole and the observer's vertex, the difference between its visible distances from the pole of the world will be the sum of the parallaxes. But if it reaches the vertex exactly, its distance from the pole will then be true and visible at once; the other visible distance, below the pole, will therefore be greater than this by as much as the parallax, and so the difference of the visible distances from the pole will be equal to the parallax belonging to the lower altitude. Finally, if at its highest meridian altitude it passes beyond the vertex towards the equator, the difference of the visible distances from the pole will be the difference of the parallaxes. Longomontanus demonstrated this with a brief and concise diagram in Book 2 of the *Spherics*, chapter 10, Problem 1; and we, with Tycho, have confirmed and illustrated it with examples in Book 8, chapter 11, from Problem 64 onwards. Let the reader therefore turn back there.

Monitum duplex & Theorema *A twofold caution, and a theorem*

1.Theorema. Differentia Diſtantiarum viſarum à vertice, per ſe quidem nec eſt differentia parallaxium, nec earum ſumma, nec ipſi parallaxi æqualis: Sed poteſt eſſe nullum, & quodlibet horum. *Theorem 1. The difference of the visible distances from the vertex is not of itself either the difference of the parallaxes, or their sum, or equal to the parallax itself; but it can be none of these, and any one of them.*

I add this against certain people who confuse the difference of the distances from the vertex with the difference of the parallaxes. That it can be any one of the three already mentioned is clear from the threefold case of Problem 40; that it can likewise be none of them is clear if the difference of the visible distances

from the vertex shows, to sense, a whole quadrant: for none of the parallaxes can be of 90°, and the sum of two parallaxes does not exceed 3° even in the Moon, etc.

[Margin: Order of the problems.]

2.Theorema. Differentia differentiarum, quæ ſunt inter duas altitudines veras & inter duas viſas eiuſdem Phænomeni ijſdem duobus momentis, æqualis eſt Differentiæ Parallaxium. *Theorem 2. The difference of the differences that lie between two true altitudes and between two visible altitudes of the same phenomenon, at the same two moments, is equal to the difference of the parallaxes.*

This proposition will be explained and made plain by an example. Let the true altitude of the Moon be 10°, but the visible 8° 54′ 41″, and so the parallax 65′ 19″. Next let the Moon's true altitude be 40°, but the visible 39° 8′ 43″, and so the parallax 51′ 17″: the difference of the parallaxes will then be 14′ 2″. Now the difference of the true altitudes is 30°, and of the visible ones 30° 14′ 2″; the difference of these, therefore, is 14′ 2″ — just as great, of course, as that of the parallaxes. And you will find the same on examining any two altitudes, visible and true, at the same moment, compared with two other altitudes, true and visible, at another single moment — provided that the phenomenon keeps the same distance from the centre of the Earth in both.

For the rest that seems to belong to this chapter, see above, chapter 2, Problems 11, 12, 13.

CAPVT X.

Chapter X.

De Modis Obſeruandi, An aliquod Phænomenon, præſertim nouum, habeat Parallaxin aliquam Altitudinis, & quantam, per Obſeruationes in eodem loco terræ factas. *On the methods of observing whether some phenomenon, especially a new one, has any parallax of altitude, and how much, by observations made at the same place on Earth.*

Although observations of this kind do not suffice for absolute evidence about the place and distance of a phenomenon, they are nevertheless easier, because they do not depend on the uncertain distance between meridians — as do those observations which are made of the same phenomenon, say a comet or a new star, at the same time by different observers in different meridians. Of these observations we shall speak in the following chapter.

50. Probl. Phænomeno & Obſeruatore in Aequatore poſitis, explorare Altitudinis Parallaxin, ſi non alio motu quàm primi Mobilis intra vnum diem moueatur, ſecluſa Refractione. *Problem 50. With the phenomenon and the observer placed at the equator, to explore the parallax of altitude, if the phenomenon*

moves within one day with no motion other than that of the primum mobile, refraction being set aside.

[Margin: Problem 50.]

In this figure let three quadrants be described from the Earth's centre C: one, AB, terrestrial; another, VR, of the celestial equator in the highest heaven; and a third, HN, in which the phenomenon is to appear.

Diagram. Set in the left column within the opening of Problem 50. A base line runs from F at the left through C and A to N and R at the right, and a vertical line rises from C towards V at the top. A large arc runs from V at the top down to R at the lower right, carrying in order E, D, I, P, Q, G, K and T; a middle arc runs from H at the left through M and L down to N; a small inner arc runs from O through B down to A. S stands small beside V at the top. Small star marks stand beside S, I, Q, M, L, K and T. Straight lines run from C and from B out to points on the arcs.

- C (on the base, left): the Earth's centre
- A (on the base): end of the terrestrial quadrant AB
- B (on the inner arc): the observer; end of the terrestrial quadrant AB
- V (top of the large arc): the vertical point, the zenith; end of the quadrant VR
- R (right end of the base): end of the quadrant VR and of the horizontal line CR
- H (left end of the middle arc): end of the quadrant HN, under V
- N (on the base, right): end of the quadrant HN, where the phenomenon rises
- L (on the middle arc): the phenomenon (Problem 50); its least altitude (Problem 51)
- M (on the middle arc): the phenomenon at its greatest altitude (Problem 51)
- K (on the large arc): end of the visible distance VK
- G (on the large arc): the true place on the line CLG
- E (on the large arc): the true place on the line CME (Problem 51)
- D (on the large arc): end of the visible distance VD (Problem 51)
- P (on the large arc): the pole of the world (Problem 51)
- S (beside V): not named in the text on this page
- I (on the large arc): not named in the text on this page
- Q (on the large arc): not named in the text on this page
- T (on the large arc): not named in the text on this page
- O (start of the inner arc): not named in the text on this page
- F (left end of the base): not named in the text on this page

Let the observer at B wait for the phenomenon until, rising from N to L, it is beyond all danger of sensible refraction, that is, until it is higher than about 40°; and with a most exquisite instrument, one showing even the seconds themselves if possible, let him take its visible distance from the vertex, VK, that is, the angle VBK. For when the straight line CLG is drawn from the centre of the Earth

through the centre of the star, the star's true place will be under G. At the same moment let a companion begin to count the times of the primum mobile with an exact pendulum — on which see our Book 2, chapter 20 — and continue until the star comes to H, under the vertical point V. For if that time, converted into degrees and minutes of the equator, is equal to the phenomenon's visible distance VK, the phenomenon will have no sensible parallax; but if it is less than the said distance, it will have a parallax of altitude as great as the small portion of the equator corresponding to the difference between the parts of the equator answering to the time and the visible distance from the vertex; and this parallax will be the angle CLB. The observer, however, must be certain that he is under the equator, must have the position of the equator known, and must not be deceived about the moment at which the phenomenon reaches the zenith V; and these three things together carry great difficulty.

51. Probl. Data Phænomeni à Refractione liberi, nunquamq. occidentis, & ſemper circa polum Mundi conſpicui, nec intra diem vnum variantis declinationem, Altitudine meridiana maxima & minima; Diſcernere Aggregatum aut Differentiam Parallaxium altitudinis, aut etiam parallaxin ipſam, ſi quam habuerit. *Problem 51. Given the greatest and the least meridian altitude of a phenomenon that is free of refraction, never sets, is always visible about the pole of the world and does not vary its declination within one day: to discern the sum or the difference of the parallaxes of altitude, or even the parallax itself, if it has any.*

[Margin: Problem 51.]

In the preceding figure let there be quadrants of three meridians: the terrestrial AB, that of the highest heaven VR, and below it HN, in which the phenomenon is. Let the horizontal line be CR and the vertical VC. Let the observer be at B, and let him observe the least visible altitude of the phenomenon at L and the greatest at M, by means of the visible distances from the vertex, the greatest VBK and the least VBD. Now, when the straight lines CLG and CME are drawn from the Earth's centre through the centre of the star, its true places will be G and E. Let the pole of the world be P, whose altitude RP we suppose to be the true one, differing insensibly from the visible or observed altitude, since this pole is supposed to be in the highest heaven, above the fixed stars themselves. With these laid down, subtract the least distance of the phenomenon, VD, from the distance of the pole from the vertex, that is, from the arc VP; there will remain its upper visible distance from the pole, which is DP. Conversely, from the greatest visible distance of the phenomenon, VK, take the distance of the pole, VP; there will remain the lower visible distance of the same phenomenon from the pole of the world, which will be PK. Now if the distances DP and PK are equal, the phenomenon will have no parallax sensible to your instrument. But if DP is less than PK, let it be subtracted from PK, and their difference will be the difference of the visible distances from the pole of the world, and will be equal to the sum of the parallaxes CLB and CMB

taken together, as Longomontanus, who will be reviewed shortly, teaches. But if the phenomenon at its greatest altitude were at the vertex V itself, then the difference of the visible distances from the pole P will be equal to the parallax BLC itself; and if at its greatest altitude it likewise passed beyond the vertex V, the said difference would be equal to the difference of the parallaxes. See the examples of Longomontanus in Book 2 of the *Spherics*, chapter 10, Problem 1, and in the Appendix to the *Astronomia Danica*, chapter 10; and of Tycho, *Progymnasmata* volume 1, page 417 and from page 443 onwards. On page 516 Tycho rightly warns that there must be a very notable difference, in degrees themselves, between the least and the greatest altitude of the phenomenon; otherwise, from a small difference an insensible difference or sum of the parallaxes could follow. Moreover, as the same author teaches on page 445, it can be gathered whether the two visible distances of the phenomenon from the pole of the world are equal: they are, if half the difference of the meridian altitudes, added on the one side to the lesser altitude and taken on the other from the greater, yields the same altitude of the pole that has been exactly explored by other means. How the parallax of altitude is drawn out of the sum or the difference of the parallaxes has been stated in chapter 1, Problems 11, 12, 13.

[Margin: Order of the problems.]

52. Probl. Datis quæ in Problemate 51. Diſcernere an Phænomenon habeat Parallaxin minorem, an maiorem Parallaxi nota, & debita alicui Planetæ in tali altitudine viſa. Secluſa interim Refractione. *Problem 52. Given what is given in Problem 51: to discern whether the phenomenon has a parallax smaller or greater than the known parallax that is due to some planet at such a visible altitude. Refraction set aside for the present.*

[Margin: Problem 52.]

First, by Problem 51, gather the phenomenon's sum of parallaxes, or its parallax, or its difference of parallaxes, according to the threefold case of that same problem. Next, from tables or from elsewhere, gather the planet's parallax of visible altitude when it is, or is supposed to be, at the two visible altitudes at which the phenomenon was observed.

[Margin: Case 1.]

Combine the planet's two parallaxes into one sum when the phenomenon at its greatest altitude was between the vertex V and the pole P. In that case, if the sum of the planet's parallaxes is equal to the phenomenon's sum of parallaxes, the parallaxes of both — that is, of the planet and of the phenomenon — will be equal, and so will their distance from the Earth. But if the sum of the planet's parallaxes is less than the sum already mentioned, the phenomenon will have greater parallaxes; if greater, smaller parallaxes than the planet.

[Margin: Case 2.]

If, however, the phenomenon at its greatest meridian altitude reached the vertex V, then a comparison of its parallaxes with the planet's will show at once which is the smaller.

[Margin: Case 3.]

Finally, if the phenomenon at its greatest meridian altitude passes beyond the vertex — that is, lies in the arc intercepted between the upper semicircle of the equator and the vertex — then subtract the smaller of the planet's parallaxes from the greater, and compare the remainder with the difference of the phenomenon's parallaxes. If they are equal, the parallaxes of both, and their distances from the Earth, will also be equal; but if the remainder is smaller, the phenomenon's parallaxes will be greater, and if it is larger, they will be smaller, than those of the planet observable at the same altitudes.

You have three examples in Tycho, *Progymnasmata* volume 1, in the new star of Cassiopeia: compared with the Moon on pages 331 and 446, with the Sun on page 423, and with Saturn on page 425. But for what was certain about that star's parallax, see what has been said in Book 8, Section 2, chapters 6 and 7.

53. Probl. Obſeruata Phænomeni circa Polum Mundi motu primi Mobilis euntis, nunquamque occidentis, nec declinationem mutantis, Diſtantia ab ijſdem ſtellis Fixis, cum quibus tranſit Meridianum in infima & ſumma altitudine; Diſcernere an Phænomenon habeat Parallaxin altitudinis ſenſibilem, & maiorem an minorem parallaxi Planetæ debita, Data Poli altitudine & Declinatione Fixæ coobſeruatæ. Secluſa Refractione. *Problem 53. Having observed the distance of a phenomenon — one that goes about the pole of the world by the motion of the primum mobile, never sets, and does not change its declination — from the same fixed stars with which it crosses the meridian at its lowest and its highest altitude: to discern whether the phenomenon has a sensible parallax of altitude, and whether it is greater or smaller than the parallax due to a planet, given the altitude of the pole and the declination of the fixed star observed with it. Refraction set aside.*

[Margin: Problem 53.]

An observation of this kind is more useful when the phenomenon at its greatest altitude comes too close to the vertex. Further, from the declination of the fixed star crossing the meridian together with the phenomenon, and from the altitude of the pole, the distance of the fixed star from the pole of the world is gathered. From this, together with each of the two distances of the phenomenon from the fixed star, the twin distance of the phenomenon from the pole of the world is gathered. From this, finally, by Problem 51, the sum or the difference of the parallaxes, or the phenomenon's parallax itself, is gathered; and by Problem 52, whether it has a greater or a smaller parallax than a planet seen at an equal altitude. For example, in the figure immediately preceding, let the distance of the phenomenon L from the pole star Q, observed with a sextant or otherwise, be the arc KQ, and let the distance PQ of the pole star from the pole of the world P be known: then the visible distance of the phenomenon from the pole of the world, the arc KP, will be known. Again, if the observed distance of the phenomenon M from the same pole star I is the

arc DI, its distance from the pole P will be the arc DP, made up of the distance from the star I and the distance of the star I from the pole P. See the examples in Tycho, *Progymnasmata* volume 1, from page 416 on.

54. Probl. Dato Aggregato, aut Differentia Parallaxium Ignotarum, duabus Phænomeni altitudinibus viſis conuenientium; Datiſq. Parallaxibus Planetæ in ijſdem altitudinibus ipſi conuenientibus; Parallaxes Altitudinis vtriuſque Phænomeni notas facere. Secluſa Refractione. *Problem 54. Given the sum or the difference of the unknown parallaxes belonging to two visible altitudes of a phenomenon, and given the parallaxes belonging to a planet at the same altitudes: to make known the phenomenon's parallaxes of altitude at both. Refraction set aside.*

[Margin: Problem 54.]

Once the sum or the difference of the parallaxes has been acquired, by the method we taught in Problem 51 or 53, or from elsewhere, and once the planet's parallax at each of the two visible altitudes is known from tables or otherwise, combine the planet's parallaxes into one sum and set up the following proportion.

[Margin: Case 1.]

As the sum of the planet's parallaxes is to the planet's smaller parallax, so let the sum of the phenomenon's unknown parallaxes be to the phenomenon's smaller parallax. When that is subtracted from the sum of the unknown parallaxes, the phenomenon's greater parallax will also become known.

[Margin: Otherwise.]

Otherwise: as the sum of the planet's parallaxes is to the planet's greater parallax, so let the sum of the phenomenon's parallaxes be to the phenomenon's greater parallax. When that is subtracted from the sum of the unknown parallaxes, the smaller remains known.

[Margin: Case 2.]

But if you use the difference of the parallaxes: as the difference of the planet's parallaxes is to the planet's greater or smaller parallax, so let the difference of the phenomenon's parallaxes be to the phenomenon's greater or smaller parallax.

Even without the planet's parallaxes, however, both of the phenomenon's parallaxes can be investigated by Problem 11, 12 or 13.

55. Probl. Experiri An Phænomenon habeat aliquam ſenſibilem Parallaxin, aut ſaltem Lunari maiorem, per obſeruationem ipſius in eodem verticali cum duabus Fixis; & alteram deinde obſeruationem eiuſdem Phænomeni ac Fixarum earumdem; dummodo Phænomenon non alio quàm primi Mobilis motu moueatur: nec Refractio interueniat; aut præcognita ſit, & detracta. *Problem 55. To find out whether a phenomenon has some sensible parallax, or at least one greater than the Moon's, by an observation of it in the same vertical as two fixed stars, and then a second observation of the same phenomenon and the same fixed stars — provided that the phenomenon is moved by*

no motion other than that of the primum mobile, and that refraction does not intervene, or else is known beforehand and taken away.

[Margin: Problem 55.]

[Margin: Digges's problem, corrected by Tycho and by us.]

This problem belongs partly to the little book of the Englishman Thomas Diggeseus [Thomas Digges], which he entitled *Alae seu Scalae Mathematicae* [*Wings or Ladders of Mathematics*], chapter 10; partly to Tycho, who corrects him in *Progymnasmata* volume 1, page 676; and partly to us. It runs as follows. Wait until the phenomenon falls into the plane of a vertical circle in which two fixed stars are found at the same time (which, given so great a multitude and density of fixed stars and so great a variety of vertical circles, will not be difficult to bring about). This, on Digges's authority, you will achieve with a ruler of wood or metal, at least 6 inches wide and 5 feet long, whose sides and straight edges are exactly parallel to one another. Set it upright, perpendicular to the horizon. Then, when you are about to look at the phenomenon, step back and place your eye in such a position that one side of the ruler appears with its edge to cut the phenomenon in two; and note carefully whether, in the same way and at the same moment, the edge of the ruler intersects two fixed stars through their centres. For then you will be certain that the phenomenon and the two fixed stars are in the plane of the same vertical. After some hours of the same night, or of the following one, when those fixed stars have declined markedly from the earlier plane, incline the ruler so that its edge passes through those two fixed stars. If it then passes through the centre of the phenomenon as well, the phenomenon will have no sensible parallax; but if the phenomenon lies outside the edge of the rule, and nearer to the horizon than the fixed stars, it will have a sensible parallax. Tycho rightly warns, however, that this is to be understood of a phenomenon that is moved by no motion other than that of the primum mobile; that it is extremely difficult to hold the eye in the same plane so that nothing wavers to one side or the other of the ruler's edge; and that this observation is better carried out with a hanging thread to which a lead weight is attached, which first

[Margin: Order of the problems.]

holds it in a perpendicular position and can then be swung round to the inclined plane in which those two fixed stars lie — although Tycho fears that here too the eye may be somewhat deceived. We, however, say that this is done more safely with our thread triangle, sufficiently described in Book 5, chapter 15, number 16: first in a position perpendicular to the horizon, and afterwards inclined. For two threads set apart from each other, one of which is covered by the other, show that the eye is in the same plane with them.

Further, Digges affirms that by this method, or rather by that method of his own, he observed on several nights the new star seen in Cassiopeia's Chair in the year 1572; that it always appeared to him to be in one and the same straight line with two little stars, one of which is in the knee of Cassiopeia and the other in the left shoulder of Cepheus; and that in the month of February of the year

1573 it did not, through any whole night, digress from the line of those stars by more than the semidiameter of its own apparent disc. From this he gathers that its parallax could not have reached two minutes.

[Margin: Digges's problem 2, without instruments.]

He adds, however, a second method, without any instrument, for gathering whether a phenomenon has a parallax greater than the Moon's, and applies it to the same new star. That star, he says, was never seen to recede from the little star that is in the foot of Cassiopeia's Chair by three times the diameter of the Sun. But if it had had a parallax greater than the Moon's, and of at least one degree, then when it moved about near the horizon it ought to have stood three times the Sun's diameter away from that star, since, when it was in the same vertical but above that little star, it seemed to be distant from it by about a single solar diameter, or 30′. This problem, however, being rough in itself, is to be refined by the problems that follow.

56. Probl. Explorare, An Phænomenon habeat parallaxim ſenſibilem, aut etiam Lunari vel Solari maiorem, per diſtantias ipſius à Polo Mundi, vel ab vna aliqua ſtella Fixa captas, eàdem vel diuerſis noctibus: Dummodo non habeat motum proprium, à motu primi Mobilis diuerſum, aut habeat, ſed diſcretè à motu viſo præcognoſcibilem aut præconceſſum; nec refractio interſit, aut cognita ſit & detracta. *Problem 56. To explore whether a phenomenon has a sensible parallax, or even one greater than the Moon's or the Sun's, by its distances from the pole of the world, or from some one fixed star, taken on the same night or on different nights — provided that it has no proper motion different from the motion of the primum mobile, or, if it has one, that this can be known beforehand distinctly from the visible motion, or is granted beforehand; and that refraction does not enter in, or else is known and taken away.*

[Margin: Problem 56.]

[Margin: Authors or practitioners of this problem.]

This problem is customary in observations of comets and new stars, and it was used above all by Thaddaeus Haggecius [Tadeáš Hájek] in his *Dialexis*, in Tycho, *Progymnasmata* volume 1, page 513; by Maestlinus [Michael Mästlin], in the same author, page 545; by Kepler in his book on the new star of Serpentarius [*De stella nova*], chapter 15; by our Cysat, *De Cometa anni 1618*, chapter 3, proposition 4; by Santutius, *De Cometa anni 1577*, chapter 8; by Snellius [Snel], on the comet of the year 1618, chapter 4; and by Longomontanus in the Appendix to the *Astronomia*, chapter 10. But they do not add the limitations that we have set down — and yet without them, as we have shown in Book 8, chapter 11, nothing certain can be gathered in this matter, and this will become plain from the present problem itself.

[Margin: Method 1, Kepler's.]

The first method is Kepler's, at the place just cited. For it, in the next diagram, let A be the centre of the Earth and B the eye on the surface of the terrestrial hemisphere MBN; let KEFP be the ecliptic of the fixed stars, and

LCDO the heaven, or as it were the heaven, of the phenomenon. Now let the phenomenon be observed by taking its distances from some known fixed stars, from which, by the laws of triangles, the visible place of the phenomenon in longitude and latitude can be deduced. Let this place on the ecliptic be at G, in the east, and to it let the line of the true place, ACG, be drawn, passing through the centre C. Then let the same place be awaited after some days or weeks, until it visibly becomes western, at H; to it let the straight line ADH be drawn from the centre of the Earth through the phenomenon D. At both times let the altitude of the phenomenon be taken, or its distance from the point G and from H, directly or by means of some star. For if it has a parallax equal to the Moon's, or a sensible one, it will not appear at both times under the same place among the fixed stars: at its rising it will be seen lower down, at E, along the line BCE, and at its setting at F, along the line BDF — given, however, the condition that Kepler adds there on page 78, namely *if it stays at rest under the same place of the fixed stars*; that is, if it is moved by no motion other than that of the primum mobile.

Diagram. A small figure set into the left column beside the account of Kepler's method. Three concentric semicircles stand on one base line; straight lines run up from the centre A and from B.

- E (top, left): on the line BCE, where the phenomenon is seen at its rising
- G (top, left, above E): the place on the ecliptic at the end of the line ACG
- C (on the middle semicircle, left): the phenomenon at the first observation
- B (on the inner semicircle, at the middle): the eye on the Earth's surface
- D (on the middle semicircle, right): the phenomenon at the second observation
- H (top, right): the place at the end of the line ADH
- F (top, right): on the line BDF, where the phenomenon is seen at its setting
- K, L, M, A, N, O, P (along the base, left to right): A the centre of the Earth; MBN the terrestrial hemisphere; KEFP the ecliptic of the fixed stars; LCDO the heaven of the phenomenon

[Margin: Method 2, the more common.]

The second method I have already taught in chapter 9, Problems 45, 46 or 47, or in chapter 10, Problems 51 and 53.

57. Probl. Datis duabus Phænomeni Altitudinibus viſis & exquiſitè obſeruatis, vtràq. ante vel poſt meridiem, cum ſuis Azimuthis, & cum Tempore inter vtramq. obſeruationem interiecto, Parallaxin eius in circulo altitudinis Inueſtigare: dummodo non habeat alium motum, quàm primi Mobilis, & altitudines viſæ per detractionem Refractionis præcognitæ, corrigantur. *Problem 57. Given two visible altitudes of a phenomenon, exquisitely observed, both before noon or both after, together with their azimuths and with the time elapsed between the two observations: to investigate its parallax in the circle of altitude — provided that it has no motion other than that of the primum*

mobile, and that the visible altitudes are corrected by taking away the refraction known beforehand.

[Margin: Problem 57.]

[Margin: The problem that is Regiomontanus's second.]

Among the 16 problems on comets that Regiomontanus left us for the study of comets, this is the second; Tycho also proposes it from that source in volume 2, from page 147 and at page 242, and so does Chiaramonti in the *Antitycho*, Book 2, chapter 16. What I said about the motion of the primum mobile alone is a limitation expressed by Regiomontanus, who says: *But let us imagine that the comet is moved, in so small a space of time, only according to the motion of the primum mobile.* Now, then, for the analysis of this problem, in the following figure let BZS be a portion of the meridian and BPC half of the western horizon. In the first observation let the true place of the phenomenon be at L but the visible place at M, and through these two places let the quadrant ZLMK of a vertical circle be drawn. Next, in the second observation, let the phenomenon be truly at G but apparently at O, and through these places let another quadrant of a vertical circle, ZGO etc., be drawn. The two parallaxes of altitude will then be the arcs LM and GO. Afterwards, through the two true places L and G, let the semidiurnal arc ALGD be drawn, parallel to the equator, in which the phenomenon moves with the motion of the primum mobile; and from the difference of the observed time between the two observations let the arc LG be known. Through the second, visible, place O let another semidiurnal arc QNOS be drawn, parallel to the first. Now let G and O be joined to the pole of the world H by the arcs of declination HG and HO, and to the earlier true place L let the arc of declination HL be drawn, which will be equal to the arc HG by 10 of Book 2 of Theodosius's *Spherics*. From H let the arc of declination HN be drawn to the parallel QOS — for this too will be equal to the arc HO by the same 10 — but let it be drawn so that the angle LHN is equal to the angle GHO. Let the true place L be joined to N by the arc LN, and the visible place M to N by the arc MN; finally, from M let the perpendicular arc MF be drawn to LN; and through N, from the vertex Z, let the quadrant ZNP be drawn. But if both observations were made before noon, BEC will be the eastern horizon, and the first true place of the phenomenon will be at G and the visible at O, while the second true place is at L and the visible at M; the rest as above.

Diagram. A figure across the right column in the course of Problem 57. A large semicircular outline stands on a base line; Z stands at the top and H at the upper right; several arcs cross from the left side to the right-hand end, and others run down from Z and from H.

- Z (top): the vertex; on the meridian BZS
- H (upper right): the pole of the world
- A (left side, upper): start of the semidiurnal arc ALGD
- Q (left side): start of the semidiurnal arc QNOS
- L (left side): the true place at the first observation
- M (left side, below L): the visible place at the first observation

- F (beside M): foot of the perpendicular arc MF on LN
- N (left side, lower): on the parallel QNOS
- G (inside, lower centre): the true place at the second observation
- B (left end of the base): end of the meridian portion BZS and of the horizon BPC
- K (below B): end of the quadrant ZLMK
- P (bottom): on the horizon BPC; end of the quadrant ZNP
- O (bottom): the visible place at the second observation
- [?] (bottom, between O and S): a small letter, E or F
- [?] (right-hand end of the base, upper): a small letter, C or G
- D (right-hand end, below it): end of the semidiurnal arc ALGD
- S (lower right): end of the meridian portion BZS and of the arc QNOS

[Margin: Step 1.]

First, therefore: because in the intervening time the point L is carried to G by the motion of the primum mobile, the point N must also be carried over to O, since the angles GHL and NHO are equal to each other: for to one and the same common angle N- [Margin: Order of the problems.]

HG the equal angles GHO and LHN have been added by construction; so the whole GHL is equal to the whole NHO, and the arc NO is similar to the arc LG of the true motion. Now from the second observation the complement of the visible altitude, ZO, is given; also given is the first azimuth, BZO, which, subtracted from 180°, leaves known the adjacent angle OZH. With this, with ZO, and with ZH, the complement of the altitude of the pole, one finds in the triangle OZH the side HO, the angle HOZ and the angle ZHO, which measures the distance of the point O from the meridian.

[Margin: Step 2.]

Second: the angle GHL is known from the time between the two observations, converted into parts of the equator. But the arc NO of the parallel is similar to this arc LG; therefore the angle NHO is equal to the angle LHG, as we were also saying above, and so it too is known. When it is taken from the angle ZHO already found, the angle ZHN is left known in the triangle ZNH, in which are given, as above, the arc ZH, the complement of the altitude of the pole, and the arc HN, since by construction, and by 10 of the second book of Theodosius's *Spherics*, it is equal to the arc HO found. So neither the arc ZN, nor the angle NZH, nor ZNH will be hidden. When NZH is subtracted from 180°, then, the angle NZB, adjacent to it, will be known; and when the azimuthal angle BZK is subtracted from this, MZN will be left known.

[Margin: Step 3.]

Third, then: in the triangle MZN, in which the arc ZN and the angle MZN have already been found, and the complement MZ of the visible altitude in the other observation is given, find the side MN and the angles ZNM and ZMN. Then combine the angle ZNM with ZNH found earlier, and the whole angle HNM will be known.

[Margin: Step 4.]

Fourth: the angles ZHO and ZHL have long been known by the first step, from the distance from the meridian known through the time. If you subtract the latter from the former, LHO remains known; and when LHG, known from the time elapsed between the observations, is subtracted — subtracted, I say, from the angle LHO — the angle GHO is left known. By construction, however, the angle LHN is equal to it. For the two triangles GHO and LHN have been set up with equal sides, and with equal angles comprised by equal sides — the side HL equal to the side HG, the side HN to the side HO, and the angle LHN to the angle GHO. So the base LN is also equal to the base GO, and the angle LNH to the angle GOH.

[Margin: Step 5.]

Fifth, then: in the triangle LHN find the base LN. For in it the angle LHN has been found, since it is equal to the angle GHO; the side HN, which is equal to the side HO found by the first step; and the angle LNH, since it is equal to the angle GOH found by the same first step. Since, therefore, the LN found is equal to the base GO, and this is a parallax of altitude, this parallax will be known.

[Margin: Step 6.]

Sixth: subtract the known angle LNH from the whole, or composite, angle HNM found above, and the angle MNL will be known in the same triangle MNL, in which the side MN has already been found by the third step and LN by the fifth. Hence the side, or base, ML will not be hidden — namely the other parallax of altitude. *For the sake of these we have wearied ourselves thus far*, says Regiomontanus; for who would not be wearied by so manifold an analysis of triangles? Then he adds: *All these things suppose that the comet, in the time between the two considerations, is not moved except according to the motion of the primum mobile; and even if it is moved meanwhile, in so short a time its proper motion will not be very sensible. But the arc HG — that is, the distance of the comet from the pole of the world, or the complement of the declination — will vary far less sensibly.* Regiomontanus perhaps supposed this because, trusting the Peripatetic doctrine about the sublunary seat of comets, and so about their great parallax, he did not think that an error of a few minutes, arising from the proper motion, in the parallax being searched out needed attending to. But how did he know that the comet's proper motion is small? For if it is small, someone will say, it will not produce even a sensible variation; or if it does produce one, it is large, and that variation arose from the comet's irregular proper motion, not from a true parallax. Therefore this method, sought out with such subtlety of mind, is useless for an absolute conclusion about the comet's parallax and distance unless it is propped up by some other aid; it holds only for a hypothetical conclusion, namely if the comet is granted no proper motion, or one imperceptible over a few hours. Besides which, the visible altitudes ought first to have been corrected, once the refraction was known.

58. Probl. Regiomontani Problema prædictum Tychonico adminiculo certius reddere, Datis Altitudine, & Declinatione viſa Phænomeni & Altitudine Poli. Sed ſupponendo Altitudinem viſam non indigere correctione Refractionis, aut iam correctam eſſe. *Problem 58. To make the problem of Regiomontanus already mentioned more certain with a Tychonic aid, given the visible altitude and declination of the phenomenon and the altitude of the pole — but supposing that the visible altitude does not need correction for refraction, or has already been corrected.*

[Margin: Problem 58.]

Tycho saw, in volume 2, page 147, that the problem of Regiomontanus already mentioned is not exact because of the proper motion — which almost all comets have, sensible even over an interval of a few hours — unless the difference that arises from the proper motion is removed. He therefore devised a method of reducing the azimuths so that they show the place of the comet as if it were unmoved, or carried by no motion other than that of the primum mobile, by the following problem. He also uses it in volume 1, page 755, and so does Chiaramonti in *De sede sublunari cometarum*, part 2, chapter 21.

[Margin: Here two observations as close together as possible are supposed, so that the altitude may not vary sensibly; and yet the phenomenon's proper motion in so tiny a time is taken as known beforehand, so that the declinations may be corrected by it, etc.]

In this other figure, then, let HAC be the semicircle of the meridian and ALC the horizon, and let the comet be seen at D in the first observation and at F in the second. Through these two places describe from the vertex A two quadrants of vertical circles, ADI and AFK; and from the pole of the world B two quadrants of circles of declination, BDE and BFG, down to the equator MEGL. With these described:

[Margin: Step 1.]

First: in the triangle ADB all the sides are given, since AB is the complement of the altitude of the pole, AD the complement of the visible altitude of the phenomenon, and BD the complement of the visible declination. Find, therefore, the angles BAD and ADB, and if need be the angle ABD — although in Regiomontanus's problem this angle was already presupposed known, from the distance in time from noon converted into parts of the equator, just as the angle ABF was, from the distance from the meridian when the phenomenon was observed the second time. So when ABD is taken from ABF, the angle DBF is left known; this is the difference of right ascension, as Tycho says, changed in the interval between the one observation and the other — just as the angle ABF becomes known from the angle EBG of the intervening time, if this had been observed, when ABD is added to it.

Diagram. A figure set into the right column in the course of Problem 58. A semicircle stands on a base line; A stands at the top and B on the arc at the upper right; arcs run down from A to the base and across from B towards the left.

- A (top): the vertex
- B (on the arc, upper right): the pole of the world
- M (on the arc, left): start of the equator MEGL
- D (inside, below A): the comet at the first observation
- F (inside, below D): the comet at the second observation
- E (inside, left): on the equator, end of the quadrant BDE
- G (inside, left, small): on the equator, end of the quadrant BFG
- H (left end of the base): end of the meridian semicircle HAC
- I (on the base): end of the quadrant ADI
- K (on the base): end of the quadrant AFK
- L (on the base): on the equator MEGL and the horizon ALC
- [?] (right-hand end of the base): a letter, C or G

[Margin: Step 2.]

Second: in the triangle AFB, too, the sides are given — AB, as above, and BF, the complement of the second declination, likewise the visible one — and the angle ABF is already known; therefore the arc AF will not be hidden. Compared with the complement of the altitude observed the second time, it will show either no difference or some difference; Tycho, however, found an insensible difference in the example of his comet, volume 2, page 149. Next, the angle BAF will not be hidden either. Subtracted from the angle BAD found by the first step, it leaves known the angle IAK, which measures the arc IK — that is, the difference of the azimuths between the place of the comet moved and at rest. So when the arc IK is added to the azimuth of the later observation, the azimuth will be reduced to what it would be if the phenomenon had not moved at all, or had moved with no motion other than that of the primum mobile. With the azimuths so corrected, the rest is to be carried out as Regiomontanus prescribed. If anyone wants examples of it, let him consult Tycho's volume 2, from page 149 to 158, or us in Book 8, Section 1, chapter 18, numbers 9 and 24. But let him remember that for the azimuths Tycho sometimes takes the distance of the vertical circle in which the phenomenon lies from either primary vertical — that is, not only from the meridian but also from the one that passes through the intersections of the equator and the horizon. So in the scheme already mentioned the azimuth of the phenomenon D is the arc IL, and that of the phenomenon F the arc KL.

[Margin: Tycho's calculations in volume 2 are less exact than in volume 1, because refraction is omitted.]

Next, let him notice that Tycho, on pages 146 and 150, uses visible altitudes of the comet — one of 28° 56′, the other of 12° 12′ — without applying the correction for refraction; and so Chiaramonti rightly censures him in Book 2 of the *An-* [Margin: Order of the problems.]

titycho, chapter 17. For from the visible altitude of 12° 12′ he ought to have subtracted 9′, according to the little table of Tychonic refractions. Moreover, throughout volume 2 Tycho used 34° 7′ for the complement of the altitude of the pole, or the arc AB, which he nevertheless later found to be 34° 5′ 30″

because of the refractions of the Sun at the winter solstice — refractions he had not yet scented out when he wrote volume 2. For this volume was written first, although it was published later by his heirs.

59. Probl. Datis altitudine Phænomeni viſa ante vel poſt meridiem, cum Azimutho, & Momento temporis tum huius Azimuthi ac altitudinis, tum eo quo Phænomenon tranſit per Meridianum; & Altitudine Poli, Inueſtigare Parallaxim altitudinis; dummodo interuallo horum temporum Phænomenon non moueatur niſi motu primi Mobilis, aut motus proprius ſit notus; & Refractio nulla ſit, aut iam detracta altitudini viſæ. *Problem 59. Given the visible altitude of a phenomenon before or after noon, with its azimuth and the moment of time both of this azimuth and altitude and of the phenomenon's transit through the meridian, and given the altitude of the pole: to investigate the parallax of altitude — provided that in the interval between these times the phenomenon is not moved except by the motion of the primum mobile, or its proper motion is known; and that there is no refraction, or it has already been subtracted from the visible altitude.*

[Margin: Problem 59, and the 3rd of Regiomontanus.]

This is the third problem of Regiomontanus in his little work *De Cometis*, from which Tycho drew it, volume 1, page 756. In the accompanying scheme let HVQ be the meridian, HOR the horizon and AOQ the equator; and let the true place of the phenomenon be at F, but its visible place at G. Through these two places draw both the quadrant VFGT of a vertical circle and the quadrants PFK and PGM of circles of declination — the former from the vertex V, the latter from the pole of the world P. With these set down, in the triangle VPF the arc VP, the complement of the altitude of the pole, is known; so is the angle FVP, if the azimuthal angle AVT is subtracted from 180°; and so is the angle VPF, from the true time between the observation and the phenomenon's transit through the meridian, converted into parts of the equator. So the side VF, which is the complement of the true altitude of the phenomenon, will not be hidden from the trigonometer. When the arc VF, then, is subtracted from the complement VG of the visible altitude, the parallax of altitude FG will remain known.

Diagram. A figure set into the left column in the course of Problem 59. A circle, with V at the top and a line across its lower half from H to R; lines run down from V and across from P.

- V (top): the vertex
- F (inside, below V): the true place of the phenomenon
- G (inside, below F): its visible place
- P (on the circle, upper right): the pole of the world
- [?] (on the circle, upper left; a sort shaped like a 4 after a short dash): A or 4
- K (inside, left): end of the quadrant PFK

- H (left end of the line across): on the meridian HVQ and the horizon HOR
- M (on the line HR): end of the quadrant PGM
- O (below the line HR): on the horizon HOR and the equator AOQ
- T (below the line HR, right): end of the quadrant VFGT
- R (right end of the line across): on the horizon HOR
- Q (on the circle, lower right): on the meridian HVQ and the equator AOQ

[Margin: What is to be done if the phenomenon moves with a proper motion.]

But if, from the beginning of its apparition up to the end, or up to the time of the observation already mentioned, the phenomenon has had a proper motion that has been ascertained, distribute that motion over the intervening times. For example, if it completed 90° in 60 days, assign one and a half degrees to each day and 3′ 45′ [?] to each hour. Or if it advances with a uniformly difform motion, correct the distribution already mentioned as the motion proper to the day of the observation requires; and to the hours between the transit through the meridian and the moment of the observation add or subtract as much as that proper motion requires, compared with the motion of the primum mobile before or after noon and with the phenomenon's tendency in the succession of the signs or against the succession of the signs, so that you have the angle VPF corrected. But either Regiomontanus did not notice that the true proper motion of the phenomenon cannot be discerned from the visible motion without prior knowledge of the parallax, or he disregarded this as something slight. Besides, if the proper motion is transverse and mixed from motion in longitude and in latitude, it can hardly be fitted to correcting the motion of the primum mobile.

60. Probl. Datis Phænomeni apparentis tam ante ortum, quàm poſt occaſum Solis, Altitudinibus viſis antemeridiana, & pomeridiana æqualibus, cum vtroque Azimutho, & Tẽpore obſeruatarum altitudinum, & Altitudine poli; Parallaxin altitudinis Inquirere, dummodo aut motum alium non habeat, quàm motum primi Mobilis, aut motus eius proprius ſit præcognitus; & Refractio nulla ſit, aut dempta iam altitudini viſæ. *Problem 60. Given the visible altitudes, before noon and after noon, and equal, of a phenomenon appearing both before the rising and after the setting of the Sun, with both azimuths and the time of the observed altitudes, and given the altitude of the pole: to inquire the parallax of altitude — provided either that it has no motion other than the motion of the primum mobile, or that its proper motion is known beforehand; and that there is no refraction, or it has already been taken from the visible altitude.*

[Margin: Order of the problems.]

[Margin: Problem 60, and the 4th of Regiomontanus.]

Let us go on to the 4th problem of Regiomontanus, in his little work *De Cometis*. For it, in the following diagram, let ABCD be the horizon and DVB the semicircle of the meridian, in which P is the visible pole of the world and V

the vertex or zenith; and let AKC be the arc that the phenomenon describes by the motion of the primum mobile. Let its first true place be at G, a point before noon, and its second at M, a point after noon; but let it be seen in the first case at O, in the second at N. Through these draw two quadrants of vertical circles, VGOH and VMNR, and to the true places two arcs of declination, PG and PM. Now since the visible altitudes HO and RN are supposed equal, the true altitudes HG and RM must also be equal, since an equal parallax belongs of itself to an equal altitude of the same phenomenon. So their complements too, the arcs VG and VM, will be equal to each other. Indeed, Regiomontanus says, it follows from this that GK and MK are equal to each other, and PG and PM to each other. From the time of the two observations the arc GKM is known, and the angle GPM, whose halves are GPB and MPB. From the azimuths, moreover, are known the angle GVK, whose supplement to two right angles is PVG, and the angle MVK, whose supplement to two right angles is the angle PVM. So in the triangle PVG, from the known angles PVG and VPG and the arc PV, which is the complement of the altitude of the pole, you will be able to find the side VG; when it is subtracted from the complement VO of the visible altitude, the parallax of altitude GO will become known. Likewise in the triangle PVM, from the known angles PVM and VPM and the arc PV, you will gather the side VM; when it is taken from the complement VN of the visible altitude, the parallax of altitude MN will be left. And if you like, you will be able, by solving the same triangles, to investigate the complement of the true declination, both PG and PM.

Diagram. A figure set into the right column in the course of Problem 60. A circle with a vertical line from D at the top to B at the bottom, carrying P and V; two arcs run down from V to the lower left and lower right, and a line crosses the lower part of the circle from A.

- D (top): end of the meridian semicircle DVB
- P (on the line DB): the visible pole of the world
- V (on the line DB, below P): the vertex or zenith
- A (left end of the line across): on the horizon ABCD and the arc AKC
- M (where the left arc meets the line across): the second true place
- G (where the right arc meets the line across): the first true place
- G (right end of the line across)
- N (below M, with a small star): the second visible place
- K (on the line DB, below the line across): on the arc AKC
- o (below G, set small, with a small star): the first visible place
- R (lower left, outside the circle): end of the quadrant VMNR
- B (bottom): end of the meridian semicircle DVB
- H (lower right, outside the circle): end of the quadrant VGOH

Finally Regiomontanus advises that if the phenomenon has a proper motion, the intermediate time — that is, the arc GKM — should be corrected, and from it the angles at P likewise, as was said in the preceding problem. This problem, moreover, is useful for phenomena that cannot be observed when they cross the

meridian because the Sun is above the horizon, provided they can be observed both before the rising and after the setting of the Sun, by waiting for them until they have reached the azimuth in which the visible altitude is equal to the altitude seen earlier; or the altitudes may be taken at equal azimuths. But then one must take, at the same moment, the altitude of a known fixed star, so that from it, by the usual rules of the primum mobile given in Section 3, each moment of time may become known.

61. Probl. Si Phænomenon fuerit cum duabus Fixis ſub eodem verticali citra Meridianum, & capiatur eodem momento diſtantia ipſius à vertice & ab vtraq. Fixarum. Deinde, cùm motu Firmamenti delatum fuerit ad alium verticalem vltra Meridianum tantum quantum prior verticalis citra Meridianum fuerat, capiatur diſtantia à vertice & ab ijſdem Fixis, & altitudo alterutrius Fixarum: Parallaxes vtriuſq temporis ſeorſim eruere, ſecluſis interim Refractionibus, aut correctis per eas diſtantijs & altitudinibus. *Problem 61. If the phenomenon is under the same vertical as two fixed stars on this side of the meridian, and its distance from the vertex and from each of the fixed stars is taken at the same moment; and then, when it has been carried by the motion of the firmament to another vertical as far beyond the meridian as the former vertical was on this side of it, its distance from the vertex and from the same fixed stars is taken, together with the altitude of one or other of the fixed stars: to elicit the parallaxes of each time separately — refractions set aside for the present, or the distances and altitudes corrected by them.*

[Margin: Problem 61.]

This problem is Thomas Digges's, in his *Dialexis*, where it is his 17th — very evident indeed, [Margin: Order of the problems.]

but, because of the slenderness of the angles, slippery in the practice of calculation, as Tycho warns, volume 1, page 666. In the next scheme let B be the vertex, from which the quadrant BIA of the meridian descends into the portion DAE of the horizon; and from the same vertex let the vertical quadrant BD be drawn for the earlier observation, in which let the true place of the phenomenon be G, but the apparent place K, and the visible distances from the fixed stars KH and KI. Next, for the second observation, let BLE be the quadrant of another vertical, whose distance AE from the meridian is as great as DA, that of the earlier one (granted that in this figure it appears greater); and in it let the apparent place of the phenomenon be L, as far from the true place G as it was in the first observation — the place being marked with the same letter; just as the stars I and H, and the trace of the earlier visible place, ought to be marked on the same transverse arc IK of a great circle. Next let the visible place L of the phenomenon be connected with the fixed stars by the arcs LI and LH of a great circle; and from B let the arc BH be drawn, the vertical to H. From these, the task is to investigate the parallaxes GK and GL.

Diagram. A figure set into the left column in the course of Problem 61. B stands at the top; an arc runs down the left side from B to D, and a curved base

runs from D through A to E; on the right an arc runs from B down to H, with L below it and I inside to the left.

- B (top): the vertex
- I (on the left arc, with a star): a fixed star in the first observation
- G (on the left arc, with a dot): the true place of the phenomenon
- K (on the left arc, with a star): the apparent place in the first observation
- H (on the left arc, with a star): a fixed star in the first observation
- D (left end of the base): on the horizon DAE, end of the vertical quadrant BD
- A (bottom of the base): end of the meridian quadrant BIA
- I (inside, left): the star I in the second observation
- G (small, near H): the true place in the second observation
- K (smaller, beside G near H, set tilted along the arc)
- H (right): the star H in the second observation
- L (below H): the apparent place in the second observation
- E (right end of the base): end of the vertical quadrant BLE

[Margin: Step 1.]

First, then, in the triangle ILH the three sides are given: namely the visible distance IL of the phenomenon L from the star I; its distance HL from the star H; and the distance IH of the fixed stars between [?], which is known either from elsewhere or from the very visible distances from the phenomenon in the earlier observation. So the angle IHL will not be hidden.

[Margin: Step 2.]

Second: in the triangle BLH, if the altitude of the star H has been taken, the three sides are known — namely LH, the visible distance of the phenomenon from the star H; BL, the complement of the visible altitude of the phenomenon; and BH, the complement of the visible altitude of the star H. So the angles BHL and HBL will not be unknown. But if the altitude of the star I has been taken, in the triangle IBL there will be given BI, the distance IL, and BL, as above; and neither the angle IBL nor BIL will be hidden.

[Margin: Step 3.]

Third: if you subtract the angle IHL from the angle BHL, the angle BHG is left. With it, and with the angle HBL — that is, HBG — and with the side BH, find the sides BG and HG. For when BG is subtracted from the arc BL, GL, the later parallax, will be known; and when KH — that is, the earlier visible distance of the phenomenon K from the star H — is subtracted, below I, GK, the earlier parallax, will be known. But if the altitude of the star I was taken, use the triangle BIG. For in it are given BI, the complement of the altitude of the star I; the angle IBG, that is, IBL; and the angle BIG, namely when HIL is subtracted from the angle BIL. Then find the arcs BG and IG. For BG, subtracted from BL, leaves the parallax GL; and the arc IG, subtracted from the earlier distance IK, leaves the earlier parallax GK.

62. Probl. Conſiſtente Phænomeno ſub eodem Verticali cum duabus Fixis, & captis eius diſtantijs ab vtraq. Fixarum; rurſuſq. in ſecunda obſeruatione, non habita ratione Verticalium, captis Phænomeni diſtantijs ab ijſdem Fixis, vnà cum altitudine phænomeni, & alterutra Fixarum: Parallaxes vtriq. tempori congruas Inueſtigare, ſecluſa interim Refractione, aut per eam correcto loco viſo. *Problem 62. The phenomenon standing under the same vertical as two fixed stars, and its distances from each of the fixed stars having been taken; and again, in the second observation, without regard to the verticals, the phenomenon's distances from the same fixed stars having been taken, together with the altitude of the phenomenon and of one or other of the fixed stars: to investigate the parallaxes belonging to each time — refraction set aside for the present, or the visible place corrected by it.*

[Margin: Problem 62.]

This problem differs from the preceding one only in that in the second observation the fixed stars and the visible place of the phenomenon have another situation. It is Digges's 19th, and Tycho reports it in volume 1 of the *Progymnasmata*, page 668, as does Longomontanus in Book 2 of the *Spherics*, chapter 10, problem 2. We, however, have drawn the scheme together into the following form. In it let ABC be the meridian and ALC the horizon; B the vertex and D the pole of the world; let BN be the vertical quadrant of the first observation, in which let one of the fixed stars be at H and the other at O; and in the same quadrant let the true place of the phenomenon be at P, but the apparent place at Q. Now let those stars, together with the phenomenon, have been carried by the force of the primum mobile into another situation, which on the same great circle shows the star H at H and the star O at G, and the true place of the phenomenon at F, with the earlier parallax EF, but the place seen later at K, with the parallax FK. Through FK, then, draw the vertical BM, and through G the vertical BL; and connect K with E, G and H by the arcs KE, KG and KH.

Diagram. A figure set across the right column in the course of Problem 62. A semicircle with B at the top and a curved base from A to C; a line runs down from near B to N, and lines run from B down to M and to L.

- B (top): the vertex
- D (on the arc, upper right): the pole of the world
- E (inside, left, with a star): the earlier apparent place carried into the second situation
- F (inside, with a dot): the true place in the second situation
- G (under B): the star O in the second situation
- H (under B, beside G): the star H in the second situation
- I (on the line to N, with a dot): not named in the prose of this page
- O (on the line to N, with a star): the other fixed star in the first observation
- P (on the line to N, with a dot): the true place in the first observation
- Q (on the line to N, with a star): the apparent place in the first observation
- K (lower left, inside): the place seen later

- A (left end of the base): on the meridian ABC and the horizon ALC
- M (below the base): end of the vertical BM
- L (below the base): end of the vertical BL, on the horizon ALC
- N (below the base, right): end of the vertical quadrant BN
- C (right end of the base): on the meridian ABC and the horizon ALC

[Margin: Order of the problems.]

[Margin: Step 1.]

With these described: First, since from the first observation the visible distance QO is known, which in the other situation is EG, and the visible distance OH, which is GH; and since from the second observation the visible distances KG and KH are known, the triangle KGH will be of known sides, and so the angles KHG and GKH can be known.

[Margin: Step 2.]

Second: in the triangle EKH the distance EH seen earlier is known, and the distance HK, with the angle KHE; so the arc KE will become known, with the angles EKH and HEK.

[Margin: Step 3.]

Third: in the triangle KBG, KB is known, the visible distance of the phenomenon K from the vertex; and BG, likewise the distance of the star G from the vertex; and KG, the distance of the phenomenon from the star G. Therefore the angle BKG will become known. Added to the angle GKH, it will make up the angle FKH; and this, taken from the angle EKH, will leave the angle EKF.

[Margin: Step 4.]

Fourth, then: in the triangle EKF, in which besides the angle EKF the angle KEF and the arc KE are known, both the earlier parallax EF and the later parallax KF will become known.

CAPVT XI.

Chapter XI.

De Modis colligendi an, aut etiam quantam Parallaxin Altitudinis habeat Phænomenon, præſertim nouum, ex Obſeruationibus in diuerſis terræ locis factis. *On the methods of gathering whether a phenomenon, especially a new one, has a parallax of altitude, or even how much, from observations made at different places on Earth.*

In almost all the following problems the distance of the two places on a great circle of the Earth is supposed known, or the distance of the meridians lying between the two places of the Earth's surface at which, or from which, the same phenomenon is observed; or at any rate the altitude of the pole at each place is known, or both are known — even if this is not always expressed in the title of the problems. And whenever in these or similar schemes a single true place of the phenomenon is marked, it is a sign that the observation is supposed to have been made at the same moment of time in both places.

63. Probl. Data Semidiametro terræ, Differentia altitudinis Poli duorum locorum ſub eodem Meridiano, vel Longitudinis ſub Aequatore, vel Diſtantiæ ſub quouis verticali, & obſeruato eodem die naturali Phænomeno in Horizonte vtriuſq. loci, Altitudinem Phænomeni & Parallaxin Altitudinis decernere, ſecluſa interim Refractione horizontali, aut per eam correcto loco viſo. *Problem 63. Given the Earth's semidiameter, and the difference of the altitude of the pole of two places under the same meridian, or of longitude under the equator, or of distance under any vertical, and the phenomenon having been observed on the same natural day on the horizon of each place: to determine the altitude of the phenomenon and the parallax of altitude — horizontal refraction set aside for the present, or the visible place corrected by it.*

[Margin: Problem 63.]

From the Earth's centre T let there be described the semicircle NKQ of the hemisphere, of a great circle under the portion of the meridian

[Margin: Order of the problems.]

ABC, or, for the second case, under the equator ABC. Then, with the straight line TKB drawn, bisecting the terrestrial semicircle at K, where one observer is to be, and standing perpendicularly on the horizontal diameter NTQ, let two places on Earth, G and M, be assumed, equally distant on either side from the point K; or, if they are already given, let their distance, that is the arc GM, be bisected at K by the straight line TKB. For GK, or KM, will be the half-difference of the altitude of the pole, if the places are under the same meridian; or of the longitude, if they are under the equator.

Diagram. A figure set into the left column in the course of Problem 63. A vertical line runs from B at the top down to T at the base; a small semicircle stands on the base from G to M, and lines from G and M cross the vertical at L and, higher, at I, reaching the arcs above.

- O (top, left of B): end of the tangent MIO
- B (top): end of the straight line TKB
- R (top, right of B): end of the tangent GIR
- I (on the vertical, below B): the phenomenon's apparent place when G and M are further from K
- A (upper left): end of the tangent MLA
- C (upper right): end of the tangent GLC
- E (left end of the middle arc): end of the arc EIH
- H (right end of the middle arc): end of the arc EIH
- L (on the vertical, lower): the phenomenon's apparent place
- D (left end of the lower arc): on the arc through L
- F (right end of the lower arc): on the arc through L
- K (on the vertical, below L): the point of one observer, on the terrestrial semicircle
- G (left, on the small semicircle): a place on Earth
- M (right, on the small semicircle): a place on Earth
- N (left end of the base): end of the horizontal diameter NTQ

- T (bottom): the Earth's centre
- Q (right end of the base): end of the horizontal diameter NTQ

[Margin: By 18 of the third book of Euclid.]

Now from G and M let the straight lines GLC and MLA be drawn out, touching the Earth at G and M and making right angles there with the Earth's semidiameters TG and TM. Where they intersect each other on the straight line TKB — namely at L — there will be the place of the phenomenon as it appears on the physical horizon of each observer, which horizon the tangents already mentioned represent. And TL will be the distance of the phenomenon from the Earth's centre. With this interval an arc can be described, either of the heavens or of the elementary region, in which the phenomenon is supposed to lie under the meridian or the equator. Its horizontal parallax, moreover, will be the arc AB, which the angle TLM measures, though not immediately; or the arc BC, which the angle TLG measures, from what was said in chapter 1. Similarly, if the places G and M are further from K, and the tangents drawn out from them are GIR and MIO, the place of the phenomenon appearing on both physical horizons will be I, its distance IT, the arc in which it will lie EIH, and the horizontal parallax OB on one side and BR on the other, which the angles MIT and GIT measure. With this set down, let the phenomenon be at L. For in the triangle GLT, right-angled at G, there is given the side GT, which is one semidiameter of the Earth, or assumed as one, or in the miles contained in it; there is given also the angle GTK, which the arc GK measures — that is, the half-difference of the altitude of the pole if the places G and M are under the same meridian, or of the longitude if they are under the equator. Therefore, by the rules of right-angled triangles, neither the distance of the phenomenon, that is the base TL, will be hidden, nor the angle GLT, which measures the horizontal parallax. And in the same way, from the triangle GIT you will elicit the altitude TI, or the distance of the phenomenon from the Earth's centre, and the parallactic angle GIT — if, that is, a straight line is drawn from I to the point of contact G, which, however, you must imagine nearer to the point N than it is now, when the phenomenon was being considered at L; just as the twin straight line from T to G must also be supplied.

EXEMPLVM *Example.*

Let G, the island of São Tomé, be under the equator, and M another place 165° distant from it. Half of these degrees, that is the arc GK, or the angle GTL, will be 82° 30′. Let the Earth's semidiameter TK, or TG, be put at 4139 of our Italian miles (as we have found). For by the analysis of the right-angled triangle TGL the interval TL is found to be 27,571 miles, that is, 6 terrestrial semidiameters and 2737 miles besides; and the parallax GLT, at its greatest, 8° 38′. But so that it may appear how great a distance between two places on Earth is required for the phenomenon to be above the Moon — whose least distance truly lies at about 52 semidiameters of the Earth — let the following little table stand. Its first column contains the distance of two places set on the same great

circle of the Earth; the second, the altitude of the phenomenon needed for it to be seen at the same time from each place, on the physical horizon of each. For if it is seen on that horizon, there is no doubt that, raised above the horizon, it can be seen from the same places, and much more by those living within G and M, towards K, and in other places less distant from each other than the arc GKM.

Arc of distance on a great circle	Semidiameters of the Earth	Italian miles
7° 30′	0	10
15° 0′	0	36
30° 0′	0	146
45° 0′	0	341
60° 0′	0	641
75° 0′	0	1078
90° 0′	0	1715
105° 0′	0	2660
120° 0′	1	0
135° 0′	1	2538
150° 0′	2	3575
165° 0′	6	2737
172° 30′	14	1200
176° 15′	29	2329
177° 30′	47	1067
178° 45′	90	1960

64. Probl. Datis Diſtantijs Phænomeni à Vertice, & ab eadem, vel ijſdem ſtellis Fixis, ex duobus Terræ Locis ſub eodem verticali, eodem momento obſeruatis; vnà cum Diſtantia locorum terræ; Inueſtigare Parallaxim Phænomeni abſolutam, vel comparatam cum Parallaxi Lunari; Methodo Tychonica, ſed corrigenda. *Problem 64. Given the distances of the phenomenon from the vertex and from the same fixed star or stars, observed at the same moment from two places on Earth under the same vertical, together with the distance between the places on Earth: to investigate the parallax of the phenomenon, absolute or compared with the lunar parallax — by the Tychonic method, but one needing correction.*

[Margin: Order of the problems.]

[Margin: Problem 64.]

Tycho, intending to demonstrate in volume 2, from page 123 to 127, that the comet of the year 1577 was not just below the Moon — that is, not distant from the Earth by only 50 terrestrial semidiameters, but by many more — describes in the following figure, from the Earth's centre T, the terrestrial circle HANu, in which A is Uraniborg and B Prague in Bohemia, from which the comet C was seen. By Tycho it was seen at Uraniborg in the year 1577 on November 16, around the sixth hour of the evening, 17° 50½′ distant from the bright star of the Vulture, D; but by Tadeáš Hájek at Prague on the same evening, at hour 6, 17° 50′ distant from the bright star of the Vulture; and he says this was done by

each observer with the aid of a radius. He assumes the altitude of the pole at Prague as 50° 7′ and at Uraniborg as 55° 53′, and the difference as 5° 46′, which the arc AB represents. For a slight difference in the longitude of the places does little harm to the demonstration, especially since in both places the comet was very nearly in the same vertical as the bright star of the Vulture.

Diagram. A figure set across the right column in the course of Problem 64. An outer semicircle stands on a base from S to the right-hand end; inside it a smaller concentric semicircle; at the base a full small circle about the centre T; straight lines run out from the small circle to the arcs.

- Z (right end of the base, with a hooked foot): on the outer arc
- u (bottom of the small circle): on the terrestrial circle HANu

[Margin: Tycho's method.]

Having supposed, then, a distance BC of the comet of 50 semidiameters of the Earth: since the chord AB, corresponding to 5° 46′, is 10,060 parts of which TA is 100,000, BC will be 5,000,000. But the distance of the comet from the Vulture's bright star, as seen from A, is, he says, the angle DAF, and as seen from B, the angle DBE. Next he supposes that the same star is seen at D from the places A and B along the lines AD and BD, which are sensibly parallel because of the immense distance of the fixed stars. He further supposes that the angles at A and B which those lines make with the chord AB are right angles, *because those lines tend to the centre of the Earth as if they were one line, and, as lines from*

the centre to the circumference, fall normally on AB, according to the laws of straight lines subtended in a circle. So he says; and he goes on. From the comet's daily motion towards the Vulture, 2½°, and from the difference of meridians, 15^m of time, he gathers that if he himself had observed at the same moment as Tadeáš at Prague — that is, at 5^h 45^m at Uraniborg, when it was the 6th hour at Prague — the comet would have been seen at both places with no difference whatever, 17° 52′ distant from the Vulture. That this would have been impossible if the comet had been below the Moon, distant from the Earth by only 50 terrestrial semidiameters, he tries to show by the following reasoning.

[Margin: Order of the problems.]

[Margin: Order of the problems.]

EXEMPLVM *Example.*

[Margin: Step 1.]

First, in the triangle AGB, with the perpendicular BG drawn to ACF, the visible distance DAC is given, and its complement GAB to the right angle DAB; this complement is 72° 9½′. Therefore the angle GBA is 17° 50½′, since the angle at G is a right angle. And AB is 10,060 parts; therefore by the rules of triangles the side BG is very nearly 9,576 parts — for this is how, by the doctrine of sines, the corrupt passage of Tycho is to be emended.

[Margin: By Euclid I.32.]

[Margin: Step 2.]

Second, in the triangle BGC, from the side BG, 9,576, and the base BC, 5,000,000, the angle GCB comes out 6′ 35″ — the angle by which the angle of the distance seen at A would be greater than that seen at B; for GBC would come out 89° 56′ 25″. If this is added to the angle ABG, 17° 50½′, the whole ABC will be 107° 43′ 55″; and if you take the right angle ABD from it, there remains the angle DBC, 17° 43′ 55″, which represents the distance of the comet from the Vulture as seen at Prague, when at Uraniborg it was seen as 17° 52′. Yet when the observation taken at the same moment is considered, there was no difference between the visible distances. Therefore, for the same visible distance to hold at both places, AB must bear no sensible proportion to the comet's distance BC, and the lines AC and BC must have been sensibly parallel; and so the comet was far above 50 semidiameters of the Earth, and much higher than the Moon. So far Tycho.

Deteguntur fallaciæ in præcedenti Pſeudoapodixi. *The fallacies in the preceding pseudo-proof are exposed.*

[Margin: Tycho's error.]

But here, surely, our Homer was nodding — which is no wonder, since it sometimes happens to great men. And so first Chiaramonti, in the *Antitycho*, Book 2, chapters 12 and 13, and then Galileo in the *Trutinator*, page 22, attacked Tycho's fallacy. For since the northern declination of the bright star of the Vulture is, for Tycho, 7° 52′, and the distance of the equator from Uraniborg's vertex R is 55° 54′, it follows that the Vulture's distance from the vertex of

Uraniborg is 48° 2′. But if DAB had to be a right angle, then, since AB is less than 6°, the distance RAD of the star from the vertex would have to be less than 3°, says Galileo; and he rightly adds that only the vertical line RA falls perpendicularly on the Earth at the point A. Chiaramonti, for his part, says that if the lines DA and DB fell perpendicularly on the Earth, they would have to meet at the Earth's centre, and so could not make right angles with AB — which is entirely true. Chiaramonti further shows, from the data Tycho gives, that the comet's distance from the vertex of Uraniborg was then 73° 30′ 30″, and from the vertex of Prague 67° 44′. Therefore, since at the Moon's distance of 43 semidiameters a parallax of 1° 15′ 30″ belongs to the former distance from the vertex, and one of 1° 13′ 26″ to the latter, the difference of the parallaxes could have been no more than 2′ 4″, and not 6′ 35″ — if Ptolemy's parallax table, in Book 5 of the *Almagest*, chapter 18, is correct. And what of Kepler here, in the *Hyperaspistes* of Tycho, pages 50 and 95? After many attempts at excuses, to be sure, he nevertheless admits that Tycho erred and assumed a false scheme in place of the true one, both because of the confused and varied intentions of his mind, and because he was distracted among a number of affairs.

65. Probl. Corrigere Tychonis Schema, Refractione interim diffimulata.
Problem 65. To correct Tycho's scheme, refraction being disregarded for the present.

[Margin: Problem 65.]

Chiaramonti goes on, in the *Antitycho*, Book 2, chapter 13, page 190. In the preceding Tychonic scheme, drawing from Prague, B, the straight line BD, and Am tangent to the Earth at A, he shows that the angle DAB was not a right angle but only 37° 13′. But earlier, on page 187, he had demonstrated from Tycho's data that on November 16, at 5^{h} 45^{m} at Uraniborg, the comet stood 73° 30′ 30″ from the vertex of Uraniborg. Therefore, if the comet stood 17° 50′ 30″ from the Vulture, as Tycho will have it, it follows that the bright star of the Vulture then stood 55° 40′ from the vertex of Uraniborg; for it was not on the meridian, as Galileo supposed above to make his argument more than sufficient. With this lemma truly demonstrated, then — as will be plain to anyone who examines Chiaramonti's calculation with me — let the arc RD, or the angle RAD, be 55° 40′. Therefore the remaining angle DAm, up to the right angle RAm, is 34° 20′. But the angle mAB is equal to the angle AuB in the alternate segment, by Euclid III.34; and this angle AuB stands on the arc AB, 5° 46′ (the amount assumed for the distance of Prague from Uraniborg on the great circle of the Earth). It is therefore half the angle ATB, which is at the centre, and so it is 2° 53′. The whole DAB, therefore, is 37° 13′, which was to be shown, and not a right angle, as Tycho supposed.

[Margin: By Euclid I.32.]

[Margin: By Euclid III.20.]

Hence GB comes out much shorter than Tycho computed; for it comes out 3,337 parts of which the Earth's semidiameter is 100,000, and not 9,576, as Chiaramonti shows on page 191. Hence, with the base BC put, as Tycho puts it,

at 50 terrestrial semidiameters, it follows from the side BG, 3,337 parts of which BC is 5,000,000, that in the right-angled triangle BGC, right-angled at G, the parallactic angle BCG is at most 2′ 18″, and not 6′ 35″, as Tycho wrongly gathers. The comet could therefore be distant from the Earth by 50 semidiameters of the Earth, and be below the Moon, and yet between its visible distances from the Vulture at Prague and at Uraniborg there could be no sensible difference, or scarcely 2′ 18″.

[Margin: Tycho's various small errors, or doubtful errors.]

Let us now consider that Tycho and Hájek used the astronomical radius, a very deceptive instrument, as he himself later admitted in volume 1 and in the *Mechanica*; and the difference of meridians between Uraniborg and Prague, which by my reckoning from eclipses is only 11′; and some deviation of the comet from the same vertical under which the Vulture is placed together with Uraniborg and Prague; and the uncorrected altitude of the pole, since later, having detected the refractions at the winter solstice, he found from a circumpolar star the altitude of the pole at Uraniborg to be 55° 54′ 30″, not 55° 53′ as he uses it in volume 2; and later the altitude of the pole at Prague was found by him to be 50° 4′, as appears from the last Tychonic observations published by Willebrord Snel, and not 50° 7′, as Tycho supposed in volume 2, page 253. Besides this, the refraction of the comet C was left out, which Tycho had not yet scented; for the comet, being nearly 74° from the vertex, was owed a refraction of at least 7′, from Tycho's little table of lunar refractions. From all these differences, then, whether certain or probable, a much greater difference could arise between the distances of the comet from the Vulture seen at Prague and at Uraniborg, and so the comet could be far lower than the Moon.

[Margin: Tycho's untrustworthy narrative.]

And what of the fact that Tycho, in questionable good faith, pretends that he observed the comet on the same day, November 16, so that he might compare his observation with Hájek's — when Tycho himself, in volume 2, chapter 1, in the history of the observations of this comet of the year 1577, had asserted that from the 15th day four days were empty of observations because of mists and the darkness of the air? We too have noted this, with Chiaramonti in the *Antitycho*, chapter 13, in Book 8, Section 1, chapter 18, number 22, where we showed that Kepler laboured in vain in defending either Tycho's lie or his boast. But before we leave Prague, let us weigh another example, and the method of Longomontanus, which he uses in solving the problem just proposed.

[Margin: Order of the problems.]

[Margin: Order of the problems.]

66. Probl. Idem Problema ſoluere Methodo Longomontani, ſed multò clariùs propoſita. *Problem 66. To solve the same problem by the method of Longomontanus, but set out much more clearly.*

[Margin: Problem 66.]

Let the figure of Problem 64 be repeated here; and in it, to avoid confusion, let Prague be on the other side, at A, and Copenhagen at I. Let the vertical lines be TR for Prague and TQ for Copenhagen; and let the comet of the year 1607 be seen at L, through which are drawn the line of the true place, TLM, and the lines of the visible places, ALP and ILO. Let the visible distance of the comet from the vertex of Prague be the angle PAR, and from the vertex of Copenhagen the angle OIQ (for the comet is supposed to have been sensibly under the same vertical as Prague and Copenhagen). Next let LT be given, the height of the comet from the centre of the Earth, which must be examined to see whether it answers to the observed distances from the vertex and at the same time to the observed distance from the same fixed star; let it be given, I say, in parts of which the Earth's semidiameter AT is known. With these laid down:

[Margin: Step 1.]

First, in the triangle TLA, the sides LT and AT are given, and the angle TAL, the complement of the visible distance from the vertex of Prague; seek, then, the parallactic angle TLA.

[Margin: Step 2.]

Second, in the triangle TIL, two sides, TL and IT, are given, and the angle TIL, which is the complement of the visible distance from the vertex of Copenhagen; so seek the parallactic angle TLI, subtract it from the angle TLA, and there will remain the difference of the parallaxes, ILA. If this is equal to the difference between the comet's distances from the same fixed star seen from A and from I, then the supposed height TL of the comet, or phenomenon, will also be right. But if the difference of the parallaxes is greater than the difference of the visible distances, the height TL was supposed too small; if less, too large. See the example in Book 8, Section 1, chapter 21, number 7.

67. Probl. Datis eiuſdem Phænomeni ſub eodem verticali Altitudinibus obſeruatis ex duobus terræ locis notæ diſtantiæ, & Differentia Parallaxium ex diſtantijs tunc ab eadem ſtella Fixa vel à vertice viſis vtrobique; Parallaxes altitudinis, cuique diſtantiæ viſæ congruentes, ac ſimul diſtantiam Phęnomeni à centro terræ determinare; Secluſa interim Refractione, vel per eam correctis altitudinibus ac diſtantijs. *Problem 67. Given the altitudes of the same phenomenon under the same vertical, observed from two places on Earth of known distance, and the difference of the parallaxes from the distances then seen at both places from the same fixed star or from the vertex: to determine the parallaxes of altitude belonging to each visible distance, and at the same time the distance of the phenomenon from the centre of the Earth — refraction set aside for the present, or the altitudes and distances corrected by it.*

[Margin: Problem 67.]

We have already taught this whole problem in chapter 9; but it is worth completing here the part of it that rests on the difference of the parallaxes, since that is more often knowable, and setting it against the Tychonic fallacy in the

same figure, so that opposites placed side by side may stand out the more clearly. Let the figure of Problem 64, then, be put back in this place. In it, one place, A, and the other, I, are on the surface of the Earth, and there is the phenomenon L, whose distance from the vertex R, seen from A and corrected by adding the refraction, is the angle LAR, and its complement LAT; while its distance from the vertex Q, seen from I and corrected, is the angle LIQ, and its complement LIT. The parallax of the phenomenon with respect to the eye at A is the angle ALT, and with respect to the eye at I the angle ILT; and so the difference of the parallaxes is the angle ILA. With the chord AI drawn, let it be known, from the quantity of the arc AI — that is, of the distance of the places on the same great circle of the Earth — in parts of which the Earth's semidiameter AT, or the radius, is 100,000.

[Margin: Step 1.]

[Margin: By Euclid I.32 and by I.5.]

First, then, since the angle ATI measures the given arc AI, in the triangle ATI, which is isosceles, with equal legs TA and TI, the sum of the angles TIA and TAI at the base will also be known, since it is the supplement of the angle ATI to two right angles; and since those angles are equal to each other, each of them will be known as well. Now, taking TIA from 180°, the adjacent angle AIQ will be known; and if you join to it the given angle QIL, which was the distance of the phenomenon L, seen from I, from the vertex Q, the whole angle AIL becomes known. Since, therefore, in the triangle AIL, besides the side AI, two angles are given, AIL and ALI, the difference of the parallax, whose supplement to two right angles is the angle LAI, seek the side

Diagram. The figure of Problem 64 set again across the right column, in the course of Problem 66 and Problem 67. An outer semicircle stands on a base from S to the right-hand end; inside it a smaller concentric semicircle; at the base a full small circle about the centre T; straight lines run out from the small circle and its centre to the arcs.

- R (top of the outer arc): the vertex of the place A, on the vertical TR
- D (just right of R): not named on this page
- D (on the outer arc, further right): not named on this page
- Q (upper left of the outer arc): the vertex of the place I, on the vertical TQ
- M (left side of the outer arc): end of the line of the true place TLM
- E (right side of the outer arc): not named on this page
- O (left side of the outer arc): end of the line of the visible place ILO
- P (left side of the outer arc, lowest): end of the line of the visible place ALP
- L (left, on the inner arc): the comet, or phenomenon
- A (above the centre): a place on Earth — Prague in Problem 66, Kassel in the Example
- C (right, on the inner arc): not named on this page
- G (right of A): not named on this page

- F (right side of the outer arc): not named on this page
- m (italic, right end of the line through F): not named on this page
- I (inside the small circle, left): a place on Earth — Copenhagen in Problem 66, Uraniborg in the Example
- R (inside the small circle, under G): not named on this page
- H (left on the small circle): not named on this page
- N (right on the small circle): not named on this page
- S (left end of the base): not named on this page
- V (on the base, left): not named on this page
- T (centre of the small circle, on the base): the centre of the Earth
- X (on the base, right): not named on this page
- Z (right end of the base, with a hooked foot): not named on this page
- u (bottom of the small circle): not named on this page

LI, that is, the distance of the phenomenon from the surface of the Earth; and with it, and with IT, and with the angle LIT, the supplement of the angle QIL to two right angles, find the distance TL from the centre of the Earth, in parts of which the chord AI and the radius AT were known. This was one of the things proposed.

[Margin: Step 2.]

Second, in the triangle ATL, in which AT, the Earth's semidiameter, is given, and TL, the distance of the phenomenon, in parts of the same kind, and the angle TAL, the complement of the visible distance from the vertex, find the parallax TLA belonging to the altitude seen from A.

[Margin: Step 3.]

Third, in the triangle TIL, in which TI, the Earth's semidiameter, is given, and TL, the distance of the phenomenon, and the angle TIL, which is the complement of the distance from the vertex Q seen from I, seek out the parallax TLI belonging to the altitude of the phenomenon seen from I; and so the problem will be satisfied.

EXEMPLVM *Example.*

I shall take an example, on purpose, from Chiaramonti's Antitycho, *Book 3, chapter 19, because it is useful to us for judging many matters concerning the height of comets; but I shall fit it to our measures of the Earth's diameter, and I shall use visible altitudes corrected by subtracting the refraction. Let I, then, be Uraniborg, and A Kassel, a city of Hesse, distant on the same vertical by the arc AI, 4° 34′, as Tycho puts it in his letters to Rothmann; and let the comet's visible distance from the vertex of Uraniborg, LIQ, have been 84°, and the difference between the distances from the same fixed star — that is, the difference of the parallaxes, ILA — be one minute.*

[Margin: Step 1.]

First, since AI is 4° 34′, its chord is 7,968 of the parts of which the radius AT is 100,000; therefore, of the miles of which AT, by our reckoning, is 4,139, AI is 330. Next, since ATI is 4° 34′, the sum of the angles TAI and TIA will be 175° 26′, and its half, TIA, 87° 43′, and the angle adjacent to it, AIQ, 92° 17′. If you add QIL, 84°,

to this, the whole LIA becomes 176° 17′. But the angle ILA was supposed to be one minute; with these angles, then, and with AI, 330 miles, LI comes out, the distance of the comet from the surface of the Earth, at 73,173 miles. If you join TI, 4,139, to these, the whole TL would be at most 77,312; for in fact TL is less than the two, LI and IT, taken together. And dividing 77,312 by 4,139, the distance of the comet would come out at most 18 terrestrial semidiameters and 2,810 miles, which is much smaller than the lunar distance. How much smaller, then, if the difference of parallax between Uraniborg and Kassel of 17′, admitted by Tycho, is admitted?

[Margin: By Euclid I.20.]

COROLLARIVM. *Corollary.*

Between two places on Earth not more than 4° or 5° apart there can be a difference of parallax of one minute — that is, such places can see the same phenomenon distant from the same fixed star, disagreeing in the visible distance by a single minute, or even by less than a whole minute — and yet that phenomenon can be much lower than the Moon, and so have a greater parallax than the Moon: namely, if it is much nearer the horizon than the vertex. This is plain from the preceding example, and Chiaramonti notes it in the *Antitycho*, Book 3, chapter 19, theorem 1; he also, in Book 2 of the *Antitycho*, chapter 20, page 223, shows the same thing in another way by two problems worthy of this place. See also the example we have brought forward in Book 8, Section 1, chapter 19, number 3.

[Margin: Order of the problems.]

[Margin: Order of the problems.]

68. Probl. Datis Phænomeni Diſtantijs viſis à duabus quibuſuis ſtellis Fixis, & omnium trium Altitudinibus viſis, vnà cum Diſtantia Fixarum, in duobus Horizontibus; Parallaxes altitudinis cuiq. altitudini cõgruas, notas facere. Secluſis Refractionibus, vel per eas correctis altitudinibus ac diſtantijs. *Problem 68. Given the visible distances of a phenomenon from any two fixed stars, and the visible altitudes of all three, together with the distance between the fixed stars, in two horizons: to make known the parallaxes of altitude belonging to each altitude — refractions set aside, or the altitudes and distances corrected by them.*

[Margin: Problem 68.]

Among other problems that Thomas Digges presents in his *Dialexis*, this is his 20th, which Tycho also reports in volume 1 of the *Progymnasmata*, page 669, asserting that it is the most laborious of all, since it requires the analysis of seven spherical triangles. In the following figure, let the meridian be MAO, and in it the vertex A and the pole of the world Q, and the horizon of the first observer MRO; the first vertical of the phenomenon AHN, in which the true place is G and the apparent place H; the places of the fixed stars K and F, in their verticals AKL and AFR; and the visible distances of the phenomenon from them, HF and HK. Now let the vertex A be carried to the point E — that is, let E be the vertex of the second observer, and BDC his horizon; and let the vertical circles

of the fixed stars be EKS and EFP; and let the vertical of the phenomenon, appearing at I, be EID, the true place of the phenomenon G, and the visible distances from the fixed stars IF and IK; and finally let the distance between the fixed stars be KF. It is now proposed to investigate the parallaxes HG and IG.

Diagram. A figure set across the left column in the course of Problem 68. A large arc rises to A at the top; below, two lower arcs run across the figure from the left to O and C at the right; straight and curved lines run down from A and from E through the fixed stars K and F and the phenomenon at H and I to the lower arcs.

- A (top): the vertex of the first observer, on the meridian MAO
- Q (upper right of A): the pole of the world
- E (right, below Q): the vertex of the second observer
- T (on the arc at the right): not named on this page
- K (middle left): a fixed star
- [?] (small sort between K and F, above them): not read
- F (middle right): a fixed star
- B (far left): on the horizon BDC of the second observer
- M (left, below B): on the meridian MAO and the horizon MRO
- I (below K): the apparent place of the phenomenon for the second observer
- H (below F): the apparent place of the phenomenon for the first observer
- L (lower left): end of the vertical AKL
- S (lower left, on the lower arc): end of the vertical EKS
- D (lower left, on the lower arc): on the horizon BDC; end of the vertical EID
- N (lower middle): end of the vertical AHN
- R (lower right): on the horizon MRO; end of the vertical AFR
- O (right end of a lower arc): on the meridian MAO and the horizon MRO
- C (right end of the lowest arc): on the horizon BDC
- P (bottom): end of the vertical EFP

[Margin: Step 1.]

First, in the triangle AKF, there are given KF, the distance between the fixed stars, and AK and AF, the complements of the visible altitudes of the fixed stars; therefore the angle AKF will be given by trigonometry.

[Margin: Step 2.]

Second, in the triangle KEF, there are given the distance between the fixed stars, KF, and EK and EF, the complements of the altitudes of the fixed stars as seen by the second observer; the angle EKF will therefore be given, and this, subtracted from the angle AKF, will leave the angle AKE.

[Margin: Step 3.]

Third, in the triangle AKE, two sides are given, AK and KE, already known above, with the included angle AKE; so neither the side AE nor the angle AEK will be hidden.

[Margin: Step 4.]

Fourth, in the triangle AFE, there are given the side AE, just found, and AF and EF, the complements of the visible distances of the fixed star F; so the angle FAE will become known.

[Margin: Step 5.]

Fifth, in the triangle HAF, there are given HF, the visible distance of the phenomenon from the fixed star F in the first observation; AF, the complement of the visible altitude FR; and AH, the complement of the visible altitude of the phenomenon. So seek the angle HAF, add it to the angle FAE already found, and the whole angle HAE will be known.

[Margin: Step 6.]

Sixth, in the triangle KEI, there are given the sides KE, the complement of the visible altitude of the star K, and IE, the complement of the visible altitude of the phenomenon for the second observer, and KI, the visible distance of the phenomenon from the fixed star K; so investigate the angle KEI, join it to the angle AEK, and the whole angle AEG will be known.

[Margin: Step 7.]

Seventh, in the triangle AEG there are given the angle AEG, just found, the side AE, found in the 3rd step, and the angle GAE, found in the 5th step, since it is the same as the angle HAE; seek, then, the sides AG and EG. For the former, subtracted from the complement AH of the first visible altitude, will give the parallax GH; and the latter, subtracted from the complement of the altitude of the phenomenon seen by the other observer, will leave the parallax GI known.

But when will it be possible for two observers at different places on Earth to observe so many things exactly at the same moment? For there must be several companions, one of whom takes the altitude of the phenomenon, two others the altitudes of the fixed stars, and two others the distances of the phenomenon from the fixed stars; indeed, if the distances are to be taken more correctly with a sextant, there will have to be seven companions observing at the same moment. But if they observe at a different moment in one horizon, and at a different moment in the other horizon, it must be supposed meanwhile that the phenomenon has no motion other than the motion of the primum mobile.

69. Probl. Data differentia Latitudinis ac Lõgitudinis inter duo loca terræ, ex quibus eodem momento idem Phænomenon obſeruatum eſt; datiſq. tum Azimuthis, tum viſis à vertice Diſtantijs vtrobiq. obſeruatis; Parallaxes altitudinis vtrique diſtantiæ viſæ à vertice congruentes dignoſcere. Secluſis interim, aut computatis Refractionibus. *Problem 69. Given the difference of latitude and of longitude between two places on Earth from which the same phenomenon was observed at the same moment, and given both the azimuths and the visible distances from the vertex observed at each place: to discern the parallaxes of altitude belonging to each visible distance from the vertex — refractions set aside for the present, or computed.*

[Margin: Problem 69.]

Let AB be a portion of the meridian, in which the pole of the world is A.

[Margin: Case 1. If the places differ only in latitude.]

And first let there be two places, C and D, under the same meridian, whose difference of latitude is CD; and let the true place of the phenomenon, observed at the same time, be at E, through which let the arcs of vertical circles be drawn from the vertices C and D to the visible place of the phenomenon — namely the arc CEH to the visible place H, and the arc DEF to the visible place F. For in the triangle CED the side CD is given, which is the difference in latitude, or in the altitude of the pole; and the angle ECD, which is the measure of the azimuth observed by the inhabitant under C; and the angle CDE, which is the supplement to two right angles of the azimuth EDB observed by the inhabitant under D. From these three data, therefore, seek the side CE, which, subtracted from the visible distance CEH of the phenomenon from the vertex, will leave the parallax EH known, belonging to that visible distance. Again seek the side DE, and subtract it from the visible distance DEF of the phenomenon from the vertex, and the remainder will be the parallax EF, belonging to this visible distance from the vertex.

Diagram. A figure set in the right half of the right column in the course of Problem 69. From A at the top an arc of the meridian runs down the right side through C and D to B; arcs from A and from C, L and O run down to the lower left, where several lines meet at E.

- A (top): the pole of the world
- L (upper left, on an arc): a place on the same parallel as C (second case)
- P (left, below L): on the azimuth KLP
- C (right, on the meridian arc): the vertex of a place
- O (inside, between C and E): the vertex of the other place (third case)
- D (right, below C, on the meridian arc): a place under the same meridian as C (first case)
- F (above and left of E)
- E (lower left, where the lines meet): the true place of the phenomenon
- G (below, left of E): the visible place (third case)
- H (below, left of E, beside G): the visible place on the arc CEH
- K (below E): the visible place on the arc LEK (second case)
- R (bottom): end of the meridian AOR (third case)
- B (bottom right): end of the meridian AB; on the azimuths EDB and BCH

[Margin: Case 2. If the places differ only in longitude.]

Second, let there be two places on Earth, C and L, under different meridians but on the same parallel, CL, described from the pole of the world A. From A let the arcs of the meridians, AC and AL, be drawn to the vertices of the places; these will accordingly be equal to each other, since the places are equally distant from the pole of the world. And from them, through the true place E of the phenomenon, let the vertical arcs be drawn — CEH as far as its visible place H,

and LEK as far as the visible place K — and the difference of longitudes will be the angle LAC. With these laid down: in the triangle ACL there are given the sides AL and AC, equal to each other, which are the complement of the altitude of the pole, and the angle LAC included by them; seek, then, both the angles ALC and ACL and the arc LC. Then in the triangle ELC you will have the side LC known, and the angles ELC and ECL; for the angle ELA is the supplement to two right angles of the azimuth KLP observed under the vertex L, and if you take from it the angle CLA found, the angle CLE will remain; likewise the angle ECA is the supplement to two right angles of the azimuth BCH observed under the vertex C, so that when the angle ACL already found is taken away, the angle LCE will be known. In the triangle ELC, therefore, seek the side LE, which, subtracted from the visible distance LEK from the vertex L, will give the parallax EK. Again seek out the side CE; for this, taken from the visible distance CEH from the vertex C, will give the parallax EH.

[Margin: Case 3. If the places differ in longitude and latitude.]

Third, let the two places on Earth differ in longitude and in latitude, and let the vertex of one be C and of the other O, which are joined by the arc CO of a great circle; and let AOR be the portion of the meridian drawn through O; and from the vertices let the vertical arcs be drawn through E, the true place of the phenomenon — CEH as far as its visible place H, and OEG as far as the visible place G. With these marked out, first, in the triangle CAO, there are given the al- [Margin: Order of the problems.]

[Margin: Order of the problems.]

titude-complements of each pole, AC and AO, and the angle CAO contained by them, which the difference of longitude of the places measures. Seek, therefore, the base CO and the remaining angles ACO and AOC. Next, from HCA, the supplement to two right angles of the azimuth ECB, subtract the angle ACO just found, and the angle ECO will remain; conversely, to EOA, the supplement to two right angles of the azimuth EOR, add the angle AOC found, and the result will be the angle EOC in the triangle EOC, in which, besides the angles at O and C, OC is given. Therefore investigate the side CE: subtracted from the arc CEH, that is, from the visible distance from the vertex C, it will leave the parallax EH known. Again seek the side OE and subtract it from the arc OEG, that is, from the visible distance from the vertex O, and the remaining arc EG will be the parallax of altitude belonging to that place. I know that Chiaramonti, in Book 1 of the *Antitycho*, chapter 5, problem 2, gives this same problem, but with another figure; he seems, however, to have used the arc LC of a parallel in place of an arc of a great circle, which can lead some people into error.

70. Probl. Data Diſtantia Phænomeni viſa ab eadem ſtella Fixa, ex duobus terræ locis, ſub eodem Meridiano poſitis, quando Phænomenon tranſit Meridianum, & Momento talis tranſitûs, ac Altitudine Poli vtriuſq. loci, ſcire tum Diſtantiam viſam Phænomeni ab vtroq. vertice, tum Altitudinis

Parallaxes vtriq. loco cõuenientes. Secluſis Refractionibus &c. *Problem 70. Given the visible distance of a phenomenon from the same fixed star, from two places on the earth set under the same meridian, when the phenomenon crosses the meridian, together with the moment of that crossing and the pole altitude of each place: to know both the visible distance of the phenomenon from each vertex and the parallaxes of altitude belonging to each place. Refractions set aside, etc.*

[Margin: Problem 70.]

Consider the right-hand part of the following diagram. In it let the arc of the meridian be ADH, and on it the pole of the world A, and two places on the earth, B and C, the complements of whose latitudes, or of whose pole altitudes, AB and AC, are given; and so, the smaller being taken from the larger, the difference BC is given. Let the true place of the phenomenon crossing the meridian be at D, but its apparent place with respect to the place B be G, and its parallax DG; while its apparent place from C is E, and its parallax DE. And let the fixed star F be joined by four arcs of great circles to the vertices of the places and to the apparent places of the phenomenon, namely by the arcs FB, FC, FE, FG; for EF and GF will be the visible distances from that same star. With these laid down:

[Margin: Step 1.]

First, from the moment of the hour there is given, by the usual tables or the problems of the primum mobile, the culminating point of the ecliptic and its right ascension in mid-heaven; from the tables of the fixed stars, too, the right ascension of the fixed star F is given; and hence the difference between these ascensions is given, and so the arc DAF; and from the same tables of the fixed stars the complement of declination AF is given; and AB is given. Therefore in the triangle BAF the angle A is given with the sides enclosing it; so seek both the side BF and the angle ABF. In this way, in the triangle CBF, the supplement CBF of the angle ABF to two right angles will be known, and the arc BF, while BC was given above.

Diagram. A figure in the right part of the left column, serving two problems: its right-hand part for Problem 70, its left-hand part for Problem 71 ("the left-hand part of the figure immediately preceding"). An arc runs down the middle from A at the top through B, C, D, E and G to H at the bottom; from A two outer arcs run down to L at the left and F at the right, and lines join L and F to B and C.

- A (top): the pole of the world, on the meridian ADH
- B (on the central arc, below A): the vertex of the first place
- C (below B): the vertex of the second place
- L (far left): the fixed star of Problem 71
- M (between L and C): the apparent place of the phenomenon from C (Problem 71)
- K (between M and C): the true place of the phenomenon (Problem 71)
- F (far right): the fixed star of Problem 70

- P (below M): the apparent place of the phenomenon from B (Problem 71)
- D (on the central arc, below the middle): the true place of the phenomenon on the meridian (Problem 70)
- E (below D): the apparent place from C (Problem 70)
- G (below E): the apparent place from B (Problem 70)
- H (bottom): end of the meridian arc ADH

[Margin: Step 2.]

Therefore, second, in this triangle you will seek the arc CF and the angle BCF; subtract the angle from 180 degrees, and you will have the angle ECF.

[Margin: Step 3.]

With these now obtained, third, in the triangle GBF there are given the side BF, found above, and GF, the visible distance from the fixed star from the place B, and the angle GBF, the same as CBF; seek, therefore, BG, the visible distance from the vertex B.

[Margin: Step 4.]

Fourth, in the triangle CFE, from CF found, the visible distance EF and the angle ECF, seek CE, the visible distance from the vertex C; add BC to it, and subtract the whole BE from the arc BG. There will remain EG, the difference of the parallaxes of altitude; from it, since the visible altitudes of the phenomenon have here been found, the quantity of the parallaxes itself is investigated, according to what was said in chapter 2, problems 8 and 9.

71. Probl. Datis quæ dantur in Problemate 70. cum Diſtantijs viſis Phænomeni ab vtroque vertice, etiam ſi fuerit extra Meridianum, Inquirere Parallaxes Altitudinis, Secluſa interim Refractione, aut per eam correctis diſtantijs. *Problem 71. Given what is given in Problem 70, together with the visible distances of the phenomenon from each vertex, even if it is off the meridian: to find the parallaxes of altitude — refraction meanwhile set aside, or the distances corrected by it.*

[Margin: Problem 71.]

Look at the left-hand part of the figure immediately preceding. In it let there first be, under the same meridian ADH, two places B and C, with the complements of the pole altitude, AB and AC, known, and so the difference BC known. Let the true place of the phenomenon be K, but its apparent place from B be P, and from C, M; and let the distances from the fixed star L be, as seen from B, the arc PL, and from C, the arc ML; and let that fixed star be joined with the pole of the world A, and with the vertex of the place B, by the arcs of great circles AL and BL.

[Margin: Step 1.]

First, then, in the triangle ALB there will be given, from the moment of time and the tables of the fixed stars, as in the preceding problem, the angle LAB, which measures the difference between the right ascension of mid-heaven and that of the fixed star, and AL, the complement of declination of the same fixed

star; and AB, the complement of the pole altitude, is also given. Therefore you will seek the arc BL and the angle ABL; when this is subtracted from 180 degrees, the adjacent angle LBC will be known.

[Margin: Step 2.]

Second, in the triangle LBP, from the side BL found, PL, the visible distance of the phenomenon from the fixed star, and BP, the complement of the visible altitude of the phenomenon, you will investigate the angle LBP; subtract it from the angle LBC found above, and the angle KBC will be left known.

[Margin: Step 3.]

Third, in the triangle LBC, from the sides BL and BC found — BC being the difference of latitude of the places — and the contained angle LBC, seek both the side CL and the angle BCL.

[Margin: Step 4.]

Fourth, in the triangle LCM, from the side CL found, the distance LM — the visible distance of the phenomenon from the fixed star from the place C — and CM, the visible distance of the phenomenon from the vertex, investigate the angle LCM; add it to the angle BCL, and the whole angle KCB will result.

[Margin: Step 5.]

Fifth and finally, in the triangle KCB, in which there are now given the angle KCB, the angle KBC found in the 2nd step, and the side BC, as above, seek the arc BK, that is, the true distance of the phenomenon from the vertex B; subtracted from the visible BP, it will leave the parallax KP known. Again, seek the arc CK, which is the true distance of the phenomenon from the vertex C, and subtract it from the visible CM; for the remainder KM will be the parallax of altitude. Nor will it be difficult, by almost the same method, to investigate the parallaxes from the data already mentioned even when the two places differ in longitude, provided the difference of longitude is known.

72. Probl. Data Latitudine ac Longitudine viſa eodem momento Phænomeni ex duobus terræ locis, atq. adeò data Differentia harum parallaxium ad Eclipticam, & eorum Altitudine polari, cum diſtantia Meridianorum, nec non Obliquitate Eclipticæ ſeu diſtantia Polorum Eclipt. & Aequatoris, & inſuper Momento obſeruationis, & inde loco Eclipticæ Culminante vtrobiq. Inuenire Parallaxin Altitudinis, vtrique loco conuenientem. Secluſa tamen Refractione aut per eam correctis locis viſis. *Problem 72. Given the latitude and longitude of a phenomenon seen at the same moment from two places on the earth, and so given the difference of these parallaxes with respect to the ecliptic; and given the pole altitude of the places, with the distance between their meridians, and also the obliquity of the ecliptic, or the distance between the poles of the ecliptic and of the equator, and moreover the moment of observation, and from it the culminating point of the ecliptic at each place: to find the parallax of altitude belonging to each place — refraction, however, set aside, or the apparent places corrected by it.*

[Margin: Problem 72.]

Chiaramonti gives this problem in the *Antitycho*, Book 1, chapter 7, problem 1, with an example of it in Book 3, chapter 4; and in part in the opuscula *De sede sublunari Cometarum*, part 1, chapter 10, problem 2, and part 2, chapters 20 and 21. It requires, however, the solution of a great many spherical triangles, in which the individual errors are small, but, collected together, they can in the end produce a somewhat larger error than the fineness of parallaxes demands, unless it is handled very accurately.

[Margin: Order of the problems.]

[Margin: Order of the problems.]

Moreover, it cannot be adapted to some cases, as the same Chiaramonti admits in Book 1, chapter 7 of the *Antitycho*, in the annotations. So it did not seem right to send the reader into this labyrinth and wear him out. And indeed the labour is worth sparing, since it can scarcely happen that two observers, in distant places on the earth, should by chance observe the same phenomenon — especially a new one — at the same moment of time, or even on the same day at hours of the same denomination or numbering. If, however, there is an interval of a few hours between their observations, and the proper motion of the phenomenon belonging to that interval is known, the observations can be reduced to the same moment. A clear example of this problem may be seen in our Book 8, Section 1, chapter 19, numbers 11 and 12.

73. Probl. Quanta fingi poſſit Maxima Parallaxis, ac Minima Lunæ Diſtantia à centro Terræ, præter eam, quam Aſtronomi recentiores poſuerunt, ſed compenſata ab æquali Refractione. *Problem 73. How great a maximum parallax, and how small a minimum distance of the Moon from the centre of the earth, can be supposed beyond that which the more recent astronomers have laid down, but compensated by an equal refraction.*

From what was said in Book 4, chapter 14, none of the recent astronomers, beginning with Copernicus, has given the Moon, however near its perigee, whether at the syzygies [Copulae] or at the quadratures, a smaller distance from the centre of the earth than 51 ⅕ terrestrial semidiameters, or a greater parallax than 67′ 6″. To this same Moon, however, Tycho, in volume 1 of the *Progymnasmata*, page 124, assigned a horizontal refraction of 33′, while supposing from his observations a maximum parallax at the quadratures of 65′ 36″ and a minimum distance of the Moon of 52 ⅖ terrestrial semidiameters. Someone might, however, suspect that the Moon's parallaxes are much greater, but unobservable for the reason that they are compensated by an equal refraction, and ask us how great a parallax and refraction of this unknown kind may be supposed without violating physical and astronomical experiments. I shall try to satisfy him with distinct replies.

[Margin: Problem 73.]

[Margin: 1st reply, excluding a parallax greater than 23 degrees.]

First, I reply that it is certain that the difference in density between the ethereal air, or purest air, and our own air, which refracts rays sensibly, is more

like the difference between the densities of water and glass than that between air and water, or between air and glass. For, as we shall say in the next Section, problems 17 and 19, the weight, and hence the density, of glass is to the density of water as 60 to 22, or almost triple; while the density and weight of water are to the weight and density of our air as 427,272 to 1 — which we here ask to be granted us. Granted, no one is so senseless as not to concede that there is a greater ratio between ether and air compared together, and between water and glass together, than between ether and air together and between air and glass compared together. Now the maximum refraction of a ray from water into glass, according to Vitellio [Witelo], Book 10, proposition 8, does not exceed 23 degrees. Therefore the refraction of a ray from the purest air into our own air cannot be supposed greater than 23 degrees; and hence neither can the unknown parallax, compensated by an equal refraction, be supposed greater than 23 degrees. And the smaller anyone thinks the excess of the density of air over that of ether to be, compared with the excess of the density of glass over that of water, the smaller than 23 degrees the refraction and parallax of the Moon he will be permitted to suppose.

[Margin: 2nd reply, excluding a parallax greater than 2° 53′.]

Second, I reply that the Moon's parallax cannot be supposed greater than 2° 53′, and hence, by problem 1, the Moon's distance from the centre of the earth cannot be supposed smaller than 20 terrestrial semidiameters. For at a distance from the vertex of only 10 or 5 degrees, no refraction of the Moon was observed by Tycho in clear air; nor is any observable by anyone, since not even at a distance of 45° from the vertex could any refraction of the Moon be detected by Tycho's people or by others. Therefore whatever refraction anyone may suppose beyond Tycho's — but a refraction compensating an equal parallax — will be wholly hidden, and not made up of a refraction partly known, partly unknown. Now at a distance of the luminary from the vertex of 10 degrees, the refraction from water into glass is no greater than 30′, and at a distance of 5 degrees no greater than 15′, by the experiments of Witelo, Book 10, proposition 8. Nor is it permitted to attribute a greater refraction to a ray passing from the ether into our air than from water into glass, by the first reply. Therefore it is not permitted to attribute to the Moon a greater refraction — and hence not a greater parallax — belonging to a distance of 5 degrees from the vertex, than 15′. To this parallax, by problem 5, there belongs a distance from the centre of the earth of at least 20 terrestrial semidiameters; and to this distance, by problem 2, there belongs a horizontal parallax not greater than 2° 53′. Which was to be shown.

[Margin: 3rd reply.]

Third, I reply: suppose someone contends that the Moon's horizontal parallax is 2° 53′, and that its minimum distance can come down to 20 terrestrial semidiameters, and that the residue from Tycho's parallax of 1° 5′ 36″ up to 2° 53′, that is 1° 47′ 24″, lies hidden because, besides the Moon's horizontal refraction of 33′, there is a refraction unknown to us, of 1° 47′ 24″, compensating

just as much parallax, so that the total refraction, composed of the unknown and the known, is 2° 20′ 24″. Such a person cannot be convicted of falsehood from the stay of the Moon visible above the physical horizon, even when the Moon is on the equator; for whatever the parallax took away from that stay by depressing the Moon would be restored by the equal refraction. And when, in Book 8, Section 1, chapter 15, I said that a distance of the Moon smaller than 47 terrestrial semidiameters cannot be supposed, I nevertheless pointed out, in number 14, that this holds on the supposition of no parallax at all, and of a true stay and motion, not an apparent or visible one.

[Margin: What about eclipses?]

Nor could such a person be refuted from the eclipses of the luminaries. For the size of the earth's shadow with the penumbra, and the apparent diameters of the luminaries, would not vary at all through this parallax, and every difference arising from the excess of this parallax over that granted by the astronomers would be compensated by an equal refraction — granted that the real size of the luminaries would turn out much smaller. And although the pure shadow of the earth, not lit through by refracted rays, would turn out much shorter because of the greater refraction, according to what was said in Book 5, chapter 5, problem 1, yet the smaller distance of the Moon from the earth rendered by this hypothesis would also bring it about that the Moon would sometimes, in the middle of total eclipses, disappear entirely and not be lit even by refracted rays — which, as we taught in the same place, is the office of that pure shadow.

[Margin: What about the increments of refractions?]

Moreover, if the lunar refraction were increased beyond the solar, and consequently the solar beyond that of the fixed stars, there would be a greater difference between their horizontal refractions than Tycho now sets, and one more consistent with the difference of inclinations, which, the smaller it is, produces the smaller refraction, other things being equal. For to Tycho the distance of the Sun is nearly twenty times the distance of the Moon, and that of the fixed stars is to the Sun's as 11 ⅔, or at most twelvefold. Therefore, if the Moon's distance were 20 terrestrial semidiameters, the Sun's would be 400 and the fixed stars' 4800; from which, by problem 2, there would follow a horizontal parallax of the Sun of 8′ 36″ and of the fixed stars of 58″. But as it is, Tycho's horizontal parallax of the Sun is 3′ 7″, and of the fixed stars 15″. The remainder, therefore, would be owed to the compensating refraction; and so to the refraction of the Sun, which he sets at 34′, 5′ 29″ would have to be added, and to that of the fixed stars, which he sets at 30′, 43″. The total horizontal refraction of the Moon would thus be 2° 20′ 24″, of the Sun 39′ 29″, and of the fixed stars 30′ 43″. Finally, although the increments of the refractions are greater, and grow steeply near the horizon, while those of the parallaxes are greater near the vertex — so that an addition of refraction as large as the parallax would not sit very neatly at every altitude — yet this incongruity would not be so great that it could evidently be convicted of falsehood. For, with the Moon's distance set at 20 semidiameters and Tycho's lunar refractions added, at the

altitudes from the horizon written below there would follow lunar parallaxes and refractions as in the small table below, with their differences.

Sequitur Tabula Parallaxium ac Refractionum Tychonicarum, deductarum ex Lunæ à terra diſtantia ſemidiametrorum terreſtrium 20. iuxta diuerſas altitudines ab Horizonte. *There follows a table of the Tychonic parallaxes and refractions, derived from a distance of the Moon from the earth of 20 terrestrial semidiameters, at various altitudes from the horizon.*

[Margin: Order of the problems.]

[Margin: Order of the problems.]

The Moon's distance set at 20 semidiameters	Moon's altitude 0°	Moon's altitude 5°	Dif-fer-ence	Moon's altitude 80°	Moon's altitude 85°	Dif-fer-ence
Parallax of the ☾ at this distance	2° 53′ 0″	2° 52′ 10″	0′ 50″	29′ 52″	14′ 56″	14′ 56″
Tychonic parallax	1° 5′ 36″	1° 5′ 26″		11′ 37″	5′ 50″	
Hidden refraction and parallax	1° 47′ 24″	1° 46′ 44″		18′ 15″	9′ 6″	
Tychonic refraction	0° 33′ 0″	0° 14′ 20″		0′ 0″	0′ 0″	
Total refraction	2° 20′ 24″	2° 1′ 4″	19′ 20″	18′ 15″	9′ 6″	9′ 9″

There would therefore be a greater difference of the parallaxes near the vertex, namely 14′ 56″, than near the horizon, namely 50″. Conversely, the difference of the refractions would be greater near the horizon, namely 19′ 20″, than near the vertex, namely 9′ 9″. Therefore the hypothesis already mentioned could not be convicted of falsehood from the increments or decrements required by the refractions and by the parallaxes either. Let the following conclusions stand, then.

I. CONCLVSIO. *Conclusion 1.*

A greater parallax of the Moon than 2° 53′, and a smaller distance from the earth than 20 terrestrial semidiameters, cannot reasonably be supposed. This is clear from what was said in reply 2, which presupposes the first.

II. CONCLVSIO. *Conclusion 2.*

If anyone supposes the Moon's minimum distance from the centre of the earth to be not greater than 20 terrestrial semidiameters, and its horizontal parallax not smaller than 2° 53′, and asserts that whatever exceeds the parallax hitherto granted by the astronomers is due to an equal refraction of the Moon, compensating the parallax, he cannot be convicted of falsehood either from the apparent stay of the Moon above the horizon, or from the eclipses of the luminaries, or from the increments or decrements of the refractions.

This is established from what was said in reply 3, and for anyone who examines the phenomena already mentioned, as we have done. But if anyone

shall evidently convict this hypothesis of falsehood on other grounds, he will have deserved well of astronomy, and I, if I am still alive, shall hear him most gladly.

74. Probl. Quanta ob Refractiones auctas & parallaxium compenſatrices, fingi poſſet maxima Parallaxis & minima Diſtantia à centro Terræ, in Sole, Saturno, ac Fixis. *Problem 74. How great a maximum parallax and how small a minimum distance from the centre of the earth could be supposed in the Sun, Saturn and the fixed stars, on account of refractions increased and compensating the parallaxes.*

[Margin: Problem 74.]

From what was said in problem 73, in reply 2, it is not permitted to suppose a lunar parallax greater than 2° 53′, nor a distance smaller than 20 terrestrial semidiameters. But from what was said in Book 3, chapter 7, on the distances of the Sun; in Book 4, chapter 14, on the distances of the Moon; in Book 6, chapter 7, on the distances of the fixed stars; and in Book 7, Section 6, chapters 2 and 3, on the distances of Saturn from the earth, the Sun's distance is to the Moon's, for Copernicus, Tycho and many of their followers, as 20 to 1; for Kepler as 61 ⅗ to 1; for us as 140 ⅖ to 1. Saturn's distance, moreover, is to the Sun's distance, for all those already mentioned and for us, nearly as 10 to 1, and that of the fixed stars a little greater; so, for a judgement about the fixed stars, it will suffice to decide about Saturn. From these two elements follow the minimum distances given below and, by problem 2, the maximum parallaxes that could be supposed.

In the hypothesis of the authors	Distance of the ☾ from the centre of the earth (terrestrial semidiameters)	Distance of the ☉ (terrestrial semidiameters)	Distance of ♄ (terrestrial semidiameters)	Horizontal parallax of the ☾	Horizontal parallax of the ☉	Horizontal parallax of ♄
Tycho's	20	400	4000	2° 53′ 0″	8′ 34″	0′ 52″
Kepler's	20	1256	12560	2° 53′ 0″	2′ 34″	0′ 17″
Ours	20	2856	28560	2° 53′ 0″	1′ 15″	0′ 9″

75. Probl. Quanta fingi poſſit Refractio horizontalis Lunæ, Solis, Saturni, ac Fixarum ſupra Tychonicam. *Problem 75. How great a horizontal refraction of the Moon, the Sun, Saturn and the fixed stars can be supposed beyond Tycho's.*

[Margin: Problem 75.]

I reply briefly that as great a refraction can be supposed as is the aggregate of Tycho's horizontal refraction and of the horizontal parallax that can be supposed beyond Tycho's horizontal parallax. Therefore, from what was said about parallaxes in Book 3, chapter 8, Book 4, chapter 14, and Book 7, Section 6, chapter 7, and from Tycho's refraction — ☾ 33′, ☉ 34′, Saturn and, nearly, the fixed stars 30′ — we have constructed the following small table.

In the hypothesis of the authors	☾	☉	♄ and ✶
Tycho's	2° 20′ 40″	39′ 27″	30′ 24″
Kepler's	2° 22′ 19″	35′ 32″	30′ 9″
Ours	2° 19′ 4″	34′ 46″	30′ 5″

CAPVT XII.

Chapter 12.

De Diſcrimine Parallaxeos veræ ac per ſe Senſibilis à falſa Parallaxi, vel inſenſibili. Vbi Theoremata 20. recondita ad diſcretionem Parallaxium, profundioremque earum notitiam ſpectantia. *On the distinction between a parallax that is true and sensible in itself, and a false or insensible parallax. With 20 recondite theorems bearing on the discrimination of parallaxes and on a deeper knowledge of them.*

[Margin: What is a true parallax, sensible in itself?]

A true parallax, sensible in itself, is one that arises from a twofold interval, one between the centre of the world and the phenomenon, when each is so great that the difference between the true and the apparent place of the phenomenon can be evidently perceived by some people with some fineness of instruments or observations; and so it is called sensible in itself, granted that, by accident, [Margin: Order of the theorems.]

it could not be perceived by some one observer taken [?] on his own. Such is the parallax of the Moon observed from the surface of the terrestrial globe.

[Margin: What is a parallax insensible in itself?]

A parallax insensible in itself is one that arises from so small an interval between the centre of the world and the observer, or between the centre of the world and the phenomenon, that no observers, even watching from different places, could evidently perceive it with any fineness of instruments or observations. Astronomers judge the parallax of the fixed stars to be of this kind, because of their enormous distance from the centre of the Earth; and the Moon's own parallax would be of this kind if it were observed at about one mile from the centre of the world.

[Margin: How great can the fineness of astronomical observations be?]

How far that evident fineness extends, however, the authors do not agree. For Tycho, in volume 1 of the *Progymnasmata*, p. 516, says that an instrument which reliably yields a difference of 48″ must be very large; and yet on p. 425 he had granted his sextant a precision down to 16″; and in the *Mechanica Astronomica*, pp. 10 and 13, he affirms that his larger quadrants show each ten seconds. Kepler, in the *Epitome of Copernican Astronomy*, Book 4, p. 493, denies that the diligence of any craftsmen is to be trusted to a fifth part of one minute, that is, to 12″. Martinus Hortensius, in his dissertation with Gassendi on Mercury seen under the Sun, denies that a difference of 30″ is evidently observable — a view from which Lansbergen rightly departed in the *Uranometria*, Book 3,

element 7. Galileo, in the third Dialogue on the two systems of the world, p. 287 of the Latin, thinks that instruments could be made whose side would span 30 or even 50 miles, so that each degree would contain a mile, each minute 50 cubits, and each second would subtend a chord of nearly a cubit. But it is one thing that the arcs described from the centre of an instrument can be so divided and subdivided as to show individual seconds with a clear distinction; it is another that the sights can be so made and fitted that, in using the instruments, we can be certain that no possible error exceeds one or two seconds. To us, given the skill and fineness we have so far been able to attain in observing, it seems that this evidence cannot go below 5″; and so we confidently declare a parallax insensible in itself to be one that is less than 5″.

[Margin: What is a false parallax?]

A false parallax is one that either is greater but appears smaller because of an unknown refraction, or is in reality nil, or not sensible in itself to any observers — that is, less than 5″ — and yet appears greater because of a varied motion, by which the phenomenon seems to recede from the same stars, or from the fixed points of the highest heaven. And so, although it arises from motion or from refraction, it is believed to arise from the interval between the centre of the world and the observer, or the phenomenon. Conversely, a parallax can be true and sensible in itself, at least to several people observing the same phenomenon at the same moment in different places on the Earth, and yet not be perceived by some one observer, at whose eye a motion or a refraction keeps the phenomenon all day, or all night, under the same points of the heavens, or at the same distance from the same fixed points.

[Margin: Summary of the foregoing.]

Thus a true parallax could be called, by a causal definition, one that arises from the interval between the centre of the world and either the observer, or the phenomenon, or both; a false parallax, one that arises not from an interval but from motion or refraction, or from illusions of the visible species. Next, a parallax sensible in itself is one that is not less than 5″; an insensible one, one that is less.

[Margin: A collection of axioms and theorems on parallaxes.]

With these laid down — besides the five common axioms on parallaxes given in Book 1, chapter 35, the 15 axioms given to the reader, by then better instructed, in Book 8, Section 1, chapter 17, and the parallactic theorems serving solar eclipses that I gave in Book 5, chapter 10 — there remain some others, bearing on the parallaxes of new phenomena and on a deeper doctrine of them, which we deliberately deferred to the last chapter of this Section; they are to be set out briefly.

1. Theorema. Ignorata Lunæ Parallaxi, ſciri euidenter & exactè nequeunt Diſtantiæ omnium Planetarum ac Fixorum Siderum à Terra, & eorumdem Parallaxes. *Theorem 1. If the Moon's parallax is unknown, the distances of all the*

planets and fixed stars from the Earth, and their parallaxes, cannot be known evidently and exactly.

[Margin: Theorem 1. The Moon's parallax is the foundation of the other parallaxes and of the celestial intervals.]

This is sufficiently proved by induction from all the methods of investigating the parallaxes and distances of the stars that we have so far given, or that the most skilful of the astronomers have devised. For all of them presuppose either the Moon's parallax, from which we derive its distance, and from this the distances of the Sun and the planets, and from the distances their parallaxes; and finally from Saturn's distance we infer the distance of the fixed stars, by the method described in Book 4, chapter 11, together with what we said in Book 3, chapter 7. Or they presuppose the altitude of the pole, which cannot be known exactly except through the true altitudes of the Sun or of the fixed stars; and these cannot be known unless it is established whether they have a parallax, and how much, so that the true altitude may be distinguished from the apparent one. A parallax, in turn, cannot be known except through the distance, which depends either on the Moon's parallax or distance, or on declinations, or right ascensions, or longitudes, or latitudes, or other true places or motions of the stars; and these cannot be distinguished from the apparent ones unless the parallax or distance being sought through them is already presupposed. Moreover, whenever the distance of a phenomenon from fixed stars, and the declination of the fixed stars, is used, astronomers presuppose that the fixed stars have no sensible parallax, and so that their observed and apparent declinations etc. are the same as the true ones; and they gather that the fixed stars lack parallax from their distance as estimated through Saturn's distance. Through the prosthaphaereses, however, and other indications, the proportions of the intervals that lie between the planets can be known.

2. Theorema. Per Obſeruationes Lunæ in vnico Terræ loco factas, cui Luna nunquam tranſeat per verticem, non poteſt ſciri euidenter & exactè Parallaxis Lunæ; etiam ſi Refractio nulla interueniret. *Theorem 2. From observations of the Moon made at a single place on the Earth, through whose zenith the Moon never passes, the Moon's parallax cannot be known evidently and exactly, even if no refraction intervened.*

[Margin: Theorem 2. The lunar parallax is hard to observe.]

For the Moon's parallax cannot be known unless one knows the difference between the Moon's true place — that is, the place reckoned from the centre of the Earth or of the world — and its apparent place, that is, the place observed from the surface of the Earth. This difference, if it can be known evidently in any way, is known chiefly from the observed altitude of the Moon and from a sure prior knowledge of its true altitude. But the true altitude cannot be known unless its true declination and latitude are known beforehand; and to investigate these, the Moon's latitude must be observed, independently of parallax, by someone for whom the Moon appears in the zenith — as we showed,

in Book 4, chapter 12, was nearly done by Ptolemy — or by someone who deduces it from some lunar eclipses, but with the true motion of the Moon, of the Sun and of the lunar nodes presupposed, as we said in the same place. And that motion cannot be evidently separated from the apparent one unless it is established from others' observations that the lunar revolutions behave in the same way in other horizons too (granted that it could be separated from the mean motion), as will be confirmed below from what is to be said about others' observations of phenomena. Granted, if the ecliptic coincided with the horizon, and the apparent motion of the phenomenon were parallel to both, the apparent and the true motion would be the same as regards longitude. Add to this the distance of the equator from the zenith, or the Sun's greatest declination, which is not exactly known unless the parallaxes of the Sun or of the fixed stars are known beforehand; and anyone who denied that these are as small as that, or nil, no one could convict of evident falsehood from observations made at one place on the Earth, since all the phenomena could be saved with respect to one place on the Earth even if a greater parallax were assumed than astronomers have so far assumed. For it cannot be settled with certainty that the fixed stars themselves move only with the motion of the primum mobile, or that they have no proper motion sensible in itself within a few days or years, unless their observations, taken at different places on the Earth, are compared. And so neither Tycho, by his observations alone made at Uraniborg or at Prague, nor any other astronomer outside the torrid zone, or outside the tract over which the Moon sometimes becomes vertical

[Margin: Order of the theorems.]

[Margin: Order of the theorems.]

to the observer, could determine the Moon's parallaxes exactly and evidently. So that you do not think I said this from an itch to carp at Tycho, hear Kepler, in a letter of 1601, written on the Kalends of June (1601 June 1) to Giovanni Antonio Magini, which we have in the supplement to Magini's own *Ephemerides*, p. 253, writing as follows:

[Margin: Kepler's testimony on the uncertainty of the Moon's parallax.]

"As I wish to conclude, there occurs to me what I wanted to write almost in the first place. The theory of the Moon causes Tycho a great deal of difficulty. It seems to me that it must start from the parallaxes that occur because of the sensible distance between the centre and the surface of the terrestrial globe. But the doctrine of parallaxes is confused by the latitudes of the Moon. There would therefore be need of a prior knowledge of the latitudes: each depends on the other" — understand: if the Moon never appears to you in the zenith, or if you do not use the revolutions of the lunar motions, or altitudes of the Moon observed at different places on the Earth. He goes on, however: *"I have therefore considered how the parallax might be investigated by observing, without knowledge of the latitude. Two ways occurred to me. One, if on the same day the Moon is observed once high and once lower, but outside the bound of refractions, when it is near the limits, where the latitude changes little within two hours. It is expedient that this also be done at the beginning of Cancer,*

where the declination too changes little. But when on the same day, after its meridian altitude, the Moon becomes sensibly lower, it acquires a parallax of longitude, which would have to be known beforehand, since it is what is being sought. The other way: that the Moon be observed at distinct times when it is in the nonagesimal degree, at the same limit, at the same distance from the Sun, once higher and once lower; but these three conditions rarely concur. Add that for every single minute in this observation of the altitude, an error of one semidiameter of the Earth is committed, and few of these are contained in the Moon's eccentricity. So, thirdly, I take refuge in this: I ask you to observe the Moon as often as you can in the nonagesimal degree, and to share the observations with us in Germany, together with a most exact altitude of the pole of Bologna. I will see to it that you in turn have our observations. In this way the Moon will sometimes be observed in both places at once, and so the altitudes will become known at various places of the anomaly. For Bohemia and Italy lie, in good part, on the same meridian."

You see him taking refuge in observations made at different places on the Earth, although he indicates that he would not have used them accurately enough, since he thinks that Prague and Bologna are under the same meridian, and that an observation of the Moon's altitude in the nonagesimal apparent to each observer is enough, as though it were then on their meridian; or that the identity of the time at which the observation was made in each place could be known without the places of the Moon, the Sun or the fixed stars, which cannot be known without a prior knowledge of the parallax, if only to exclude it. But since all of Tycho's lunar observations were made before the year 1601, as is plainly established from the appendix to volume 1 of the *Progymnasmata*, it is also clear that neither Tycho nor his followers could then have used the observations that Kepler wished to be made in future — wished, and no more. And in hunting the parallaxes Tycho always used a latitude of the Moon that he could not know through his own observations alone, and it depended on those observed by Ptolemy, as is established from what was said in Book 4, chapters 12 and 14. The same Kepler, however, in the *Astronomiae Pars Optica*, p. 313, had first set out a method of investigating the parallaxes of the Moon and of the stars through different observations taken at different places on the Earth's surface; and yet he added another, through observations made at one place, but supposing that the Moon's true altitude can be known by astronomical calculation, so that it can be compared with the observed one.

3. Theorema. Neq. Parallaxis ſine præcognitione Refractionis aut diſtantiæ à terra, neq. Refractio ſine præcognitione Parallaxeos; aut diſtantiæ à terra, ſiue in Luna, ſiue in alio quouis ſidere, poteſt exactè atq. euidenter ſciri per vllas obſeruationes naturales. *Theorem 3. Neither parallax without prior knowledge of the refraction or of the distance from the Earth, nor refraction without prior knowledge of the parallax or of the distance from the Earth, can be known exactly and evidently by any natural observations, whether in the Moon or in any other star.*

[Margin: Theorem 3. The mutual dependence of parallaxes and refractions.]

For every parallax of any star whatever, if it is to be known independently of the distance from the Earth, presupposes that star's parallax in the circle of altitude to be known beforehand — granted that the parallax of altitude could be confirmed a posteriori through a presupposed parallax of another kind, namely of declination or of right ascension.

[Margin: Proof of the first part, on parallax.]

But the parallax of altitude itself cannot be known except by comparing the star's true altitude with its apparent or observed altitude; and the difference between the true and the observed altitude does not give the correct parallax unless it is certain from elsewhere that no refraction intervenes, or how much refraction must be subtracted from the observed altitude (since refraction visibly raises the star), so that the observed altitude may be corrected and the corrected one compared with the true. Nor is it enough to suppose the observation made outside the hazard of sensible refractions; for that very thing must be known beforehand — namely, how great the apparent altitude of the star is at which it has no sensible refraction. That is why, in all the problems of chapters 10, 11 and 12 that can be solved by observations taken at one or at several places on the Earth, I deliberately warned that the parallax of altitude could be investigated provided there is no refraction, or provided that the apparent altitudes, or the apparent distances from fixed stars or points of the heavens, or the apparent places, are corrected by it. Accordingly Tycho prudently defined the Moon's parallaxes with the refraction subtracted from the apparent altitudes, as I showed by examples in Book 4, chapter 14.

[Margin: Second part, on refraction.]

Refraction itself, moreover, cannot be known unless the refraction in the circle of altitude, or vertical circle, is known; and this cannot be known if you know beforehand neither the parallax of the same star nor its distance from the centre of the Earth, as is proved by sufficient induction. For the refraction that intervenes and apparently raises the star is either equal to the parallax, which apparently depresses it, or greater or less than the parallax. If it is equal, the observed star will appear no higher than its true place; and one cannot conclude that it therefore appears in its true place except because the parallax is known beforehand, by force of which it ought to appear less high, or more depressed, than its true place; and so it is concluded that the whole parallax is corrected by an equal refraction and the star restored to its true place. If the refraction is greater than the parallax, as is supposed in the Sun, the difference between the true altitude computed from tables and the apparent altitude observed with instruments will not give the whole refraction; the parallax will have to be added to it, because the refraction first corrects the parallax and cancels its effect, and then apparently raises the star above its true place, as I shall show with Tycho in the next section, Problem 24. Finally, if the refraction is less than the parallax, it does not emend the whole parallax, nor does it make the star appear absolutely higher than it really is, but only comparatively, relative to

the depression that would otherwise result by force of the parallax; that is, it makes the star appear not as far from the zenith as it would appear if parallax alone intervened. Therefore, for the refraction to become known, one must in such a case add the parallax to the star's true distance from the zenith, so as to have the apparent distance, that is, the distance that would be seen by force of the parallax; for the difference between this and the distance from the zenith observed with instruments will be the refraction, as we shall show in Problem 26 of the next Section. And do not say that the refraction can be known if the height of the refractive air is known, together with the Earth's semidiameter and the angle of inclination; for it will be clear from what is to be said in the next section, from Problem 44 on, that these givens are not enough without the star's distance or parallax. On the contrary, we shall be compelled to hunt out the very height of the refractive air, and the inclination, from a refraction known beforehand.

4. Theorema. Omnibus tamen penſitatis, non licet fingere maiorem parallaxin Lunæ Gradib. 2. 53′. Solis 1′. 15″. & Saturni 9″. Nec Refractionem in Zonis calida & temperatis, ſerenoq. cælo, maiorem Lunæ Gradib. 2. 19′. 4″. Solis, 34′. 46″. & Saturni 30′. 5″. in noſtra quidem hypotheſi, nec multò maior in Tychonica, aut Kepleriana. *Theorem 4. All things weighed, however, one may not suppose a parallax of the Moon greater than 2° 53′, of the Sun greater than 1′ 15″, or of Saturn greater than 9″; nor, in the hot and temperate zones and with a clear sky, a refraction greater than 2° 19′ 4″ for the Moon, 34′ 46″ for the Sun, and 30′ 5″ for Saturn — in our hypothesis, at least; nor much greater in Tycho's or in Kepler's.*

[Margin: Theorem 4.]

All this has been sufficiently proved above, from Problem 73 to 75. We are not speaking, however, of extraordinary refractions at places or times at which thicker vapours are raised.

[Margin: Order of the theorems.]

[Margin: Order of the theorems.]

5. Theorema. Diſtantia viſa Phænomeni ab aliquo ſidere, poteſt eſſe veræ diſtantiæ æqualis, & maior, aut minor quàm vera diſtantia, quamuis magnam Parallaxim altitudinis habeat. *Theorem 5. The apparent distance of a phenomenon from some star can be equal to the true distance, and greater or less than the true distance, however great a parallax of altitude the phenomenon has.*

[Margin: Does parallax increase or diminish the distance from the stars?]

[Margin: Theorem 5.]

This is demonstrated by Scipione Chiaramonti in Book 1 of the *Antitycho*, chapter 8, proposition 1. But without a further diagram it will become evident on an astronomical globe, if you suppose a planet to be at the beginning of Cancer under the meridian, and a fixed star in the equator having no parallax, and the planet to have so much parallax that it appears now in the equator, now

at the beginning of Capricorn, now below the tropic of Capricorn. For in the first case the apparent distance will be less than the true, in the third greater, and in the second equal to the true. These cases, transferred onto a diagram, will at once supply the middle term of the demonstration.

6. Theor. Motus viſus Phænomeni per idem planum euntis, ſed à verticalis plano diuerſum, inferior eſt motu vero. *Theorem 6. The apparent motion of a phenomenon that goes through one and the same plane, but a plane different from that of a vertical circle, is lower than its true motion.*

[Margin: Theorem 6.]

This is against Kepler in the *Hyperaspistes*, p. 13, who concedes it only of the diurnal motion of the primum mobile; but Chiaramonti demonstrates that it is true of the phenomenon's proper motion as well, in Book 1 of the *Antitycho*, chapter 11, and in his *Apologia* for the same work, Book 1, chapter 6. For when the line of motion does not pass through the observer's zenith, the apparent place is always more remote from the zenith than the true place of the phenomenon; and so the apparent path of the phenomenon is always lower than the path of its true motion.

7.Theor. Phænomenon parallaxin habens continuam & ſenſibilem, ſi vero motu deſcribit circulum maximum, à verticali circulo diuerſum; viſo motu non deſcribit circulum maximum. *Theorem 7. A phenomenon having a continuous and sensible parallax, if by its true motion it describes a great circle different from a vertical circle, does not describe a great circle by its apparent motion.*

[Margin: If the true motion is along a great circle, what of the apparent motion?]

[Margin: Theorem 7.]

Chiaramonti demonstrates this in Book 1 of the *Antitycho*, chapter 11, proposition 2; and Kepler admits it in the *Hyperaspistes*, p. 18, and after him Cabæus [Niccolò Cabeo], on *Meteorologica* 1, text 37, question 1. The reason is that the only great circles on a sphere are those that bisect each other at two opposite points, by proposition 11 of the first book of Theodosius's *Spherics*; but the apparent path of the phenomenon in question is always lower than the path of its true motion, by Theorem 2, and the one never cuts the other. Otherwise, if it intersected it, whether at the zenith and nadir or at any other points, the parallax would cease there and would not be continuous; for those points of intersection would be common to the circle of the true and of the apparent motion, and the true and the apparent place would be the same there.

8.Theor. Phænomenon parallaxin habens continuam & ſenſibilem, ſi motu viſo deſcribit circulum maximum à verticali diuerſum; motu vero non deſcribit circulum maximum. *Theorem 8. A phenomenon having a continuous and sensible parallax, if by its apparent motion it describes a great circle different from a vertical circle, does not describe a great circle by its true motion.*

[Margin: If the apparent motion is along a great circle, what of the true motion?]

[Margin: Theorem 8.]

This is the converse of the preceding theorem and is proved in the same way. Otherwise, if both circles — that is, the circle of the apparent and that of the true motion — could be great circles, they would intersect each other at two opposite points, by proposition 11 of the first book of Theodosius's *Spherics*; and if they intersected there, the parallax would not be continuous, etc.

9. Theor. Poteſt Phænomenon magnam & continuam parallaxim habere, & tamen viſo motu deſcribere circulum in ſphæra maximum: & viciſſim. *Theorem 9. A phenomenon can have a great and continuous parallax and yet by its apparent motion describe a great circle on the sphere; and conversely.*

[Margin: An apparent motion along a great circle admits a great parallax.]

[Margin: Theorem 9.]

This is against Kepler in the *Hyperaspistes*, p. 18, but it is Chiaramonti's, in the *Apologia* for the *Antitycho*, p. 53, and Cabeo's, on *Meteorologica* 1, text 37, question 1. Kepler's words are: *"For it is true that, if the comet by its true motion held to the path of a great circle, it did not hold to it by its apparent motion, since it produced a parallax. But with less circumlocution this too is true — and Scipio has not yet refuted it — that if by its apparent motion it marked out an arc of a great circle, it also marked one out by its true motion, because in that way a sensible parallax is taken away from it."* Let those little words *"because in that way"* be noted: for they signify that from an apparent motion along a great circle there necessarily follows the absence of a sensible parallax. But, as Chiaramonti rightly says in the place cited, *"there is no such necessity"*, which he thinks he has shown in Book 1 of the *Antitycho*, chapter 11; I, however, show it as follows. It is not contradictory that some phenomenon should move by its true motion continuously, either along one and the same circle parallel to the equator, or along various circles with a winding course, but in such a way that — by reason of its distance from the Earth in the first case, or of its winding path — it always undergoes just as much parallax as is precisely required for it always to appear in the equator. For just as the parallaxes of altitude continually decrease from the horizon up to the meridian, so too the arcs of the circles of altitude between the equator and that same parallel decrease from the horizon to the meridian. Therefore no contradiction can be shown, from this or from anywhere else, why the distance of the phenomenon from the centre of the Earth could not vary in such a way that it always goes through the plane of the same parallel, and yet the parallactic arc is as great as the arc between the parallel and the equator.

Moreover, because Tycho, in volume 2 of the *Progymnasmata*, from p. 92 on, inferred from the apparent motion of the comet of the year 1577 along a great circle that it was above the Moon, and so had no parallax greater than the Moon's, Kepler judged it to follow from this that the comet had no sensible

parallax; indeed, that this was why Tycho investigated, and why one must investigate, whether a phenomenon goes visibly along a great circle — so as to know from this whether it has a parallax — whereas Chiaramonti had said that the parallax must be examined first, so as to know along what circle the comet went. So Kepler, in the *Hyperaspistes*, p. 12, said:

[Margin: Kepler's perverse order in examining parallax.]

"Hear me, Peripatetic: we attend to whether the comet proceeds in a great circle so that we can decide about its parallax; we seek the parallax so that from it we may learn its place in the diameter of the world as well; the kind of circle comes first in this inquiry, it does not follow."

[Margin: Cabeo judges rightly, but does not defend Tycho adequately.]

Father Cabeo, indeed, judged rightly when he teaches that, with a sensible parallax already presupposed — the Moon's, say — it is rightly inferred that if the body described a great circle by its apparent motion, it does not describe a great circle by its true motion. But he does not rightly defend Tycho against Chiaramonti when he thinks that Tycho, having first presupposed an insensible parallax of the comet, inferred that if it described a great circle by its apparent motion, it also described a great circle by its true motion. For Tycho, in volume 2, first dealt with motion along a great circle from p. 92 to p. 103, deducing from it that the comet had been above the Moon, and then, from p. 110, began to deal with parallax.

10. Theor. Quamdiu non conſtat Vllane, aut Senſibiliſne ſit an inſenſibilis Parallaxis; non poteſt certò conſtare, ex ſolo motu viſo an Phænomenon feratur per circulum maximum motu vero. *Theorem 10. As long as it is not established whether there is any parallax at all, or whether it is sensible or insensible, it cannot be established with certainty from the apparent motion alone whether the phenomenon is carried along a great circle by its true motion.*

This proposition is against Kepler, whose words from the *Hyperaspistes*, p. 12, I reported a little earlier; but it is Chiaramonti's, in Book 1 of the *Antitycho*, chapter 11, proposition 10, and it follows from our Theorems 8 and 9. Chiaramonti explains himself, moreover, in the *Apologia* for the *Antitycho*, p. 33: namely, that if the parallax is unknown, the kind of circle along which the comet goes by its true motion is unknown. Granted, in the *Antitycho*, by more obscure wording, he gave Kepler occasion to suspect that in Chiaramonti's opinion the parallax had to be known beforehand, before the inquiry into the parallax — which would be to argue in a vicious circle, and to overturn the whole of astronomy from its foundations, as Kepler said on p. 12 of the *Hyperaspistes*.

[Margin: Order of the theorems.]

[Margin: Order of the theorems.]

[Margin: Motion along a great circle alone is not a necessary argument for the comet's distance.]

11. Theor. Ex ſolo Phænomeni per circulum maximum motu quamuis regulari ſeu vero, ſeu viſo, non poteſt neceſſariò deduci, Vtrùm illud ſit ſupra [?]n infra Lunam, ſeu vtrùm minorem Lunari, an maiorem Parallaxin habeat. *Theorem 11. From a phenomenon's motion along a great circle alone — however regular that motion may be, and whether it is true or apparent — it cannot necessarily be deduced whether the phenomenon is above or [?] below the Moon, or whether it has a parallax smaller or greater than the Moon's.*

[Margin: Theorem 11.]

For there can be some mobile body in the elementary region that is nevertheless carried with a true motion along a great circle, that is, along the plane of a great circle. Thus balls fired from bombards or fire-spewing tubes travel in a single plane, in such a way that in their descent they are always carried towards the centre of the Earth; and the pendulum [?], which we treated in Book 2, chapter 20, can be set swinging in that same plane and yet, by the inclination of its weight, tend as far as it can towards the centre of the Earth; and finally, on walls erected perpendicular above the horizon and directed towards the centre of the Earth, motions can take place along their planes. Now planes that intersect one another at the centre of the Earth lie in the plane of a great circle of the Earth, by the 6th of the first book of Theodosius' *Spherics*. And it is admitted that this kind of motion, along a great circle, can belong to celestial bodies. Nor, on the other hand, is it inconsistent for an elementary body to be kept to a great circle in its apparent motion, as we said in Theorem 9; and still less is this inconsistent for celestial bodies. Therefore these motions stand indifferently towards bodies below and above the Moon. Tycho's argument, then, by which he inferred from the comet's course along a great circle that it had been above the Moon, is not a necessary one, as we showed at greater length in Book 8, Section 1, chapter 11, number 9.

12. Theor. Ex eo quòd Phænomenon moueattur motu proprio tardiùs quàm Luna, non ſequitur neceſſariò, illud eſſe ſupra Lunam. *Theorem 12. From the fact that a phenomenon moves with its proper motion more slowly than the Moon, it does not necessarily follow that it is above the Moon.*

[Margin: Theorem 12.]

We showed all this in Book 8, Section 1, chapter 11, number 6, where we also showed that Tycho in the end, and Kepler, acknowledged that there is nothing in this argument but mere probability; and against it, as we showed, arguments no less probable, drawn from the motion of comets, are available for a sublunary place of the comet. Granted, on this ground Tycho tried to show that the comet of the year 1577 was higher than the Moon, because, judged by its distances from the stars of Pegasus, it appeared in three hours to have fallen behind the motion of the primum mobile by 3′ 12″, whereas in those hours the Moon, seen at the same longitude and latitude, would have fallen behind it by 15′.

13. Theor. Ex ſola Phænomeni perſeuerantia ſub eâdem ſtella Fixa, vel in eâdem diſtantia ab ijſdem Fixis punctis vel ſtellis obſeruatâ in vnico terræ loco; non poteſt certò colligi Aequalitas in Parallaxi cum Fixis, ſeu Carentia ſenſibilis Parallaxis, aut merus motus primi mobilis; Poteſt autem, ſi obſeruata ſit ex quibuslibet pluribus terræ locis eodem tempore, ſaltem ſecluſa Refractione. *Theorem 13. From a phenomenon's persistence alone under the same fixed star, or at the same distance from the same fixed points or stars, observed at a single place on the Earth, one cannot infer with certainty an equality of parallax with the fixed stars, or the lack of a sensible parallax, or a mere motion of the primum mobile. One can, however, if it is observed from any number of places on the Earth at the same time — at least when refraction is set aside.*

[Margin: Theorem 13.]

[Margin: An argument that is not necessary for the lack of parallax.]

This proposition, as to its negative part, is directed against many in Tycho, *Progymnasmata* volume 1 — namely Hájek, p. 515; Fabricius, 528; Peucer, 539; Mästlin, 545; Digges, 678; Camerarius, 694, these being Tycho's pages — and against Tycho himself, pp. 416 and 515, and in the *Epistolae*, p. 18, and against Longomontanus in the Appendix to the *Astronomia*, p. 32. These concluded that the new star of Cassiopeia of the year 1572 was necessarily very close to the fixed stars, or even had no sensible parallax, because at both meridian altitudes it kept the same visible distance both from the same fixed stars and from the pole of the world — each of them, indeed, relying on the observations of a single place on the Earth. Let Tycho be heard, standing for all the rest, p. 416: *"Both above and below the pole I saw exactly the same arrangement of the stars relative to one another, and the interval precisely the same. This certainly could not have happened if this new star had been subject to any trace of parallax, even the smallest."*

[Margin: Of Tycho, Longomontanus, Hájek,]

[Margin: Fabricius, Peucer, Mästlin, Digges, Camerarius.]

And on p. 515, speaking of the various syllogisms of Thaddaeus Hájek, he says: *"As regards the first syllogism, there is no doubt that phenomena having no parallax necessarily exist above it. So too, what he brings in [?] in the second argument, from the star's distance from the neighbouring fixed stars and from the pole, equal everywhere and always the same, proves sufficiently that it lacked all parallax"*; and shortly after: *"Indeed, if it constantly kept the same interval from the neighbouring fixed stars, however it revolved with the motion of the universe, the consequence will be to admit neither a proper motion of its own nor any motion that arises accidentally by reason of parallax."*

[Margin: The first part of the theorem is proved.]

But there is no such necessity: both from what was demonstrated by Chiaramonti in Book 1 of the *Antitycho*, chapter 10, proposition 14, conceded by Tycho's *Hyperaspistes* on p. 111, and demonstrated by us in Book 8, Section 2, chapter 6; and because a phenomenon of this kind could be very close to the Earth, and so have a large parallax, and have some true proper motion, at least in declination, and yet be held by some internal or external directing force

always [?] in the same line of the apparent place under the fixed stars as long as it is above the visible horizon of one observer — while, if it set below that horizon, it would move with other motions forward and back in longitude and sensibly vary its distance from the fixed stars. For imagine, for the sake of example and clarity, that from a single small loop on the surface of the Earth, where the eye of one observer is, a thread that has first been passed through a luminous globe is drawn out as far as the pole star, and is held stretched without any bending by the force of some Intelligence at the centre of the pole star, and is so carried round with it about the pole: would that globe not always appear under the pole star, though it stood only one semidiameter of the Earth from the eye? Imagine the same with respect to a setting star, say the Dog Star; or — as Aristotle teaches, in Book 1 of the *Meteorologica*, chapter 6, once happened to certain haloes or comets, and as Chiaramonti, not inappropriately, recalls against Tycho in Book 2 of *De tribus novis stellis*, chapter 1, p. 232 — that, attracted by some star, they followed it with a most obedient motion and always appeared under it, with respect to one place on the Earth: suppose this very thing to happen in other phenomena. For no reason can be adduced why it could not happen. Finally, this is confirmed by the stations of the planets, during which they appear motionless for some hours or even days, and in the same place under the fixed stars, notwithstanding parallax: the same thing, therefore, can happen in any phenomenon.

[Margin: The second part of the theorem is proved.]

But if, not with respect to one observer or another, but with respect to several, and indeed any whatever, the same distance from the same fixed stars occurs, observed at the same time, it will be a physico-mathematically evident argument that the phenomenon has no proper motion sensible to anyone, and therefore moves only with the motion of the primum mobile and lacks all parallax sensible in itself. Otherwise, if it were close to the Earth, two visual lines drawn from different places on the Earth's surface through the centre of the phenomenon would necessarily intersect there in such a way as to make a sensible angle at it, and hence a sensible parallax. I said "at the same time"; otherwise, if this happened on different nights or days, and one observer were at Rome on one night and another at Goa or Antwerp, etc., on different nights, that phenomenon could be kept on one night always in the same line of the apparent place as seen at Rome, and on other days in the same line of the apparent place as seen at Goa or Antwerp; and so the individual observers could, by accident, fail to perceive a parallax, although the phenomenon had one that was in itself very sensible — perhaps even perceived by the senses of others, who observed it at different places but at the same time. Therefore, if that identity of distance from the fixed stars, observed in the new star of Cassiopeia in the year 1572 at Uraniborg, Prague, Lucanij and elsewhere, was observed at the same time, then Tycho, in volume 1, p. 123, showed by a stronger argument indeed that it lacked a sensible parallax — leaving aside, however, the consideration of refraction. For if someone were to say that it did have a parallax, sensible in itself

so far as its distance from the Earth goes, but rendered insensible by accident, because the refraction was always as great as the parallax and so prevented the parallax from being perceived, and he is not convicted of falsehood on other grounds, it will not be possible to establish the lack of paral- [Margin: Order of the theorems.]

[Margin: Order of the theorems.]

lax sensible in itself, but only that the parallax was not perceived by the senses.

14. Theor. Ex æquali, ſimilibus plurium dierum momentis, variatione diſtantiæ Phænomeni ab ijſdem Fixis, obſeruata in vnico terræ loco; non poteſt certò colligi merus motus primi Mobilis & cauſam illius varietatis eſſe ipſam Pallaxin,atque adeò nec Quantitas Parallaxis: Eſto id poſſit colligi ſi talis varietas obſeruata ſit in pluribus quibuſuis terræ locis; ſaltem ſecluſa Refractione. *Theorem 14. From an equal variation in a phenomenon's distance from the same fixed stars, at like moments of several days, observed at a single place on the Earth, one cannot infer with certainty a mere motion of the primum mobile, nor that the cause of that variation is the parallax [?] itself, and so neither the quantity of the parallax; granted that this can be inferred if such a variation is observed at any several places on the Earth — at least when refraction is set aside.*

[Margin: Theorem 14.]

[Margin: What if a phenomenon returns daily to an equal variation of distances?]

I explain the theorem first and then prove it. Let there be a phenomenon which at Rome, on September 24, at exactly 7 o'clock after noon, appears to be 1° west of the bright star of the Eagle, near the zenith, and at 12 o'clock, near the horizon, 3°. And let the same phenomenon, on the following night, the 25th, at Rome, at 7 o'clock, again appear to be 1° west of the Eagle, and at 12 o'clock 3°; and so on, every night showing an equal variation at like hours, that is, at every 12 o'clock after noon having an apparent distance of 3° west of the Eagle. Someone could therefore infer from this that such a phenomenon has no motion other than that of the primum mobile, since at like hours, returning after 24 hours, it comes back to the same point under the fixed stars and is not seen to move away from it either forward or backward; and further, since near the zenith it appears less far west of the Eagle than near the horizon, and the Eagle is supposed to move with no motion other than that of the primum mobile, or with none that is sensible within a few days, he could conclude that this variation comes from a parallax sensible in itself, depressing the phenomenon towards the horizon, as parallax does.

[Margin: The first part of the theorem is proved.]

But I say that neither argument is necessary so long as we are not certain that the same alternations are seen in any other horizon. For that return to the same point at like hours, and that variation of the apparent distances, could come from a proper motion of the phenomenon, now slow, now quick, and

now direct, now retrograde, whose alternations returned daily at like hours. For example, the phenomenon could complete 2° in the 5 hours from 7 o'clock to 12 by its proper motion, but afterwards, having sunk below that single observer's horizon, go back towards the Eagle with a slower but regressive motion, in such a way that, having retraced those two degrees in 19 hours, on the following night at 7 o'clock it would again be 1° from the Eagle. And all this could happen even if it were at any distance whatever from the Earth, and so even if it lacked a true parallax sensible in itself. Conversely, however, that alternation could arise from a true parallax of a phenomenon having no motion other than the motion of the primum mobile. Which of these, then, is the cause of that apparent variation cannot be determined with certainty unless we know that exactly the same alternations are observed at any places on the Earth — I do not say at all of them collectively — but at any several of them, and at as many as are required for an induction sufficient to produce physical certainty.

[Margin: The second part of the theorem is proved.]

But if those alternations occurred alike, indeed equally, at like hours anywhere on Earth, this could no longer be attributed to a proper motion. For when the phenomenon, at, say, 18 o'clock after noon at Rome, was going back towards the Eagle, somewhere — indeed in many places — it would be the moments of those hours that lie between 7 and 12, at which it would have to be truly moving away from the Eagle; and it is impossible for the same mobile body, by a continuous true motion, to approach and to move away with respect to the same term towards the same quarter of the world. It would therefore be inferred rightly, and with physical necessity, that that variation and depression, or increase of the apparent distance, comes from parallax; and so some parallax at least could also be known from that difference of distances, if not the whole of it, because of its mixture with refraction.

15. Theor. Ex inæquali Variatione diſtantiæ viſæ Phænomeni ab ijſdem Fixis ſtellis, ſimilibus plurium dierum momentis obſeruata in vnico Terræ loco; non poteſt certò colligi motus proprius Phænomeni potiùs, quàm parallaxis in Longitud. aut Latitud. per ſe ſenſibilis, nec potiùs parallaxis, quàm motus proprius, nedum vtriuſuis determinata quantitas: ſaltem ſi Phænomenon non compleat, nec repetat Reuolutiones ſuas: Poteſt autem ſi prædicta inæqualitas obſeruata fuerit in pluribus quibuslibet terræ locis, ſaltem ſecluſa Refractione, & multò certiùs ſi compleat ac repetat reuolutiones ſuas. *Theorem 15. From an unequal variation in a phenomenon's apparent distance from the same fixed stars, observed at like moments of several days at a single place on the Earth, one cannot infer with certainty a proper motion of the phenomenon rather than a parallax in longitude or latitude sensible in itself, nor a parallax rather than a proper motion, still less a determinate quantity of either — at least if the phenomenon does not complete and repeat its revolutions. One can, however, if the inequality already mentioned has been observed at any several places*

on the Earth — at least when refraction is set aside — and much more certainly if it completes and repeats its revolutions.

[Margin: Theorem 51 [?].]

This seems to be against Kepler, p. 77 of *De Cometis*, against whom I said enough in Book 8, Section 1, chapter 20, number 10, refutation 7. I explain the theorem, and then prove it. Let a phenomenon appear at Rome, on September 24, at 7 o'clock after noon, to be 1° east of the Eagle; on the 25th, at 7 o'clock, 2°; and on the 26th, at 7 o'clock, 3°; and so on, more and more, uniformly or even difformly — say, always at 7 o'clock, on the 24th 1°, on the 25th 1° 20′, on the 26th 1° 40′, or with some other like increment of a uniformly difform motion. From this the observer at Rome could deduce that this comes from a proper motion of the phenomenon in the order of the signs; for it is from like observations, it seems, that the proper motion of the planets in the order of the signs has so far become known — namely from their moving eastward away from some fixed star.

[Margin: The first part of the theorem is proved.]

I say, however, that this argument is not necessary in itself, so long as it is not known whether the same thing happens at like hours in any horizon whatever, with the proportion of motion preserved that is due to the distance of the places and of the meridians. For nothing prevents that variation and inequality from coming wholly from parallax, increased or diminished because of the phenomenon's varying distance from the centre of the Earth, just as much as that apparent variety of motion requires. But if an evident constancy in the phenomenon's apparent size stood in the way of this opinion, or the appearance of a larger diameter at a time when, according to that opinion, it ought to be smaller because of the greater interval, then the argument would no longer be taken from the mere inequality of the distances from the fixed star in longitude, but from elsewhere.

[Margin: The second part of the theorem.]

So if astronomers are certain about the proper motion of the planets, they have acquired that certainty from observations made at several places on the Earth, and after many revolutions of the phenomenon, or by considering the visible increase and decrease of the apparent diameter, and many other conditions; and from these it has been established that the variation is not something accommodated, by means of mere parallax, to the observer of a single horizon. Since, however, for so great a variety of motions to be accounted for by the variation of the parallaxes alone, several conditions would be required whose concurrence is not as probable as a proper motion, a proper motion is therefore inferred from the observations of a single place on the Earth more probably than mere parallax; and if anyone were to infer mere parallax, excluding a proper motion in longitude, he would be doing so neither necessarily nor more probably. Hence, rightly, Tycho, in volume 1 of the *Progymnasmata*, p. 515: *"Although, conversely, it does not follow that a phenomenon which keeps an unequal distance from the fixed stars is for that reason subject to a sensible parallax: for it can*

have a proper motion of its own which alters the distances without any parallaxes, as happens in the star of Saturn, whose parallaxes are scarcely perceptible, and which nevertheless, in one revolution of the heavens, is not equally distant from the fixed stars."

[Margin: Confirmation from the motion of Saturn and Jupiter.]

And Cysat urges the same in his book *De Cometis*, chapter 3, Lemma 8, teaching that a comet can have a proper motion without any parallax; and he gives the example of Jupiter when swift, whose parallaxes, too, he thinks can scarcely be recognised: for if it is 10° 20′ from the fixed star it is approaching, then after 6 hours, he says, its distance from the same fixed star will be observed as 10° 18′, because its motion over 6 hours, when it is swift, is 2 minutes. And

[Margin: Order of the theorems.]

[Margin: Order of the theorems.]

this difference of distances arises only from the true motion, he says.

16. Theor. Ex eo quòd Phænomenon, ex vno terræ loco obſeruatum, in diuerſis altitudinibus viſis, videatur minorem vel maiorem differentiam altitudinum aut parallaxium ſuſcipere, quàm Luna in ijſdem altitudinibus ſuſciperet, non poteſt certò colligi, illud eſſe ſupra vel infra Lunam; ſeu minorem, aut maiorem Lunari Parallaxin habere; & multò minùs ſi Differentia parallaxium non ſit eiuſdem ſpeciei. Poteſt autem, ſi hoc eueniat in quibuſuis terræ locis, ſaltem ſecluſa Refractione. *Theorem 16. From the fact that a phenomenon observed from a single place on the Earth, seen at different altitudes, appears to undergo a smaller or greater difference of altitudes or of parallaxes than the Moon would undergo at the same altitudes, one cannot infer with certainty that it is above or below the Moon, or that it has a parallax smaller or greater than the Moon's; and much less if the difference of the parallaxes is not of the same kind. One can, however, if this happens at any places on the Earth — at least when refraction is set aside.*

[Margin: Theorem 16.]

Let this be said with all due respect to Tycho, volume 2, p. 110; to Kepler, *De stella nova*, chapter 15; to Cysat, *De Cometa anni 1618*, chapter 3, lemma 3, and p. 49; and to Longomontanus, in the Appendix to the *Astronomia Danica*. The first part of the theorem can be gathered from what has been said and what is still to be said; and it is enough to point out that the diversity already mentioned can be attributed no more to parallax than to an anomaly of the proper motion. The second part is clear from the contrary argument: if the same thing is observed at any places on the Earth, that is a physically evident argument of uniformity in place or in motion, and so the diversity must be referred either to parallax or to refraction.

17. Theor. Ad diſcernendas Parallaxes Phænomeni certò & euidenter, cæteris partibus præferendæ ſunt obſeruationes, factæ in diuerſis terræ locis,obſeruationibus in vnico terræ loco factis; & inter illas illæ, quæ factæ

ſunt eodem momento temporis. *Theorem 17. To discern a phenomenon's parallaxes certainly and evidently, observations made at different places on the Earth are to be preferred, other things being equal [?], to observations made at a single place on the Earth; and among the former, those made at the same moment of time.*

[Margin: Theorem 17.]

The first part is against Tycho, *Progymnasmata* volume 1, chapter 7, p. 451, and chapter 8, p. 489, and volume 2, chapter 6, p. 89; and against Kepler in the *Hyperaspistes*, p. 129, and in *De Cometis*, p. 77. For Kepler, relying on Tycho's observations, and Tycho on his own — gathered, as they were, at such great expense and with such diligence, though made at a single place, namely Uraniborg — not only preferred them to the observations of others, but laid down universally that the observations of a single place are more certain than those of different places for drawing out the parallax. Chiaramonti rightly judged the opposite of this in the *Antitycho*, Book 3, chapter 3, and in the *Apologia* for the *Antitycho*, Book 2, chapter 4.

[Margin: Tycho's mistaken opinion.]

Now, Tycho's opinion on that p. 451 is expressed in these words: *"Although — to say how the matter stands — those trials are far stronger and more certain that are carried out by some one observer in the same horizon and with the same instrument carefully made, provided that each thing is in order and not subject to any sensible fault, than if the working-out of the thing sought is looked for from different horizons and sightings."* And in volume 2, p. 489, he thinks he has demonstrated the place of the comet of the year 1577 from observations made at a single place on the Earth so thoroughly *"that they cannot be overthrown with just reasons by anyone who understands these matters"*, and that it therefore needs *"no vote of others, nor observations made elsewhere and decisions deduced from them, by way of confirmation."* But we have already shown sufficiently, in Theorems 2, 14, 15 and 16, that observations made at a single place on the Earth are not sufficient for this — so far are they from being better. And I said "other things being equal", that is, with equal certainty in the altitude of the pole, equal size or quality of the instruments, and equal diligence and circumspection in observing. For a distance between the meridians is not always presupposed; it is enough if, at the same moment, the places of the observations are on the same meridian or vertical. And the fact that human trust mixes itself in here, and that the observations have to be believed, is likewise common to many astronomical conclusions that are derived from more recent observations compared with the observations of the ancients.

The second part, concerning observations made at the same moment, is clear enough, since in them the investigation of the distance from the Earth, or of the parallaxes, depends on no motion of the phenomenon; rather, the parallax and the distance can be gathered from distances purely as seen from the same fixed star, or from the zenith, and from the distance of the places on the Earth on the same great circle, as is clear from what was said in chapter 8 and chapter 11. Akin to these are the observations made at like hours — as

when one observer at Rome observes at the 1st hour of the night and another at Toledo likewise at the first hour of the night — and so for the rest.

18. Theor. Quamuis parua & aliquando vnius tantùm Minuti differentia Locorum viſorum, aut Parallaxium inueniatur ex obſeruationibus eiuſdem Phænomeni, eodem momento factis in diuerſis locis Terræ, ſub eodem verticali poſitis; poteſt tamen eius eſſe magna, & valde maior Lunari, Parallaxis. *Theorem 18. Although a small difference of the apparent places, or of the parallaxes — sometimes of only one minute — is found from observations of the same phenomenon made at the same moment at different places on the Earth situated under the same vertical, its parallax can nevertheless be great, and much greater than the Moon's.*

[Margin: Theorem 18.]

I wanted to point this out here, so that from this too it may be further confirmed how circumspect one must be in pronouncing on the parallax and place of new phenomena. For who, inferring from observations of this kind a parallactic difference of one minute, would not at once cry out that the phenomenon is far beyond the Moon? But it is one thing for the parallax to be smaller than the Moon's, another for the difference of the parallaxes to be so; and we showed above, in chapter 11, Problems 67 and 68, with Chiaramonti, that this difference can be one minute and the phenomenon nevertheless have a parallax of many degrees.

[Margin: The argument of Kepler and Longomontanus is fallacious.]

From this you will gather that the argument is not necessary by which Kepler, in his book on the new star of Serpentarius, chapter 15, p. 81, tries to show that it was above the Moon, on the ground that he at Prague and Fabricius in Frisia observed its place without a difference of six minutes; and I say the same of a similar argument of Longomontanus, in the appendix to the *Astronomia*, chapter 10, for the comet of the year 1607.

19. Theor. Ad Parallaxes Phænomeni eliciendas, meliores ſunt cæteris paribus obſeruationes factæ per Diſtantias à Fixis, quàm per Azimutha & temporum Momenta, quibus capiuntur Altitudines. *Theorem 19. For drawing out a phenomenon's parallaxes, observations made by distances from the fixed stars are better, other things being equal, than those made by the azimuths and moments of time by which altitudes are taken.*

[Margin: Theorem 19.]

Tycho rightly pronounced on this, in volume 1 of the *Progymnasmata*, p. 604, and in the *Epistolae*, p. 295: in the matter of parallaxes, observations founded on the distances of the phenomenon from the fixed stars are more certain than those that rest on altitudes and azimuths together with observed moments of time. For in a short time, and with a slight change in the azimuths, the altitudes undergo a large increase or decrease if they are not near the meridian; and about the meridian the altitudes change little, it is true, but much time slips

by at the same sensible altitude. Distances from the fixed stars, on the other hand, are taken at once, with no dependence on the time, and if they are to be repeated a short time afterwards they do not vary sensibly — at least when they are beyond the hazard of refractions. But since mention of refractions has occurred more than once here and above, there remains a last knot to be untied, arising from the very close entanglement and almost inextricable connection of refractions and parallaxes. For if someone posits much greater refractions than Tycho and others after him did, he must also posit much greater parallaxes, and smaller distances of the stars from the Earth. Next, it is doubtful which of these is to be known beforehand, or can be known beforehand, while the other is unknown. In the meantime, however, what we taught in this Section in Problems 73, 74 and 75, and then in Theorem 3, where we discussed this difficulty sufficiently, can suffice for the solution of this knot.

20. Theor. Etiam ſi Phænomenon habeat lucem totam à Sole, & tota nocte conſpicuum ſit, nullam patiens Eclipſim; non concluditur neceſſariò illud eſſe altius tota vmbra Terræ, imò nec altius Luna. *Theorem 20. Even if a phenomenon has all its light from the Sun and is visible the whole night, suffering no eclipse, it is not necessarily concluded that it is higher than the whole shadow of the Earth — indeed, not even that it is higher than the Moon.*

[Margin: Theorem 20.]

This can be seen against Peter Apian, in Part 2 of the *Astronomicum Caesareum*, in his observation of the third comet, which he saw in the year 1533, in the month of June. There he admits that the comet never had a northern latitude of less than 32 degrees, and yet he says this of it: *"For if it had been near the Earth, and farther from the Sun, it could never have happened that it did not fall into the Earth's shadow, and so it would have remained hidden."* For he supposes that comets shine from no other source than the Sun. But Apian does not say that it was higher than the whole shadow of the Earth, nor even that it was higher than the Moon; he says only that it was not near the Earth with the nearness the ancient Peripatetics assigned, namely in the upper region of the air. It could, however, have been seen the whole night even if it were below the Moon, as is clear from Book 8, Section 1, chapter 15, Problem 7; and from the fact that a great latitude and declination of the phenomenon towards one side, together with a great inclination of the cone of the Earth's shadow towards the opposite quarter, can exempt the phenomenon from every eclipse.

SECTIO SEXTA PROBLEMATA REFRACTIONVM SIDEREARVM IN AERE.

Section Six. Problems of the Refractions of the Stars in the Air.

CAPVT I.

Chapter I.

Quæſtiones præcipuæ de Refractionibus Indicatæ tantùm,& alibi ſoluendæ, aut fuſiùs tractandæ. *The principal questions on refractions — only indicated here, to be solved elsewhere or treated more fully.*

We are not dealing here with the refractions of any luminous body whatever, but only with those of the rays of the stars; and not with these in every denser medium either, but only in our own air, into which the ray of the stars falls as it passes from the purer air, or from the ethereal [?] breath. For the other matters — what happens in refractions in water, glass, crystal and so on, and what serves for determining the burning point of a glass or crystal sphere, for the lenses of telescopes or of spectacles, and for the humours of the eye, all of which we have derived not only from the experiments of others but also from our own — have been worked through diligently by us in our book on optics, which, God willing, will be the third of the Second Volume of this New Almagest. In that book we have also untied many questions about this matter, raised partly by recent writers and partly by ourselves; it has nevertheless seemed good to indicate them here.

The first question is about the cause of refraction: why the ray of a luminous body, in passing from a rarer medium into a denser one, is refracted towards the perpendicular, and in passing from a denser into a rarer one is refracted away from the perpendicular. This cause is treated above all by Alhazen [Ibn al-Haytham], Book 7 of the *Optics*, proposition 8; Vitellio, Book 2, proposition 47; Kepler in the *Astronomiae Pars Optica*, chapter 1, proposition 20; Niccolò Cabeo on Book 3 of the *Meteorologica*, text 8, question 4, p. 95; Pierre Gassendi, *De apparenti magnitudine Solis*, letters 2 and 4, pp. 70 and 134; René Descartes in the *Dioptrics*, chapter 2; Father Emmanuel Maignan, most diligently, in the dioptrics of his *Horaria*, from proposition 10 to 44; Fortunio Liceti, Book 2 of *De natura luminis*, chapter 22; Athanasius Kircher, Book 8 of the *Ars magna lucis et umbrae*, p. 653; and Hérigone, Axiom 5 of the *Dioptrics*.

[Margin: Question 1: on the cause of refraction.]

The second question is whether a greater distance of the luminous body from the centre of the Earth and of the atmosphere causes, other things being equal, a smaller refraction. Kepler seemed to deny this in the *Astronomiae Pars Optica*, pp. 112 and 137, and in the *Rudolphine Tables*, p. 120. But it should certainly have been affirmed. For it is established by experiment that where the inclination of the ray to the surface of the denser medium is smaller, the refraction is smaller, other things being equal; and of two stars placed at equal altitude or depression, all else being equal, the one whose distance from the centre of the Earth is greater has the smaller inclination, as will also be clear from what is to be said below. On the argument against the infinite distance of the fixed stars taken from refraction, see Book 6, chapter 7, in the scholia.

[Margin: Question 2: on the distance of the luminous body.]

The third question is whether a difference in the regions of the Earth makes a difference in the quantity of the refractions. Tycho seems to have doubted this in the *Epistolae*, p. 64; but there, and on pp. 79 and 280, he contends

only that in Hesse they could not have been twice as great as in Denmark. Otherwise, on p. 85, and in the *Progymnasmata*, volume 1, p. 144, and elsewhere, he admits that variation, and greater refractions in the northern tracts — as does Longomontanus too, in Book 2 of the *Spherics*, chapter 11, who admits refractions twice or three times greater in maritime places and those nearer the Arctic pole than elsewhere. Kepler agrees, in the *Astronomiae Pars Optica*, pp. 134 and 136, adding that they are more constant in maritime places than in inland ones, and almost nil on some mountains. And since in Bohemia they were found about two minutes smaller than in Denmark, Scheiner in the *Sol ellipticus*, p. 31, and Martinus Hortensius in his dissertation with Gassendi, think, not without reason, that Tycho's tables of refractions cannot be applied safely to all places without fear of error in a few minutes; and Lansbergen sets down in his table Dutch refractions different from Tycho's. On the monstrous refraction at Novaya Zemlya, see what was said in Section 3, Problems 13 and 14.

[Margin: Question 3: on the difference of places.]

The fourth question is whether a difference of weather — yearly, monthly or daily — changes the refractions. Ptolemy seems to suppose this in Book 8 of the *Almagest*, near the end, where he says that the risings, appearances and occultations of the stars vary with the different changes of the air; and so does al-Battānī, chapter 27, when he says that the autumnal equinox is to be observed rather than the vernal, because of the smaller disturbance of the air. Tycho says the same in the *Progymnasmata*, pp. 79, 124 and 280; and in the *Epistolae* and in the observations of the year '87 he also said that refractions appear greater about the solstices. Kepler too, in the *Astronomiae Pars Optica*, p. 137, thinks that the refractions of the fixed stars were found by Tycho to be smaller than those of the Sun, because he observed the fixed stars on the clearer and longer winter nights, but the solar refractions at the summer solstice, following Tycho's own instruction in the *Progymnasmata*, volume 1, p. 93. We, for our part, have certainly found the morning refractions greater than the evening ones, the winter ones greater than the summer ones, and the spring ones generally greater than the autumn ones, especially while observing the quantity of twilight — which, for that reason too, we think has been found to vary from one author to another. Father Emmanuel Maignan supports this variation in Book 1 of the *Perspectiva Horaria*, from proposition 23 to 25. In proposition 24 he rightly teaches that the air is not always made denser by more intense cold, since ice becomes lighter and rarer by the force of cold, as it floats on top, etc.; and so it can happen that somewhere and at some time the air, congealing under greater cold, is nevertheless rarer than where or when the cold is less, and so the refraction becomes smaller. In proposition 37, moreover, he teaches that no thermoscope can give certain knowledge of the inequality or equality of the astronomical refractions that light undergoes in the air on different days or at different hours — whether you use a glass tube, in which water rises as the cold increases and falls as it decreases (on which see our Bettini,

Apiaria 8, Progymnasma 3), or the little awn of an oat as an indicator of dryness and humidity (on which see Io. Bapt. Porta [Giambattista della Porta], Book 2 of the *Magia naturalis*, chapter 14). For the density of the air varies not only with the coming of cold but also through a mixture of denser or rarer vapours, from which the air shut inside that tube is free. Then again, the changes of the air that occur in the highest part of the refracting atmosphere are one thing, and those in the thermoscopes we keep in our bedrooms or chambers are another — to which the constant breath of our mouths contributes not a little.

[Margin: Question 4: on the difference of times.]

[Margin: Note on the variation of the air, and on the use of the thermoscope.]

The fifth question concerns the shape of the air that refracts the rays of the stars. Most of the recent writers who treat this matter agree that it is not perfectly spherical but as it were elliptical, or fluctuating unevenly like a sea driven by winds, and very rough; Emmanuel Maignan pursues this at length in Book 1 of the *Perspectiva Horaria*, from proposition 26 to 32. From this it follows that the refraction of a solar ray in the air is not a sure index of the vertical circle in which the Sun stands, and that, when that refraction has taken place, the surface of refraction is not always the vertical circle itself.

[Margin: Question 5: on the shape of the air.]

The sixth question concerns the size of the luminous body, or at least a greater intensity of its light: whether, that is, a larger star, or one endowed with a more intense light, undergoes a smaller refraction. For Kepler denies it, in the *Astronomiae Pars Optica*, p. 111, and so does Cabeo on Book 3 of the *Meteorologica*, p. 91; and indeed in the fixed stars, which do not appear brighter than the Sun, Tycho found a smaller refraction. Yet a reason must be given why, if density causes refraction by resisting the direct propagation of light, this resistance is not overcome more by a stronger light. But of this elsewhere.

[Margin: Question 9 [?]: on the size or intensity of the light.]

The seventh question is whether, and why, opacity — which obstructs the propagation of light more — nevertheless does not of itself vary the refractions; and whether hardness, just as it is suited to reflection, also contributes something to varying refraction.

[Margin: Question 7: on opacity and hardness.]

The eighth question is whether the straight line of a ray refracted in the air is a single one, or rather several, one after another. Granted that — as Emmanuel Maignan teaches, not without reason, in Book 1 of the *Perspectiva Horaria* — one refraction after another occurs very frequently, not only from the aether into the air but also from one part of the air into another, denser part, it does not follow from this, as I once suspected together with Father Bonaventura Cavalieri, that the line of refraction, or refracted ray, is curved; rather, it consists of several straight lines, and our eye sees by the last of them. For it is more probable that there is some depth of air of one and the same physical density, and that its density does not increase continuously and uniformly difformly towards us. Nevertheless Albertus Linemannus [Albert Linemann], in his disputation

on uranic refractions, and Io. Graves [John Greaves] of London, as Hevelius reports on p. 197 of the *Selenographia*, affirm that the line is conic — that is, parabolic, elliptical or hyperbolic — because of three regions of air of different density. But not all of these are suited to a sensible refraction.

[Margin: Question 8: on the shape of the refracted ray.]

The ninth question is whether, because the air between the mountains or islands that we view from the sea, or on the sea, is denser than air farther off, the refraction in it can be so great that the summits of mountains, or islands, or the sails of ships, which would otherwise lie hidden below the straight ray touching the surface of the sea, can be seen. Father Athanasius Kircher affirms that this happened to him, in a letter written to me on 1647 February 17. He says that once, when he was on the island of Malta, he saw Etna, which he nevertheless could not make out on the clearest days; and that the same happened to Don Carolus Vintimilius [Carlo Ventimiglia] looking from Monte Pellegrino at some islands or other. Nor does Snel disagree, in the *Eratosthenes Batavus*, Book 2: from this illusion he reduces the height of Etna — which would otherwise, from the distance of the observers, come out at 6 miles — to 4 miles, and he refers to this the sight, from Lilybaeum in Sicily, of ships still lying in the harbour of Carthage. To me it has always seemed hard to believe that the difference of density between that air and the rest, which is nearer to those mountains and islands, is so great; I would rather believe that on the clearest days, because of the glare of the Sun, things could not be made out on the horizon which were made out at other times.

[Margin: Question 9: on things seen on the surface of the sea.]

The tenth question concerns the height of the air that produces sensible refraction. For it is not the same as the height of the exhalations that produce twilight — though this itself is very uncertain among authors, as is clear from what was said in Book 2, chapter 19, and Book 8, Section 1, chapter 14, where I also taught that this very height of the exhalations depends on refraction; and so, since neither can be determined with certainty without the other, both remain uncertain to this day. Maignan contends the same with other arguments in Book 1 of the *Perspectiva Horaria*, proposition 38, but above all because he himself, at Toulouse, on a clear night in the month of August, saw from the 11th hour after noon until midnight, with the Moon below the horizon, a certain bright little cloud spread out near the meridian almost to the zenith; which, all things considered, could not have been illuminated except by the Sun, and so must have been higher than the whole shadow of the Earth. He adds that something similar happened to Michelangelo Ricci when he was staying among the Sabines — a man most learned in mathematics. We think, however, that two extremes are to be avoided: one, that of Tycho and Longomontanus, who confuse the height of the refracting air with the height of the vapours, or rather of the twilight exhalations; the other, that of Kepler, who distinguishes these heights but nevertheless grants the refracting air no greater height than half a

German mile. Whether, and on what hypothesis, the height of this air can be known, if not absolutely, will be told below in the Problems.

[Margin: Question 10: on the height of the refracting air.]

The eleventh question is whether, if the height of the refracting air is unknown, the angle of refraction cannot be known, as Emmanuel Maignan contends in Book 1 of the *Perspectiva Horaria*, propositions 39 to 43; or whether it can at least be known a posteriori, through altitudes of the stars corrected for parallax. But we have already indicated our view on this in Section 5, Theorem 19, and from Problem 73 to the end. Below, however, on the occasion of Tycho's problem, this string will be struck again.

[Margin: Question 11: on the uncertainty of refraction because of the uncertain height of the air.]

The twelfth question concerns the effects of the refraction of the stars' rays in the air. But I have already listed the chief of these in Book 3, chapter 9, in the scholia. Among them is the elliptical shape of the Sun and the full Moon appearing on the horizon, on which I discoursed in Book 3, chapter 2, and Book 4, chapter 15. Likewise the variation of the equinoctial moments, and the deceptiveness of the equinoctial armillae, on which see Book 3, chapter 14, number 8. Likewise the contraction and interruption of the Earth's shadow, and the portion of the Earth illuminated by the Sun being greater than the ancients thought, on which see Book 5, chapter 5. Likewise the contraction — or rather the enlargement — of the height of the vapours, on which see Book 8, Section 1, chapter 14. Likewise the increase of the Sun's diurnal arc, and of the arc of the ecliptic that is always visible, on which see this Book 10, Section 3, from Problem 12 to 15. It remains to propose a question about the apparent size of the stars as changed by the force of refraction.

[Margin: Question 12: on the effects of the refraction of the stars.]

The thirteenth question, then, is whether the stars appear (especially on the horizon) larger or smaller by the force of refraction than they would appear without refraction. That they appear smaller, even at the vertex, was demonstrated by Alhazen, Book 7 of the *Optics*, from proposition 52 to 54; by Vitellio, Book 10, from proposition 51 to 53; by Maurolycus, Book 1 of the *Diaphaneon*, theorem 2; by Kepler too, in the *Rudolphine Tables*, p. 98; and by Wendelen in the *Idea* of the Atlantic tables. As for the cause for which the Sun appears larger on the horizon, Alhazen, Book 7, proposition 55; Vitellio, Book 10, proposition 54; Baccon [Roger Bacon], Part 2 of the *Perspectiva*, distinction 3, chapter 6; the author of the *Perspectiva communis*, Book 1, proposition 82; Kepler in the *Astronomiae Pars Optica*, p. 133, and in the *Epitome of Copernican Astronomy*, p. 81; René Descartes, chapter 6 of the *Dioptrics*; and Hortensius in the dissertation with Gassendi refer it to our estimation. That is, the eye looking upward has nothing from which to estimate the distances of the stars, or of their edges, and so takes them to be nearer; but when it views them on the horizon, the tracts of land or sea lying in between warn the eye of an immense distance, and the estimative faculty judges them larger, because it already knows beforehand that

things seen under the same angle are larger if they are seen at a greater distance. But if you take the diameters of the luminaries with instruments, they appear larger rather on the meridian and nearer the vertex than on the horizon: so says Kepler above all, in the place cited. Yet he, like Wendelen, grants that the Moon's apparent diameter is larger at the vertex than away from the vertex; and Regiomontanus supports this in the *Epitome of the Almagest*, conclusion 1. Pierre Gassendi, on the other hand, in *De apparenti magnitudine Solis humilis et sublimis*, pp. 6, 43, 82 and 85, refers the cause to the dilation of the pupil: shaded, as it were, by the horizontal vapours, and looking with less injury at the rays of the stars, which are tempered and intercepted, it makes the visual angle larger by its opening. Scheiner too favours this dilation, in the *Oculus*. They add, moreover, that if the Sun's apparent diameter is taken while it is on the horizon, either from the shadow of a tablet or from the bright image of the Sun, it is found somewhat smaller than far from the horizon; and so that larger emphasis of the rising or setting Sun is a deception of sight — either because you judge visible things larger from a greater interval, or because of the dilation of the pupil.

[Margin: Question 13: on the apparent size of the stars.]

[Margin: Opinion 1.]

[Margin: Opinion 2.]

Alhazen, however, in Book 7, proposition 51, and Vitellio, in Book 10, propositions 53 and 54, grant that the stars appear larger on the horizon — not always, it is true, but for the most part. This is not because of the first refraction of the rays, from the aether into the air, which takes place towards the perpendicular, but because of the second refraction, which takes place as the rays pass out of the thick and watery vapours into the rest of the air, lying between those vapours and our eye, and purer; for this refraction, they say, takes place away from the perpendicular. And so, just as through a similar refraction the image of a coin placed under water is enlarged at the common surface of water and air, so too is the image of the stars. The same cause is given by Petzanus, the author of the *Perspectiva communis*, Book 3, proposition 12; by Roger Bacon, Part 3 of the *Perspectiva*, distinction 2, chapter 4; and by Bettini, *Apiaria* 8, Progymnasma 4, propositions 1 and 2. There Bettini admirably reconciles with themselves Alhazen, Vitellio and Maurolycus, who teach that the stars appear now larger, now smaller by the force of refraction; and he cites Cleomedes, Book 2 of the *Cyclical Theory*; Giambattista della Porta, Book 1 of *De refractione*, chapter 11; and, in Porta, Seneca, Macrobius and Aphrodisaeus [Alexander of Aphrodisias], who assert that the stars appear larger when the south wind, a vapour-bearing wind, is blowing. To these I add Ptolemy, Book 1 of the *Almagest*, chapter 3; Sacrobosco and Clavius on the *Sphere*, pp. 108 and 109; and Barocius [Francesco Barozzi] in the *Cosmographia*, p. 17, who grant that the stars appear larger absolutely, because of the horizontal vapours. But above all, Posidonius in Strabo, Book 3 of the *Geography*: *"For Posidonius relates that it is commonly said that the Sun sets much larger on the shores bordering the*

Ocean"; and shortly after: *"The cause why the apparent image of its size is increased at rising and likewise at setting on the seas is that more vapours are raised upward from the moist places; the sight, broken through them as through tubes, receives broader images — just as when you look at the setting or rising Sun, or the Moon, through a dry and thin mist, when the star also appears reddish."*

I once replied that the stars appear larger on the horizon absolutely, by the force of the second refraction, made away from the perpendicular because of the watery vapours lying between the ethereal breath outside our atmosphere and the air nearer our eye, which is not as dense as those horizontal vapours are; and that this always happens so, as will be clear by experiment. Nor is this to be attributed to a fallacy of estimation, because of the intervening tract of valleys, plains and seas. For if in a room or a garden you look at the Sun rising or setting, so placed that a hedge, or a wall, or the lower edge of a window blocks all view of the intervening space as far as the horizon, and you see nothing but the Sun, you will nevertheless see it enormously larger than far from the horizon. Nor, again, is it to be attributed to mere dilation of the pupil. For if you try to contract the pupil by voluntary motion, you will still see the image of the rising or setting Sun, or of the full Moon, much larger than at other times; and you will observe the same in Jupiter, Venus and the other stars. Conversely, if about noon you look at the Sun through clouds, or through coloured glass, and dilate the pupil as much as you like, you will never see it as large as on the horizon. Lastly, I, together with Father Grimaldi, often observed the rising Sun with a sextant; with me directing my eye to the right edge of the Sun and him to the left, the Sun's transverse diameter was taken, and it always appeared much larger than at other times. For sometimes it was seen to extend to almost a whole degree, and often to about 45′; in the Moon, too, we noted 38′ and 40′. That it does not appear so great to someone taking its quantity by the shadow or the bright image on a tablet has this cause: the horizontal vapours blunt the rays of the edges and do not allow a clear boundary to be painted by them on the tablet. The second refraction, away from the perpendicular, therefore outweighs the first, which takes place towards the perpendicular — the refraction by whose force the stars would otherwise appear smaller than their just size, but by a difference quite negligible, as Kepler too teaches in the *Astronomiae Pars Optica*, p. 130.

[Margin: Our view.]

For let V be the vertex, and VH and VR two quadrants of a vertical circle, intercepting the arc HR of the horizon, of 90°; and at H and R let there be two stars whose true distance HR is 90°, but whose apparent distance is AB, because of the refraction raising the stars by 34′, as Tycho observed in the Sun. Then in the triangle AVB the sides AV and BV will each be 89° 26′, and with these and the angle V of 90° the arc AB is found to be 89° 59′ 42″. So the difference from the true distance HR is only 18″. But if the arc HR and the angle V were 45°, the difference would be 9″; and if V were of one degree, the difference would not reach even one second. Now let HR be the distance

between the edges of the Sun or of the Moon, since this is not of one degree: by the refraction already mentioned it will certainly not come out smaller by one whole second, which is a quite contemptible difference.

Diagram. A figure beside the demonstration of the triangle AVB, standing at the right of the right column. From V at the top a curved line, the quadrant VR, runs down to R at the lower right, and straight lines run from V down to A and to H at the lower left; a horizontal line joins A and B, and the base runs from H to R, with straight lines crossing the figure between C, F, D, G, B and R.

- V (top): the vertex
- C (upper left, on the line from V): unexplained on this page
- F (left, below C): unexplained on this page
- D (right, middle): unexplained on this page
- G (right, below D): unexplained on this page
- A (left, above H): apparent place of the star at H
- B (right, above R): apparent place of the star at R
- H (lower left): a star on the horizon
- R (lower right): a star on the horizon

The fourteenth question. What if, between our eye and the outermost surface of the air, which causes the first refraction, there lies only air of a single density, and the ray, having entered the denser air, does not leave it before it reaches our eye? Will the distances of the stars, or their diameters, appear larger by the force of refraction, or smaller? To answer this question the following figure must be set out. In it let the hemisphere AOB of the Earth be understood as described from the centre C, its true horizon being ACB but its apparent horizon DE; and in it let there truly be two stars, D and E, and let their true distance, viewed from the centre C, be the arc DE. Through these stars and through the vertex V let two quadrants of vertical circles be drawn, namely HDV and KEV, which are not in the same plane, as you see them here on the paper, but are inclined to each other and intersect in the vertical line CV, their common section. You will conceive this better if you fold this paper along the line CV, bending the plane CVK towards CVH. Now by the force of refraction let star D appear at F and star E at G, and through the apparent places F and G let the arc FG of a great circle be drawn, representing the distance of the apparent places. Let the apparent places be joined by straight lines both with the eye O, by the straight lines OF and OG, and with the centre of the Earth, by the straight lines CG and CF; and let the true places be joined with the centre C by the straight lines CD and CE, and be understood as joined with the eye O by the straight lines OD and OE, which are inclined to each other and lie in the plane of the physical horizon. With this set out, a manifold distinction is needed in answering.

[Margin: Question 14.]

Diagram. A figure beside the setting-out of the fourteenth question, at the right of the right column: a semicircle on the base AB with the centre C at its

midpoint, H and K on the base between A and C and between C and B; above it, lines from H and K rise to the vertex V, crossed by the chord DE and by the chord FG, with straight lines from the small letter o near the centre and from C to D, E, F and G.

- V (top): the vertex
- F (upper left): the apparent place of star D
- I (between F and G): unexplained on this page
- G (upper right): the apparent place of star E
- o (centre): the eye O
- D (left, middle): star D, on the apparent horizon DE
- E (right, middle): star E
- A (lower left): end of the true horizon ACB
- H (base, left of C): foot of the vertical quadrant HDV
- C (base, middle): the centre of the Earth
- K (base, right of C): foot of the vertical quadrant KEV
- B (lower right): end of the true horizon ACB

First, then, I say that if refraction alone, in the vertical circles

[Margin: Reply 1.]

taking place towards the perpendicular, is considered, and the seen places F, G are, as actually happens, seen from the surface of the Earth by the eye O, and the seen distance FG is compared with the true distance DE, as estimated from the centre of the Earth C, then the seen and the true distances are equal if the refraction is precisely as great as the parallax of altitude; and in that case the refracted ray FO is parallel to the unrefracted CD, just as the refracted GO is parallel to the unrefracted CE. But if the parallax is smaller than the refraction, the seen distance is smaller than the true one; and if the parallax is greater than the refraction, the seen distance is greater than the true one. I say the same of the apparent diameters of the stars, seen by the eye O and compared with those that astronomers estimate from the centre C, in so far as diameters are considered as distances between the extreme luminous points.

Second, I say: if the seen places F, G are considered now as seen from O and now as estimated from C, the distance seen from O is always greater than the distance as if seen from C; that is, the angle FOG is greater than the angle FCG. But if the seen places are considered as if from C, and the true places are likewise considered as seen from C, then the seen distance of the true places is greater than the seen distance of the apparent places; that is, the angle DCE is greater than the angle FCG — even if these angles are not in the same plane, as they are represented here, but in different planes — provided that only the refraction towards the perpendicular, in each star's own vertical circle, is considered.

[Margin: Reply 2.]

Third, I say: notwithstanding what has been said, the diameters of the stars can appear larger not only from the double refraction, as was said in the reply to Question 13, but also from a threefold cause. 1. From the trembling of the vapours, on account of which, in the same physical instant, any luminous points

whatever are seen to be now to the right and now to the left, although in reality they occupy a single place at any one instant. 2. From the very swift motion of the primum mobile, that is, the diurnal motion of the stars, which outruns the swiftness of any eye, and of the estimation that relies on the eye, and which causes the extreme and intermediate luminous points of the diameter — of the whole solar disc, or of any star — to be seen in two places at the same time or physical instant, and to occupy both the point from which and the point to which, as it carries the stars on, moment by moment, to different azimuths and to different planes of the almucantar circles [circulorum Almuncatarath]. This swiftness has a greater effect near the horizon, where these changes are greater. In the same way, if because of too great a distance I could not tell the motion of a very swift bird across a space of two palms from rest, the bird, though itself only a palm long, would seem to me to occupy a space of two palms at the same time. And indeed lightning, because of its swiftness, seems to us to occupy a great tract of the sky even when it is short, nor are different exhalations always kindled one after another. 3. If someone were to admit that refraction takes place not only in the vertical circle but in another plane as well, and that the rays of the intermediate points are refracted to the eye in such a way that each of them would be seen farther from the others and larger, some to the right and some to the left, he could give from this an account of this apparent magnitude. But he would defend himself only with difficulty against the common opinion of the opticians, who require that the direct ray, the refracted ray and the perpendicular to which, or from which, the refraction takes place be in the same plane. More on these matters in the *Optics*.

[Margin: Reply 3.]

The fifteenth question is whether the thickness or depth of the denser medium, as such, increases the refraction, as Tycho seems to have held; against him Kepler, in the *Astronomiae Pars Optica*, chapter 4, p. 83. But Kepler attributes this not to the mere thickness but to the greater obliquity and inclination of the rays.

[Margin: Question 15.]

CAPVT II.

Chapter II.

In quo Definitiones & Axiomata Refractionum in communi. *In which the definitions and axioms of refractions in general are given.*

In the following figure let a straight line AB be drawn, representing a plane surface cut by this sheet of paper and cut at right angles, at the point C, by the straight line DCE. From D, with the radius CD, let the arc FCG be described; and from E, with the radius EC, let the arc HCI be described. The first of these represents a concave surface and the second a convex one, with respect to an eye placed at D. For ACB will touch each arc at C and will make with the semidiameters DC and EC a right angle on either side at the point of contact

C, by proposition 18 of Book 3 of Euclid. Indeed, the arcs just mentioned, and the surfaces they represent, will also touch one another at C. Now let there be a luminous body at D, radiating to C by the perpendicular ray DC onto a denser surface — of water, say, or of glass, etc. — whether concave, FCG, or plane, ABC, or convex, HCI. If the ray is reflected, it will be reflected back into itself from C towards D; but if it penetrates these surfaces, it will penetrate them straight through C towards E. Next let there be a luminous body at L, radiating obliquely to C by the ray LC. If this ray is reflected, it will be reflected from C towards K, so that the angle of inclination LCD is equal to the angle KCD, and the angle of incidence LCA is equal to the angle of reflection KCB. But if the ray LC penetrates any one of these surfaces, it will not be propagated straight from C towards M — so that the outer ray LC and the inner ray CM would lie in one and the same straight line LCM. Rather, if it falls on a denser surface, it will be bent (as if it were broken at C) towards the perpendicular DCE and will be propagated along another straight line CR. LC will then be the incident ray and CR the refracted ray; the refracted angle will be ECR, and the angle of refraction RCM. Taken together, these make up the angle ECM, which is equal to the angle of inclination LCD, since it is set vertically opposite it, by proposition 15 of Book 1 of Euclid. Conversely, if the luminous body were in the denser medium, say at R, and passed through C into the rarer medium, it would not go straight from C to P but would be refracted towards L; CL would then be the refracted ray, LCD the refracted angle, and LCP the angle of refraction, which is part of the refracted angle. Finally, if from any point of the reflected ray CK — from K, say — the perpendicular KM is let fall to AB, until it meets the incident ray LC produced as far as the meeting point, KM will be called the Cathetus

Diagram. A figure in the right column for the definitions of reflection and refraction: a horizontal line AB through the point of incidence C, and a vertical line DCE through it; an arc FCG, concave upward, and an arc HCI, concave downward, both touching AB at C; a solid line from L at the upper left to C, continued below C as a solid line to R near E; a dotted line from P through C to M at the lower right; a solid line from C to K at the upper right, with a dotted vertical from K down to M.

- D (top): the luminous point on the perpendicular; centre of the arc FCG
- L (upper left): the oblique luminous point
- P (upper left, beside D): end of the dotted line, where the ray from R would go unrefracted
- K (upper right): on the reflected ray CK
- F (left): end of the concave arc FCG
- G (right): end of the concave arc FCG
- A (left): end of the plane surface AB
- C (centre): the point of incidence
- B (right): end of the plane surface AB
- H (lower left): end of the convex arc HCI

- I (lower right): end of the convex arc HCI
- M (lower right): end of the unrefracted continuation LCM, and foot of the cathetus KM
- E (bottom): on the perpendicular DCE; centre of the arc HCI
- R (bottom, right of E): end of the refracted ray CR

Definitiones. *Definitions.*

1. The perpendicular to a straight line, or to a plane surface, is a straight line making a right angle with the straight line taken by itself, or with a straight line lying in the plane surface. Such is DC with respect to ACB.
2. The perpendicular to a curved line, or to a concave or convex surface, is a straight line that makes a right angle, at the point of contact, with another straight line touching the curve. Such is CD with respect to ACB, which touches the curved surfaces FCG or HCI at the point C. Understand the same of a perpendicular drawn to a parabolic, hyperbolic or elliptical line: for the tangent must first be drawn, or conceived as drawn, and a straight line drawn at right angles at the tangent's point of contact. If the perpendicular is to a circle or a sphere, this line, produced, will fall on the centre of the circle or sphere.
3. The line of incidence, or the incident and direct ray, is a ray from a luminous body terminating at a point of some surface, and that point is called the point of incidence. This ray is either right, that is, coinciding with the perpendicular line, as DC, or oblique and different from the perpendicular, as LC.
4. The reflected ray is a ray distinct from the direct ray, returning from the point of incidence straight or obli- quely towards the origin of the direct ray, that is, making with the direct ray at the point of incidence either no angle or an angle less than two right angles. If the direct ray is perpendicular, as DC, it is reflected back into itself from C towards D, and in the same straight line there are two distinct rays, one DC, the other CD. But if it diverges from the perpendicular, as LC, the reflected ray is CK.

Diagram. The figure of the preceding page printed again, in the left column beside the definitions: a horizontal line AB through the point of incidence C and a vertical line DCE; an arc FCG, concave upward, and an arc HCI, concave downward, both touching AB at C; a solid line from L to C, continued below C to R; a dotted line from P through C to M; a solid line from C to K, with a dotted vertical from K down to M.

- D (top): on the perpendicular
- L (upper left): the oblique luminous point
- P (upper left, beside D): end of the dotted line
- K (upper right): on the reflected ray CK
- F (left): end of the arc FCG
- G (right): end of the arc FCG

- A (left): end of AB
- C (centre): the point of incidence
- B (right): end of AB
- H (lower left): end of the arc HCI
- I (lower right): end of the arc HCI
- M (lower right): end of the dotted line, foot of KM
- E (bottom): on the perpendicular
- R (bottom, right of E): end of the refracted ray CR

5. The refracted ray is a ray proceeding from a ray that falls obliquely on a transparent medium of a density different from the preceding one and penetrates it; it is propagated along a straight line different from the line of the incident ray, that is, one making with the incident ray an obtuse angle at the point of incidence. Such is the ray CR, compared with the incident LC, or the ray CL, compared with the incident RC.
6. The unrefracted ray is a ray proceeding from a ray that falls obliquely on a transparent medium of the same density — or one feigned in the imagination as of the same density — and penetrates it; it is propagated along the same straight line as the incident ray. Such is, or would be, the ray CM with respect to the incident LC, or the ray CP with respect to the incident RC, if the transparent medium of both rays were of the same density.
7. The cathetus of reflection is a straight line drawn from any point of the reflected ray perpendicular to the plane of the mirror, as far as its meeting with the incident ray produced in imagination: such is KM. The cathetus of incidence, by contrast, is a straight line drawn from any point of the incident ray perpendicular to the plane of the mirror, etc.
8. The angle of incidence is the angle made at the point of incidence by the incident line and by a straight line lying in the plane, or touching the surface, on which the ray falls. Such is the angle ACD, if the incident ray is perpendicular, as DC; or the angle ACL, if the ray falls obliquely, as LC.
9. The angle of inclination is the angle made at the point of incidence by the incident line and by the perpendicular. Such is the angle ACD, if the incident ray is AC and the perpendicular DC; or the angle LCD, if the incident ray is LC and the perpendicular DC. Therefore, if the incident ray is DC, the inclination is nil, but the incidence is greatest and strongest; but if the incident ray is AC, at right angles to the perpendicular, the incidence is nil, but the inclination is greatest, and of 90 degrees. Yet Vitellio, Book 10, and Kepler in his *Optics* often use, or name, the angles of inclination and of incidence indiscriminately.
10. The angle of reflection is the angle made at the point of incidence by the reflected ray and by a straight line lying in the plane surface, or touching the curved surface, from which the reflection takes place. Such is the angle KCB, if the reflected ray is CK.

11. The reflected angle is the angle made at the point of incidence by the reflected ray and by the perpendicular drawn through the point of incidence. Such is the angle DCK, if the reflected ray is CK.
12. The angle of refraction is the angle made at the point of incidence by the refracted ray and by the other, unrefracted ray, or the ray assumed as unrefracted. Such is the angle RCM, if the refracted ray is RC and the unrefracted MC; or LCP, if the refracted ray is LC and the unrefracted PC.
13. The refracted angle is the acute angle made at the point of incidence by the refracted ray and by the perpendicular. Such is the angle ECR, if the refracted ray is RC. I said "acute" because the same RC makes with DCE the obtuse angle DCR, but that is not the refracted angle. But if the refracted ray is LC, the refracted angle will be LCD.
14. Refraction towards the perpendicular is when the refracted ray comes closer than the unrefracted ray to the perpendicular produced on the same side, that is, makes a more acute angle with it. Such is the refraction of the ray CR, which comes closer to the perpendicular CE and makes a more acute angle ECR than MC, which makes the angle ECM.
15. Refraction away from the perpendicular is when the refracted ray draws farther than the unrefracted ray away from the perpendicular produced on the same side, that is, makes a less acute angle with it. Such is the refracted ray LC, compared with the unrefracted PC and the perpendicular CD.
16. A dense body is one that has much corporeal substance, and a rare body one that has little substance, in an equal bulk or space. Therefore density is the multitude, and rarity the fewness, of the parts of corporeal substance within the same bulk or within an equal space; and neither is said absolutely, but comparatively.
17. An opaque body is one that is impervious to light, that is, stops the further propagation of light. A transparent or pellucid body, on the other hand, is one that is pervious to light, that is, a body fit to admit the further propagation of light within itself — whether transparency consists in the privation of opacity or in a positive quality contrary to opacity.

Axiomata vel quaſi Axiomata aut Poſtulata. *Axioms, or quasi-axioms, or postulates.*

1. A perpendicular ray, if it is reflected, is reflected back into itself; but if it is not reflected but penetrates a different transparent medium, it passes through unrefracted.
2. The angle of reflection of rays is always equal to the angle of incidence, and the reflected angle to the angle of inclination. So hold Euclid, theorem 1, from hypothesis 3; Alhazen, Book 4, propositions 10, 11, 12 and 18; Vitellio, Book 5, propositions 10 to 20; and René Descartes, *Dioptrics*, chapter 2. This also holds for an elliptical, parabolic and hyperbolic surface, provided that a straight line touching those surfaces is used and

the angles made by the tangent and the incident ray are considered, as geometers commonly consider them — with Apollonius, *Conics*, Book 3, proposition 48; Vitellio, Book 9, proposition 42; Kepler, in the *Astronomiae Pars Optica*, chapter 1, proposition 19; and Cavalieri, *De speculo ustorio*, chapter 7. Granted that Cabeo, on Book 3 of the *Meteorologica*, text 8, question 4, rejects that tangent as something fictitious; yet it is not merely feigned, since it really exists in the intervening medium, say in the air, as the perpendicular does too. And granted that it is not really distinct from the surface and the depth, nature does not on that account cease to operate in relation to such lines. So too we measure the angle of refraction even though one of its lines is the unrefracted ray, which is not such in reality but is feigned as what it would be.

3. A ray falling obliquely from a rarer medium into a denser one is refracted at the point of incidence towards the perpendicular; but a ray falling obliquely from a denser medium into a rarer one is refracted away from the perpendicular. So teach, from a sufficient induction drawn from experiments, Alhazen, Book 7, p. 3 to 14; Vitellio, Book 2, propositions 42 to 45, and Book 10, propositions 3 and 4; Maurolycus at the beginning of the *Diaphaneon*; Porta, *De refractione*, Book 1; Kepler, *Dioptrics*, axioms 2 and 3; and the writers on dioptrics generally.
4. The incident and the reflected ray, compared with each other, just like the incident and the refracted ray compared with each other, are in the same plane, and that plane is called the surface of reflection, or of refraction. So postulate, or even try to prove, Alhazen, Book 4, proposition 13; Vitellio, Book 5, proposition 25, and Book 10, proposition 2; and Kepler in the *Astronomiae Pars Optica*, chapter 3, proposition 16 — who add that the surface of reflection and of refraction is at right angles to the mirror. But whether they demonstrate this without a vicious circle, see Emmanuel Maignan, *Perspectiva horaria*, Book 3, postulate 2, and Book 4, likewise postulate 2.
5. The greater the inclination of the ray, the smaller the angle of reflection, but the greater the angle of refraction. So Vitellio, Book 10, proposition 14; Kepler, *Astronomiae Pars Optica*, chapter 4, proposition 1, and *Dioptrics*, axiom 2. Kepler calls Vitellio's demonstration of this proposition faulty and obscure, and attempts another himself.
6. The refraction of a ray on its way out of a denser transparent medium into a rarer one is as great as on its way into that denser transparent medium from the same rarer one. For the same refracted ray is, under another aspect, the incident ray, and the reverse. So Alhazen, Book 7, proposition 34; Vitellio, Book 10, proposition 9; Kepler, *Dioptrics*, axiom 3, and in the *Astronomiae Pars Optica*, chapter 4, proposition 6; Hérigone, *Dioptrics*, proposition 1; Descartes, *Dioptrics*, chapter 2, number 10; Maignan, *Perspectiva horaria*, Book 4, proposition 2, in the Admonitions. But see what I shall say in chapter 3, proposition 10.

7. The refraction at a circular surface, whether concave or convex, is the same as it would be at a plane surface touching it, if the density of the medium and the inclination of the incident ray are equal. So Descartes, *Dioptrics*, chapter 2, number 12; and it is gathered from the definitions set out above.
8. In the denser medium the angle of inclination is equal to the refracted angle and the angle of refraction taken together; but in the rarer medium the refracted angle is equal to the angles of refraction and of inclination taken together. This is clear from the construction of the figure set out above, from the definitions set out above, and from experiments, for which consult the tables of Vitellio to be given at the end of this Section. Kepler, however, in chapter 4 of the *Astronomiae Pars Optica*, proposition 7, says that in the densest medium the refraction would be equal to the inclination; but he means the greatest, that is, an infinite, density.
9. Other things being equal, the refraction in a different transparent medium is the same whether its depth is great or small. For refraction takes place at once at the surface of the transparent medium of different density; and that density, if it does not vary, does not twist the ray, once refracted, away from the straight line of its first refraction. This is what Kepler meant when he said, in chapter 1 of the *Astronomiae Pars Optica*, p. 10: "Light is not impeded by the solidity of bodies in so far as they are solid"; and he repeats it in chapter 4, proposition 2.
10. The reflected ray and the refracted ray are a straight line, no less than the incident ray. This is to be supposed from experiments, with Euclid, *Catoptrics*, supposition 1; Alhazen, Book 1, propositions 14, 18 and 28, and Book 7, proposition 2; Vitellio, Book 2, theorem 1; Kepler, in the *Astronomiae Pars Optica*, chapter 1, proposition 4; and Emmanuel Maignan, *Perspectiva horaria*, Books 3 and 4, postulate 1.

CAPVT III.

Chapter III.

In Quo Theoremata quædam ſelecta de Quantitate Refractionum, Experimentis aut rationibus ab alijs demonſtrata. *In which certain selected theorems on the quantity of refractions are given, demonstrated by others through experiments or reasoning.*

Although the experiments on refractions depend on the problems to be proposed in chapter 4, I wish nevertheless, before the problems, to add to the axioms and postulates certain theorems — demonstrated as far as could be done in this matter, and accepted by most of those skilled in dioptrics — besides the theorems on the connection of refractions with parallaxes set out in the preceding Section, chapter 12.

Proposition 1. The refractions of crystal and of glass are very nearly the same. So Kepler, axiom 6, and Hérigone, *Dioptrics*, art. 3; and it will be clear from the tables of refractions to be given at the end of this Section.

Proposition 2. The angles of simple refractions are proportional to the angles of inclination, if the density of the medium is considered by itself. For absolutely and in reality the total angles of refraction grow by greater increments of ratio than the angles of inclination. The first part of the theorem is Maurolycus's, *Diaphanorum* Book 1, proposition 10, and Kepler's, in the *Astronomiae Pars Optica*, chapter 4, proposition 8 — but it is to be understood with the limitation, already mentioned, that Kepler himself attached in the corollary to proposition 1. Accordingly he gave the second part of the theorem in proposition 3, giving the reason that a twofold cause of increase is mixed in: one from the density, the other from the obliquity of a ray that has met a greater density at the surface. And in proposition 12 of the *Dioptrics* he said that refractions, weighed exactly, are not proportional to the inclinations. This can be established from the tables to be given at the end. The refractions of crystal, however, are sensibly proportional up to the 15th degree of inclination, or at most the 30th: for 15 degrees Hérigone has it, *Dioptrics*, proposition 2, in the scholium, and for 30 Kepler, *Dioptrics*, axiom 7.

Proposition 3. The refractions of crystal up to the thirtieth degree of inclination are very nearly a third part of the inclination. So Kepler, axiom 8, and Hérigone, *Dioptrics*, axiom 4. Maurolycus, from his own experiments, holds a little differently in Book 1 of the *Diaphanorum*. In proposition 10, in the corollaries, he said that the refraction of a crystalline sphere is to the angle of inclination very nearly as 3 to 8, that is, as 1 to 2⅔; and in proposition 11 he said that within the 70th degree of inclination the refraction is less than half of the inclination. Yet in proposition 10 he had admitted that, if the inclination is greatest, the refraction contains three eighths of one right angle, that is, 33° 45′, which is very nearly a third part of the inclination. For the refraction is much greater near the end of the quadrant of inclination, as we have learned from the more accurate experiments of recent writers and from our own. Cavalieri adds, in *Exercitatio* 6 of the *Geometrica*, proposition 7, that for rays passing out of crystal into the air at an inclination of less than 20 degrees the refraction is very nearly half of the inclination. From the aether into the air, however, it is always less than half of the inclination.

Proposition 4. As the sine of one angle of inclination is to the sine of its refracted angle, so is the sine of another angle of inclination, in the same transparent medium, to the sine of the refracted angle — but considering the simple refraction that arises from the mere difference of specific density. The first part is Hérigone's, *Dioptrics*, proposition 2; Descartes's, *Dioptrics*, chapter 2, number 7; and Emmanuel Maignan's, *Perspectiva horaria*, Book 4, proposition 34. But the second part, or the limitation of the first, is to be added from Kepler, Book 4 of the *Astronomiae Pars Optica*, proposition 1, where, having shown that "light, the more obliquely it falls, is refracted by so much the greater angle",

he adds this corollary: "If the medium itself, on account of its density, were considered by itself, the angles of refraction would become proportional to the angles of incidence." But because another cause is joined to it that increases the refraction, the proposition just stated does not hold of the whole, composite refraction. What this other cause is will be shown shortly by proposition 5.

[Margin: What simple refraction is, and what composite refraction is.]

Proposition 5. When light falls more obliquely, the resistance from the same medium is greater than in a more direct incidence, with respect also to the medium itself. So Kepler, chapter 4 of the *Astronomiae Pars Optica*, proposition 2. For since a ray of light is not a mathematical line but a physical one having breadth, the breadth of a ray falling straight is smaller than that of one falling obliquely; and therefore at the very surface of the denser medium a greater density, that is, a greater portion of the dense body, meets and resists the more oblique ray. From this arises an addition over and above the simple refraction.

Proposition 6. The angles of refraction grow by greater increments of ratio than the obliquity of incidence. So Kepler, chapter 4 of the *Astronomiae Pars Optica*, proposition 3. For by proposition 4 they would grow proportionally; but by proposition 5 a part of the refraction is added from the greater portion of the dense body meeting the oblique ray. This portion grows little at first, but much at a low incidence, in the way the secants do; therefore the whole refraction grows by greater increments than the inclination.

Proposition 7. The sines of the distances from the vertex are not proportional to the sines of the refractions; and near the horizon the refractions grow by precipitate proportions of increments. The first part is Kepler's, in the *Astronomiae Pars Optica*, chapter 4, p. 84; the second is his too, in the same place, proposition 5. The first part is clear from experiments, and from the fact that otherwise the refractions would grow in the same form in all media, which is unacceptable; the second, because they have an addition from the secants, which grow by a precipitous difference near the horizon, that is, near the end of the quadrant.

Proposition 8. The secants of those angles of incidence concur in the measure of the refractions that are formed at the surface of the denser medium. So Kepler, in the *Astronomiae Pars Optica*, proposition 6, and in the *Epitome of Astronomy*, p. 62, where he says that the proportion of two angles of refraction is compounded of two proportions: one between the angles of inclination whose refractions lie within the dense medium — that is, between their sines — and the other between the secants of the same angles. But whether this agrees exactly with observations, see what is to be said against Kepler at the end of Problem 49, reason 4.

Proposition 9. The second secants of the angles of incidence, proportio-

[Margin: Order of the problems.]

nal to the second secants of the refracted angles. So Mersennius, *Optics*, Book 6, theorem 7.

Proposition 10. If in two transparent media there are two lines to the common surface of their contact, together making an angle at the point of

refraction, and light falling first along one is refracted along the other, then, if on returning it falls along the latter, it will in turn be refracted. So Emmanuel Maignan demonstrates in *Perspectiva horaria*, Book 4, proposition 2: for if they do not together make an angle, what was said in axiom 6 is not universally true.

Proposition 11. Whatever combination of different transparent media is made, although in the rare medium there is no angle of inclination at which the incident ray is not refracted in the dense one, yet in the dense medium there is necessarily some angle of inclination at which the incident ray is not refracted in the rare medium, but in the dense medium itself, from which it falls. So Maignan, in the same place, proposition 3. And he adds that in this case the refracted angle comes out greater than a right angle, and that this is how Vitellio, Book 10, proposition 8, is to be understood: in his small table of refractions from glass to air, for an angle of inclination of 80° in the glass, he assigns a refracted angle in the air of 118°; from water to air, a refracted angle of 110°; and from glass to water, one of 98°.

Proposition 12. If a ray of light is transmitted from any rare medium into a similar rare medium through a dense one whose two surfaces, on either side, touching the rare medium on each side, are plane and parallel to each other, then the angle refracted the second time from the perpendicular will be equal to the angle of the first inclination, and the ray refracted the second time will be parallel to the first incident ray produced. So Maignan, above, proposition 4.

Proposition 13. When a ray of light falls from one transparent medium into any other different one, at whatever angle of incidence, then although refraction takes place, some part of it is nevertheless reflected — and indeed with the equality of the angles of incidence and reflection preserved. Likewise Maignan, in the same place, proposition 5, showing it from experiment.

Proposition 14. When a ray falls from a dense medium into a rare one in such a way that it does not go forward into the rare medium, one part of it is refracted within the same dense medium and the other is reflected within the same. Likewise Maignan, in the same Book 4, proposition 6, of the *Perspectiva horaria*.

Proposition 15. If a ray is propagated from a first, rare, transparent medium into a third, dense one, through a second that is denser than the first but less dense than the third, and which moreover has both the surfaces by which it touches each of them plane and parallel to each other, then the refracted angle in the third transparent medium will be equal to the angle that would arise if the second were removed and the first kept, with the same angle of inclination. So Maignan, *Perspectiva horaria*, Book 4, proposition 7. He shows this not only a priori but also a posteriori, from the corrected tables of Vitellio, Book 10, proposition 8, which give the refractions from air into water, from water into glass, and from air to glass. For if the angle of the first inclination is 80°, the refracted angle in water is 50°, which is the size of the second inclination, in

the water; and to this corresponds in glass a refracted angle of 42° 30′. But from the same corrected tables, if the angle of inclination from air into glass is 80°, the refracted angle in the glass will be 42° 30′.

Proposition 16. If a ray is propagated from a first, rare, transparent medium into a third, dense one, through a second denser than both, and which has both the surfaces by which it touches each of them plane and parallel to each other, then the refracted angle in the third transparent medium will not be the same as would arise if the second were removed, other things being equal, but smaller than it; it will, however, be the same as would arise if the second transparent medium were put in place of the third and, in turn, the third in place of the second. So, finally, Emmanuel Maignan, *Perspectiva horaria*, Book 4, proposition 8 — who, by his doctrine of refractions in Books 1 and 4 of that work, has indeed deserved supremely well of this part of dioptrics.

CAPVT IV.

Chapter IV.

In Quo Problemata ad Refractiones ſpectantia. *In which are the problems concerning refractions.*

We shall set out here only a few things about refractions from air into water or glass, or from water into glass, and only as much as suffices for considering the analogy with the refractions from the aether into our air. The rest we refer to the book on optics, where the refractions of the crystalline and glass sphere, of the lenses of spectacles and telescopes, and of the humours of the eye, are treated at length.

1. 2. 3. 4. 5. 6. Probl. Refractiones ex Aere in Aqua, vel in alio liquore contingentes metiri modis 7 *Problems 1, 2, 3, 4, 5, 6. To measure, in 7 ways, the refractions that occur from air into water or into another liquid.*

[Margin: Problem 1, from Ibn al-Haytham, Vitellio and Maignan.]

The first way is by the round instrument of Alhazen [Ibn al-Haytham], Book 7, propositions 2, 10, 11 and 12, and of Vitellio, Book 10, propositions 5, 6, 7, 8. This is certainly laborious, especially since they used the same instrument to measure the refractions produced in glass and crystal as well; and it would be more advisable to measure these separately. Nor is the instrument of Father Emmanuel Maignan, which he describes in *Perspectiva horaria*, Book 4, proposition 46, much easier. We shall therefore proceed to easier ways.

[Margin: Problem 2, from Kepler and Cabeo.]

Kepler gives the second way in his *Dioptrics*, problem 4, and Cabeo in the *Meteorologica*, Book 3, text 8, question 4: namely, by means of a square box. Let it be ABCD. It will be better if it is cubic, made up of four equal and parallel square boards together with a fifth fixed underneath at the bottom of the box, that is, as its base. On one of its sides, say ABHD, describe the quadrant AGD from the centre B, both inside and outside, and divide it into degrees or even

into minutes of degrees. At the centre B erect two styles perpendicular to the plane of the quadrant AGD: one, BM, inside the box, the other, BK, projecting outside the box. Then fill the box with water, or with whatever transparent liquid you please, and set it squarely on the plane of the horizon, so that the sides of the box stand perpendicular to it. With the styles turned towards the Sun R, and the plane of the quadrant placed in the vertical in which the Sun is, observe the degree and minute on which the shadow of the outer style BK falls: it will be, for example, the point G, on which the ray RBG, the boundary of the shadow, falls directly. Meanwhile let the other partner in the observation observe the point on which the shadow of the inner style BM falls. That point will be lower than the outer one — say F — because the ray RB, entering water, which is denser than air, will be refracted in the water towards the perpendicular BD. The difference between the points just mentioned, marked on the arc GF, will be the measure of the angle of refraction FBG; the unrefracted ray will be RBG, and the refracted ray BF. The refracted angle, however, is FBD; and the inclination will be known from the altitude of the Sun's upper limb taken at the same moment, since it is its complement.

Diagram. Woodcut of a cubic box in perspective, set in the right column beside the description of the second way. A ray from R, at the upper right, runs to the top corner B; K stands just left of B on the top edge. An arc on the inner face runs from near G down through F to D.

- R (top right, outside the box): the Sun
- K (top edge, left of B): the outer style
- A (top left corner)
- B (top right corner): the centre of the quadrant
- G (on the inner face, upper)
- F (on the arc, below G)
- D (lower right corner)
- H (lower left of the front face)
- C (bottom left corner)

[Margin: Problem 3, from Bettini.]

The third way is proposed by Father Mario Bettini, *Apiaria* 8, Progymnasma 1, proposition 3, by means of a scaphe, or hemispherical vessel, DCE, at whose bottom stands a style CM, equal to the semidiameter of the hemisphere DCE and perpendicular to the plane of the horizon ACB, so that, with the vessel resting on it, the style makes right angles at C on either side with the horizontal AB. In the other, inner quadrant of the scaphe, say DC, let a quadrantal arc be described from the centre M and divided into degrees and minutes. When the Sun R has risen, let the point G be marked on that arc on which the ray RMG falls, passing through the tip of the style and bounding the shadow. The arc GC will then be the measure of the Sun's apparent distance from the vertex, and at the same time of the inclination of the ray MR by which it departs from the perpendicular MC; while the arc DG will measure the apparent altitude of the Sun's upper limb. Next let the scaphe be filled with water up to the top of

the style, and let the point F be observed on which the refracted ray FM will fall. For if the observation of the points G and F were made at the same moment, GF — that is, the angle FMG — would be the measure of the refraction sought. But it is impossible

[Margin: Order of the problems.]

to do both at the same moment, unless two equal scaphes are available, one full of water and the other of air, and there are two observers. Without these the operation is unreliable, because the Sun moves in the meantime and the inclination of the ray varies. The procedure could nevertheless be carried out with a single vessel and a single observer, if the vessel were used empty of water in the morning and full in the evening, but with the Sun at the same altitude, known through another instrument or indication; or if, on two days with the Sun at the same altitude, the point G were observed once with the vessel empty, and the point F once with the vessel full of water.

Diagram. Woodcut of Bettini's hemispherical vessel (the third way), at the head of the left column. The bowl, its rim stippled, rests on the horizontal line ACB; a style drops from M, at the centre of the rim, to C at the bottom; a line rises from M to R, the Sun, at the upper right; lines run from M to G and F on the inside of the bowl.

- R (upper right): the Sun
- M (centre of the rim): the tip of the style
- D (left end of the rim)
- E (right end of the rim)
- G (left side of the bowl, upper)
- F (left side of the bowl, lower)
- A (left end of the horizontal line)
- C (bottom of the bowl, on the horizontal line)
- B (right end of the horizontal line)

[Margin: Problem 4, from Father Kircher.]

Father Athanasius Kircher suggests the fourth way, near the beginning of Book 8 of the *Ars Magna Lucis et Umbrae*. It uses a scaphe DCE, again full of water and standing upright on the horizon ACB, but with an astronomical quadrant DMH standing on it from outside, so that the side HM and the semidiameter MC lie in the perpendicular HC, which passes through the centre M of the scaphe. Let the limb DRH of the quadrant be divided into degrees and minutes, just like the quadrant EC of the scaphe, which lies in the same plane as DRH. One observer, then, turning the dioptra PR about the centre M towards the Sun, is to note the arc DR that the dioptra cuts off. DR will be the apparent altitude of the Sun, which, subtracted from 90 degrees, will give the arc RH, that is, the angle RMH, which measures the inclination of the ray RP taken from the perpendicular HC. At the same moment the partner in the observation, with his eye applied at K, is to note the point F, which lies on the cathetus of incidence and at which the refracted ray PF ends — the ray propagated from the unrefracted ray PR that passes through the slits or the little

tube of the dioptra — and he is to count the degrees and minutes of the arc FE. For the difference, or excess, of the arc FE over the arc RH, the measure of the true inclination — that is, the arc FG, or the angle FMG, equal to the angle RMS — will be the refraction sought, and the angle CMF will be the refracted angle. I shall give the anaclastic tables that Father Kircher made by this device at the end of the Section, Table V.

Diagram. Woodcut of Kircher's apparatus (the fourth way), in the left column: a hemispherical scaphe with an astronomical quadrant standing on it. The quadrant's arc runs from D at the left up to H at the top; a diameter D–P–M–K–E crosses the rim of the scaphe; a vertical runs from H through M to C; the horizontal line ACB lies beneath. Lines run from R through M, and from M to F and G inside the bowl.

- S (on the quadrant's arc, near the top)
- H (top of the quadrant's arc)
- R (on the quadrant's arc, below S)
- D (left end of the diameter)
- P (on the diameter, left of M)
- M (centre)
- K (on the diameter, right of M)
- E (right end of the diameter)
- G (inside the bowl, right)
- F (inside the bowl, below G)
- A (left end of the horizontal line)
- C (bottom of the bowl, on the horizontal line)
- B (right end of the horizontal line)

[Margin: Problem 5, our own.]

Our fifth way is as follows. Let a box ABP be made of sides of which at least two — namely AP and BK — are plane, opaque, four-sided, equal and parallel, standing perpendicular on the horizontal bottom AC. On the second side, BK, let there be a straight line CK, perpendicular to the horizon and divided into equal parts as small as possible. Let a gold coin be placed on the bottom of the box where the bottom meets the line CK, that is, at the place C, where there is to be a little loop; from it a thread, stretched over the edge D of the side AP, is to be tied to a staff or rule HE perpendicular to the horizon, so that E, D, C lie in one and the same straight line. For an eye placed at E will not see the gold coin, since the opacity of the side AP stands in the way, or at most it will see the extreme edge of the coin. Then fill the box with water up to the top edges DK. For the central ray of the gold coin, which is propagated unrefracted through the water from C to D, will, passing at its exit into the rarer air, be refracted at D, departing from the perpendicular AD etc., so that the refracted ray is DF. With the eye placed at F, therefore, you will see along the ray FDR the point R; note it carefully, taking account of the semidiameter of the coin. With these noted, the height AD and the length AB — known beforehand in the same kind of parts as make up CK — will, in the triangle

ADB, right-angled at A by the construction of the box, give by proposition 5 of plane right-angled triangles the angle ABD, which is equal to the angle next to it at C, and the angle ADB; and the angle ADB will measure the inclination of the ray BD, by which it departs from the perpendicular AD. Again, if from the height of the side CK, which is equal to the height AD, you subtract the parts CR, and use the length AB, that is DK, as above, then in the right-angled triangle DKR you will find, by the same proposition 5, the angle DRK, greater than the angle DCK. The difference of these angles, therefore, will be, by Euclid I.32, the angle CDR, which is equal to the refraction FDE by Euclid I.15. Moreover, the refraction towards the perpendicular is as great as that away from the perpendicular, by axiom 6 of chapter 2. Nor will the enlarged image of the coin disturb the operation, for the intervals between the parts of the line CK are enlarged in the same way.

Diagram. Woodcut of the rectangular box of the fifth and sixth ways, at the head of the right column. To the left stands a vertical staff with E and F at its top and H at its foot; from F a line runs to P and D on the upper left edge of the box and on into it. The box has K at its top right corner, R on its right inner side above C, A at its bottom left and B at its bottom right.

- E (top of the staff)
- F (top of the staff, below E): the eye, or the lamp flame
- H (foot of the staff)
- P (upper left edge of the box)
- D (upper left edge of the box, below P)
- K (top right corner)
- R (right inner side)
- C (foot of the right inner side)
- A (bottom left)
- B (bottom right)

[Margin: Problem 6, our own.]

Our sixth way is the converse of the preceding one. I use the preceding box ABP, but first filled with water. I fix the flame F of a lamp to the staff HE — or rather insert it in a tube, so that it can be moved up and down and stopped at any point I like — and cover it with a plate pierced by a large round hole, so that by this device the image of the pyramidal flame comes out round and imitates a star or a gold coin. Then I move the lamp upwards until the ray FD, propagated from the upper edge of the round flame over the edge D of the box and refracted along DC, ends the straight shadow AC at C, where the bottom AC meets the side CK. Then, with the water let out — that is, with the box full of air alone — I note the point R at which the same ray FD, but now unrefracted along DR, ends the shadow in a straight line. In the right-angled triangle DAB, from the known sides AD and AB, I find as above the angle ABD, that is ACD, and the angle ADC, which, together with the angle CDR that is still to be found, measures the inclination of the ray FD from the perpendicular AD etc., an inclination equal to this angle by Euclid I.15. The complement of the angle

ACD to a right angle will be the angle DCK. Again, having subtracted the parts CR from the side CK, and keeping the length DK, I find in the triangle DKR, right-angled at K, the angle DRK, which I find greater than the interior angle KCD. Their difference, therefore, by Euclid I.32, is the other interior angle CDR, that is, the measure of the refraction towards the perpendicular, whose complement to the inclination is the refracted angle. In this way I measure the refractions of a ray going out of water and of a ray entering water even at night, let alone in cloudy weather; and I need neither a partner nor the altitude of the Sun or of any star.

Probl. 7. 8. 9. 10. 11. Refractionem Radij ex Aere in Vitrum aut Cryſtallum ingredientis factam, metiri modis 5. *Problems 7, 8, 9, 10, 11. To measure, in 5 ways, the refraction undergone by a ray passing from air into glass or crystal.*

[Margin: Problem 7, from Ibn al-Haytham and Vitellio.]

The first way is suggested by Ibn al-Haytham, Vitellio and Father Maignan: by the round instrument mentioned in Problem 1, but not explained by us because it is too laborious.

[Margin: Problem 8, from Kepler and Cabeo.]

The second is the one taught by Kepler and Cabeo. It differs from Problem 2 only in that the box ABCD shown there is filled with a cube of glass or crystal; everything else is to be done in exactly the same way.

[Margin: Problem 9, from Descartes.]

The third way is taught by Descartes, *Dioptrics*, chapter 10. It is very laborious but full of ingenuity, and suited to finding the vertex and the foci of a hyperbolic glass; we therefore reserve it for the book on optics.

[Margin: Problem 10, our own.]

Our fourth way is as follows. Let there be a glass vessel made of square sides, equal and parallel, of the kind that the four-sided flasks roughly are, in which wine is usually carried in carriages or ships, set into the little cells of cases. Let this vessel be represented, in whatever way, by the figure

[Margin: Order of the problems.]

below, ABCD. Let this vessel be filled with water and its bottom BC set on the horizon, so that the sides AB and DC, parallel to each other, stand perpendicular to it. Next, let the side AB, which is to be turned towards the Sun, be covered with a plate of paper or of metal, on which the straight line AB, perpendicular to the horizon, is divided into equal parts as small as possible; and in the same plate let there be a hole G, through which the straight line GM is understood to be drawn parallel to the horizon, its length known in parts of the kind in which the height BG, or CM, equal to it, is known. Now let the Sun's ray S pass through the hole G. If the vessel were not full of water above the point G, the ray would pass straight to K, and the Sun's apparent altitude would be measured by the angle GKI, since IK must be understood as parallel to the horizon. But because it passes through glass, then through water, and

again from the water into glass, the ray will appear to an eye looking from outside to end at the point R; and the refracted ray will be GR, and the angle of refraction KGR. At the same moment as one of the observers marks the point R, let the other take the apparent altitude of the Sun, so that through it the angle GKI becomes known, whose complement to a right angle, namely the angle IGK, equals the angle SGA, that is, the complement of the inclination, to be reckoned from the perpendicular PG. We must now find the angle GRH, made by the refracted ray GR and the straight line HR parallel to the horizon. This angle measures the Sun's apparent altitude under the force of the refraction, and its difference from the angle IKG measures the refraction itself. That angle is easily found by proposition 5 of plane right-angled triangles, in the triangle GRH, right-angled at H: for HR is given, equal to GM, and GH, equal to MR, measured with the help of compasses, the compasses being carried over to the straight line AB, divided into the smallest parts. Nor is it an obstacle that a threefold refraction takes place here — the first from air into glass immediately after the hole G; the second from glass into water; the third from water into glass at the point R. For since the sides of the vessel are supposed to be of equal density, the second refraction, away from the perpendicular, is corrected by the third, towards the perpendicular, and the ray that passes through the water is restored to the position it had when it passed through the first glass side; for the refraction of a ray entering and of a ray leaving is as great, etc.

[Margin: Problem 11, our own.]

We have, however, used a fifth way, so that no one should be in doubt about the fourth. We had a four-sided glass cast, bounded by two square faces, parallel and equal, whose side BG, or CM, as also BC and GM, contains in its length 4½ inches of the ancient Roman foot; while the breadth of the other four surfaces that bound the glass — that is, the lesser thickness of the glass — is very nearly one inch. This glass, fastened at its lower part BC to a brass rule, can be turned with the rule towards the Sun in such a way that, by raising the rule, each of the sides GB and MC can nevertheless be set perpendicular to the horizon with the help of a very fine plumb line. Further, the side, or surface, to be turned towards the Sun is covered with a very thin metal plate, in which the Sun's ray is received through the hole G. The ray does not go straight to K but is refracted upwards to the point R, towards the perpendicular PGM. This point is seen clearly enough on the surface of the side CM, like a little shining star, and is marked there by placing a grain of wax opposite it, or by a thread HR carried through it round the outside of the glass, so that the thread HR is parallel to the horizon. At the same moment the altitude of the Sun is taken by another partner, and so the angle GKI becomes known. Since the sides HR and GH are also known in the smallest parts, as above, the angle GRH is sought, by proposition 5 of plane right-angled triangles, in the triangle GHR, right-angled at H; its difference from the angle GKI is the refraction sought. Further, the angle IGK — that is, the complement of the Sun's altitude GKI to

a right angle — is equal to the angle of incidence SGA; and the complement of this will be the inclination.

Diagram. Woodcut of the square glass vessel in elevation, in the left column. A rectangle with A at top left, D at top right, B at bottom left, and a fourth corner at bottom right; horizontal lines cross it at E–F, G–M (dotted), H–R and I–K. Outside at the left, S, with a small circle below it, sends a ray in at G, which runs down to R; a second line runs from G to K. P stands outside beside G.

- A (top left corner)
- D (top right corner)
- S (outside, upper left): the Sun
- E (left side, upper)
- F (right side, upper)
- P (outside, left of G)
- G (left side): the hole
- M (right side, level with G)
- H (left side, below G)
- R (right side, level with H)
- I (left side, below H)
- K (right side, level with I)
- B (bottom left corner)
- C [?] (bottom right corner; the letter reads as C or G)

You will, however, work more surely and accurately if you apply to the side AB a plate whose upper part, parallel to the horizon, projects outside the glass — to the right, for example — so that its shadow, cast towards K, grazes the top of another plate applied at right angles to the glass at the side DC and projecting outside the glass to the same right side. For it will happen that the shadow cast by the upper part G of the first plate is refracted through the glass and rises to R; you will mark this point more clearly if you apply a sheet of paper to the glass itself at CD. With very sharp compasses, then, mark the interval KR in parts of the kind in which the whole IK, or HR, is known. If at the same moment of time you have observed with an exact instrument the altitude of the Sun's upper limb, that is, the angle IKG, equal to the angle of inclination PGS, you will then be able, by trigonometry, to find the side GI in the right-angled triangle GIK. When HI, which is as great as RK, is subtracted from it, GH will remain; with this and with HR, in the right-angled triangle GHR, find the angle HRG. Subtract it from the angle GKI, and there will remain the refraction sought, KGR, for the observed altitude of the Sun's upper limb, that is, for the given inclination PGS. By these ways, but chiefly by the last, I investigated with Father Francesco Maria Grimaldi the refractions to be given in Table VI at the end of this Section.

12. Probl. Data vna radij Inclinatione, & Angulo refracto, inclinationi vni reſpondente; inuenire Angulum refractum, alteri datæ inclinationi

reſpondentem, in eiuſdem denſitatis diaphano. *Problem 12. Given one inclination of a ray, and the refracted angle corresponding to that one inclination, to find the refracted angle corresponding to another given inclination, in a transparent medium of the same density.*

[Margin: Problem 12.]

Make it so that, as the sine of the given inclination is to the sine of the given refracted angle, so the sine of the other given inclination is to the sine of the other refracted angle. As in the following figure, let MBN be the perpendicular and B the point of incidence; let the rarer medium be within CMD and the denser within CND, so that the ray KB is refracted along BL and the ray AB along BI. Therefore, as the sine KM of the given inclination KBM is to the sine NL of the refracted angle GBL, so the sine AH of the other given inclination ABH is to the sine GI of the other refracted angle GBI. Here, however, we are speaking of simple refraction, arising from the mere difference of specific density, according to what was said in chapter 3, from proposition 4 to 9.

Diagram. Woodcut of a circle in the right column, with horizontal diameter CBD (the surface between the two media) and vertical diameter MHBN (the perpendicular). Incident rays run from K and A on the upper left of the circumference to the centre B, with horizontals K–M and A–H to the perpendicular; refracted rays run from B to I and L on the lower right, with short horizontals to G and N near the foot of the perpendicular.

- K (upper left, on the circumference)
- M (top of the vertical diameter)
- A (left, on the circumference, below K)
- H (on the vertical diameter, below M)
- C (left end of the horizontal diameter)
- B (centre)
- D (right end of the horizontal diameter)
- G (on the vertical diameter, lower)
- N (foot of the vertical diameter)
- I (lower right, on the circumference)
- L (lower right, on the circumference, below I)

EXEMPLVM

Example.

In Vitellio, Book 10, proposition 8, at an inclination of 80 degrees the refracted angle from air to water is 50 degrees. Now let the refracted angle corresponding to an angle of inclination of 45 degrees be sought. Make it, then, that as the sine AH, 9848077, of the inclination ABH of 80 degrees is to the sine GI, 7660444, of the refracted angle GBI of 50 degrees, so the sine, 7072061, of the inclination KBM of 45 degrees is to the sine NL, 5499990 — namely, of the refracted angle NBL, 33° 22′. Therefore the refracted angle corresponding to an inclination of 45 degrees is 33° 22′, considering only the difference of density of the transparent media.

13. Probl. Data Inclinatione, & Refractione illi correſpondente, inuenire Refractionem ſimplicem alteri datæ Inclinationi reſpondentem. *Problem 13. Given an inclination and the refraction corresponding to it, to find the simple refraction corresponding to another given inclination.*

[Margin: Problem 13.]

Subtract the given refraction from the given inclination, and the refracted angle will remain; with it, by Problem [?] 12, find the refracted angle for the other

[Margin: Order of the problems.]

given inclination, and subtract it from this other inclination: the remainder will be the refraction corresponding to the other given inclination — but the simple refraction, not the integral one. Understand all this of a ray entering a denser medium; otherwise, add the refraction to the inclination to obtain the refracted angle.

EXEMPLVM.

Example.

In Vitellio's table, Book 10, proposition 8, a refraction from air into water of 30° corresponds to an inclination of 80°; subtracted from 80°, this leaves a refracted angle of 50°. From these values, for an inclination of 45°, a refracted angle of 33° 22′ is obtained by Problem 12; subtracted from 45°, this leaves a refraction of 11° 38′. Therefore a refraction from air into water of 11° 38′ belongs to an inclination of 45° — if Vitellio's experiments hold good, and if we are speaking of the simple refraction that arises from the mere difference of density.

14. Probl. Datis duobus Angulis refractis in eiuſdem denſitatis diaphano, & Inclinatione vni refractorum reſpondente, inuenire Inclinationem, alteri refracto angulo debitam, ſpectata ſimplici refractione. *Problem 14. Given two refracted angles in a transparent medium of the same density, and the inclination corresponding to one of the refracted angles, to find the inclination belonging to the other refracted angle, considering simple refraction.*

[Margin: Problem 14.]

Make it so that, as the sine of one refracted angle is to the sine of its inclination, so the sine of the other refracted angle is to the sine of the inclination corresponding to its refracted angle. This is said of simple refraction.

15. Probl. Data Refractione integra ſeu compoſita, Inclinationi datæ reſpondente, inuenire Refractionis partes componentes, & ſimplicem refractionem eidem inclinationi conuenientem methodo Kepleri. *Problem 15. Given the integral, or compound, refraction corresponding to a given inclination, to find the component parts of the refraction, and the simple refraction belonging to that same inclination, by Kepler's method.*

[Margin: Problem 15.]

What compound refraction is was stated in chapter 3, from proposition 4 to 9. Now, following Kepler in the *Astronomiae Pars Optica*, chapter 4, proposition 8: subtract the given refraction from its given inclination, and the refracted angle will remain; find its secant. Then make it so that, as the secant of that angle is to the whole sine, so the given compound refraction is to the simple refraction belonging to the same given inclination. He also gives this method in the *Epitome of Copernican Astronomy*, p. 65; but whether it always agrees with observations will become clear from what is to be said in Problem 49 against Kepler, especially in reason 4.

EXEMPLVM.

Example.

For an inclination of 80° of a ray entering from air into water, Vitellio, above, assigns a refraction of 30°. Taking this from 80° leaves a refracted angle of 50°, whose secant is 155,572. Now if one makes it so that, as 155,572 is to the whole sine 100,000, so 30° is to another quantity, 19° 17′ will be found. Therefore the simple refraction belonging to an inclination of 80° is 19° 17′. The remaining addition to the refraction, which is 10° 43′, accrues to it because the medium meets the ray refracted under the water as denser than it meets the direct ray, in the proportion of the secant 155,572 to the radius 100,000.

16. Probl. Data Inclinatione, eiuſque refractione integra ſeu compoſita; reperire Refractiones integras ſeu compoſitas, cæteris inclinationibus in eodem diaphano reſpondentes, methodo Kepleriana. *Problem 16. Given an inclination and its integral, or compound, refraction, to find the integral, or compound, refractions corresponding to the other inclinations in the same transparent medium, by Kepler's method.*

[Margin: Problem 16.]

By Problem 13, find the simple refraction corresponding to any other given inclination. Then subtract the refraction found from its given inclination, just as if it were integral, and there will remain a refracted angle not yet fully known. Find its secant; multiply the excess of the secant over the whole sine by the simple refraction found, and divide the total by the whole sine: the part of the refraction that comes from the secants will result. Next subtract this part again from the refracted angle not yet fully known, and a diminished refracted angle will remain. Find its secant, multiply the excess of the secant over the whole sine by the simple refraction found in the first operation, and divide the total by the whole sine; there will remain the portion from the secants. If it differs insensibly from the portion found before, the problem will be complete; but if they differ by many minutes, let the search for the secant be repeated until no discrepancy remains between the refraction arising from the secants and the one found in the immediately preceding operation. But the obscurity of the rule will be cleared up by an example — a rule set out by Kepler in the

Astronomiae Pars Optica, proposition 8, in a form even more obscure than it is here with us.

EXEMPLVM.

Example.

For an inclination of 50° of a ray entering through the air, let the simple refraction found be 12° 4′. When this is subtracted from 50°, there remains a refracted angle of 37° 56′, not yet fully known, whose secant is 126,787; and its excess over the whole sine, 100,000, is 26,787. This, multiplied by 12° 4′ and divided by 100,000, gives 3° 14′ for the part of the refraction arising from the secants. Again, let 3° 14′ be subtracted from 37° 56′: there remain 34° 42′, whose secant is 121,633, and the excess over 100,000 is 21,633. This, multiplied by 12° 4′ and divided by 100,000, gives 2° 37′, a portion that differs too much from the one found before, 3° 14′. So let 2° 37′ again be subtracted from 37° 56′: there remain 35° 19′, whose secant is 122,554, and the excess over the whole sine is 22,554. This, multiplied by 12° 4′ and divided by 100,000, gives a portion of 2° 43′, still differing from the one just found, 2° 37′. So again subtract 2° 43′ from 37° 56′: there remain 35° 13′, whose secant is 122,402, and the excess over the whole sine is 22,402. This, multiplied by 12° 4′ and divided by 100,000, gives a portion of 2° 42′, differing insensibly from the one just found, 2° 43′. Keep this, then, as the true portion of the refraction arising from the secants, and add it to the simple refraction found in the first place, which was 12′ 4′ [?]; the total refraction will then be 14° 44′, corresponding to an inclination of 50° — granted that Vitellio, from an unreliable experiment, puts it at 15°. Kepler compared the integral refraction deduced a priori in this way, in a small table, with the one Vitellio gave from experiment; we shall give that table at the end of this section as number VIII, together with another small table of refractions in air. But whether this is demonstrative will become clear from what is to be said.

17. Probl. Quãta ſit proportio Vitri ad Aquam in Denſitate, ex ponderis coniectura inueſtigare. *Problem 17. To investigate, by inference from weight, how great the proportion of glass to water is in density.*

[Margin: Problem 17.]

Although it is not entirely evident that density stands to density as weight to weight, other things being equal, this nevertheless seems next to evident. For, as Father Emmanuel Maignan says in Book 1 of the *Perspectiva horaria*, proposition 24, running through all heavy and light things, a large quantity of matter in a small bulk always has heaviness attached to it, while a small quantity of matter in a large bulk always has lightness. From this he rightly concludes that ice is rarer than water: since it floats on water, it is lighter than liquid water of equal bulk, by what Archimedes demonstrated in his book on things carried in water (*On Floating Bodies*). With this reasonably assumed, I weighed the very glass that I have used most often for measuring refractions, and its weight

was exactly 27 ounces. This glass is a parallelepiped as nearly as possible an inch thick, with two square faces, flat and parallel, each side of which is 4½ inches of the ancient Roman foot long. I built a vessel fit to hold exactly this; I weighed it full of water, and when the weight of the vessel was taken away, the water came to 10 ounces exactly, without the addition of any drachma — for the balance that I usually use, the drachmas themselves, and indeed, if one likes, the half-drachmas, it shows distinctly. I therefore concluded that the heaviness of glass is to the heaviness of water in the same bulk as 27 to 10, and consequently that the density of glass is to that of water very nearly as 27 to 10, or nearly as 60 to 22.

[Margin: The proportion of glass to water in weight and density.]

[Margin: Order of the problems.]

[Margin: The proportion of glass to water in weight and density.]

18. Probl. Quanta ſit Proportio Denſitatis Aquæ ad Aeris noſtratis denſitatem, duplici coniectura attentare, vna Kepleri, altera Noſtra. *Problem 18. To attempt, by a twofold conjecture — one Kepler's, the other our own — how great the proportion of the density of water to the density of our air is.*

[Margin: Problem 18.]

Mersennius, in his *Optics*, Book 3, part 4, proposition 32, teaches from Kepler's *Astronomiae Pars Optica*, chapter 4, proposition 10, that water is denser than air 1,533,304,682 times. For Kepler proceeds as follows. The simple refraction of a ray from air into water, at an inclination of 80°, is 19° 17′, by Problem 13. But at the same inclination of 80° the simple refraction of a ray from the aether into our air is 59″. Therefore the simple refraction from the aether into water would be 19° 18′. So the proportion of these refractions is that of unity to 1177⅔. If you form a cube from each term of the proportion, the proportion of the density of air to the density of water will be that of 1 to 1,533,304,682. Yet Kepler adds in the same place, p. 128: "I myself doubt, however, whether it would not suffice to square the terms of the proportion, or rather to multiply them into their own roots, etc.; but neither is this proportion perpetual, nor is it to be ascribed to any part of the air except the one that occupies the highest spaces of the purified sky." From this it is apparent how uncertain and merely arbitrary this method of Kepler's is.

[Margin: Kepler's method for this proportion, but uncertain.]

Here indeed that saying of Horace holds: "It is something to get so far, if one may not go beyond." For in this matter one may proceed by conjectures up to a point, but not beyond. I therefore tried to reach the proportion in density from the proportion in weight, since it is otherwise certain that the same heavy body, when denser, other things being equal, is also heavier than itself when rarer. Accordingly, I hung a bladder of very thin membrane, well inflated, from a balance of such exact sensitivity that it shows the twentieth part of one grain (I speak of the grains with which goldsmiths weigh out small weights of gold), and I found its weight to be 200 grains, that is, 2 drachmas, 2

scruples and 8 grains. But when all the air had been let out of the same bladder and it had been well pressed together, I found it to be 197 grains; so the excess due to the air, arising from the condensation in inflating, was three grains. For although air has some heaviness, as many assert together with Cardano [Girolamo Cardano] and with Kepler in the *Astronomiae Pars Optica*, chapter 4, proposition 3, it still cannot be weighed unless it is condensed, or unless someone moves up into the aether, since the elements do not gravitate in their own place. Further, I found that the same bladder, filled with well water, held 4 pounds and 3 ounces of water. There were therefore 51 ounces of water, that is, 408 drachmas, or 1224 scruples — namely 29,376 grains. Hence the condensed air, or at any rate the excess arising from condensation, was to the water in weight — and, not improbably, in density — as 3 to 29,376, or as 1 to 9792, or nearly 9800. Granted, then, that the air around us, condensed no further than its ordinary thickness, would be lighter and so rarer than when condensed and forced into the bladder; still, it is not so much lighter that it could stand to water in the proportion Kepler wants. Rather, it is about as 1 to 10,000.

[Margin: Our method, of whatever kind, but more probable than Kepler's.]

19. Probl. Proportionem inter Vitri & noſtratis Aeris Denſitatem, ex coniectura ponderis attentare. *Problem 19. To attempt, by inference from weight, the proportion between the density of glass and that of our air.*

[Margin: Problem 19.]

By Problem 17, the weight of water was found to be to the weight of glass in the same bulk as 22 to 60, as nearly as possible; and by Problem 18 the weight of air enclosed in a bladder was found to be to water in the same bulk nearly as 1 to 10,000. Now, as 22 is to 60, so is 10,000 to 27,272. Therefore the weight of the air in question is to the weight of glass — and so, not improbably, the density of the former to the density of the latter — as 1 to 27,272. But now let there be a limit to these subtleties, and let us come to the refractions of the stars from the aether into the air, which are to be investigated by observation; for this is what we chiefly aim at here, intending to treat afterwards, in the book on optics, of refractions from air into glass, with a view to the making of spectacles and telescopes.

Probl. Refractionem in circulo altitudinis, Sideris à Parallaxi ſenſibili immunis, inuenire, Datis præter obſeruatam ſideris Diſtantiam à vertice, vel Altitudinem; 20. Altitudine Poli, Declinatione & Azimutho ſtellæ 21. Altitudine Poli, Declinatione, & Diſtantia Aequatoria Stellæ à Meridiano 22. Altitudine Poli, Azimutho ſtellæ, & Diſtantia Aequatoria à Merid. 23. Stellæ Azimutho, Declinatione, & Diſtantia Aequatoria à Merid. *Problem. To find the refraction, in the circle of altitude, of a star free from sensible parallax, given, besides the observed distance of the star from the vertex, or its altitude: 20. the altitude of the pole, and the declination and azimuth of the star; 21. the altitude of the pole, the declination, and the equatorial distance of the star from the meridian; 22.*

the altitude of the pole, the azimuth of the star, and the equatorial distance from the meridian; 23. the azimuth of the star, its declination, and its equatorial distance from the meridian.

In the accompanying figure let HVRD be the meridian, HAR the true horizon, and VAD the semicircle of a vertical circle, in which a fixed star, by the force of refraction, first appears at the point A of the horizon — for, owing to the lack of sensible parallax, the apparent horizon does not differ at all from the true one in this case. But let its true place be at B; the refraction to be found will then be the arc AB, and it will be called the horizontal refraction [Refractio Horizontalis]. Then from the true place of the star let the arc of declination BP be drawn to the pole of the world P. This arc will be either the complement of the declination, if the star declines toward the visible pole, or the sum of the quadrant and the declination of the star toward the invisible pole; or, if it declines toward neither side, BP will be 90°. But if the star appears above the horizon, as at C, but is truly below it, as at A, draw from A the arc of declination AP.

Diagram. Woodcut of a circle in the right column, representing the meridian. The horizontal diameter is the horizon HAR; the vertical diameter runs from V at the top through C, the centre A and B to D at the foot. P stands on the circumference to the upper right, and straight lines run from P down to the left to the vertical diameter.

- V (top of the vertical diameter)
- P (upper right, on the circumference)
- C (on the vertical diameter, above A)
- A (centre, on the horizontal diameter)
- H (left end of the horizontal diameter)
- R (right end of the horizontal diameter)
- B (on the vertical diameter, below A)
- D (foot of the vertical diameter)

[Margin: Problem 20.]

First, then, from the data of Problem 20: in the triangle VPB the side VP is given, which is the complement of the altitude of the pole, and the side BP, from the declination of the star, known as above; and the angle BVP opposite it, known from the azimuth HVA, of which BVP is the supplement to 180°. Therefore, by [proposition] 2 of oblique-angled spherical triangles, find the third side, or base, VB, which will be the true distance of the star from the vertex; and if the angle at P is obtuse, use the vicarious triangle, according to what was said in Section 1, chapter 4, scholium 1. From this subtract the visible distance VA, which, if the star appears on the horizon at the time the azimuth is observed, as we suppose, will be 90°; and the remainder will be the arc AB, that is, the horizontal refraction. But if the star appears above the horizon, as at C, but is at A, use the triangle VAP, in which VP, AP and AVP are given, as above; and from the base VA, once found, subtract the visible distance from the vertex, VC, and you will have the refraction AC — though no longer the

horizontal one. This first way, however, is useless for distinguishing morning refractions from evening ones, as I shall say at the end of Problem 25.

[Margin: Problem 21.]

Second: in the triangle BVP of the earlier case, if, according to the data of Problem 21, VP and EP are given, as above, together with the angle VPB, that is, the equatorial distance of the star from the meridian — obtained either by reckoning the time from the moment the star appeared until its arrival at the meridian, or in some other way — find the base VB by [proposition] 4 of oblique spherical triangles, take from it the observed distance AV, that is, 90°, and you will have the horizontal refraction AB. But if the star appears above the horizon, use the triangle AVP, in which VP and AP are given, as above, and the included angle APV; with these, by the same [proposition] 4, seek the base VA. Subtract from it the observed distance from the vertex, VC, and the remaining arc AC will be the refraction belonging to such a distance.

[Margin: Problem 22.]

Third: in the earlier triangle BVP, if, according to Problem 22, there are given VP, the complement of the altitude of the pole, and BVP, known from the azimuth as above, and VPE, the equatorial distance from the meridian, seek the base VB by [proposition] 11 or 12 of oblique spherical triangles; subtract from it the quadrant VA, and you will have AB, the horizontal refraction. But if the star appeared at C, use the

[Margin: Order of the problems.]

triangle AVP, and by the same [proposition] 11 seek VA, since VP and the adjacent angles AVP and APV are given, as above; for when the visible distance of the star, VC, is taken from AV, there will remain the refraction AC belonging to such a distance.

[Margin: Problem 23.]

Fourth: in the earlier triangle BVP, if, according to Problem 23, BP is given from the declination, the angle BVP from the azimuth, and the angle VPB of the equatorial distance, find the side VB by [proposition] 1 of oblique spherical triangles; take from it the quadrant AV, and you will have the horizontal refraction AB. But if the star is seen at C, use the triangle VAP: with AP, known from the declination, AVP, the supplement of the azimuth to 180°, and VPA, the equatorial distance from the meridian, find the side VA by the same [proposition] 1; take from it the visible distance VC, and the refraction AC belonging to such a distance of the star from the vertex will be known.

[Margin: Advice on observation.]

How we usually observe the azimuths of the stars, or their equatorial distance from the meridian, we indicated in Book 3, chapter 9.

Probl. 24. & 25. Refractionem Horizontalem Solis aut cuiuſuis Sideris, minorem refractione Parallaxim habentis inquirere; ac Refractionem Solis Tychonicam eiuſque quadruplex vitium emendare. Datis ternis quibuſue, quæ Problemate 20. 21. 22. aut 23. recenſui, & Parallaxi horizontali

ſideris. *Problems 24 and 25. To investigate the horizontal refraction of the Sun, or of any star whose parallax is smaller than its refraction; and to correct Tycho's solar refraction and its fourfold defect — given any of the sets of three quantities that I listed in Problem 20, 21, 22 or 23, together with the horizontal parallax of the star.*

[Margin: Problem 24.]

In the following figure let HVRD be the meridian, HAR the true horizon, and FBM the apparent horizon parallel to it; and from V, the point of the vertex, let VAD, the semicircle of a vertical circle, be drawn, in which the Sun is in reality at E but, by the force of horizontal refraction, appears at B, a point of the physical horizon. For to one observing it from the surface of the terrestrial globe it will seem to be a whole quadrant from the vertex; that is, the arc VB will be taken for a quadrant, although in reality it is less than a quadrant by a deficit as great as the arc AB — which, in any star, is as great as the horizontal parallax, by what was said in Book 2, chapter 2, scholium 2. Then, when the arc EP, which is a portion of a circle of declination, has been drawn from E[62], there will arise the triangle VEP, in which the true distance of the Sun from the vertex, VE, must always be found. If you take the quadrant VA from it, you will have the simple refraction AE, that is, the refraction not corrective of parallax; therefore the horizontal parallax AB must be added to AE itself, so that the whole effect of the horizontal refraction may be had, as Tycho prescribes in volume 1 of the *Progymnasmata*, p. 94. Or rather, take the horizontal parallax AB from the quadrant VA, take the remainder VB from the true distance VE, and you will have the integral horizontal refraction EB.

Diagram. Woodcut of a circle in the left column, representing the meridian. The vertical diameter runs from V at the top to D at the foot. Two horizontal chords cross it: the upper, FBM, the apparent horizon, and the lower, HAR, the true horizon, with B and A where they meet the vertical. K stands on the vertical below V; G and a small o lie between K and B; a small c lies between B and A; E lies on the vertical below A. P stands on the circumference to the upper right, and straight lines run from P down to the left to the vertical.

- V (top of the vertical diameter)
- K (on the vertical, below V)
- P (upper right, on the circumference)
- G (on the vertical, above B)
- o (small, just right of the vertical, beside G)
- F (left end of the upper chord)
- B (on the vertical, at the upper chord)
- M (right end of the upper chord)
- H (left end of the lower chord)
- c (small, on the vertical, between B and A)
- A (on the vertical, at the lower chord)
- R (right end of the lower chord)

[62] printed "eſt E"; construed as ex E

- E (on the vertical, below A)
- D (foot of the vertical diameter)

Further, the true distance of the star, VE, is obtained by one of the four ways given from Problem 20 to 23 inclusive, which there is no need to repeat.

[Margin: Problem 25.]

Now, on the one hand it is certain, other things being equal, that where the inclination of the ray to the surface of the denser medium is smaller, the refraction there is smaller; and that the ray of a star which, at the same distance from the vertex, is farther from the centre of the Earth and of the refracting air is less inclined to the convex surface of the air; and so the refraction of the Sun must be smaller than that of the Moon, the Sun being farther from the Earth. On the other hand, Tycho assigned to the Sun a horizontal refraction of 34′, but to the Moon one of 33′, as is clear from volume 1 of the *Progymnasmata*, pp. 79 and 124. Kepler therefore suspected, in precept 197 of the *Rudolphine Tables*, that Tycho erred in this: that he added to the arc AE a horizontal parallax of the Sun, AB, that was too large, namely 2′ 54″ — as much as he assigns to the Sun at apogee in the same volume 1, p. 80. For that the refractions of the Sun were observed chiefly at the summer solstice, when the Sun is nearest its apogee and through the whole day varies its declination insensibly, is clear from Tycho himself, volume 1 of the *Progymnasmata*, p. 93, and from his observations of the year 1589 sent to me by Father Curtius.

[Margin: First defect of Tycho's refraction.]

But for us the truer parallax of the Sun at that time, from Book 3, chapter 8, is only 27″. Therefore, when 2′ 54″ is taken from 34′, there remains the arc of simple refraction EA, 31′ 6″; if you add 27″ to it, the corrected horizontal refraction of the Sun, drawn from Tycho's observations, comes out at 31′ 33″.

[Margin: Second defect of Tycho's refraction.]

Yet because, owing to a parallax larger than it should be, he also increased the maximum declination of the Sun, as we said in Book 3, chapter 27, number 3, the complement of the maximum declination on the day of the summer solstice, that is, the arc EP, was for Tycho smaller than it should be, and indeed by a minute and a half: for he puts the maximum declination of the Sun at 23° 31′ 30″, whereas it is 23° 30′, as I showed in the same place. Therefore the arc VE too, and so AE, came out a little smaller than it should be — granted, not by as much as the excess of the parallax over the right parallax. So there was indeed a double error, but one was partly corrected by the other, though without Tycho's knowing it.

[Margin: Third defect of Tycho's refraction.]

Finally, Tycho used chiefly Problem 20, which relies on azimuths without the equatorial distance from the meridian; so it is no wonder that he thought the morning refractions equal to the evening ones, although the morning ones are usually greater, since the air is then moister and thicker and not yet cooked through by the heat of the day. Now if, on the day of the solstice, the solstice falls at noon, then the azimuths of the rising and setting Sun will be equal,

and the declinations equal; so on the same horizon entirely equal refractions will be gathered, and yet in reality they can be unequal because of a change in the density of the air. That is why I warned at the end of Problem 20 that this way is useless for distinguishing them. But if the refractions are unequal because of the unequal density of the air, the angle VPE will necessarily be unequal; and so, for distinguishing morning refractions from evening ones, the equatorial distance of the Sun from the meridian, obtained from the time converted into degrees of the equator — which Problems 21, 22 and 23 use — is more useful. Moreover, the nature of the air requires that the summer refractions be somewhat smaller than the equinoctial ones, and these than the winter ones; and we have learned this by experiment, as, God granting, we shall show in volume 3 of the *New Almagest*.

[Margin: Fourth defect of Tycho's refraction.]

But the observer is often, if not on a mountain or a tower, at least in some elevated place, higher than the horizontal line in which the centre of the rising Sun first appears; and so he takes the visible distance of the Sun from the vertex for a quadrant of exactly 90°, and yet it is then greater than 90°. Moreover, it is difficult to make out the centre of the rising Sun or Moon because of its imperfect elliptical figure, more contracted below, as is clear from what was said in Book 3, chapter 2, and Book 4, chapter 15. Therefore, to avoid both inconveniences — which I do not in the least doubt were a hindrance to Tycho — we stretched toward the rising Sun two threads parallel to the horizon and a cubit apart from each other, and so set equidistant from the horizontal plane that the plane they intercepted was parallel to the horizontal plane — and indeed at the height of our eye. With the head resting on a support very well suited to this, the eye unmoved, and the line of sight directed through the two threads so that the farther one was covered by the nearer, and with a green lens tempering the brightness of the Sun, we waited until the centre of the Sun's disc was bisected by both threads at the same moment. At that moment we gave a signal to a companion, who was counting the time with a pendulum, the count having begun from an altitude taken of a fixed star, so that from the time we might obtain the angle at the pole of the world.

EXEMPLVM

Example.

Ex Noſtra Obſeruatione. *From our own observation.*

In this very year in which this volume is sweating under the press, namely 1651, it was decided to repeat the observations of the solar refractions. Among them, on 1651 June 27, in the morning before sunrise, the distance of Aquila from the vertex toward the west was taken, 47° 42′; and at the same moment the counting of the time with the pendulum was begun, up to the rising of the centre of the Sun on the physical horizon of Bologna, marked out by two

threads equally equidistant from the horizon; and immediately, when I had given the

[Margin: Order of the problems.]

signal, Father Francesco Maria Grimaldi ended the count and found that the corrected time of the primum mobile had been $42^{m}\ 33^{s}$, to which correspond 10° 38′ 15″ of the equator. We completed the rest of the working of the calculation as below.

[Margin: First step: for the right ascension and declination of the Sun ☉.]

[Margin: Second step: for the angle at the pole of the world.]

[Margin: Third step: for the refraction.]

Item	Value
The Sun's place at noon on June 26, from our corrected tables, was in ♋ Cancer	4° 31′ 54″
But at noon on the 27th, in Cancer	5° 29′ 2″
Right ascension of the Sun at noon on the 26th	94° 52′ 34″
But at noon on the 27th	95° 58′ 59″
Difference of the right ascensions of the Sun ☉	1° 6′ 25″
Declination of the Sun at noon on June 26	23° 25′ 39″
But at noon on the 27th	23° 23′ 0″
Difference of the declinations of the Sun	0° 2′ 39″
Semidiurnal time of the 27th, in hours	$7^{h}\ 40^{m}\ 0^{s}$
To which there corresponds, from the difference of the declinations	0° 0′ 51″
Therefore the declination of the rising Sun	23° 23′ 51″
And its complement	66° 36′ 9″
To the semidiurnal time add the counted time, $42^{m}\ 33^{s}$; the hours come to	$8^{h}\ 22^{m}\ 33^{s}$
To which there corresponds, from the difference of the right ascensions of the Sun	0° 23′ 1″
Therefore, when Aquila was observed, the right ascension of the Sun ☉ was	95° 35′ 58″
Right ascension of the bright star in Aquila at that moment, from our tables	293° 27′ 54″
Its northern declination	8° 1′ 1″
Its complement	81° 59′ 59″
Complement of the altitude of the pole at Bologna	45° 30′ 30″
Distance of Aquila from the vertex	47° 42′ 0″
Therefore, by Problem 25 of Section 3, the angle at the pole of the world	35° 27′ 0″
When this is added to the right ascension of the western star, the right ascension of mid-heaven becomes	328° 54′ 52″
Its complement to the circle is	31° 5′ 8″
If you add to this the right ascension of the Sun at this moment	95° 35′ 38″
The equatorial distance of the Sun from the meridian becomes	126° 41′ 6″
If you take from this the arc of the equator that rose from the taking of Aquila's altitude to the physical rising of the Sun, and it was	10° 38′ 15″
There remains the true equatorial distance of the Sun at the moment when it physically rose, that is, the angle EPV	116° 2′ 51″
But VP at Bologna is	45° 30′ 30″
And SP, the complement of the true declination	66° 36′ 9″
THEREFORE the true distance EV of the Sun E from the vertex V	90° 31′ 58″
But the visible VB was a quadrant, or	90° 0′ 0″
Therefore the simple refraction of the Sun, EB	0° 31′ 58″
If you add to it our horizontal parallax of the Sun ☉ at that time	0° 0′ 27″
The integral horizontal refraction of the Sun becomes	0° 32′ 25″

Item	Value

If I had added Tycho's parallax of 2′ 54″, but had used Tycho's obliquity of the ecliptic, 23° 31′ 30″, the refraction would have come out at about 34′ 30″. So now, as on other occasions too, we were very glad that our air here at Bologna is of almost the same density at the summer solstice as it is in Denmark, and that the refractions have come out nearly the same for us as for Tycho.

By the same method, from the observations of the preceding years from 1641 up to 1651, we computed the refractions of the Sun, the Moon and the fixed stars about the solstices and equinoxes, as will be seen in Table IX at the end of this Section.

[Margin: Order of the problems.]

26. Probl. Sideris ſupra horizontem apparentis Refractiones in circulo altitudinis inquirere: & Inuenire terminum altitudinis, in quo ceſſant ſenſibiles refractiones, Datis præter Parallaxim ijs, quæ dantur in Probl. 20. 21. 22. aut 23. *Problem 26. To investigate the refractions, in a circle of altitude, of a star that appears above the horizon; and to find the limit of altitude at which sensible refractions cease — given, besides the parallax, the quantities that are given in Problem 20, 21, 22 or 23.*

[Margin: Problem 26.]

In the figure immediately preceding, let the Sun appear at K but be in reality at G. Draw the arc GP; then in the triangle VGP find the arc GV, that is, its true distance from the vertex V, by one of the four ways given from Problem 20 to Problem 23. Next take from the arc VG the visible distance of the Sun from the vertex, namely the arc VK, and there will remain the simple refraction GK; but to this add the parallax belonging to such a distance. For the Sun, being at G, would, if there were no refraction, be seen from the Earth's surface lower down by the force of parallax, say at B. Since, then, it is seen above its true place, at K, the whole refraction is the arc BK, of which the part BG corrects the parallax, while the remainder, GK, raises the star above its true place.

[Margin: First case: for a greater refraction.]

But if the visible distance turns out equal to the true distance VG, that will be a sign that the refraction — say the arc BG — raising the star is equal to, and as great as, the parallax GB that would otherwise depress it; and so G will be the place both seen and true.

[Margin: Second case: for an equal refraction.]

Now if the star is, for example, at G, and yet is seen below, say at B — but not as far below as the parallax, let it be GC, would demand — then the refraction will be smaller than the parallax. In this case the true distance VG, found by one of the four ways given from Problem 20 to Problem 23, must be subtracted from the observed or visible distance VB, and the arc GB will

remain; subtracted from the parallax GC, this will leave the required refraction CB.

[Margin: Third case: for a smaller but sensible refraction.]

Finally, if the star is seen below its true place by as much as the known and sensible parallax demands, and there is no fault in the observation or in the parallax — as, for example, if it is at G and is seen at O, lower by as much as the parallax GO — that is a sign that no sensible refraction intervenes, since nothing diminishes the sensible parallax. And the evidence of this absence of refraction will be if the parallax GO, added to the true distance VG found by one of the four ways already mentioned, makes VO equal to the visible distance. It is reasonable to believe that this is how Tycho found that the ordinary refractions of the Sun and Moon cease to be sensible near 45° of altitude, and those of the fixed stars near 20°, even though neither he nor anyone else has disclosed these problems to us.

[Margin: Fourth case: for a smaller but insensible refraction.]

27. Probl. Refractionem ſimplicem in circulo altitudinis ſecernere à data integra Refractione obſeruata, ſi detur Parallaxis, qua vſus eſt obſeruator in colligenda Refractione integra. *Problem 27. To separate the simple refraction in a circle of altitude from a given observed integral refraction, if the parallax is given that the observer used in deriving the integral refraction.*

[Margin: Problem 27.]

If the integral refraction is greater than the observer's parallax, then when the parallax is subtracted from it the simple refraction will remain. But if they are equal, or the refraction is smaller than the observer's parallax, the given refraction will be simple, and no other separation will be needed — provided that the observer's parallax is correct. But if the refraction is equal to or smaller than the parallax, and the parallax the observer used was larger or smaller than it should be, first find the difference between the correct and the incorrect parallaxes. Add it to the given refraction if the observer's parallax was smaller than the correct parallax; subtract it if larger; and so you will have the correct simple refraction, which will at the same time be integral and will need no separation from another refraction. But if the difference that is to be subtracted from the refraction cannot be subtracted, that is a sign that the observation was disturbed.

EXEMPLVM.

Example.

Tycho — as is found in volume 1 of the *Progymnasmata*, pages 79, 81, 92 and 93 taken together — the Sun's horizontal refractio- [Margin: Order of the problems.]

n he derived as 34′ on the days of the summer solstice, using a parallax of 2′ 54″ for the Sun, which was then almost at its apogee. When I take this from 34′, there remains a simple refraction of 31′ 6″. But since at an altitude of 25°

he puts the parallax at 2′ 38″ and the refraction at 2′ 30″, the simple refraction he deduced was 2′ 30″, for this is how he reasoned: "At the moment when I saw the centre of the Sun through the instruments at an altitude of 24° 59′ 52″, its true altitude by calculation was 25°; but on account of the parallax of 2′ 38″ it ought to have been seen at an altitude of only 24° 57′ 22″. Therefore, by the force of a refraction of 2′ 30″, which corrects the parallax but not the whole of it, it appeared at an altitude of 24° 59′ 52″."

But the parallax Tycho assumed was larger than it should have been: on our hypothesis, on which see Book 3, chapter 8, it was then 18″ at an altitude of 25°. The difference of this from Tycho's 2′ 38″ is 2′ 20″, and this, taken from the refraction of 2′ 30″, leaves a corrected simple refraction of only 10″. By this device we corrected Tycho's simple refractions of the Sun in Table 8 at the end of this Section; but where the integral refraction was greater than the parallax, we added our parallax to Tycho's simple refraction so as to have the integral refraction. Beyond 25° of altitude, however, it was not possible to go.

28. Probl. Refractionem Horizontalem Lunæ, aut ſideris cuiuſuis, minorem parallaxi refractionem habentis, inuenire Datis præter Parallaxim horizontalem ijs, quæ dantur Problemate 20. 21. 22. aut 23. Vel ſi neſciatur ſitne maior an minor, idipſum determinare. *Problem 28. To find the horizontal refraction of the Moon, or of any star whose refraction is smaller than its parallax, given, besides the horizontal parallax, the quantities that are given in Problem 20, 21, 22 or 23. Or, if it is not known whether the refraction is greater or smaller, to determine that very point.*

[Margin: Problem 28.]

The first case is the one we suppose from Tycho's observations, namely when the horizontal parallax is greater than the horizontal refraction. Look, then, at the figure immediately preceding, in which let the Moon be truly at C but appear, by the force of refraction, at B, a point of the physical horizon, at which it would seem to be a whole quadrant from the vertex. Now draw the arc CP, and in the triangle VCP find the true distance VC by one of the ways given from Problem 20 to Problem 23. For if you find it smaller than a quadrant, you will conclude that the refraction BC is smaller than the horizontal parallax AB. Then subtract the true distance VC from the quadrant VA, and subtract the remainder AC from the horizontal parallax AB; for the horizontal refraction BC will remain.

[Margin: First case: for a smaller refraction.]

Second: if the star is at A, a point of the true horizon, but appears by the force of refraction at B, the horizontal refraction AB will be equal to the horizontal parallax BA. The evidence of this will be if, for a star seen at the point B of the physical horizon, the true distance from the vertex, found by one of the four ways already mentioned, is a quadrant.

[Margin: Second case: for the sign of an equal refraction.]

The third case is the one I set out in Problem 24, and its sign is if, for a star appearing in the physical horizon, the true distance from the vertex found by calculation is greater than the quadrant AV — for example, if it is EV.

[Margin: Third case: for the sign of a greater refraction.]

29. & 30. Probl. Refractionem Sideris per obſeruationem altitudinis & declinationis, Data Poli Altitudine, & Parallaxi ſideris, ſi quam habet, veraq. Declinatione, inuenire duobus modis, & Tychonicum Problema ampliare. *Problems 29 and 30. To find the refraction of a star in two ways, by observing its altitude and declination, given the altitude of the pole, the parallax of the star if it has one, and its true declination; and to extend Tycho's problem.*

[Margin: Problem 29.]

Tycho teaches this other way in volume 1 of the *Progymnasmata*, p. 94. He directs that on the day of the summer solstice — on which, that is, the declinations vary insensibly through the whole day — the altitude of the Sun be taken with a large quadrant, so that, when it is subtracted from 90°, the Sun's visible distance from the vertex may be known; and that at the same moment its declination be taken with very large equatorial armillae, properly set up, so that, when this too is taken from 90°, the complement of the declination may be known. And this not once, but from the rising of the Sun up to noon, and from then up to its setting, so that we may be certain of the increase, decrease and cessation of the refractions. When these have been observed, let the figure of Problem 24 be repeated here, in which let the Sun be at C but appear by the force of refraction at G. From these points let there be drawn the arcs CP, which is the complement of the Sun's true declination, and GP, which is the complement of the visible or observed declination.

[Margin: Order of the problems.]

Diagram. Woodcut of a circle in the right column, the figure of Problem 24 repeated, as the text says. The vertical diameter runs from V at the top to D at the foot. Two near-horizontal chords cross it: the upper, F–B–M, and the lower, H–A–R, with B and A where they meet the vertical. K stands on the vertical below V; G stands on the vertical above B, with a small o just to its right; a small c lies between B and A; E lies on the vertical below A. P stands on the circumference to the upper right, and straight lines run from P down to the vertical.

- V (top of the vertical diameter)
- K (on the vertical, below V)
- P (on the circumference, upper right)
- G (on the vertical, above B)
- o (small, just right of G)
- F (left end of the upper chord)
- B (where the upper chord meets the vertical)
- M (right end of the upper chord)
- H (left end of the lower chord)

- c (small, on the vertical between B and A)
- A (where the lower chord meets the vertical)
- R (right end of the lower chord)
- E (on the vertical, below A)
- D (foot of the vertical diameter)

Now in the triangle VGP three sides are given: VP, the complement of the altitude of the pole; VG, the complement of the visible altitude; and GP, the complement of the observed declination. Therefore by [proposition] 14 of oblique spherical triangles you will find the angle VGP; when this is subtracted from 180°, the angle CGP in the triangle CGP will be known. In that triangle GP is given, as above, and CP, the complement of the true declination; therefore by [proposition] 2 of the same triangles the third side, CG, will become known, namely the simple refraction. To this, however, the parallax, say the arc CA, must be added, so that the integral refraction may be had.

[Margin: Problem 30.]

Otherwise: in the triangle GVP, from the three sides given as above, find the azimuthal angle GVP by [proposition] 14 of oblique spherical triangles; then in the triangle CVP find the side VC by [proposition] 2 of the same, for VP, the complement of the altitude of the pole, and CP, the complement of the true declination, are given, and the angle CVP has been found. Afterwards subtract the visible distance VG from the side VC, that is, from the true distance, and the simple refraction GC will remain; if the parallax is added to it, the whole refraction will result. Tycho adds another way, by solving a right-angled triangle after drawing a perpendicular. But it is neither necessary now, for those who are used to logarithms and know how to solve oblique-angled triangles very quickly, nor geometrically exact, since it assumes the external angle VGP equal to the internal opposite angle GCP. So far Tycho. His problem can, however, be adapted to the fixed stars, as being free of parallax, on any night, since their declination does not vary sensibly over one whole night or on neighbouring nights; and it can be adapted to the Sun as well outside the summer solstice, if, according to the hours before or after noon, known in whatever way, the true declination is corrected by the proportional part corresponding to the variation of the whole day. Tycho is, however, deficient in all these problems, because he does not teach what is to be done if the parallax is equal to or greater than the refraction, nor does he teach the sign of these cases, or when sensible refractions cease — which we have supplied, from Problem 26 to Problem 29.

[Margin: Defect of Tycho's problem in the matter of refraction.]

It is worth while, moreover, for testing the reliability of Tycho's table of the Sun's refractions, and for illustrating this problem, to examine one observation out of the 80 observations of Tycho's of the year 1589, from June 11 to 17 — that is, in the new style, from the 21st to the 27th — taken before and after noon with the armillae and the azimuthal quadrants at Uraniborg. These observations, at my request, Father Albertus Curtius [Albert Curtz] of our Society, the man

who by order of the Emperor has been put in charge of bringing out all Tycho's observations, sent me, very generously transcribed from Tycho's journals.

EXEMPLVM

Example.

Ex Tychonicis obſeruationibus. *From Tycho's observations.*

In the year 1589, on June 11, old style, in the evening, with the solstice approaching and due at about midnight, the altitude AG of the Sun's centre was taken with the steel quadrant as 2° 20′, and at that time the declination of the Sun observed with the armillae was 23° 40½′. Therefore the complement of the visible altitude, that is GV, was 87° 40′, and that of the visible declination, or GP, was 66° 19′ 30″; and VP, the complement of the altitude of the pole at Uraniborg, is 34° 5′ 30″. Therefore by [proposition] 14 of oblique spherical triangles the angle GVP was 48° 56′ 40″.

[Margin: First step.]

Next, in the triangle CVP, VP is given, 34° 5′ 30″, and the angle CVP has been found, 48° 57′; and CP, the complement of the true declination, is for Tycho 66° 28′ 30″ but for me 66° 30′. Therefore by [proposition] 2 of oblique-angled spherical triangles there follows the true distance CV of the Sun from the vertex: by Tycho's reckoning 87° 50′ 12″, but by mine

[Margin: Second step.]

[Margin: Order of the problems.]

87° 51′ 47″. When the visible distance VG, 87° 40′, is taken from these, there remains the simple refraction GC: by Tycho's reckoning 10′ 12″, by mine 11′ 47″. If you add to these — to Tycho's, Tycho's parallax at that time, 2′ 54″, and to ours, our parallax, 27″ — the integral refraction comes out: Tycho's 13′ 6″, ours 12′ 4″, much smaller than the refraction that Tycho, in the small table in volume 1 of the *Progymnasmata*, p. 79, gives for an altitude of 2⅓°, for there he gives 19′. Perhaps it is because he used the first way, solving the triangle CPG, where the angle P, being too acute, and GC, being too small an arc compared with the arcs GP and CP, could easily slip an error into the calculation; or because he assumed the angle VGP equal to the angle VCP, as he himself teaches above may be assumed; or because he judged other observations more to be trusted; or because he thought that a small table suited to the morning refractions held good for the evening ones, which, however, are reasonably smaller because of the purer temper of the air, cooked through all day. Wherever this disagreement comes from, I wanted to point it out. For my calculation was clear and accurate to me, and I appeal to the trigonometers.

[Margin: Disagreement of Tycho's small table of refractions with the observations.]

31. Probl. Data Parallaxi Sideris, ſi quam habet, eiuſq. Diſtantia viſa à vertice, ac reliquis ad diſtantiam veram eruendam per Problemata præcedentia requiſitis, Determinare an ſidus ſit infra horizontem verum, an ſupra, an in ipſo horizonte. *Problem 31. Given the parallax of a star, if it has one, its visible distance from the vertex, and the other things required by the preceding problems for deriving the true distance, to determine whether the star is below the true horizon, above it, or on the horizon itself.*

Although this has already been indicated in Problems 26 and 28, a separate rule nonetheless had to be given. First, then, find the true distance of the star from the vertex by Problem 20, 21, 22, 23 or 30; for if it is a quadrant, the star will be on the true horizon; if greater than a quadrant, below the horizon; if smaller than a quadrant, above the true horizon.

[Margin: Problem 31.]

32. Probl. Refractionem Solis Horizontalem ex apparenti ipſius ortu vel occaſu deducere, Data ipſius Parallaxi horizontali, & Altitud. Poli, ac Declinatione Solis. *Problem 32. To deduce the horizontal refraction of the Sun from its apparent rising or setting, given its horizontal parallax, the altitude of the pole and the declination of the Sun.*

First count the time with the help of the pendulum (on which see Book 2, chapter 21) from the apparent rising of the Sun's centre up to noon, or from noon up to its setting, and you will have the apparent semidiurnal time; convert it into degrees of the equator. In this way you will have, in the preceding figure, the angle VPE. With this, with VP, the complement of the altitude of the pole, and with PE, known from the declination — for PE is the complement of the declination if the Sun is on this side of the equator, a quadrant if it is on the equator, or the sum of the declination and a quadrant if the Sun is beyond the equator — with these, I say, find by [proposition] 4 of oblique spherical triangles the true distance of the star from the vertex, that is, the base VE. Subtract the quadrant from it, but add the horizontal parallax to the remainder, and you will have the integral horizontal refraction of the Sun. But if so long a counting of the time is tiresome, take the altitude of a known fixed star about one hour before the rising or after the setting of the Sun, so that by Problem 25 of Section 3 you may have the time before or after noon; but let someone else be on hand at once to begin counting the time up to the apparent rising of the Sun's centre, or from its setting up to the taking of the star's altitude. From this the stretch of time from the apparent rising of the Sun to noon, or from noon to the apparent setting, will be known, and so you will have the apparent semidiurnal time and arc; use it as above.

[Margin: Problem 32.]

33. Probl. Refractionem horizontalem Solis ac Lunæ per Eclipſes Lunæ horizontales attentare methodo P. Bettini, ſed fallaci. *Problem 33. To*

attempt the horizontal refraction of the Sun and Moon by horizontal eclipses of the Moon, by the method of Father Bettini — a fallacious one.

Enough may seem to have been said about this method in Book 5, chapter 5, number 18. Add, however, that if the Moon is truly on the astronomical horizon, diametrically opposite the Sun, the Sun will indeed appear above the physical horizon by the force of refraction, because its horizontal refraction is greater than its horizontal parallax; but the Moon will not appear on the physical horizon, much less above it, because its horizontal refraction, even with the apparent lunar semidiameter added, is smaller than its horizontal parallax.

[Margin: Problem 33.]

[Margin: Order of the problems.]

34. & 35. Probl. Refractiones Solis ac Lunæ extraordinarias ex Eclipſibus horizontalibus aut ortu Solis inexpectato, ſubodorari. *Problems 34 and 35. To scent out extraordinary refractions of the Sun and Moon from horizontal eclipses or from an unexpected rising of the Sun.*

For Problem 34 see Kepler in the *Astronomiae Pars Optica*, p. 137, where from a horizontal eclipse of the Moon seen at Tübingen he infers a refraction of one luminary or the other greater than one degree. For Problem 35, see the same author in the same work, p. 139, and what we said in this Book, Section 3, Problem 14, where we dealt with this fully.

[Margin: Problem 34.]

[Margin: Problem 35.]

36. Probl. Data Refractione Sideris ac Parallaxi, Viſam eius Altitudinem in Veram, ac viciſſim Veram in Viſam ſeu obſeruatori apparentem, conuertere. *Problem 36. Given the refraction and the parallax of a star, to convert its visible altitude into the true one, and conversely the true one into the visible, that is, the altitude apparent to the observer.*

From the visible altitude take the refraction, and to the remainder add the parallax: the true altitude will result. Conversely, from the true altitude take the parallax, and to the remainder add the refraction: the visible altitude of the star will result. Everything is to be done the opposite way if a visible distance from the vertex is to be changed into the true one, or a true one into the visible.

[Margin: Problem 36.]

37. & 38. Probl. Diſtantiam Viſam duorum Siderum in Veram, ac viciſſim Veram in Viſam conuertere, Data Refractione integra & Parallaxi ipſorum (ſi quam habet vtrumq. vel alterum;) & in primo caſu Altitudine viſa ipſorum, in ſecundo autem Altitudine vera. *Problems 37 and 38. To convert the visible distance of two stars into the true one, and conversely the true into the visible, given their integral refraction and parallax (if both or either of them has any), and, in the first case, their visible altitude, but in the second their true altitude.*

Let V be the zenith, from which let the quadrants VA and VB of two vertical circles be drawn, both intercepting the arc AB of the true horizon; let them be produced to H and R and joined by the arc HR. Now let the true place of one star be F, but seen by the force of refraction at C; and the true place of the other G, but seen at D; and let the visible or observed distance be the arc CD, but the true one FG. First subtract the visible altitudes AC and BD separately from 90°, and there will remain the visible distances from the vertex, VC and VD. With these, and with the visible distance between the stars, CD, find the angle V by [proposition] 14 of oblique-angled spherical triangles. Then to the arcs VC and VD add their own refractions, but take away their own parallaxes, so that you have the true distances from the vertex, VF and VG; with these, in the triangle FVG, and with the angle V, find the true distance FG by [proposition] 5 of the same triangles. You have an example in Book 6, chapter 11, at the end of Problem 8, in the distance of the Sun and Sirius — but with Sirius supposed free of parallax.

[Margin: Problem 37.]

Diagram. Woodcut in the right column: a tall spherical triangle with its apex V at the top right. Its left side runs down from V past C and F to A and then H; its right side runs down past D and G to B and then R. An arc joins A to B, and below it an arc joins H to R. Straight lines run from the points on the left side across to points on the right side.

- V (apex, top right)
- C (on the left side, upper)
- F (on the left side, below C)
- D (on the right side, middle)
- G (on the right side, below D)
- A (left end of the arc AB)
- B (right end of the arc AB)
- H (lower left corner)
- R (lower right corner)

But if only one of the stars, say F, has a sensible refraction, and the other, D, does not, the visible distance will be CD, but the true one FD. Then, when the angle V has been found as above from the sides VC, VD and CD, and afterwards, in the triangle VFD, VF — the true distance of the star from the vertex — has been obtained as above, and the parallax of the star D has been taken from VD itself, find the true distance FD by [proposition] 5 of oblique spherical triangles. Or if the star C lacks refraction but the star G has it, the visible distance will be CD but the true one CG; and the triangle CVD must be used first, as above, then the triangle CVG. It can also happen that one star is truly below the horizon at R, and is seen above it by the force of refraction, as at G, while the other is above, at F; and the visible distance is FG but the true one FR. It is enough to have pointed out these cases, for all of them are to be worked out in a similar form.

[Margin: Order of the problems.]

Conversely, let the true distance, say FG, be converted into the visible one, CD, both stars having undergone refraction. Subtract the true altitudes AF and BG, each separately, from 90°, so that you have the true distances from the vertex, VF and VG. With these, and with the true distance FG of the stars from each other, find the angle V in the spherical triangle FVG by [proposition] 14 of oblique-angled triangles. Then from the arcs VF and VG subtract one by one the refractions of their own stars, FC and GD, but add their own parallaxes, if they have any; and with the arcs CV and DV and the angle V already found, find in the triangle CVD, by [proposition] 5 of oblique spherical triangles, the visible distance CD — the distance that is to be seen. From this it is clear how to proceed in the other cases of Problem 37. For in them the angle V must always be sought by means of the true distance of the stars from the vertex and from each other; then, by the angle V and the visible distances from the vertex, the base must be sought, that is, the visible distance of the stars from each other, whether that be CD or FG, etc.

Problems 39 and 40. Given the altitude of the pole and the refraction and parallax of a star in a circle of altitude, to convert its given true declination or right ascension into the visible one, and conversely the given visible one into the true; given, besides, in the first case the true altitude of the star, in the second the visible.

[Margin: Problem 39.]

For these, go back to the fifth section of this book and its chapter 6, and use the figure set out there. For this Problem 39 use Problem 28 of that chapter: to the complement of the given true altitude add the parallax but subtract the refraction, and carry out the rest exactly as there.

[Margin: Problem 40.]

For Problem 40, that is, the conversion of the visible into the true, use Problem 31 of the same chapter: from the complement of the given visible altitude subtract the parallax but add the refraction, and carry out the rest exactly as was said there, in any one of the five cases. For just as parallax, by depressing the star, so refraction, by raising it in appearance, sometimes increases the declination, sometimes diminishes it, sometimes annuls it, and sometimes changes it into the other kind.

Problems 41 and 42. To convert the given true latitude and longitude of a star, with the true altitude, into the visible; or the given visible into the true, with the visible altitude — given, besides, the parallax and refraction of the star in a circle of altitude, the altitude of the pole, and the distance of the poles.

[Margin: Problem 41.]

For both problems go back to Book 5, chapter 10, and use Problem 5 directly or conversely. But for Problem 41, add the parallax to the complement of the true altitude while subtracting the refraction; for Problem 42, subtract the parallax while adding the refraction; and carry out the rest as there.

[Margin: Problem 42.]

Yet the occasion for bringing this problem into practice in astronomy is extremely rare.

Problem 43. To attempt the height of the refractive air, given the semidiameter of the Earth and the horizontal refraction of the Sun, by the method of Father Mario Bettini — but a fallacious one.

[Margin: Problem 43.]

In the present figure let A be the centre of the terrestrial hemisphere BCD, of the refractive air EFG, and of the Sun's heaven LM, in which let the upper limb of the Sun be NHQ; from this let the ray HP, propagated, touch the convex surface of the air at F and pass through it unrefracted. Let another ray be drawn from the higher point S, the Sun being now raised by one minute in its heaven, which enters the air through the point of contact F, or very near it; let it be supposed to go on unrefracted to R, and let SR be that ray. Because of its nearness to F, then, let it make the angle PFR of about one minute. But in reality let it be refracted so that the refracted ray is FC and touches the Earth at C, and let the horizontal refraction be CFR. From the centre A let the straight lines AF and AC be drawn to the points of contact, making the angles AFP and ACF right, by [proposition] 18 of the third [book] of Euclid. Since, then, the horizontal refraction RFC is given, if the assumed minute RFP is added to it, the angle CFP will be known; subtracted from the right angle AFP, it will leave the angle AFC known in the triangle ACF, right-angled at C. Therefore by [proposition] 6 of right-angled plane triangles the base AF will be found, since in that triangle the Earth's semidiameter AC is given, and the opposite angle AFC; and when AV is taken away, the height of the air VF will remain. So Father Bettini, in the *Apiaria*, apiary 8, progymnasma 2, proposition 3: taking from Tycho the horizontal refraction of the Sun, RFC, as 34′, and adding RFP so that PFC is 35′, he subtracts the 35′ from the right angle AFP and obtains the angle AFC, 89° 25′. With this, and with the Earth's semidiameter AC of 3035 5/11 Italian miles, as he himself assumes, he derives VF, the least height of the refractive air, as only 151 paces.

[Margin: Father Bettini's error concerning the height of the refractive air.]

But a great fallacy lies hidden in this method. Let the ray SR be refracted near the contact F: it is nevertheless assumed that, once refracted, it reaches the Earth and touches it at C — although it could pass above the Earth towards I; and between that and the tangent CF there are innumerable other rays refracted from other and yet other points lying at a distance from F towards G. So, for example, the ray refracted at O can be refracted from K, and the ray refracted at C, or rather at Z, can be refracted from the point T, far distant from the point of contact F. Therefore the angle of refraction made at T will not be part of the right angle AFP, nor can it be subtracted from it so that the angle AFC becomes known. What should have been shown is that a ray entering so near the point F that it departs from the right angle by a single minute is refracted there in such a way as to touch the Earth — which, however, cannot be demonstrated while keeping the horizontal refraction of the stars found by Tycho, and the inclination of the ray above the convex surface of the air that is due to it.

Diagram. Woodcut in the right column. A horizontal base line runs from E on the far left through B, A, D and G to N and H at the right, with Q just beyond H. Two concentric semicircles stand on the base about the centre A: the inner (the Earth) through B, C and D, the outer (the air) through E, O, I, F and G. At the right a large arc, part of the Sun's heaven, descends from L at the top through S to H on the base and M below it. Rays run from S and from H up to the left towards F, the point where the outer semicircle is touched, and on beyond it to R and P at the upper left; further lines join F, K, O, C, Z, V and T, and straight lines run from A up to C and to F.

- P (upper left, end of a ray)
- R (upper left, below P)
- I (on the outer semicircle, left of F)
- F (point of contact on the outer semicircle)
- K (right of F, where rays cross)
- O (left, on the outer semicircle below I)
- C (on the inner semicircle, left)
- Z (inside the semicircles, right of C)
- V (top of the inner semicircle, above A)
- T (right of V)
- L (top of the large arc at the right)
- S (on the large arc, above H)
- E (left end of the base)
- B (on the base, foot of the inner semicircle)
- A (centre, on the base)
- D (on the base, right foot of the inner semicircle)
- G (on the base, right foot of the outer semicircle)
- N (on the base, left of H)
- H (on the base, at the foot of the large arc)
- Q (just right of H)
- M (below the base, end of the large arc)

Problem 44. To investigate the height of the refractive air, given the inclination of a ray above the convexity of the air, the inclination of the same ray, once refracted, upon the Earth, and the refraction and the semidiameter of the Earth.

[Margin: Problem 44.]

Kepler, from whom I took this problem and completed it, rightly warns in Book 1 of the *Epitome of Copernican Astronomy*, page 62, and in the *Astronomiae Pars Optica*, chapter 4, proposition 9, that the inclinations of the refracted rays through which we see the stars are the ones we measure on the Earth, not the ones the rays have above the curvature of the refractive air before refraction. Moreover, the inclination of a ray upon the Earth is as great as the distance of the star from the vertex as seen through the refracted ray. On these premises, in the following figure let A be the centre of the terrestrial quadrant BVT and of the quadrant of the air DEM, and let the eye be at B; and let ABD be drawn perpendicular both to the true horizon AM and to the apparent one BG. Let

EB be the refracted ray through which the stars are first seen when they rise physically, touching the Earth at B; for its inclination upon the Earth will be the angle DBE, which in this case is a right angle. Let FE be the ray outside the air, unrefracted, which, produced by supposition straight through the air to O, makes with BE the angle of refraction OEB, equal to its vertically opposite angle GEF. Through the point E let the straight line HI be drawn, touching the convexity of the air at E, and from the centre A let the straight line AEP be drawn perpendicular to it through E; for the inclination of the ray FE above the air will be the angle PEF. Once this is known, if the refraction O

[Margin: Order of the problems.]

EB, that is GEF, which is given, is subtracted from it, the angle PEG will be known; by [proposition] 15 of the first [book] of Euclid it is equal to the angle AEB, which is called the refracted angle. Therefore, Kepler says, let it be made that as the sine of the angle AEB (which he himself, rather equivocally, calls the inclination upon the concave surface of the air) is to AB, the semidiameter of the Earth, so the sine of the angle ABE — the inclination, that is, upon the Earth, which in this case is the whole sine, since B is right — is to AE, the semidiameter made up of AC, the Earth's semidiameter, and CE, the height of the refractive air. But Kepler did not notice that if the eye B is raised above the convex surface of the Earth and the sea, as often happens, the height CE grows by as much again and more.

Diagram. Woodcut in the left column, beside the narrow lines of Kepler's proportion. A vertical line runs from D at the top down through B to A at the foot, and a horizontal line runs from A along the bottom to T and M. Two quadrant arcs are drawn about A: the inner (the Earth) from B down to T, the outer (the air) from D through E down to M. From B a horizontal line runs right through E to G. From the upper left, lines from I and from O run down to E; from E a line runs up to P on the right, and lines run on down to F and H at the right. A long line from A runs up through C, on the inner arc, to E, and another from A runs up through K to H.

- I (top, upper left of E)
- O (upper left, below I)
- P (upper right)
- D (top of the vertical line)
- E (on the outer arc, where the lines cross)
- B (on the vertical line, start of the horizontal BG)
- G (right end of the horizontal line)
- F (right, below G)
- H (right, below F)
- C (on the line from A to E, at the inner arc)
- K (on the line from A to H)
- A (lower left corner, the centre)
- T (on the base, foot of the inner arc)
- M (on the base, foot of the outer arc)

Example.

From Kepler.

Let AB be 860 German miles, and the sine of the angle ABE the whole sine, 100 000; but the angle AEB of 88° 1′, whose sine is 99,940. Multiplying, then, 860 by 100,000 makes 86 000 000; dividing these by 99 940, AE comes out at 860 45,600/99940 German miles. Therefore, when AC, that is 860 miles, is taken away, the height of the air CE remains at 0 46/100 of a mile — that is, a little less than half a German mile.

Problem 45. To find the inclination of a ray above the curvature of the refractive air, given the height of the air, the semidiameter of the Earth and the horizontal refraction of the ray.

[Margin: Problem 45.]

Let everything in the figure of the preceding problem be as set out there. For if the refraction is horizontal, the inclination of the refracted ray EB upon the Earth is the right angle DBE, equal to the angle ABE. Join, then, the Earth's semidiameter AC to the height of the air CE, so that the whole AE is known; then let it be made that as AE is to the sine of the angle ABE, that is, the whole sine, so the semidiameter AB is to the sine of the angle AEB, which is equal to the angle PEG. To this add the horizontal refraction OEB, that is GEF, and you will have the angle FEP, namely the inclination of the ray FE above the curvature of the air DEM.

Problem 46. To find the inclination of a ray above the curvature of the refractive air, given the height of the air, the semidiameter of the Earth, the refraction of the ray, and the distance of the star from the vertex seen through that ray.

[Margin: Problem 46.]

In the same preceding figure consider the triangle ABE, whether it is right-angled or oblique-angled at B. In it are given the side AB, the semidiameter of the Earth, and AE, made up of AC, the semidiameter of the Earth, and CE, the height of the air; and the angle ABE, since it is the supplement to two right angles of the angle DBE, which measures the distance of the star from the vertex seen through the refracted ray BE. Therefore, if B is not a right angle, you will find the angle AEB, that is PEG, by [proposition] 1 of oblique-angled plane triangles; and by adding to it the angle GEF, equal to the given refraction OEB, you will have the inclination sought, PEF.

Problem 47. Given what is given in Problem 45 or 46, to find the length of the refracted ray, or the thickness of the refractive air.

[Margin: Problem 47.]

In the figure immediately preceding, if AB, the semidiameter of the Earth, is given, and AE, compounded of the semidiameter AC and the height CE, and the angle ABE is right, as happens when the refraction is horizontal, then by [proposition] 9 of right-angled plane triangles you will learn the side BE. But if ABE, the complement of the visible distance of the star from the vertex, that is, of the angle DBE, is oblique, then by [proposition] 6 of oblique-angled triangles you will find BE, that is, the length of the refracted ray or the thickness

of the refractive air. Tycho, in volume 1 of the *Progymnasmata*, page 95, and Longomontanus, in Book 1 of the *Spherics*, chapter 11, problem 2, took the height of the twilight vapours or exhalations from Ibn al-Haytham and Witelo as about 12 German miles — though Longomontanus found it to be 13 miles — and took AB, or AC, as 860 miles; with these they derive the thicknesses of the refractive air written below, for the visible distances of the star from the vertex written below.

[Margin: The thickness of the twilight air rather than of the refractive air.]

Visible distance of the star from the vertex (deg.)	Thickness, or length BE, in German miles: Tycho	Thickness, or length BE, in German miles: Longomontanus
90	142	150
75	41½	
60	23	
45	16⅓	18⅓
30	14	

[Margin: The mistake of Tycho and Longomontanus.]

But, as Kepler noted in the *Astronomiae Pars Optica*, pages 79, 117, 129 and 135, the refractive air is a liquid matter, moist and heavier than the twilight exhalations (which he calls the twilight lamps), which are drier and smokier. For that reason the refractive air is not raised as high as the matter of the twilight exhalations; nor is their opacity, sufficient to reflect the ray and make twilight, an argument for a density suited to sensible refractions — for mists and smokes are more opaque, and yet they are not equal to glass or water in refracting.

Problem 48. To find the refraction, given the visible distance of the star from the vertex, the inclination of the ray above the refractive air, together with the height of that same air, and the semidiameter of the Earth.

[Margin: Problem 48.]

Going back to the figure set out in Problem 44, and to its triangle ABE: since in it are given AB, the Earth's semidiameter, and AE, made up of the Earth's semidiameter AC and the height of the air CE, and the angle ABE, which is the supplement to two right angles of the given apparent distance from the vertex, DBE, find the angle AEB — either by [proposition] 2 of right-angled plane triangles, if the visible distance is 90°, in which case the refraction will be horizontal, or by [proposition] 1 of oblique-angled triangles, if DBE is less than 90°. Then subtract the angle AEB from the angle AEO, which is known from the given inclination PEF, being equal to it; for the angle BEO of the refraction sought will remain.

Problem 49. To investigate the height of the refractive air by Kepler's method, through known refractions and inclinations on the Earth, and through the position of a false value differing as little as possible from the true, as he himself thought. But his conclusion is rejected.

[Margin: Problem 49.]

As long as the inclination of the ray above the air is unknown, the height of the air is not known; and while that is unknown, the inclination above the air is unknown — so Kepler thinks in the *Astronomiae Pars Optica*, proposition 9, and in the *Epitome of Copernican Astronomy*, Book 1, page 65. Therefore, in both places,

[Margin: First step.]

he first assumes various heights of the air in parts of which the semidiameter of the Earth is known; and with that, and with the semidiameter of the Earth, and with the inclination of the ray upon the Earth, that is, the visible distance of the star from the vertex, and with the Sun's refraction, the Tycho- [Margin: Order of the problems.]

nic one corresponding to this distance, he investigates the inclination of the ray above the air by Problem 45 or 46. So, in the *Astronomiae Pars Optica*, page 117, in the figure of Problem 44, having assumed CE, the height of the refractive air, as 95 parts, and so the whole AE as 100,095 parts of which AB is 100,000, he derives the inclinations in the air written below; to these I have added the visible altitudes and Tycho's solar refractions.

[Margin: From Tycho, volume 1, *Progymnasmata*, page 79.]

Visible altitude	Inclination on the Earth	Refraction of the Sun ⊙	Inclination in the air
0°	90°	34′ 0″	87° 30′
1°	89°	26′ 0″	87° 19′
2°	88°	20′ 0″	86° 48′
3°	87°	17′ 0″	86° 6′
4°	86°	15′ 30″	85° 17′
5°	85°	14′ 30″	84° 25′
30°	60°	1′ 25″	59° 54½′

[Margin: Second step.]

Secondly, by Problem 15 he seeks the simple refraction corresponding to an inclination of 60°, and finds it to be 43″; and by Problem 13 he finds the refraction corresponding to one degree of inclination, 43‴. Then by Problem 16, by means of the secants and of the inclinations assumed in the air, he investigates the integral refractions until he finds that they agree with Tycho's observations without sensible discrepancy. Now, at a visible altitude of one degree, to which a refraction of 26′ is due according to Tycho, he himself, through the inclination assumed in the air of 87° 19′, resting on a height CE of 95 parts, finds an integral refraction very different from 26′. From this he concludes that the position of 95 parts, or of an inclination of 87° 19′, was false. By the same method, through many windings of calculation from page 117 to page 120, he never satisfies himself, until, as if awakened, he notices that Tycho's table of refractions contains a great dissonance, and decrements of the refractions out of proportion to the decrements of the inclinations — not from any fault in the observations, but because Tycho observed the refractions of the Sun on different days of the year, on which the constitution of the air, its

density and its height varied; and from all of them he chose those he thought more certain and put them into one table, as though he had observed them all on one day.

[Margin: Third step, and a new way of investigating the refractions of altitude.]

Thirdly, therefore, from page 122, so that the variation of the refractions observed within a single day may appear, he sets out an example from Tycho's observations of 1587 January 16, made at Uraniborg from $3^h\ 26^m$ after noon to $3^h\ 58^m$. Within that time of 32^m the declination of the Sun was observed nine times with the armillae, and the visible altitude with the quadrants. From these; from the complement of the altitude of the pole at Uraniborg, which he puts at 34° 5′ 15″; from the true declination of the Sun for that day and hour, south, 18° 45′ 10″ — which, added to a quadrant, completes the other side, that is, the declination arc between the Sun and the north pole of the world, making it 108° 45′ 10″; and from the time after noon, which, converted into parts of the equator, constitutes the angle at the pole of the world made by the meridian circle and the circle of the Sun's declination — from these, I say, and from the declinations corrected for parallax, the Sun's parallax being then assumed as 3′, he derives the refractions as below.

Series of observed altitudes of the Sun	Declination observed	Parallax of declination	Declination without parallax	True declination	Refraction of declination	Addition for the refraction of altitude	Refraction of altitude
3° 50′	18° 35′ 30″	2′ 42″	18° 32′ 48″	18° 45′ 30″	12′ 52″ [?]	1′ 30″	14′ 22″
3° 30′	18° 34′ 0″	2′ 42″	18° 31′ 18″	18° 45′ 28″	14′ 10″	1′ 35″	15′ 45″
3° 10′	18° 32′ 30″	2′ 41″	18° 29′ 49″	18° 45′ 26″	15′ 37″	1′ 37″	17′ 14″
2° 50′	18° 31′ 45″	2′ 40″	18° 29′ 5″	18° 45′ 24″	16′ 19″	2′ 2″	18′ 21″
2° 40′	18° 30′ 30″	2′ 40″	18° 27′ 50″	18° 45′ 22″	17′ 39″ [?]	2′ 12″	19′ 44″
2° 5′	18° 29′ 0″	2′ 39″	18° 26′ 21″	18° 45′ 20″	19′ 0″	2′ 23″	21′ 23″
1° 15′	18° 23′ 30″	2′ 38″	18° 20′ 52″	18° 45′ 16″	24′ 24″	3′ 29″	27′ 53″
1° 0′	18° 22′ 30″	2′ 38″	18° 19′ 52″	18° 45′ 14″	25′ 22″	3′ 37″	29′ 0″
0° 35′	18° 20′ 0″ [2]	38″	18° 17′ 52″	18° 45′ 12″	27′ 20″	3′ 54″	31′ 10″ [?]

[Margin: Fourth step.]

Fourthly, in order to find by Problem 16, from the last refraction, 31′ 10″, the first, 14′ 22″: first, through the inclination ABE of 90° 35′, corresponding to the visible altitude of 35′, and through the radius or whole sine AB, and the assumed angle BEA of 87° 30′, he investigates by Problem 44 the straight line AE, which he finds to be 10,009,000 parts of which AB is 10,000,000. Then, using the first altitude, 3° 50′, that is, the angle ABE of 93° 50′ (at which the refraction was found to be 14′ 22″), he finds by Problems 44 and 16 that the refraction compounded from the proportion of the sines and secants does not come close to the observed 14′ 22″ unless the angle BEA is 88°. For then by Problem 44 the secant AE comes out at 10 005 578 parts of which AB is 10 000 000, and from this, by Problem 16, the integral refraction is derived as 14′ 49″,

which does not differ sensibly from the observed refraction of 14′ 22″. Hence, on pages 124 and 129, he concludes that AE is to AB as 10 005 578 is to 10 000 000. And since there are 860 German miles in AB, multiplying these by 10 000 000 makes 8 600 000 000; dividing these by 10 005 578, AE comes out at 860 48/100 miles. Therefore at Uraniborg the height of the refractive air CE was not greater than half a German mile, or two Italian miles.

Kepler's conclusion is rejected, and some points about the height of the refractive air worth noting are brought forward.

[Margin: The height of the refractive air is established as greater than two miles.]

Although the height of the refractive air in Denmark may seem to have been demonstrated above as not greater than two Italian miles — not geometrically, as Kepler himself admits on page 117 of the *Astronomiae Pars Optica*, but quasi-physically — for many reasons I cannot rest content with it. First, the evident sign of refraction for Kepler himself, in the *Epitome of Copernican Astronomy*, Book 1, page 60, is the elliptical shape of the rising or setting Sun; and I do not doubt that this appears to those observing from mountains much higher than two Italian miles. Nor is it necessary to have recourse to rays refracted by a second refraction on their exit from the denser air, carrying the image of the Sun to mountain ridges higher than this air: even granting that this happened, that very thing would be an argument for a double refraction, by force of which the elliptical figure of the Sun ought to be seen different from how it is seen below the mountain by force of a single simple refraction. Secondly, because in the preceding calculation, by which he deduced the refractions of the Sun, he used a solar parallax of 3′; he afterwards condemned it in the *Rudolphine Tables*, reducing it to a single minute and confessing, on page 120 of those tables, in the last precept, that the refractions of the Sun derived by Tycho were larger than they should be because too great a parallax of the Sun had been assumed. Thirdly, because the same Kepler, in the *Epitome of Copernican Astronomy*, page 65, says openly

[Margin: Order of the problems.]

that for this business an examination of at least three observed refractions is required. He ought therefore, of the nine refractions derived in the third step, to have examined at least three, keeping AE at 10 005 578 parts and the angle AEB at 88°; for perhaps it would not have agreed with some of them. Thus the refraction found by this method differs by 4′ from the Sun's refraction at 15° of altitude, which Tycho determined as 7′ 30″, as Kepler admits in the *Astronomiae Pars Optica*, page 126. Indeed it differs in not a few others as well, as is clear from the table set out there on page 124: for to the inclinations of the solar ray above the air written below he assigns, by this method, compound or integral refractions, which, as you see, differ greatly from the observed ones. From this I conclude that this method of deriving refractions is not so certain and reliable — at least for this purpose, that the height of the air should be derived from it.

Inclination of the ray above the air	Refraction computed by Kepler	Refraction observed by Tycho
45°	0′ 47″	0′ 5″
50°	1′ 0″	0′ 10″
55°	1′ 13″	0′ 35″
60°	1′ 28″	1′ 25″
65°	1′ 53″	2′ 30″
70°	2′ 31″	5′ 0″
75°	3′ 32″	7′ 30″
80°	5′ 36″	10′ 0″
85°	11′ 30″	14′ 40″

From this I conclude that, although the steep increase of the refractions bears a strong analogy to the steep increase of the secants near the horizon, it is nevertheless not certain that nature follows this analogy exactly; and therefore Kepler's method is unreliable, both in determining refractions by means of secants and in constructing this height of the refractive air.

Fourthly, the height of Mount Caucasus, treated below in Problems 50 and 51, suggests that around the Caucasus the refractive air is much higher than two Italian miles, and not less than 20 Italian miles; and so it is more probable that in Denmark too it is much greater than two miles. Kepler himself, moreover, grants in the *Epitome of Astronomy*, Book 1, page 72, that on the highest mountains there is some refraction, especially in summer, though at times none. Nor do the confirmations he adds in the *Epitome of Copernican Astronomy*, page 60, and in the *Astronomiae Pars Optica*, page 135, stand in the way. For even if many mountain ridges covered with almost perpetual snow do not have humid air around them from melted snow, they nevertheless have it from elsewhere — from lakes, from marshes, or from the sea lying not very far off — so that the rays of rising stars, refracted through its vapours, reach the mountain ridges. As for the report that on Olympus, as Aristotle testifies, life could once not be sustained without sponges to moisten the air, and that the same happens now in the mountains of America through which one passes from Nicaragua into Peru: this is not a necessary argument that the air is so rare as to be unfit for refractions, since that effect could come from exhalations that are sulphurous, or that infect the breath with some other malign quality. Next, granted that in that nearer air the density were not so great, yet in the air that lies between the mountains and the extremity of their physical horizon, and through which the rays of rising stars pass, there is, or can be, air much denser from watery vapours raised from humid ground, sea, marshes, pools, rivers and so on. Moreover, against Olympus and the mountains of Nicaragua we set Mount Athos, which in Section 4, Problem 35, we showed to be higher than 28 Italian miles; and yet around its summit stood the towns called Acrothon, Uranopolis and Apollonia, where men lived — men indeed called Macrobii from their longevity, as Pliny testifies, Book 4, chapter 10. Therefore, if Kepler's argument held, the air there is endowed not only with a healthy quality but also

with much humidity, suited to the respiration of animals and so to refractions. Finally, the fact that neither on Olympus nor on Athos, nor on the summit of Cyllene and of Mount Satabyrius, did winds hold sway, and that letters and ashes were found undisturbed when the year came round, is not an argument that the air is free of all vapour or exhalation, but only of the turbulent ones and those not yet evenly attenuated by the Sun. Thus the clouds that flow down in showers, and the exhalations that run out into winds and storms, are in the lowest part of the second region of the air, far below the summits of the higher mountains; the remaining clouds, lighter and drier, with exhalations more thoroughly concocted and brought to an even temper, are in the upper part of the second region of the air, mixed with certain vapours not unsuited to some refraction.

Now, in order to derive a more probable height for this air, we must first set up a new Problem on the height of certain mountains, especially the Caucasus.

Problem 50. To correct, by means of refractions, the given height of the Caucasus and of certain other mountains, given the height of the refractive [?] air, the inclination or refraction of the visible species, the distance of the eye from the mountain's perpendicular in the vertical circle, and the Earth's semidiameter.

[Margin: Problem 50.]

In Section 4 of this Book, Problem 30, I taught how to find the height of mountains, given the arc of a great circle between the mountains seen and an eye on the surface of the sea that first sees the mountain's peak, and given also the Earth's semidiameter. By three examples I derived there the height of Etna as 5 9/10 Bolognese miles, from a given arc of 3°; of the Peak on the island of Tenerife as 10 1/10 miles, from a given arc of 4°; and finally of the Caucasus as 57 97/100 miles, or 58, from an arc of 9° 32′. Snel, on the other hand, in the *Eratosthenes Batavus*, Book 2, suspects that the heights of the Peak and of Etna appear greater because of refractions; and my very dear friend, the most learned Father Athanasius Kircher, in a letter written to me on 1647 February 17, timely warned that heights of mountains found in this way are subject to refractions, and that the species of islands and mountains are refracted in our air and therefore appear higher and nearer than they really are. For often, while he was staying in Malta, Etna was visible to him, which on the following day, however clear, he could not see; and Don Carolus Vintimilius at Palermo had at times seen the island of Luprica standing wholly above the sea from Monte Pellegrino, which at other times he could not see, however clear the sky.

[Margin: Father Athanasius Kircher's salutary warning, and an observation for refractions.]

And although this variation could be referred, wholly or in part, to other causes — for example to the glare of the Sun and the position of the reflected rays, or to exhalations dispersed through the air, or to the disposition of the eye — it can nevertheless, not improbably, be attributed to the variability of the refractions in the thick and vaporous air which, spread over the sea between the eye and the object, is now denser, now rarer. It is therefore our task to

investigate how great a contraction these refractions can produce in a height of mountains supposed from other sources. For this, let us recall here the figure set out in Problem 44, in which let BCT be a vertical quadrant of the Earth, and DEM one of the refractive air; and let AC and AK be semidiameters of the Earth, which the height of the air CE and the given, uncorrected height of the mountain KG meet perpendicularly and in a straight line. Let the mountain's peak G be seen from the eye B at sea along the straight line BG, tangent to the Earth at B, where the angle ABG is right by Euclid III.18; and through the point E let the straight line HI be drawn, tangent to the curvature of the air at E and making the angle PEH right. Now it is certain that the species and rays propagated from the mountain's summit towards the air DEM, so that they can enter it and be refracted to the eye B, must lie above the tangent HEI; and therefore it is certain that the

Diagram. A woodcut in the right column, recalled from Problem 44. A vertical line D–B–A rises from A; a horizontal base line runs from A through T to M. A smaller quadrant arc runs from B through C and K down to T (the Earth's surface), and a larger arc from D through E and F down to M (the upper surface of the refractive air). Straight lines run from A through C to E and on to P, and from A through K and H towards G; BG is a horizontal line from B; a line from I passes through E down towards H (the tangent HEI); a curve runs from O towards E.

- D (top left, on the vertical line): top of the refractive air above B
- I (top, above E): end of the tangent HEI
- O (small letter between D and E): point on a curve
- P (upper right): end of the line from A through E
- E (on the outer arc): point where the ray meets the air
- B (left, on the vertical line): the observer's eye at sea
- G (right): the mountain's peak
- F (on the outer arc, right): point on the arc of the air
- H (beside F): end of the tangent HEI
- C (on the inner arc): foot of the height of the air CE
- K (on the inner arc, lower): foot of the mountain KG
- A (bottom left): centre of the Earth
- T (on the base line): end of the Earth's quadrant
- M (on the base line, far right): end of the quadrant of the air

[Margin: Order of the problems.]

apex of the mountain cannot in fact lie below the point H, but must be somewhat above H. Let it therefore be at F, so that the ray FE, incident at the point E, is inclined to the perpendicular AP at an angle PEF less than 90°; and let the same ray FE, which unrefracted would go on straight to O, be refracted towards B, so that BEO is the refraction, to which the vertical angle GEF is equal by Euclid I.15. With these assumptions, and given what we have stated, you will solve the Problem as follows.

[Margin: First step.]

First, add the Earth's semidiameter AK to the uncorrected height of the mountain KG, and the whole AG will result, known in miles; likewise add AC to the height of the air CE, and the whole AE will result, also known in miles. And since the arc BK between the eye B and the mountain's perpendicular AKG is given, look up its secant AG, and make the proportion: as AG of so many miles is to the secant AG, so is AE of so many miles to AE, the secant of the arc BC. Look up this arc in the tables of secants and subtract it from the arc BK, for the remainder will be the arc CK, which measures the angle CAK.

[Margin: Second step.]

Secondly, consider the triangle AEF, in which are given the side AE, as above; the angle EAF, found by the first step; and the angle AEF, which is the supplement of the inclination PEF to two right angles. Therefore, by Euclid I.32, the third angle AFE will be known, as the supplement of the two already mentioned to two right angles; and so, by [proposition] 2 of oblique-angled plane triangles, the side AF will become known. Subtract from it the Earth's semidiameter AK, and the corrected height of the mountain KF will remain; or subtract AF from AG, given above, and the portion FG will be known, by which the visible height of the mountain exceeds its true height. The image of the mountain, however, will appear nearer, at the surface E, than the mountain itself really is. But if the eye B sees not along the tangent BE but along a higher refracted ray — inasmuch as it sees not the bare apex but some notable portion of the mountain's summit — then we are certain that the true height of the mountain is greater than KF. Conversely, if an eye at F could not by itself see the island B, it would nevertheless see it at F by means of the ray BE, issuing from the air and refracted away from the perpendicular at the point E — and indeed much nearer, namely at E, than it really was.

[Margin: Another method, by means of the refraction.]

But if the refraction is given, look up as above the arc BC, that is, the angle BAE. Its complement to a right angle will be AEB, that is, PEG; add to this the refraction GEF, and PEF will result, whose supplement to two right angles is AEF. With this and the rest, look up AF as above, and so on.

Example: on Mount Caucasus.

In Section 4, Problem 30, we showed that between the Deeps of the Euxine, lying at the mouth of the Cimmerian Bosporus through which one sails into the Maeotian Marsh — that is, between B and the perpendicular AG of the Caucasus — there lies a minimum arc of the vertical circle, BK, of 9° 32′, whose secant is 101 400 of the parts of which the radius AB is 100 000. Therefore, taking AB as 4139 Bolognese miles, as demonstrated in Book 2, chapter 7, the height KG comes out at 57 97/100 miles, since the whole secant comes out at 4196 97/100 miles.

[Margin: First step.]

First, then, let there be given the minimum height of the refractive air, which Kepler set at 2 Italian miles; ACE will then be 4141 miles. Now as 4196 97/100 is to the secant AG of 101 400 parts, so is AE, 4141, to the secant AE, 100,047,

to which corresponds the arc BC of 1° 45′. Subtracting this from the arc BK of 9° 32′ leaves CK, that is EAF, 7° 47′. Now let the inclination PEF be 89°; then AEF will be 91°. Adding to this the angle EAF of 7° 47′ gives a sum of 98° 47′, which, subtracted from 180°, leaves the angle AFE of 81° 13′. With these angles and the side AE of 4141 miles, AF is found to be 4190 miles, by [proposition] 2 of oblique plane triangles — or by dropping a perpendicular from E to AF and resolving the triangle AEF into two right-angled triangles. Subtracting, then, AK, 4139, there remains KF, the corrected height of Mount Caucasus, 51 Bolognese miles; and there remains the excess FG of the visible height over the true height — a height that will be greater still, the smaller the inclination of the ray EF is assumed to be, and if the mountain's summit has been seen by a ray higher than the ray BE, or if the height of the air has been assumed greater.

[Margin: The same, by another method.]

Otherwise, by a given refraction, as follows. Since, from what was said a little earlier, BC, that is BAC, is 1° 45′, AEB, that is PEG, will be 88° 15′. Now suppose the refraction GEF at the surface of the air to be whatever you please. For suppose the horizontal refraction greater than the lunar, but proportional to it, since the more distant objects are from the centre of the Earth, the smaller, other things being equal, is the inclination of the ray. But the ratio of the Sun's distance to the Moon's, from what was said in Section 5, Problem 74, is for us as 140 2/5 to 1; and yet the refraction of the Moon does not exceed the horizontal refraction of the Sun by more than two or three minutes. Therefore, since the apex of the Caucasus is not two semidiameters of the Earth distant from the Earth's centre, and the Moon's distance is to the Caucasus's distance at most as 59 to 1, the ordinary refraction of the Caucasus cannot reasonably be supposed much greater than 35′; and a great density from the vapours of the Euxine and the Maeotis would be needed for the refraction to be 45′. Granting this, PEG will be 91° and AEF 89°, and so KF will come out, as above, at 51 miles — or greater, if a refraction smaller than 45′ is supposed, or a greater height of the air. Thus I hold it certain that the height of the Caucasus is 51 Bolognese miles, so that, as stated above, it is truly called in Aristotle the greatest of the eastern mountains; and perhaps the ark first came to rest on these, or on similar mountains of Armenia, as the first to emerge from the waters of the Flood.

The height of Etna and of the Peak is corrected by refractions.

From what was said in Section 4, Problem 30, there lies between the eye B, beyond Malta, and Etna KG an arc BK of at least 3°, from which the whole AG was found there to be 4144 9/10, and its secant is 100 142. Therefore, if AE is 4141 miles, the secant AE will be 100 045 and the arc BC 1° 43′, and so CK, that is EAF, 1° 17′. From these, and from the inclination PEF of 89°, that is, the angle AEF of 91°, and so the angle AFE of 87° 43′, it follows that AF is 4144 8/10 miles; and so the corrected height of Etna, KF, remains at 5 8/10 miles — that is, scarcely sensibly less than the visible height.

By the same method, from what was said in Section 4, Problem 30, and from what has been supposed here, the corrected height of the Peak comes out at 10

Bolognese miles. For BK is 4°, and its secant AG 100 244, and it was found to be 4149 1/10 miles. Therefore, if AE is 4141, the secant AE will be 100,050 1/2, and its arc BC 1° 49½′, and the arc CK, that is the angle EAF, 2° 10′ 30″. Hence, assuming as above the angle AEF of 91°, AFE will be 86° 49′ 30″, and so the whole AF 4149 miles. Subtracting, then, AK, 4139, there still remains the height of the Peak, KF, of 10 miles — scarcely less than the visible height.

Corollary: against Kepler.

From what has been said here, and in Section 4 from Problem 30 on, it is clear that Kepler strayed far from the truth in the *Epitome of Copernican Astronomy*, Book 17, page 26, where he said that the highest mountains do not exceed half a German mile, or two Italian miles, and that from them the horizon is not seen depressed by more than 2°, whereas from Athos it is seen lower by at least 6°, and from the Caucasus by 8°.

Problem 51. From what has been said about the height of the Caucasus in the preceding Problem, and about the same in Section 4, Problems 30 and 36, to derive a more probable height of the refractive [?] air around the Caucasus, above the sea — the Euxine on one side, the Caspian on the other.

[Margin: Problem 51.]

After so many windings, the outcome of our labours has at last reached the point where, from the height of the Caucasus, we may derive a very probable height of the refractive air around it; this we shall do in distinct propositions.

[Margin: First step.]

First, from Problem 50 of this Section and Problem 30 of Section 4, it is clear that the perpendicular height of the Caucasus, if refractions do not alter its appearance to those sailing through the Cimmerian Bosporus, is not less than 58 Bolognese miles; but if the ordinary refractions in that region are not supposed greater than 45′ — and I have shown that they cannot be so supposed — its height is not less than 51 miles, the height of the air being taken as 2 miles and the inclina- [Margin: Order of the problems.]

tion of the ray at practically its greatest, 89°.

[Margin: Second step.]

Secondly, in Section 4, Problem 36: since Aristotle affirms of the same Caucasus that the Sun is seen there for a third part of the night, both at dawn — that is, before the sunrise due at the foot of the mountain — and after sunset, I demonstrated that, if the height of the refractive air is only 2 Bolognese miles, and Tycho's refraction, corrected by our parallax, is 32′ both for the rising Sun in the air above the Caspian and for the setting Sun above the Euxine and the Maeotis, a double refraction must be used: one of the solar ray entering the curvature of the air, the other of the ray leaving it and reaching the summit of the Caucasus. From both together I showed that the height of the Caucasus cannot be set less, nor much greater, than 35 Bolognese miles; and I added that it increases by about as many miles as are added to the assumed height of the air of 2 miles.

[Margin: Third step.]

Thirdly, therefore: since, by proposition 1 of this problem, the height of the Caucasus is established on other grounds as not less than 51 miles, however much refraction is admitted for this purpose, it follows from this and from proposition 2 that the height of the refractive air must be increased by as many miles as are wanting from the number 35 to 51, namely 16. And therefore it must be set at no less than 18 Bolognese miles, and indeed somewhat larger still, say 20; for as it increases, the true height of the Caucasus also increases, by Problem 50, and from that height in turn the height of the air is increased — at least in that region, where the air is dense and very cold because of the thicker vapours raised from the Caspian, the Euxine and the Maeotian Marsh.

[Margin: How great is the height of the refractive air?]

Elsewhere, however, it is probable that the air — dense indeed, but still fit for a sensible refraction — rises higher, though never above 50 Italian miles, and is nowhere depressed below 2 miles. Within these limits the height of this air varies greatly, according to the variety of the waters and the soil from which the vapours are raised, and of the seasons of the year, and indeed of the same day. Kepler, moreover, notes in the *Epitome of Astronomy*, Book 1, page 72, that in maritime places the height of this air is more constant, while on the highest mountains there is at times almost no refraction, especially in winter, when the air is less vaporous; but when it has boiled up, the height of the air increases — both of the refractive and of the twilight air. And in this sense I grant to Father Emmanuel Maignan, *Perspectiva horaria*, Book 1, proposition 38, that the height of the refractive air is uncertain.

Problem 52. To determine the height of the twilight exhalations by means of rays of the Sun first twice refracted, then reflected, then refracted a third time; and to correct this height, found by the ancients by means of unrefracted rays.

[Margin: Problem 52.]

For Problem 52, which involves an incredible subtlety, see Book 8, Section 1, chapter 14, Problems 4, 5 and 6, where I set out a table of the height of the exhalations according to my own opinion, and showed that their height should not be contracted as much as our friend Wendelen thought.

Problem 53. To find the greatest thickness of the air lying between the twilight exhalations and our eyes.

[Margin: Problem 53.]

Go back to Problem 47, for this is the same as that, except that here, in place of the height of the refractive air, the height of the exhalations must be used, and joined to the Earth's semidiameter, so that the secant is obtained in miles.

Problem 54. To find by how much the arc of the sphere of refractive air illuminated by the Sun is smaller than the arc of the Earth illuminated by the Sun through unrefracted rays, this being given; given the semidiameter of the said sphere and the true semidiameter of the Sun, with its distance from the Earth's centre; and to show that it is not smaller by a single second.

[Margin: Problem 54.]

In the following figure, let ABCD be the orb of the terrestrial sphere together with the refractive air, with centre H; and let EMF be the Sun, at the distance KH. From its extremities let two rays EG and FG come, tangent to the Sun at E and F and, by Euclid III.18, making right angles at E and F with either semidiameter of the Sun, KE and KF. Let the same rays, touching the sphere of the air at A and at C, likewise make right angles at A and C with the semidiameters AH and CH. Let KH be produced to the meeting point G, and from H let HL be drawn parallel to the ray AE; for by Euclid I.29 and I.33 the angle AHL and the two angles at L will be right, and the lines AH and EL equal. Therefore, subtracting the semidiameter AH from the semidiameter EK, the side LK will be known in the triangle HKL, right-angled at L, in which the base HK, the Sun's distance, is given; and so, by [proposition] 2 of right-angled plane triangles, the angle LHK will become known, which measures the arc BI. Added to the arc AI of 90° — as subtending the right angle AHL — it will give the semiarc AB of the air illuminated by the Sun; and this, doubled, will give the illuminated arc ABC, which, compared with the arc of the Earth illuminated by the Sun's unrefracted rays, will show the difference sought.

Example.

In Book 3, chapter 11, we showed that the true semidiameter of the Sun, EK, is about 34 terrestrial semidiameters; and from the Sun's perigee distance HK of 7000 terrestrial semidiameters we showed that the arc AIB is 90° 16′ 8″, as is clear from Problems 1, 4 and 5 of that chapter. Now suppose that AH adds five-sixths of a terrestrial semidiameter to the Earth's semidiameter, so that the height of the refractive air is 3358 miles, of which the terrestrial semidiameter has 4139, from what was said in Book 2, chapter 7. Indeed, for good measure, let us suppose AH to be double the terrestrial semidiameter: for subtracting 2 from EK, which is about 34, LK will remain at 32 of the parts of which HK is 7000. From this will follow the angle LHK, that is the arc BI, of 15′ 42″, and AIB of 90° 15′ 42″, smaller by only 26″ than the terrestrial semiarc illuminated by the Sun's unrefracted rays, which is 90° 16′ 8″. Therefore, if the refractive air is supposed to be only 20 miles high, or at most 50, according to Problem 51, the semiarc of the refractive air illuminated by the Sun will not be smaller by even one second than the semiarc of the Earth illuminated by the Sun's rays taken as unrefracted.

Diagram. A woodcut in the right column. A long, narrow triangle has its apex G at the foot and its upper side running through E, K and F. A semicircle hangs from E to F through M (the Sun, centre K). A vertical line runs from K through M, B, H and D down to G. A small circle about H (the Earth with the refractive air) carries B at its top, A on the left, C on the right and D at the bottom, A and C being where the sides EG and FG touch it. A line runs from L down through I to H, and a line from E through L towards K.

- K (top centre): centre of the Sun
- E (top left): point of tangency of the ray EG on the Sun
- L (on the line from E): foot of the parallel HL

- F (top right): point of tangency of the ray FG on the Sun
- M (on the vertical, below the semicircle's lowest point): point of the Sun's disc
- I (left of B): end of the arc BI
- B (top of the small circle): point on the sphere of the air
- H (centre of the small circle): centre of the Earth
- A (left of the small circle): point of tangency of EG on the air
- C (right of the small circle): point of tangency of FG on the air
- D (bottom of the small circle): point on the sphere of the air
- G (bottom apex): meeting point of the two rays

Problem 55. To find by how much greater the arc of the Earth illuminated by the Sun's refracted rays is than that illuminated by unrefracted rays.

[Margin: Problem 55.]

We have already solved this Problem in connection with the Earth's shadow, lit through or truncated by the Sun's rays, in Book 5, chapter 5, Problem 3; and we showed with Kepler that this arc exceeds the arc illuminated by unrefracted rays by as much as the Sun's horizontal refraction taken on both sides, or doubled, and that this semiarc is greater than the semiarc of the Earth illuminated by unrefracted rays by as much as the Sun's horizontal refraction — that is, in Tycho's reckoning, by mi- [Margin: Order of the problems.]

[Margin: The arc of the Earth illuminated by the Sun's refracted rays.]

nutes 34′; but according to the refraction corrected by our parallax, 31′ 33″. Thus the semiarc illuminated by the Sun is, without refraction, 90° 16′ 8″, from what was said in Book 3, chapter 11, Problem 4; with Tycho's refraction added, 90° 50′ 8″; but with ours, 90° 47′ 41″. And the whole arc is, by Tycho's reckoning, 181° 40′ 16″, but by ours 181° 35′ 22″. Nor does Father Bettini differ much, in *Apiaria* 8, progymnasma 2, proposition 4, where he says that 35′ must be added to the arc of the ancients: because, as we said in Problem 43, he took the angle made by the ray tangent to the air and the ray refracted by the horizontal refraction to be one minute greater than Tycho's horizontal refraction. For the rest, since both Kepler there and Bettini suppose the height of the refractive air to be so small that the arc illuminated by the Sun's rays tangent to the air differs insensibly from the arc illuminated by the Sun's rays tangent to the Earth — and we showed this in Problem 54 — we thought that proposition should be confirmed here. I add, however, that in Book 5, chapter 5, Problem 5, I used, with Kepler in the *Astronomiae Pars Optica*, Tycho's horizontal solar refraction of 34′, as I also did in Book 3, chapter 11, Problem 4. But strictly speaking, because Tycho made this refraction larger than was right — since to the simple refraction of 31′ 6″ he added a parallax of 2′ 54″, when no more than 27″ ought to have been added, as I said in Problem 25 of this section — I wished to point out that this arc needs some correction.

Problem 56. To determine whether, from the horizontal refraction of the fixed stars alone, together with the Earth's semidiameter and the height of the refractive air, the

inclination of the ray of the fixed stars and their distance, or their parallax, can be demonstrated.

[Margin: Problem 56.]

I showed the negative in Book 9, Section 4, chapter 31, from number 6, and I set out the argument taken from this against the Copernican hypothesis. Go back there, then, reader, to obtain a fuller doctrine of refractions; and on that occasion recall what I said in the same place about the parallax derived from the semidiameter of the sphere enclosing the refractive air, and what I shall say in the following problem.

Problem 57. To determine whether the height of the refractive air, or the inclination of a star's ray, can be demonstrated exactly from nothing more than the given semidiameter of the Earth, the horizontal refraction and parallax of some star, and its distance from the centre of the Earth, together with its true distance from the vertex.

[Margin: Problem 57.]

I add this because, having investigated the height of the refractive air with so careful an inquiry in Problems 43, 44, 49 and 51, I might seem less than diligent if I had neglected this method, which found favour with Father Francesco Maria Grimaldi. So, lest anyone think it untried: in the following figure let A be the centre of the Earth, and from it let there be arcs of a vertical circle greater than a quadrant — in the heavens, the star's arc BDC; on the surface of the refractive air, HGK; and on the surface of the Earth, OIL. Let the eye be at O, and let the vertical line AOB fall at right angles on the physical horizon OE and on the rational horizon AD. From A, through the point where the arc HGK and the horizon DE intersect — that is, through the point G — let the straight line AP be drawn, which will be perpendicular to the arc HGK. Now let the Sun or a fixed star truly be at C, and let its true distance from the vertex be the arc BC, which the angle BAC measures. But let it shine along CG and, at G — where it would go on to R if it were not refracted — let it be seen there, by the refracted ray GO, along the straight line OGE, as if it were at E. For the horizontal refraction will be OGR, to which EGC is equal, by Euclid I.15. Finally, let C, the true place of the star, be joined to the eye O by the straight line CO. The task now is to find the semidiameter AG, so that, when the Earth's semidiameter AI is subtracted, the height IG of the air may be known; and some have thought that this can be known from the five data in the title of the Problem.

[Margin: First step.]

For, first, in the triangle OAC there are given AO, the Earth's semidiameter; AC, the star's distance; and the included angle OAC, which is the true distance of the star from the vertex. Therefore, by propositions 3 and 5 of oblique-angled plane triangles, the base OC can be known, and each of the angles ACO and AOC; and when this is subtracted from the right angle AOG, COG becomes known.

Diagram. A woodcut at the head of the right column. A vertical line on the left runs from B at the top down through H and O to A, the centre of the

Earth, at the foot. From B a large arc (the star's vertical circle, BDC) sweeps down the right side through E, M and D to C at the lower right. Two smaller concentric arcs cross the figure about A: an upper one through H, G and K (the surface of the refractive air) and a lower one through O, I and L (the surface of the Earth). A straight line runs from A up through I and G to P at the upper right. From O a horizontal line runs through G to E (the physical horizon), and from A a horizontal line runs to D (the rational horizon). A short line rises from G to R at the upper left. Straight lines join A to C, O to C and G to C. Dotted lines run from V through G to M, from O to M, and from A to M.

- B (top of the vertical line): the vertex on the star's circle
- P (upper right, end of the line from A): end of the perpendicular AP
- H (on the vertical, below B): end of the arc of the refractive air
- R (above and left of G): where the unrefracted ray would continue
- V (on the vertical, below H): end of the dotted line VGM
- G (centre): the point of refraction on the surface of the air
- O (on the vertical, below V): the eye, on the Earth's surface
- E (right, on the large arc): the apparent place of the star
- I (on the line AP, below G): point on the Earth's surface
- M (right, on the large arc, below E): the star above the true horizon (second case)
- A (lower left): centre of the Earth
- D (right, on the large arc, below M): end of the rational horizon AD
- L (foot, on the lower arc): end of the arc of the Earth's surface
- K (foot, on the upper arc): end of the arc of the refractive air
- C (lower right): the true place of the Sun or fixed star

[Margin: Second step.]

Second: with COG, with the base OC, and with the obtuse angle OGC — which is the supplement of the refraction OGR to two right angles, by Euclid I.13 — and so with the angle GCO, which is the supplement of the two already mentioned to two right angles, by Euclid I.32: with these three data, I say, the side OG can be known, by proposition 2 of oblique-angled plane triangles.

[Margin: Third step.]

Third: in the triangle AOG, right-angled at O, from the sides AO, the Earth's semidiameter, and OG, found just now, the base AG can be known by proposition 8 of right-angled plane triangles, and the angle AGO by proposition 5. When AI, the Earth's semidiameter, is subtracted, IG will remain, the height of the refractive air. And since, by Euclid I.15, PGE is equal to the angle AGO just found, and the angle EGC to the horizontal refraction RGO, the whole angle of inclination PGC will certainly be known.

[Margin: Second case of the problem.]

But if the star were above the true horizon, as at M, when it appears at E — which is supposed in the case of the Moon, since it undergoes a horizontal refraction, but one smaller than its parallax — then, drawing the straight lines AM, OM and VGM, one would have to solve first the triangle OAM, according

to what was said in the first step; then the triangle OGM, according to what was said in the second step; and finally the triangle AOG, according to what was said in the third step.

I answer, however, that although one may approach the truth quite closely, it cannot be obtained exactly, with geographical or astronomical rigour, from the five data already mentioned alone. For the refraction of the stars OGR can be known by observation in no other way than by comparing their apparent distance from the vertex with the true one, and from that deriving the simple refraction; and by adding the parallax to it we are taken to have the whole effect of refraction. For example: the true distance of the Sun C from the vertex is by calculation BDC; and yet, appearing to us at E, it seems to be distant by a full quadrant BD, because the angle BOE is a right angle, and so it is believed to be at D. Hence the difference between the true and the supposed distance is the arc DC, namely the simple refraction. Adding to it the arc DE, which the angle EAD measures — that is, AEO (supply here the line AE in the figure) — namely the horizontal parallax, we take the whole effect of refraction, and its measure, to be the arc EDC. But it is not, because otherwise the angle EGC, which is equal to the angle of refraction OGR, would be the exact measure of the arc CDE, although that arc is not described from the centre G. Yet the arc owed to this angle is greater; and the parallax of the star C seen from G along the straight line GC is greater than when it is seen from O along the straight line OC; and anyone at G would see it somewhat lower than someone at O. And therefore the angle of refraction OGR, weighed exactly, equals the simple refraction CD, plus the parallax ED of the star seen from the surface of the Earth, plus the increment of parallax from the surfa- ce of the refractive air, which is nearly equal to the angle OCG. Add to this that, when the refraction is unknown, we do not know the exact parallax, and when the parallax is unknown we do not know the refraction — though within certain limits of ignorance, on which see Section 5, from Problem 73 to 75. Finally, the excessive smallness of the angles ACO and OCG relative to the side AC makes the investigation of the side OG slippery. We have therefore judged that this problem is not much to be trusted; instead, we investigate AG by a safer method, especially in Problem 51. Now follow the tables so often promised.

TABVLÆ ANACLASTICÆ SEV REFRACTIONVM.

Anaclastic Tables, or Tables of Refractions.

Table I. Witelo's, from Book 10 of the Optics, Proposition 8.

Refraction toward the perpendicular.

In volume 1 of the *Progymnasmata*, p. 280, Tycho recognized that the refractions of the Moon must be greater than the Sun's, because of the greater inclination of the ray issuing from a nearer star. But he made the Sun's refraction near the horizon greater because of the excessive solar parallax, as Kepler indicates in the last precept of the *Rudolphine Tables* — Kepler who, however, when he sets out in the *Astronomiae Pars Optica*, p. 123, to reform Tycho's refraction of the Sun, uses a parallax of 3′. Lansbergen also erred in making the lunar refractions equal to the solar, when they ought to have been greater.

Table IX. Of the refractions observed by us at Bologna, morning and evening — but mostly in the morning — at the times of the solstices and equinoxes, at a pole height of 44° 29′ 30″.

The Sun's refractions were worked out on the assumption of our parallax of 27″ at apogee, 28″ at mean distance and 29″ at perigee; but if the parallax is greater, the refraction must be increased too. The Moon's refractions were computed using our parallax appropriate to her at mean distance; when the Moon is at apogee they decrease, and when she is at perigee they increase, roughly in the ratio by which the mean parallax exceeds the least, or is exceeded by the greatest. The refractions of the planets can be taken either from values intermediate between the Moon and the Sun, if the planets are nearer the Earth than the Sun is, or from values intermediate between the Sun and the fixed stars, if they are much higher than the Sun.

APPENDICVLA PRO PARTE HAC II. TOMI I.

A Short Appendix for This Part II of Volume I

Ad Librum Octauum.

On the Eighth Book

[Margin: Trimarchus's opinion on the location of comets.]

Chapter I, No. 3. Among the authors who have treated comets with sufficient care must be counted Hieronymus Trimarchus, in disputation 4 on Book 1 of Aristotle's *Meteorologica*, from section 1 to section 8. In section 3, however, he maintains that comets are below the Moon but above the middle region of the air, because he thinks the heaven is ingenerable and incorruptible; and that those which astronomers saw above the Moon were true stars, beneath which a coma was born, and that the astronomers took them for a single body — provided they were not deceived in the use of their instrument. Caussin too, in Book 1 of *De Domo Dei*, chapter 10, holds that comets are perpetual and are not made anew, but appear.

Chapter XIV. On the altitude of the regions of the air, see what I said in the Appendix to Book 2, chapter 19.

Ad Librum Nonum.

On the Ninth Book

Section I. For this section see Nicolaus Caussinus [Nicolas Caussin], Book 1 of *De Domo Dei*. There, in chapter 1, he deals with the name of heaven; in chapters 2 and 3, with the matter and solidity of heaven, defending its fluidity, and he considers comets to have been shown to lie above the Moon; in chapter 4, that there are no waters above the starry heaven; in chapter 5, that there is no fire in the concave of the Moon; in chapter 6, that the heavens and the stars are of a fiery nature, but of fire of a different species; in chapters 7 and 8, that the heavens are not animate, nor is light the soul of the stars; in chapter 9 he argues for the incorruptibility of the heavens; in chapter 10, that comets are not made anew but appear; in chapter 12, that angels do not move the stars but preside over their motions; and in chapter 14, that there are not several worlds.

[Margin: Fluidity of heaven.]

[Margin: Solidity of the Firmament.]

Mersennius, however, argues for the solidity of the Firmament in his commentary on Genesis, pages 814 and 819. Caussin deals with the Empyrean in Book 4 of the work cited above. Volume 3 of the *Dogmata Theologica* of Dionysius Petavius [Denis Pétau] has also recently appeared, in which he treats learnedly of the work of the six days and maintains the fluidity of heaven.

[Margin: Angels the movers of the heavens.]

Section II, Chapter I. Although Caussin, in Book 1 of *De Domo Dei*, chapter 12, denies that the celestial bodies are moved by angels, Nicolaus Serarius nevertheless teaches that they are moved, and indeed by the Virtues, following St Thomas Aquinas (Opusculum 10, article 17, and *Contra Gentiles* III, chapter

80), in his commentary on Joshua, chapter 10, question 20. And Lorinus [Jean de Lorin], at that place, understands the words of Ecclesiastes 1, *The spirit goes on in its circuit*, of an angel moving the Sun, with [?] St Thomas, Opusculum 10, article 6. Mersennius teaches the same in his commentary on Genesis, page 844.

[Margin: The number of the heavens.]

Section III, Chapter I. On the number of the heavens see Caussin, Book 1 of *De Domo Dei*, chapter 2, and Pétau, Book 1 of *De Opificio sex dierum*, which is in volume 3 of the *Dogmata Theologica*.

Chapter V. What concerns the number of the spheres of Eudoxus and Callippus is learnedly pursued by Boulliau in the Prolegomena to his *Astronomia Philolaica*, page 19.

Section IV, Chapters II and III. See Caussin, Book 1 of *De Domo Dei*, chapter 11, arguing for the immobility of the Earth.

[Margin: The motion of the Earth asserted by Anaximander.]

For the motion of the Earth, on the other hand, Theon of Smyrna in his *Astronomica* cites Anaximander of Miletus, saying: *Eudemus relates in his Astrologica that Oenopides was the first to discover the oblique position of the zodiac and the constitution of the great year; Thales, the eclipse of the Sun;* and Anaximander, that the Earth hangs aloft and moves about the middle of the world.

Chapter X. In Argument 3 I promised to say more about the libration of the Moon in the Appendix to Book 4, because I had not yet decided to reprint the leaves of Book 4 in which, in chapter 9, I have now discussed this libration sufficiently, as far as the observations made so far allowed. For the rest, which depends on future observations, we have reserved either for Volume 3 or for a separate book, which Father Francesco Maria Grimaldi, a most diligent observer of these matters, will perhaps publish, if time and life do not allow it to me.

In the same Argument I named a spot on the Moon the *Lake of Posidonius*, as though it had been so called by van Langren and by us. But in the reprinted leaves it seemed best to name it the *Spot of Grimaldi*, and, out of regard for antiquity, to move Posidonius to the upper part of the Moon.

FINIS TOMI PRIMI.

End of the First Volume.

INDEX RERVM AC NOMINVM INSIGNIVM

Index of Notable Subjects and Names

Contained in the Second Part of the First Volume.

The first number signifies the page; the second, the column.

AE

- System of the Egyptians, p. 281.2 and 283
- Use of the circle of the equant, 345.1
- To convert parts of the equator into hours, 575
- Ratio of the equator to a parallel, 585.1

- To find the rising or setting point of the equator, 565.2
- Height of the air, 58.2
- Air included under the name of heaven, 197.1
- Whether the highest region of the air is carried round by the motion of the primum mobile, 297.2
- Ratio of air to water and to glass in density, 652
- To attempt the height of the refractive air from the horizontal refraction, by Bettini's method, 657.1
- To investigate the height of the refractive air otherwise and more safely, 657.2 and 658.2; see also 663
- To find the thickness of the refractive air, 658.1, 662.1
- Kepler's height of the refractive air rejected, 659.2
- To infer the height of the refractive air above the Euxine and the Caspian from the height of the Caucasus, p. 661.2
- How much smaller is the part of the sphere of refractive air illuminated by the Sun than the portion of the Earth illuminated by it, through refracted and unrefracted rays, 662.2
- Height of Etna, 593.2
    - But corrected by means of refractions, 661.2

AL

- Elevation of the pole at Alexandria, 605
- Time of Alexander the Great, 4.1
- Method of Almaeon [al-Maʾmūn] in investigating the circuit of the Earth, 589
- System of Alpetragius [al-Biṭrūjī], 285
- To find the altitude of a star, 551.2, 572.2, 573
- To measure the altitude of the Sun from a shadow, 603
- To find the altitude of a star in the prime vertical, 555.2
- To convert the true altitude of stars into the apparent, 656.2
- Elevation of the pole: see under *Poli altit.*

AM, & AN

- System of Amicus, 286.1
- To find the rising amplitude of the ascendant, or the setting amplitude of the setting point, 568.1
- Anaxagoras's opinion on comets, 37.1
- Angels: see *Intelligentiae.*
- To find the angle at the pole of the world made by the solstitial colure and a circle of declination, 570.1
- To find the angle at the pole of the world made by the equinoctial colure and a circle of declination, 570.1
- To find the angle at the pole of the world made by the equinoctial colure and a circle of latitude, 570
- To find the angle at the pole of the world made by the meridian and the solstitial colure, 570.1

- The angle at the pole of the world made by the meridian and the equinoctial colure, 570
- The angle at the pole of the ecliptic, 570.2
- To find the angle of the ecliptic and the meridian, and to construct a table of it, 552.2
- To find the angle of the ecliptic and the horizon, 566.1 and 2
- To find the angle of the ecliptic and a vertical at the centre of a star without latitude, 559
- To find the angle of the ecliptic and a vertical for a star having latitude, 559
- To find the angle of the horizon and a circle of declination at the centre of a star, 561.2
- To find the angle of the horizon and a circle of declination drawn through the centre of a star, 569.1
- To find the angle of the horizon and a circle of latitude made at the centre of a star, 570
- To find the angle of the meridian and a vertical drawn through the nonagesimal, 567
- To find the angle of a circle of declination and a circle of latitude made at the centre of a star, 558.1
- To find the angle of a circle of declination and the ecliptic made at the centre of a star, 558.1
- To find the angle of the equator and a circle of declination, or of latitude, made at the centre of a star, 559
- To find the angle of a circle of declination and a vertical made at the centre of a star, 554.1
- To find the angle of an hour circle, 573
- To find the angle of a vertical and a circle of latitude, 575.2
- To find the angle of the meridian and a circle of latitude, 571.1
- The Antipodes: by which Fathers they were denied, and for what reason, 489

AP, & AQ

- Aphelion and perihelion of the Earth, 301.1
- Opinion of Apollonius of Myndus on comets, p. 36.1
- Ratio of water to air and to glass in density, 652
- To measure the depth of waters, 397
- Waters above the heavens: whether they exist, of what kind, and for what use, 220 to 224
- Whether the waters above the heavens are holy angels, or clouds or vapours, 223

AR

- System of Archimedes, 277.1
- To find the arc of the ecliptic between the meridian and the horizon, 567

- To find the arc of the meridian between a star and the culminating point of the ecliptic, 569.1
- To find the arc of the horizon cut off by an hour circle, 573
- To find the arc of a vertical cut off by an hour circle, 573
- To find the arc of position, 574.1
- To find the arc of vision, or of shining forth, of the stars, 584
- Argoli's system, 283
- Aristarchus's opinion on the motion and place of the Earth, p. 293.1
    - Condemned, however, by Archimedes and Cleanthes, 293.2
- Time of Aristotle, 4.1
- Aristotle on the extinction of comets, misunderstood by some, 29
- Selected texts of Aristotle on the motion of heavy and light bodies, 439 to 443
- Aristotle's system, 283 to 285
- Aristotle's error on the increase in velocity of heavy bodies, 382.2
- Modesty of Aristotle's intellect, 62.2
- The Aristoxenian musicians, 507.2
- Artemidorus's opinion on comets, 36.2

AS

- To find the right ascension of the Sun, or of a point of the ecliptic, and to construct a table of it, 552 and 553
- To observe the right ascension of a star, or to investigate it otherwise, 557, 560, 563, 564
- To find the right ascension of any star whatever, 561
- To find the difference of right ascension, 559
- To find the right ascension of the midheaven, p. 561.1
- To find the ascensional difference, and to construct a table of it, 561.2
- To find the oblique ascension, and to construct a table of it, 562
- To find the oblique ascension of the ascendant, p. 566
- To determine the time of a decreasing right ascension, 585
- Description of the Asinelli Tower, and its suitability for experiments, 385
- Whether the aspects of the stars have force from harmonic configurations, 533
- Table of the stellar aspects, old and new, 534 and 535

AT

- Height of Mount Athos, 595
- Praise of Athanasius Kircher in music, 529.2

AV

- System of Averroes, 285
- The perpetual breeze within the tropics, 297.2 and 327

AZ

- To find the azimuth of a star, 554.2, 596
- Azimuths common to two places, 599

B

- Height of Monte Baldo, 595
- Bede's system, 283
- Bettini's method in measuring the Earth examined, 587
- Bettini's harmonic intervals of the stars, 527
- Biancani's opinion on comets, 109.2
- Biancani's system, 287
    - His error in the height of mountains, 595
- Bodin's ravings on comets, 39.1
- Experiments with cannon against the motion of the Earth, 424 to 428
- Velocity and range of a cannon ball, p. 424.2
- Boulliau's opinion on the cause of the apparent acceleration in the motion of heavy bodies, 398

CA

- Cabeo's opinion on comets, 32.2, 118.2, 125.2
    - And his method in measurements of the Earth, 588
- Whether the celestial motions are, in themselves and in reality, uniform or non-uniform, 262 to 268; and whether they follow geometrical laws, 268, or rational proportions, 269 and 270
- Whether the density and size of the celestial bodies derive from harmonic proportions, 531.1
- Analogy of the celestial motions with musical strings, 523
- What kind of machines the celestial motions have, 251
- Number of the celestial movers, 250.2
- Simplicity of the celestial motions, 239
- Figure of heaven, 311 and 489.2
- Whether the heavens and the stars are moved by Intelligences, or by their own form or nature, 247 to 251
- How the creation of heaven and earth was accomplished by God, and what Moses meant by these names, 193 to 200
- Whether there is a harmony of the heavens, and of what kind, 501
- Thickness and distinction of the heavens, 334
- Number of the heavens created by God on the first and second day, 224, 225
- Number of the heavens according to the various opinions, 271 to 276
- The aerial heaven, 197.1 and 223.1
- Whether heaven and the stars are animate, 244
- Whether heaven is generable and corruptible, 237 and 318
- Whether heaven is solid or fluid, 216 to 220, and 238 to 244, and 669
- Whether heaven is infinite on the outside, 316, 317
- Whether heaven is simple, 232; of what matter or elements it is made, 233 to 237
- System of Callippus, 283 to 285
- System of Capella, 282.2
- Cardano's opinion on comets, 36.2

- The Congregation of Cardinals defended in the censure against Galileo, 487 to 499
- Height of Mount Casius, 597.2
- Height of the Caucasus, 594 and 597; but corrected by means of refractions, 660.2
- Position of the comet's tail, and its turning away from the Sun, 26.1 and 47.2; causes of this turning away, 121 to 127

CE

- Concurrence of the centres of the world and of the Earth, p. 442
- Validity of ecclesiastical censures in physical and astronomical matters, 487

CH

- Opinion of the Chaldeans on comets, 36.1
- What chaos is among the poets, the natural philosophers and the theologians, 201 to 204
- Names and order of the musical strings, 517
    - Their application to the heavens, 523 to 525
- The nativity of CHRIST imprudently treated by some, 189

CI, & CL

- Cicero's system, 277.1 and 281
- Praise of Chiaramonti, and comparison with Tycho in geometry, 71 to 75 and 81.2
- Chiaramonti's calculations on the new star examined, from p. 161 to 164
- Chiaramonti's slips, or the inconclusiveness of his arguments, 82, 114 and 117
- Chiaramonti's notable problem for the parallax of altitude, 93.2 and 633
- Clavius's weak argument for the position of the Earth in the middle of the world, 449.2
- Clavius's system, 278, 279
    - His method for measuring the Earth, 588
- Cleanthes's accusation against Aristarchus over the motion of the Earth, 293.2

CO

- A comet eclipsing the Moon, 7.2
- A comet reaching all the way to the Earth, p. 6.1
- The comet of the year 1577: observations, 10 to 13; and examination, 77 to 94; opinions on it, 87
- The comets of the years 1585 and 1590: observations, pp. 13 and 14; examination and opinions, 95
- The comet of the year 1607: observations, 15; examination, 96
- The comet of the year 1618: observations, from p. 16 to 23; its examination and opinions, 100 to 116
- Whether comets are an aggregate of small stars that are invisible in themselves, 44

- Whether comets arise from an abundance of exhalations, 45 to 56
- Whether comets are made of elementary matter, not ignited but illuminated by the Sun, 57.1
- Whether comets come into being anew by condensation, or alteration, or generation, p. 57.2
- Whether comets are ancient planets that become visible to us as they approach, 42
- Comets extinguished before setting, 29.1
- Whether comets are lucky or baleful: opinions of the poets, astrologers, meteorologists, astronomers and recent natural philosophers, from p. 29 to 35
- Comets lucky or baleful to some, 5, and 29 to 35
- Notable comets observed by Pontanus, 8.1; by Regiomontanus, 8.2; and by Apian, 9.1
- Comets divided into several, or fused from several, 23.2
- In what region of the heavens comets usually arise or are extinguished, or towards which they are usually carried, 26.2
- At what time of year comets usually appear, p. 23.2
- That a comet is not a mere appearance of light, or a joint appearance of several known stars, 40 to 42
- Whether the height of comets can be investigated by parallaxes, 70
- The height of comets investigated independently of parallax, 63 to 70
- The height comets must have to escape the shadow of the Earth, 69
- The height comets must have to be seen in different, distant places, 63
- Concurrence of comets at the same time, 23.1
- Digression of comets from the Sun, 28, 121
- Duration and apparent size of comets, 24, 54 and 55
- Catalogue of lucky or baleful comets, 34
- Figure, colour, smell and transparency of comets, 29.1 and 55
- Chronological and astronomical history of comets, 3 to 23

- Pythagorean intervals of the stars, 526

R

- Whether the refraction of the fixed stars is preserved in the hypothesis of a moving Earth, 463 and 464
- How great the refraction of the fixed stars is, 635, 667
- To measure the refraction, or the refracted angle, from the inclination and by other means, 578.1, 650.2, 651, 652.2, 655
- To measure the horizontal refraction of the Sun, the Moon and the other stars in various cases, 653, 654, 655, 656
- To separate simple refraction from the whole, or compound, refraction, 654.2
- Tables of refractions: see *Tabulæ Refractionum*.
- To measure refractions from air into water in seven ways, 648.2 and 649; tables for them, 664
- To measure refractions from air into glass or crystal in five ways, 649.2 and 650; tables for them, 664 to 666
- Axioms of refractions, 646.2
- Definitions of refractions, 645.2
- Fifteen questions on refractions, 642 to 645
- Species of refractions, 645
- Selected theorems on refractions, 647

- Regiomontanus's problems of parallaxes[65], 625 and 626
- Regiomontanus's system, 278.1
- Reisacher's observation and opinion on the new star, 152
- What the retrogradation and station of the planets are like in the Copernican hypothesis, 302, 341, 342
- Altitude of the pole at Rome, 605.1
- Rothmann's opinion on comets, 93.1, 122.2

SA, SC, SE, SI, & SN

- Santucci's observation and opinion on the new star of the year 1572, 164
    - His opinion on comets, 88
- The musical scale, 518, 519 and 520
- Scipione Chiaramonti: see *Claramontius*.
- How Sacred Scripture teaches physical and astronomical matters, 487 to 490
- The literal sense of Sacred Scripture to be retained, and rules on this, 491
- To find the semidiurnal arc, and the authors of these tables, 562
- To find the apparent semidiurnal time, where the parallel cuts the horizon or does not cut it, 577
- To find the true semidiurnal time, and the authors of these tables, 576, 577
- Seneca's doubt on the motion of the Earth, 290.1
- Seneca's opinion on comets, 36.2, and 42.2, and 122.2, 128.2
- Oracles of the Sibyls on new stars, 179
- Snel's method of measuring the circuit of the Earth, 590.2

SO, & SP

- The Sun the centre of the planetary system, 331
- Why the Sun is called the greater luminary, 231
- Whether the Sun was placed, on the fourth day of the world, at the point of the equinox or of the solstice, 232
- The Sun the source of light and of motion, 332
- How much sooner the Sun rises for the summit of a mountain than for its foot, 582
- How the Sun went back on the dial of Ahaz, p. 482 to 485
- How the Sun stood still at the command of Joshua, 481 and 482
- To find the altitude of the Sun, 551, 555, 572, 573, 603
- In how much time the whole disc of the Sun rises, p. 581.2
- To find the rising of the Sun's limbs, 581
- To find the place of the Sun in the ecliptic, 551.2
- Spots of the Sun: see *Maculæ*.
- Size of the Sun, 333

[65]printed "Parallax.um", a point where a letter should stand

- The motion of the Sun asserted from Sacred Scripture, 480, and by the Fathers, 481 to 486, while the Copernicans evade these in vain, 487 to 495. Whether this motion is a matter of faith, 490
- The motion of the Sun halted or altered by many miracles, 481, 482
- The nobility of the Sun above that of the Earth, 330, 333
- To investigate the rising and setting of the Sun, 581.2
- The production of the Sun: whether it was made on the first or on the fourth day of the world, and how, 226 to 231
- Whether the sound of the heavens is real, 503
- What the Spirit of the Lord over the waters is, 199

ST

- The star of the three holy Magi: opinions of the Fathers and of the astronomers on it, 179 to 186; errors or abuses concerning it, 186 to 193
- How long stars are visible from a well in the hypothesis of a moving Earth, 435
- Observations of the new star of the year 1572 in Cassiopeia, and opinions on it, 150 to 165; conclusions on its place, 150.1 and 155.2 and 159.1 and 160.1 and 163.2 and 165
- History, observations, etc., of the new star in the breast of Cygnus, 166; conclusion on its place, 167, 168; and its size, 173.2
- History and observations of the new star in Serpentarius, opinions on its parallax and distance from the Earth, 168 to 171; conclusions on its place, 172.2; and on its size, 173.2
- Catalogue of new stars, 130 to 132
    - Wendelen's opinion on their newness, 131.2
- The efficient and final cause of new stars, and opinions on these, 177 to 179
- Why the production of the stars was put off by God to the fourth day of the world, 225
- The matter, nature and generation of new stars, and opinions on these, 174 to 177
- To find the position of the stars with respect to east or west, and whether above or below the horizon, 572

SV, & SY

- System of al-Biṭrūjī, Amico, Averroes and Giovanni Antonio Delfino, 285 and 286
- System of the Egyptians, 281.2 and 283
- System of Archimedes, 277.1
- System of Aristotle, Eudoxus and Callippus, 283
- System of Bede, Capella, Macrobius and Vitruvius, 282 and 283
- System of Cicero, 277.1 and 281
- System of Clavius, Magini, etc., 278.1 and 279

- System of Copernicus, Philolaus, etc.: its supporters, 290; its opponents, 291; an exact explanation of it, from p. 291 to 311. A long and careful examination through arguments discussed on both sides, from pure reason, 311 to 478; from sacred authority, 479 to 495. Censures against it, and their discussion, 495 to 500. Conclusions on it, 478 and 500
- System of Girolamo Fracastoro and Turrianus, 286
- System of Geber and Theon, 281.1
- The harmonic system, 519, 520
- What the system of the world is, and how many kinds there are, 275 to 311
- Our system, 288, 289
- System of Plato and of the Platonists, 280, 281
- System of Pliny the Elder, 277.2
- System of Ptolemy, 277.2
- The Pythagorean system, 277.1, 279 and 280
- System of Regiomontanus, 278.1
- System of Tycho and of the Tychonics, 287
- Writers on the systems, 271

TA

- Small table of the least altitude of comets, etc., 64 and 65
- Small table of the great conjunctions that occurred near the new stars, 192
- Small table of the greatest parallax of the annual orb, 451
- Small tables of proportions, 504 to 506
- Table of the altitude of vapours, 63
- Table of the observed altitude and parallax of comets, 118
- Table of the altitudes of the pole, ancient and more recent, 351
- Table of the celestial chords and intervals, etc., 522 to 527
- Table of the musical chords, 517
- Chronological table of the comets that were auspicious to some, or baleful, 34
- Table of consonances, 509
- Table of the distance of the fixed stars from the Earth in the Copernican hypothesis, 456 457
- Table of the flux of the sea, that is, of the hours at which there is high water in the ports of Europe, etc., 370, 371
- Table of the magnitude of the fixed stars in the Copernican hypothesis, 461
- Table of the months in which comets have usually appeared, 23
    - And of the duration of comets, 24
    - And of the length of the tail, 23
    - And of the diurnal motion, and of the arc described, 28
- Table of the miles the Earth would cover by its diurnal and annual motion, 415, 430

- Table of the motion of heavy bodies descending naturally, 387 to 392 and 402
- Table of the motions of the comet of the year 1577, 12
    - And of the comets of the years 1585 and 1590, 14
    - And of the comet of the year 1607, 15, 16
    - And of the comet of the year 1618, 20, 22
- Table of observations of the new star of the year 1572, pp. 138, 139, 146, 148, 161, 173
- Table of observations of the new star of the year 1604, 169
- Table of opinions on the number of the heavens, 275
- Table for the divisions of the monochord, 511, 512
- Table, or catalogue, of comets, 3 to 22
- Table, or catalogue, of new stars, p. 130
- Table of the systems, or scales, of music — diatonic, chromatic, enharmonic, etc., 518, 519, 520
- Table of tetrachords, 515
- Tables of refractions from air into water and glass, or from water into glass, and the reverse, from Witelo, Kepler, Mersennius, Maignan and Kircher, and ours, 664, 665, 666
- Tables of the refractions of the heavenly bodies in air, that is, of the Moon, the Sun, the fixed stars, etc., 666, 667, 668
- Authors of various tables, namely:
    - Of the angle of the ecliptic and the meridian, 553.2
    - And of the ecliptic and the horizon, 566
    - Of the ascensional difference, 561.2
    - Of the right ascension of the Sun, 553.1
    - Of the right ascension of the other planets, 557.2
    - Of oblique ascensions, 562.2
    - Of the declination of the Sun, 553.1
    - Of the declination of the other stars, 558
    - Of the distance of the nonagesimal from the vertex, 566
    - Of the distance of sight, 598
    - Of gnomonics, or of shadows, 604
    - Of the conversion of hours into minutes of the day, and the reverse, 576
    - Of the conversion of hours into degrees of the equator, and the reverse, 576
    - Of the mediations of the heavens, 563.2
    - Of the proportion of a parallel to the equator, 585
    - Of semidiurnal arcs, 562
    - Of semidiurnal times, 577

TE

- To deduce the moment of time from an observation of the Sun, 578
    - The same from an observation of the fixed stars, 580.1, 581

- The moment of time at which, on a given day, a star rises or sets absolutely, 584
- The moment of time at which a given point of the ecliptic, or a star, crosses the mid-heaven, 583.2
- Problems of time, from p. 575
- The time of a star's arrival at the equator, 584; or at the circle of perpetual apparition, 584; or at the polar circle, 584; or at the pole of the world, 584
- To convert equal time into apparent, and the reverse, 576.2
- The time between two risings or settings, 584
- The time between the transits of two stars, or of points of the ecliptic, through the mid-heaven, 583
- The time of the rising of the Sun's limbs, and of its whole disc, 581
- The time in which the right ascension of a star decreases, 585
- The time at which, on a given day, a star reaches the nonagesimal degree of the ecliptic, 583
- The time in which a given arc of the ecliptic crosses the prime vertical, 583.2
- The time at which a star reaches a given altitude, 582
- The time at which the Sun, or any star, reaches any vertical, 582.2
- The time by which the Sun rises sooner for the summit of a mountain, or of a tower, than for its foot, 582
- The time at which a star once rose or set, 584
- The time at which a star rises or sets heliacally, 584
- What the darkness over the face of the deep is, 199
- Whether the Earth is a great magnet, and its magnetism, 298, 299, 329
- Chemical earth, 328
- What the Earth was like when empty, void, invisible and unformed, 197 and 198
- To measure the circuit of the Earth by the method of Eratosthenes, 589.1; of Ptolemy and Marinus of Tyre, 589.1; of al-Maʾmūn and many Arabs, 589.2; of Jean Fernel, 589.2; of Nonius and Jacopo Mazzoni [?], 590.1; of Snel, 590.2; of Father Francesco Maria Grimaldi, and ours, 591.1 and 2
- The portion of the Earth illuminated by the Sun through rays both refracted and unrefracted, 662.2
- What the creation of the Earth on the first day of the world was like, 193 up to 199
- To measure the diameter of the Earth by the method of Maurolico, 585.2; of Grienberger, 586; of Bettini, 587.1; of Clavius, 587; of Father Paolo Casati, 587.2; of Kepler, 588.1; of Cabeo and Isaeus, 588.1
- The immobility of the Earth from Sacred Scripture, 479, 480. The trifling evasion of the Copernicans, 487
- To investigate the size of the Earth, 585
- The annual motion of the Earth: by whom denied or asserted, 291, 293; explained at length with its properties, 299 to 308; supported by many

arguments, but non-evident ones, from p. 339 to 380, and from 469 to 472; but refuted by many arguments, partly evident, partly non-evident, 413 to 417, and 429, and from 439 to 465, and from 475 to 478
- The motion of the Earth: by whom asserted or denied, from p. 291, 292
- The efficient cause of the motion of the Earth, hard to assign, p. 436, 438
- The diurnal motion of the Earth explained at length, 296 to 299; supported by many arguments, but non-evident ones, 311 to 330, and from 465 to 469; but refuted by many arguments, partly evident, partly non-evident, 409 to 439, and from 472 to 475
- What figure the motion of the Earth would describe, 309, 398, 399
- The motion of the Earth with respect to declination, 308, 309
- Various attributes of the motion of the Earth, 295
- The motion of the Earth excluded by various conclusions, p. 478 and 500
- The velocity of the Earth, if it moved, 415, 430, 431
- The magnetic terrella, 328
- Various genera of tetrachords, 515, 516

TH, TO, & TR
- Theon's system, 281.1
- Thomas Digges's observations and opinion on the new star of the year 1572, 152
    - Problems of parallaxes, 627, 633
- What a tone is, and whether it can be divided into two equal semitones, 510
- Nine rules of oblique-angled plane triangles, with examples, 540
- Thirteen rules of right-angled plane triangles, with examples, 538
- General rules of triangles, 537
- Fourteen rules of oblique-angled spherical triangles, with examples, 545
- Sixteen rules of right-angled spherical triangles, with examples, 541

TV, & TY
- To measure the height of a tower in six ways, 592
- The heights of several towers, 587
- Whether Tycho was a heretic, 74
- Tycho's non-evident arguments for the place of comets above the Moon, 77 to 96, or of the new star, 146
- Tycho's comparison with Chiaramonti, 70 to 72
- Tycho's errors, 73, 74 and 83, 629 and 630
- Tycho's astronomical reliability open to suspicion, 73.2, 84.1
- Tycho's observations of comets, 10 to 14; and of the new star, 133 to 140
- Tycho's system, 287

V
- Valesius's opinion on the new star
- The altitude of vapours from twilight and from refractions, 58, 662.1
- The incredible velocity of the fixed stars, 320, 321
- The velocity of the Earth's motion, 430, 431

- The perpetual wind within the tropics, 297.2, 310.2, 327 and 360.1
- Venus taken for a comet more than once, 29.2
- Why Venus and Mercury have the same motion as the Sun, 343
- Whether Vesta was the Earth, or Fire, 293
- Bishop Virgilius: whether, and why, he was condemned by Pope Zachary for asserting the Antipodes, 489.2
- The distance of sight, and its table, 598
- The proportion of glass to water and to air in density and weight, 651.2
- Vitruvius's system, 282.2
- Problems of shadows, and their proportion to the gnomon, 603
- The names, order, etc., of the musical notes, 517

Z

- Pope Zachary: on what ground he condemned the asserters of the Antipodes, 489.2
- Zeno's opinion on comets, 37.1

Diagram. The printer's device, engraved, standing between the register and the imprint. A winged cherub's head at the top looks down over a scroll bearing a three-line motto; foliage and scrolled ornaments fill the upper corners. Two putti stand at the sides holding a cartouche that frames a scene of heavy clouds over a rough sea. At the foot, in the scrollwork, is a small shield patterned with lozenges.

- Scroll (top centre), line 1: FLVCTIBVS ET FREMITV
- Scroll, line 2: ASSVRGENS BENACE
- Scroll, line 3: MARINO
- Motto in English: "rising with waves and a sea's roar, O Benacus" — BENACE, a vocative; its last letter stands against the curl of the scroll

Bologna,
from the press of the Heir of Victorius Benatius [Vittorio Benacci], 1651.
With the permission of the superiors.
